Another strand of political-economic theory research which was influential in regional development during the 1980s and 1990s is the regulation approach. Derived from the work of a group of French economists in the 1970s, the regulation approach stresses the important role that wider processes of social regulation play in stabilizing capitalist development. These wider processes of regulation find expression in specific institutional arrangements which mediate and manage the underlying contradictions of the capitalist system, enabling renewed growth to occur. This stabilization occurs through the coming together and consolidation of specific modes of regulation: that is, the institutions and conventions which shape the process of capitalist development. When these act in concert, a period of stable growth, known as a regime of accumulation, ensues. In the 1980s the regulation approach provided theoretical support for the idea that postwar Fordism – based on mass production and mass consumption, linked through rising wages for workers and increased productivity in the workplace – had given way to a new regime of flexible accumulation, defined by the growth of more individualized consumption patterns and new information and communication technologies.

The shift to post-Fordism and flexible accumulation was seen to be underpinning new geographies of industrial production in the 1980s, based on the rise of new industrial spaces and regions in hitherto nonindustrialized areas such as Silicon Valley in California and other areas of the US Sun Belt, the M4 corridor in southern England, and the “Third Italy” of Emilia-Romagna, Tuscany, and the Veneto. In addition, the regulation approach was also deployed to study the politics of regulation at the regional scale. For instance, Alain Lipietz, one of the original French regulationists, developed the concept of regional armatures to highlight the role of regional elites in regulating conflictual social relations through the construction of a distinctive regional interest and identity. The activities of this group are instrumental, Lipietz (1994) argues, in the conversion of a “space-in-itself,” which is defined by the prevailing social relations of production in a region, to a “space-for-itself,” which is endowed with the institutional capacity to intervene in processes of economic and social change. At the same time, Jamie Peck and Adam Tickell (1995) drew on earlier research on industrial restructuring and uneven development to develop the concept of local modes of social regulation. These are distinguished by their “unique position within wider (national and international) structures of accumulation and regulation” (Peck and Tickell 1995, 27). They argued that the “regulatory deficit” of southeast England, reflecting the contradictions of uneven development under Thatcherism, meant that it was unable to reproduce the conditions for sustained growth into the recession of the early 1990s.

Beyond political economy? Rethinking regional development in the 1990s and 2000s

By the late 1980s, Marxist political economy was becoming subject to increasing criticism, informed by the emergence of postmodern thought. Marxism had become rather out of
POLITICAL ECONOMY AND REGIONAL DEVELOPMENT

touch with the new times of the 1980s, marked by the dominance of neoliberal ideas, particularly in the United Kingdom and the United States. In the realm of left-wing politics too, the focus was shifting from the traditional politics of distribution, concerned with work, wages, and welfare, to a politics of identity, concerned with asserting the rights to recognition and justice of groups such as women, ethnic minorities, and gay people. Such claims were channeled through broader social movements rather than the traditional labor movement.

Three main criticisms of Marxist political economy in geography can be identified.

1. Its apparent neglect of human agency in terms of an impoverished view of individuals and a failure to recognize human autonomy and creativity. Instead, Marxists tend to privilege wider social forces such as class, and to see people as bearers of class powers and identities, reading their behavior in terms of such attributes instead of seeing them as unique individuals.

2. Its emphasis on economic forces and relations. While the political-economic concept of production is, as has been shown, much broader than conventional notions of the economy, political economists have been criticized for stressing the determining role of economic forces.

3. Its overwhelming emphasis on class, and neglect of other social categories like gender and race. Leading Marxists such as Harvey were attacked by feminist geographers in the early 1990s for their neglect of gender issues and accused of subsuming these within a class-based Marxist analysis.

These are important criticisms, although it is questionable whether Marxist political economy really was as economically deterministic as its critics allege. The criticisms were, nonetheless, influential in encouraging the reorientation of the field of regional development toward a range of new approaches from the early 1990s, emphasizing the institutional and cultural foundations of economic processes. The key context here is the cultural turn which took place in human geography and the social sciences in the late 1980s and 1990s, fostering a new cultural geography focused on questions of identity, meaning, and discourse.

This led to talk of a “new” economic geography which examines the links between economic action and social and cultural practices in different places. As Wills and Lee (1997, xvii) put it, “the point is to contextualise rather than undermine the economic, by locating it within the cultural, social and political relations through which it takes on meaning and direction.” The links between economy and culture are of central importance here, with many observers agreeing that the economy has become increasingly cultural in terms of the growing importance of sectors such as entertainment, retail, and tourism, while culture has become increasingly economic as it is viewed as a set of marketable commodities. Three main strands of culturally orientated research on regional development can be identified.

1. Consumption, with studies focusing, for instance, on the creation and experience of particular landscapes of consumption such as shopping malls and heritage parks. The marketing of localities and regions for tourists and potential new residents has been a particular theme of research in this area.

2. The development of the so-called cultural industries, encompassing art, performance, music, film, broadcasting, museums, and theaters, among others. These cultural industries were identified by governments...
as key growth sectors in the 1990s and 2000s. They tend to be highly concentrated in large metropolitan regions, and are often clustered together close to central business districts, which gives them access to suppliers and provides large markets for their products. Notable examples of such clustering include the motion picture complex of Hollywood, the media complex of Manhattan, and the publishing industry of London. More recently, the focus on cultural industries has given way to an emphasis on the importance of creativity in regional development and the need for cities to attract talented “creatives,” based on the influential writings of Richard Florida.

3 Culture has come to play a key role in local economic strategies in recent years. In particular, industrial cities in Western Europe and North America that faced catastrophic declines in their manufacturing sectors in the 1970s and 1980s have sought to attract and develop cultural facilities and attractions in response, generating new investment and employment opportunities. Bilbao provides a good example of culture-led regeneration, alongside UK cities such as Glasgow, Liverpool, and Newcastle–Gateshead.

A second set of ideas are drawn from institutional economics and economic sociology, emphasizing the social context of economic life. Institutions, defined broadly as rules, conventions, and norms, are important because they link the economic and the social through a set of habits, practices, and routines. The notion that economic processes are grounded, or “embedded,” in social relations is derived from economic sociology. This has been spatialized in regional development studies through the idea of territorial embeddedness, emphasizing how particular forms of economic activity are rooted in particular places. One area in which this idea has been particularly influential is in studies of foreign direct investment (FDI) in response to claims that multinational corporations’ (MNCs) affiliates were becoming increasingly embedded in host regions in the United States and United Kingdom during the 1990s, partly as a result of the increasingly sophisticated set of supports offered by regional institutions, but research has found limited evidence of this.

Institutionalist ideas have encouraged the rise of a new regionalism in economic geography which examines the effects of social and cultural conditions within regions in helping to promote or hinder economic growth. In particular, inherited institutional frameworks and routines are held to be of considerable importance in influencing how particular regions respond to the challenges of globalization. Individual places have, as such, attracted renewed attention, as economic geographers have attempted to identify the social and cultural foundations of economic growth and prosperity in successful regions such as Silicon Valley in California, and Cambridge and “Motorsport Valley” in southeast England. In contrast to the political economy approaches of the 1980s, institutionalist perspectives emphasize the importance of internal conditions within regions in shaping their experience of economic development as opposed to external processes, and treat localities and regions as active participants in economic development rather than as passive arenas that are exploited by capital (e.g., large MNCs).

Third, research in regional development has also been reshaped by an engagement with concepts from evolutionary economics, particularly the notion of path dependence. This means that the ways in which economic actors respond to wider processes of economic change are shaped and informed by past decisions and experiences. As such, the past is expressed and reproduced
through technology, machinery and equipment, and organizations as well as a broader set of attitudes and habits. Regional culture is a product of the past in this sense. The process of path dependence can be illustrated with reference to “old” industrial regions such as the Ruhr Valley in Germany, and northeast England, where cultural factors have been closely associated with decline. The industrial cultures of these areas seemed to have become rigid and fossilized, meaning that firms and institutions were tied to obsolete production systems and methods. This militated against more positive responses to economic change in terms of generating new products and methods. These declining areas can be seen as what Gertler (2003, 134) terms “hard-luck cases”: once successful places where local cultures have become overly rigid and fixed, blocking the emergence of new ideas and new ways of doing things. In this sense, declining regions tend to become locked in to outmoded practices and habits, which prevents them from acquiring new knowledge in an economically effective manner.

The influence of these diverse approaches has not, however, completely supplanted that of Marxist political economy, which is still important. Economic geography and regional development remain haunted by Marx, and Harvey continues to be an important figure, with critics still feeling the need to define their position in relation to his (Sheppard 2011, 320). Some of the key arguments advanced by political economists in the 1970s and 1980s around the unstable and crisis-prone character of capitalism as a mode of production, the inseparability of the economy from the social, political, and ecological spheres, and the need to relate regional problems to wider processes of uneven development continue to be widely accepted by many researchers in the field. The continuing influence of Marxist political economy into the 1990s and 2000s was sometimes explicit, for instance in work on labor and geographical scale, and sometimes more implicit and understated than in the 1970s and 1980s, such as in research on the commodification of places through heritage and tourist consumption. There is also evidence of cross-fertilization between political economy and cultural, institutional, and evolutionary approaches: for example, through the development of a cultural political economy (CPE).

Marxist political economy continued to inspire research in labor geography and regional development through the 1990s and 2000s. While a previous generation of Marxist work had treated labor as a relatively passive factor, considering its distribution and organization across space, the “new labor geography” emphasized the active role that labor plays in shaping the economic landscape (Herod 2001). In particular, labor geographers have been pursuing research that highlights the proactive role of organized labor in creating their own spatial fixes, focusing attention on the need for trade unions to rethink their own geographical strategies to respond to the more global production networks being developed by MNCs. At the same time, political-economic approaches have also dominated geographical theorizing on scale, with particular scales such as the regional or national being seen as products of wider social, political, economic, and cultural processes rather than as predefined arenas within which such processes unfold. This insight has been exemplified by numerous studies of rescaling processes since the 1980s which have analyzed the upscaling of powers from the national to the global and supranational levels, and a parallel downscaling to the regional and local, which has underpinned the new regionalism.

The emergence of CPE in recent years shows how aspects of political economy have been integrated with elements of a cultural approach. More specifically, CPE combines a critical semiotic analysis of language, narrative, and
The continued relevance of political economy to regional development

The new regionalism attracted increasing criticism in the early 2000s, with some of these criticisms invoking long-standing themes of geographical political economy. The first concerned a tendency to take regions for granted as objects of analysis, failing to consider how they have been historically constructed and institutionalized as spaces of policy intervention. Second, the prevailing focus on endogenous capacities and relations entailed a neglect of exogenous networks and institutions, particularly those associated with MNCs and national states. Third, an orientation toward providing accounts of successful regions at particular points in time meant that longer-term questions of regional adaptation and renewal were overlooked. In addition, such accounts were often divorced from wider issues of uneven development and socioeconomic inequality. The continued, indeed increased, pertinence of these issues in the wake of the economic crisis of recent years underlines the ongoing relevance of political-economic categories for analyses of regional economies subject to processes of crisis-driven restructuring aimed at restoring the conditions for profitability. In particular, the adoption of a political-economic perspective helps to connect regionally based research to the big questions of uneven development, social justice, and environmental degradation on a global scale. In the remainder of this short section, the continuing influence of political-economic
thinking is exemplified, with reference to three main areas of contemporary research.

The first of these is work on neoliberalism and the institutional variety of capitalism. In essence, neoliberalism involves the promotion of market forces, individual choice, and a limited state as key principles of economic and social organization. Two of the three principal perspectives on neoliberalism in geographical research are political-economic in nature and origin: Harvey’s conception of it as a class project designed to restore profitability following the economic crisis of the 1970s, and Peck and Tickell’s regulationist-inspired definition of it as a set of constantly evolving policies and practices which have spread globally, but unevenly, through elite policy networks (in addition to the poststructuralist understanding of it as a form of governmental). From a regional development perspective, the adoption of neoliberal doctrines of free trade and capital mobility at the national and international scales have effectively set the underlying rules of the game, establishing a framework of interregional competition which has led to the proliferation of regionally specific competitiveness strategies. At the same time, geographical political economy approaches have focused attention on variegated forms of capitalism at different scales of analysis, going beyond the national orientation of the varieties of capitalism school of comparative political economy to emphasize how economic development is structured by locally and regionally specific institutional arrangements.

Research on global production networks (GPNs) is the second area of interest. This is informed by political-economic research on global commodity chains and writing on actor-network theory (ANT and value chains). A GPN is defined as “the globally organized nexus of interconnected functions and operations by firms and non-firm institutions through which goods and services are produced and distributed” (Coe et al. 2004, 471). As a broad relational framework for the study of economic globalization, the GPN approach signals a renewed interest in extra-regional relations. This is redolent of earlier political economy approaches, although extra-regional processes are conceptualized in relational rather than structural terms, emphasizing multiple actors and relations rather than external domination and control. Regional assets provide an important resource for regional development, but must be harnessed by regional institutions to complement the strategic needs of lead firms in global production networks. From this perspective, regional development is a product of the strategic coupling of global production networks and such regional assets. MacKinnon (2012) argues that strategic coupling should be seen in dynamic terms, focusing attention on processes of decoupling and recoupling between regions and GPNs. Decoupling involves rupturing the relationship between a region and a GPN through plant closure and disinvestment. Recoupling, by contrast, is related to the attraction of repeat investment, recombining existing plants and regional assets with a new round of investment. In many respects, the GPN approach represents a political economy informed framework that is better able to capture the multidimensional and fast-moving character of FDI in contemporary regional economies than the clunkier formulations of the 1970s and 1980s.

The third area of contemporary political economy informed research highlighted here concerns the impact of the financial and economic crisis and subsequent austerity policies. Political economy analyses interpret this recent episode within the broader context of uneven development under capitalism and the evolution of neoliberal governance, focusing attention on the distributional politics of restructuring.
in terms of the unequal effects on different social groups and places. Contrary to initial expectations that the greater impact of the crisis would be on financial services and the relatively prosperous cities and regions where much financial services employment is located, research has demonstrated that workers in manufacturing and lower-income groups, often based in poorer regions, have been worst affected. In the United States, the pattern is complicated by the magnitude of the preceding housing boom in dynamic Sun Belt regions, such that the impact of the initial wave of foreclosure in 2007 was felt most severely in states such as California, Nevada, Arizona, and Florida, in addition to the traditional Rust Belt of Ohio and Michigan. In the United Kingdom, the effect has been to widen existing spatial disparities, with research showing that “the places and people most severely impacted by the last five years of recession and hesitant recovery are those that were already the worst-off” (Townsend and Champion 2014, 3). Thus, the post-2008 decline in employment was steeper and more persistent in the provincial city-regions of the north and the Midlands compared to the United Kingdom as a whole, while London diverged strongly by experiencing a marked recovery from 2010. In both the United States and the United Kingdom, fiscal austerity has been disproportionately concentrated on local government, involving the displacement and downloading of financial responsibility from the national and federal to the local scales, resulting in severe cuts to services and the erosion of collective entitlements. This has been most severe in the cases of municipal bankruptcies in the United States, most notably Detroit, where unelected administrators and emergency managers have assumed draconian powers to slash budgets, cancel contracts, and privatize services.

Conclusions

This entry has assessed the influence of the political-economic approach on regional development research since the 1970s. Political economy has been an important source of theoretical inspiration and direction over this period, exhibiting considerable flexibility and an openness to engage with other perspectives, although its precise influence has fluctuated over time. It became the dominant theoretical approach to regional development by the mid-to late 1980s. Subsequently, however, political economy became the target of criticism for its perceived determinism and neglect of agency, and its dominance was supplanted by the development of new cultural, institutional, and evolutionary approaches. In particular, the new regionalism became highly prominent in the 1990s and early 2000s, based largely on institutionalist thinking. But political economy remained significant and continued to structure and inform research on issues such as labor and scale. It became increasingly complex and diffuse in nature, particularly as a result of its engagement and cross-fertilization with insights from other perspectives, as exemplified by the development of CPE. If anything, political economy has become more prominent in regional development research in the wake of the 2008 financial and economic crisis, as its insights have been deployed to assess the uneven geographical effects of the crisis and its attendant policies of fiscal austerity. It is likely to remain influential, continuing to provide a theoretical framework for linking regional development issues to the larger problems of uneven geographical development, social inequality, and environmental degradation that may themselves become more acute and politically charged over the next few years.

Political geography

John Agnew
University of California, Los Angeles, USA

Political geography is about the geographical distribution of power, how it concentrates in some hands and some places, the human and environmental consequences of such concentration, and of how it shifts between places over time. Political geography at its origins as an organized academic field in the late nineteenth century saw the geography in its name as determining the political. More recently, the political is seen as conditioning what is understood as geography. Geography was long understood as the distribution of such physical features of the Earth as mountains, rivers, and oceans but it has since broadened to include politically mediated human reactions to and impacts on the physical environment from settlement and economic-development patterns to human-induced climate change. Compared with political sociology and political science, political geography is less concerned, respectively, with the politics of social groups and the political preferences of individual persons and more with how social groups and people organize and orient themselves in terrestrial space for political purposes. Obvious examples include the field’s long-term focus on such phenomena as the dynamics of interstate borders, the history of modern statehood, electoral geography (including the geographical organization of elections), and the strategic ranking of world regions in foreign policies. Historically, the field has focused on the links between space, regions, and the natural environment, on the one hand, and politics (and polity), on the other. Such linkages were important to ancient and early modern political theory but have weakened in recent political theory, as its practitioners have tended to become largely state focused. Political geography, therefore, recalls a historically more integrative and perhaps more wide-ranging approach to understanding political phenomena.

General intellectual trajectory
1890–present

As a modern field of study, political geography dates from the 1890s as initially an “aid to statecraft” in organizing their empires and confronting their adversaries on the part of the great powers of the day. Largely analogous to what was also known after 1899 as geopolitics, this political geography took contemporary national political identities and reason-of-state as givens. The “needs” of territorial states (given their own personhood in this perspective) and the role of relative location on the Earth’s surface and the resources available in driving and determining the outcome of competition between them were the main concerns of the field. Lurking in the early history of political geography is the history of thinking about how nature relates to nation-state as inherited from the eighteenth-century European enlightenment and the early nineteenth-century Romantic reaction against it. If the idea of levels of development associated with different national territories comes from eighteenth-century enlightenment thought, then that of hierarchies of national territories on a racial–natural basis competing...
with one another for domination comes out of nineteenth-century German idealism.

This intellectual trajectory long dominated the field. Indeed, until very recently, many political geographers were either cameralists (advocates of state-based economies that maximize their self-sufficiency and minimize their transactions with others) or imperialists (favorable to empire building and controlling distant territories). Some of both are still around, even if many advocates of cameralism now think of themselves as on the political left rather than on the nationalist right. Changing times can produce strange bedfellows. But over the past twenty years, liberal perspectives, pitting states against markets, and social perspectives, looking to a plurality of forms of governance, have tended to become more influential than the older statist vision. Of course, disputes among cameralists (both nationalist and state socialist), imperialists, liberals, anarchists, and romantic localists have deep roots in many genres of modern political thought.

But it is not only the range of implicit political projects informing the field that has changed. Intellectual attitude has moved 180 degrees. Since the 1960s, a more independent and critical approach has begun to develop, acknowledging the need to question critically rather than to serve actively the particular interests of the “home state” of the political geographer. At the same time, the empirical scope of the field has widened to consider questions about the origins, spread, and support for political movements and parties, the links between places and political identities, and geographies of nationalism and ethnic conflict. Along with many other parts of political study, political geography has gone from presuming that states (particularly “my” state) are everything to seeing “the political” as everywhere. This intellectual expansion of the field has simply transformed political geography from a particularly state-centered field at its origins to one interested in the range of ways in which geography intersects with “the political” broadly construed: from the material and discursive construction of states and their interrelations to the connections between places and political identities.

Over the entire history of modern political geography a fundamental issue has been the combination of making claims to universal or scientific objectivity while serving national or other particular interests or purposes. This project revolves around the implicit claim to offer a “view from nowhere,” or the idea that the whole world can be known totally from beyond the particular geographical and intellectual location of the person making the claim. But as the philosopher Thomas Nagel (1986, 25–28) has pointed out, there can never be complete objectivity: there is always a necessary “incompleteness” to objective reality. The solution for Nagel is to “enrich the notion of objectivity” by adding the views of oneself and of other selves so as to incorporate the insights of subjectivity. As Nagel concludes: “to insist in every case that the most objective and detached account of a phenomenon is the correct one is likely to lead to reductive conclusions. I have argued that the seductive appeal of objective reality depends on a mistake. It is not a given. Reality is not just objective reality.” So, even though acknowledging the prospect of knowing that is not completely subjective or the result of a singular experience, Nagel is suggesting that the quest for complete objectivity is a fruitless one. There can never be a view from nowhere that is not also, and profoundly, a view from somewhere. In recent years this sort of philosophy has provided an important justification for developing theoretical perspectives sensitive to the discourses, representations, and social practices of those studied around the world rather than simply focusing on the “objective”
causal relationships presumed by the external but invariably privileged observer.

Notwithstanding this critical turn, the early history of the field has had persisting influence even if often in terms of negative appraisal. Canonical writers have cast a long shadow. Friedrich Ratzel and Halford Mackinder, in particular, were a looming presence across the first fifty years of modern political geography and have continued to exert fascination long after their ideas might seem to have faded into the intellectual sunset. They and their major critics constitute the historic canon upon which more recent political geography has been built and against which it has often revolted. There are obvious discontinuities and differences across the writings of the various figures important to the early history of the field. There are, however, a number of continuities that also provide an important backdrop to what was to happen in political geography later on (Claval 2010; Agnew and Muscarà 2012).

The first is the rather unrelenting focus on territorial states as the singular geographical units par excellence of political geography. Although not without its critics (such as the anarchist geographer Elisee Reclus), the enterprise was largely state-oriented almost to the exclusion of political processes operating at other geographical scales and in other ways. The conception of the political was almost entirely statist and territorial, with weaker liberal currents eddying around the edges. The “hard-nosed,” masculinist, and realist conception of the world is here rooted in the geographical facts of an Earth that rewards only those who take what they can. The second is the merging of a naturalized claim to knowledge, based on various mixes of the “view from nowhere” and biological metaphors, with the idealist goal of serving one’s own nation-state. Perhaps only Reclus and much later Karl Wittfogel stand out as major examples to the contrary, at least in so far as serving a particular state is concerned. Although, by the 1930s figures such as Owen Lattimore (1941) in the United States and Jacques Ancel in France can be seen as offering much more critical perspectives on the conventional wisdom: Lattimore because he was largely self-taught and brought his intimate familiarity with Central Asia to bear in all that he wrote; Ancel because he hoped to counter Nazi geopolitics with a more “open” version of geopolitics of his own. The third is a “problem solving” orientation that animated all of the major figures. They aspired to influence policy: to whisper in the ear of the Prince, to paraphrase the Renaissance-era Florentine political philosopher and diplomat Machiavelli. Though geared towards establishing a presence within the new universities of the time, this goal could be served only by appearing “useful” to raison d’état. The prospects for political geography were thus tied to the national flag.

The fourth continuity, and one that distances many of us today so much from the thinking of the time, was the ready acceptance of the language of racial difference and the possible environmental causes of racial divisions. There was no sense of the social construction of racial differences. The American authors, often so critical of European colonialism for its subjugation of other peoples, nevertheless had blind eyes for the reality of American racism at home and in its colonies (such as the Philippines). The fifth, and final, continuity is that Europe and, at least since 1918, the United States are seen as being at the center of the world. The rest of the world is ancillary: bit players or pawns in a world politics driven almost entirely by Great Power competition and inter-imperial rivalries. Of course, the world wars of the period 1875 – 1945 did begin in Europe. But the rest of the world had long figured and increasingly did so in the machinations
of the powerful. And it did so not just as a passive object of desire for the powerful but as an active participant in both its victimization and its own incipient liberation.

These five continuities from the late nineteenth century have not been readily transcended. Indeed, elements of all of them live on today in political geography and beyond: an urge to naturalize knowledge claims to grasp the mantle of science, a Euro-American centered view of the world in which all others are seen as backward when compared to a Euro-American based modernity, and the aspiration to influence national policies to underwrite disciplinary success and gain the ear of political leaders. But beyond these continuities much has also changed in both purposes and subjects of study. Changing political and economic circumstances have had important effects on the empirical substance and theoretical orientations of the field.

Geopolitical contexts and political geography

A good case can be made that the geopolitical context of the time has been crucial to the making of political geography over the past one hundred years. The field has not evolved simply as the result of an internal dynamic, as one paradigm simply replaced another because of intellectual fancy or academic competition. It is not that such considerations have been absent. But they have been relatively less salient to the making of the field than the nature of the world that political geography has claimed to directly report on and interpret. Obviously, the logic of the historical periods used and the geopolitical themes (including the main geopolitical protagonists) identified as crucial to those periods are subject to dispute. Contexts (be they social, cultural, historical, or geopolitical), as Peter Burke (2002, 172) reminds us: “are not found but selected or even constructed, sometimes, consciously, by a process of abstracting from situations and isolating certain phenomena in order to understand them better. What counts as context depends on what one wishes to explain.” The dilemma is that in trying to avoid both “the assumption of eternal wisdom to be found in American political science and great books programs” (Burke 2002, 170) and an internalist account of political geography as a succession of paradigms or great men theorists (the typical alternatives) we can “imprison” all ideas in their contexts not just those that had the closest “fit” with the times. To try to avoid doing so is why identifying ideas that either remained largely marginalized in their time or that arise in times of geopolitical transition out of the merging of previously distinctive perspectives is necessary. But a focus on historical–geopolitical contexts is vital in providing us with summaries of the very materials that political geography has always tried to understand.

The age of inter-imperial rivalry

The time of modern political geography’s founding in the 1890s was one of burgeoning inter-imperial rivalry and arms races between a set of great powers – Germany, Britain, France, the United States, Russia, and Japan – that reached its twin peaks in the two world wars. This period gave rise to the political geography that privileged the role of physical geography and relative global location in determining or conditioning state prospects and limits. Making arguments for control over oceanic sea-lanes and articulating geopolitical pretexts based on the relative propensity of different states to expand were major features of political geography in this phase.

The late nineteenth century was both the zenith of European empire building and the
time when new extra-European great powers, the United States and Japan, emerged into global prominence. So, not only were the European great powers, particularly Britain and France, renewing their colonial activities under stimulus from the colonialism of newly unified Germany and Italy, Europe was no longer the sole center of global imperialism. At the same time, and as noted by the British political geographer Halford Mackinder in 1904, the relatively easy expansion of worldwide empires into “open spaces” that began with Columbus’ voyage in 1492 had come to an end. With the exception of the polar regions, the expansion of any one empire now had to be completely at the expense of the others. More great powers and shrinking space for their expansion spelled possible doom for established and up-and-coming alike unless strategies could be fashioned to protect and enhance what they had from the threats posed by the others.

Of course, the “open spaces” were almost invariably occupied, but by peoples who had succumbed to European deceit, military prowess, and disease. As a result of this history, such peoples had long been judged the civilizational inferiors of Europeans but now they were also categorized as natural racial inferiors too. Into a political atmosphere of intense inter-imperial rivalry, therefore, came a new way of explaining the global political hierarchy based on the increasing acceptance of ideas of environmental and racial determinism. European “success” was, henceforward, to be explained in terms of the climatic and/or racial characteristics of Europeans relative to those whom they had conquered or dominated. If in the past providence had shone down or God had offered a helping hand, now natural characteristics associated with different world regions and the peoples who lived in them were to become popular ways of explaining global political arrangements and offering insights into how best to plan for this or that empire’s future success or brilliance.

The enmity between the great powers was not based solely on sheer willfulness or the will to power of this or that domestic group, such as the military or armaments manufacturers or other capitalists. The period from 1875 to 1945 was one of fundamental instability in the world economy because of the arrival of new great powers wanting to muscle their way into markets controlled by others and the declining capacity of Britain, the main commercial as well as colonial power, to provide its lending services to the world economy without damaging its colonial position. It is worth saying a little more about this because it provides the historical context in which modern political geography came into being.

The period 1815–1875 was one in which Britain held the balance of power in Europe, enjoyed a significant edge in sea power that allowed it a coercive role in imposing its trade and monetary policies around the world, and sponsored a set of doctrines – comparative advantage, free trade, and the gold standard – that, though appearing universal, benefited influential interests in Britain. This combination of European concert and British hegemony elsewhere began to collapse after 1870 once other states with powerful economic and military assets began to challenge Britain. Germany was by far the most important of these. Its capabilities could not be translated into an enhanced global political role without upsetting both the concert and the global flows of trade and capital centered in Britain. Concurrently, the increased industrial production of the United States and the European states undermined British industrial pre-eminence and led British business and governments into the use of nontariff barriers and colonial trade to restrict global free trade and price competition. The net result was an erosion
of the system of trade and finance centered around Britain and the emergence of a set of competitive imperial states dividing the world into zones based on territorial monopoly.

The Cold War era

The Cold War of 1945–1991, with its emphasis on global ideological competition between two models of “modernity” – the democratic capitalism of the United States and the state socialism of the Soviet Union – initially produced a diminished interest in the study of political geography. The field as it had existed before World War II did not seem to offer much food for thought in the new circumstances. Of course, the period did encourage a freezing of political borders and a seemingly permanent standoff between the two sides. Ideology not geography was what mattered. Nevertheless, even during this period geopolitical claims to spheres of influence and the definition of “buffer states” between the two “sides” were important parts of the overall conflict.

The political tenor of the times played an important part in the relative eclipse of political geography. Between 1945 and 1949 a whole new geopolitical order was constructed based on the values, myths, catchwords, and political-economic orientations of the two dominant states: the United States and the Soviet Union. The intellectual genealogy of political geography was ill-suited to this new world. For one thing, in their rhetoric both sides offered different conceptions of the political, on the American side liberal and on the Soviet side Marxist, from the statist one that had long dominated political geography. For another, the entire world was drawn into the bipolar conflict in a way that the world had never been divided previously. But this struggle was seen by all sides as ideological more than territorial, even if it had obvious geographical correlates (the “Iron Curtain” running through Europe, the threefold division of the world into US and allies, the Soviet Union and allies, and a “Third World” of mainly formerly-colonized countries in which the US and Soviet Union competed for influence, etc.) Of course, a more adaptive field in touch with intellectual currents in adjacent fields such as political science and diplomatic history might have had something of a more positive response. The personal danger of questioning the conventional wisdom needs emphasizing. In the United States, figures who did offer alternative perspectives were likely to receive subpoenas to appear before congressional committees investigating “un-American activities” or find difficulty in acquiring academic posts. As it was, in the 1950s nothing very new emerged in political geography in Western Europe and North America that was not based on a conventional wisdom that in eschewing the imperial hubris of pre-World War II geopolitics substituted descriptive gazetteers of border disputes and possible resource conflicts.

As the Cold War slowly eroded, however, political geography underwent something of a revival in the United States and elsewhere, as what had seemed frozen melted in unpredictable ways. The disastrous impact of the Vietnam War on the American economy and politics, the civil rights struggles in the United States, the major economic challenges facing the United States and the world economy following the collapse of the postwar economy, and the rediscovery of “the market” as an abstract guiding political concept all conspired beginning in the late 1960s and early 1970s to create what Daniel Rodgers (2011) called an “Age of Fracture” in which old assumptions about political and economic predictability and certainty were openly called into question. Few fields have been untouched by the wrenching changes of the period beginning at
this time. For political geography in the United States in particular, not only did the distinction between the “domestic” and the “foreign” begin to break down as a meaningful device for organizing thinking in the face of a globalizing world economy but all manner of new topics emerged for study; from the regional-ethnic movements empowered by the end of the Cold War and the invocation of an oft ill-defined “neoliberalism” as the ruling ideology of the age in explaining just about anything, to the challenges facing definitions of citizenship and understandings of nationality in a world of vastly increased international migration.

The revitalization of geography as a whole in the United States in the 1960s had a stimulating effect on political geography. A new generation of geographers discovered an interest in the spacing of social forms, such as urban settlements, land uses, and migrant flows. They increasingly addressed these empirically using the quantitative research methods popular in fields such as economics, demography, and urban sociology. The net effect was to improve the social status of geography as a university subject, at least among adjacent fields in the social sciences. Though the initial revival was to become the subject of controversy, particularly over theoretical and methodological issues, it set the scene for a revival of political geography.

Increasing opposition to Cold War sensibilities was also very important to the revival. While the nuclear arms race gathered pace and Cold War hysteria entered one of its darkest moments, a new generation started to react democratically by beginning to ask how the Cold War had arisen and how it could be made less dangerous. The paradoxical atmosphere of the time is well caught in Stanley Kubrik’s film Dr. Strangelove that in exposing the continuity between World War II and the Cold War also underlined the tragic risk of an accidental nuclear holocaust by presenting it as a comedy.

The events of the late 1960s in North America and Western Europe brought practical politics to the fore in the everyday lives of both ordinary people and academics. The race riots, civil rights marches, Vietnam War demonstrations, and student rebellions of the time had a deep impact on social science. In all fields they brought political questions to the center of concern in ways that they had never been before. In geography this tendency was expressed in three ways. One was by bringing issues of the distribution of power into the analysis of economic and social phenomena, such as residential segregation by race and class in American cities and the global distribution of economic development. These were no longer seen as purely market driven or a matter of free choice but the outcome of systematic bias in political institutions, such as local governments and school districts, managing the distribution of public goods. From this point of view, all of geography became political geography, at least of a kind. From the mantra of “states are everything” that had long animated political geography, geography as a whole confronted the claim that “politics is everywhere.”

Another expression of the political quality of the period was the politicization of geography through public analysis of the field itself: who runs it, for whom, with what ends in mind? In the 1960s higher education had expanded massively in the United States and elsewhere. An important consequence was the recruitment into student bodies and the ranks of university teachers of people from social backgrounds hitherto largely excluded from this world. They did not always accept the norms of personal conduct and political outlook that had evolved in academia during the postwar years. They also challenged the benign acceptance of statehood and international geopolitical hierarchy as “facts
of nature.” A significant example of this comes from France where Yves Lacoste (1976) crafted a new “geopolitics” based on a critique of the old version as essentially geography’s contribution to war-making by powerful states and insisted on the irreducible spatiality of politics within as well as between states. Lacoste’s “geopolitique” is one of the most obvious fruits of the explicit politicization of political geography to emerge in the early 1970s.

In addition, there was a dramatic increase in academic mobility, particularly within the English-speaking world, that brought people with very different social and national backgrounds to those countries, such as the United States, Canada, and Australia, that were most active in recruiting new graduate students and staff. The politicization was not simply disinterested or idealistic, however, because power within the field over staff appointments, publication outlets, professional reputations, and external influence was also very much at stake. The expansion of universities had the effect of dramatically increasing the number of students and faculties, increasing the volume of research and publication, and encouraging new intellectual trends and “niches” so as to find employment for graduate students and gain access to funds for research and graduate financial support.

Finally, political geography was discovered by a new generation without much background or interest in the old studies. They tended to view the subfield naively as something they were inventing afresh rather than an old enterprise into which they should be inducted. Without the old obsession with defining disciplinary boundaries, they searched around in other fields for inspiration and found it in economics, radical sociology, anthropology, economic history, and, even, in political science. At the same time, they embarked on explicitly redefining the field as the geography of politics more than the geography of states. Whatever the geographical scale or context – urban, regional, national, world-regional or global – as long as power pooled up in some places, political organization privileged some in some places over others elsewhere, and territorial boundaries were used to exclude and include, political geography had research questions of interest.

After the Cold War

The final collapse of the Cold War system first mapped out at international conferences at Bretton Woods and Yalta in 1944–1945 had actually begun two decades earlier than 1990. These two agreements imposed geopolitical order, respectively, on world monetary and territorial affairs. Bretton Woods created a fairly stable system of fixed currency exchange rates and Yalta froze the boundaries of postwar Europe and established the spheres of influence of the Cold War. The Bretton Woods Agreement ended in 1971 with the US abrogation of the use of the dollar as the world’s reserve currency and of the US as the lender of last resort. In 1989 Yalta came to a close. The end of the bipolar order started at the urban scale with the downing of the Berlin Wall (1989). It soon extended to the European scale with the reunification of Germany (1990), the collapse of the Iron Curtain and the disintegration of Yugoslavia, and reached its peak at the global scale with the implosion of Soviet Union (1991), officially ending the Cold War in 1992. After an interregnum of a decade in which a unipolar world dominated by the United States seemed in evidence, the geopolitical context began to take on a more complicated cast after 2001. The attacks by agents of the militantly Islamist al-Qaeda Network on the New York Trade Center and the Pentagon building of the US Department of Defense in Washington DC on September 11, 2001 were followed by the
US government’s declaration of war on “international” terrorism. Many Americans reacted by flying the national flag both as a symbol of their threatened identity and as a sign of their mobilization and support of a military response. These events seemed to portend the emergence of a geopolitical context in which states, however mighty, would confront shadowy networks of discontented and fanatic groups following this or that objective, often of a religious or ethnic nature. As this feature of a new world order, and other dimensions of it, such as increased flows of money, goods, and people between localities and regions in it, have taken geographical shape, political geography has also changed its shape in order to deal with what has changed. More recent events signal a very different global political environment from that of 40 years ago. Such events include the financial crisis of 2007–2009 and its pointing towards a restructuring of the world economy around an ascendant Asia and a declining Europe and United States, if also with an apparently enhanced role for national governments; the emergence of global environmental challenges such as climate change, a polluted food chain, and regional water shortages; the rebirth of militant nationalism around the world; and the collapse of many erstwhile states, such as Somalia.

One major difference with the past, therefore, is the complexity of the geopolitical context in which political geography is today being remade as opposed to the relative simplicity of the previous periods. Two background conditions are important in understanding much of what follows. First, a conversation rather than a dialogue of the deaf has begun to emerge between advocates of the three major theoretical “waves” that have swept over political geography since the 1970s. Some examples are provided in the section on Theoretical Perspectives in Contemporary Political Geography. This perhaps reflects the de-radicalization and routinization of what were once seen as totally opposing perspectives as their proponents achieve professional recognition and higher intellectual status. But this trend is also possibly the result of changing times in which geopolitical instability and uncertainty makes the theoretical certainty (even if about the certainty of uncertainty in some varieties of postmodernism) of the different positions increasingly untenable. While an increasing theoretical eclecticism would seem both more necessary and likely, then, as students educated more broadly than past generations emerge into prominence to deal with an increasingly volatile and geographically complex world, in some cases, post-Cold War geopolitical instability may produce an opposing trend: a hardening of perspective boundaries to defend against heresy.

Second, this world to which political geography directly addresses itself seems divided by identity-based (religious, national, local or economic) divisions that take very different geographical forms from the state-based colonial and worldwide-ideological systems that characterized the periods of inter-imperial rivalry (1875–1945) and the Cold War (1945–1991) during which political geography was previously made and remade. On the one hand, the world economy and many political movements (including religious ones) are organized in terms of spatial networks more than territorial blocs, as noted above; on the other hand, claims are made by leaders of dominant states and political movements on behalf of the welfare of huge geographical areas and their populations (such as the West, the Islamic World, etc.) as if these were homogeneous entities. These claims are often informed by a tremendous nostalgia for a period in the past (from medieval Islam to a golden age of state-based capitalism or the European welfare state) and for the “purity” of territories from “foreign” contamination but which now must confront a world in which people of diverse
cultural origins increasingly live intermingled with and interdependent on one another on a practical everyday basis.

In this context, three trends in political geography appear particularly significant. The first is a return to the old physical–human nexus of political geography, now in relation to how human threats to the natural “environment” are mediated by political institutions and movements. As climate change becomes increasingly connected to geopolitics, the risk of a reappearance of environmental determinism seems still far from being removed. So, one task of political geography is to offer approaches that steer well away from this reinvention of what previously proved to be a dead end for the field. The second represents the continuing drift away from state-centrism towards according a central role for “geographical scale” in understanding the geography of power. If the global war on terror has regressively renewed the importance of nation-states, the global financial crisis and the increased importance of the financial markets seem to subtract from conventional understandings of state territorial sovereignty. The third is the question of the nature of politics and its connection to the diversity of human experience. Political geography is finally addressing normative political issues concerning citizenship, democracy, group rights, and the role of intellectuals. These issues are increasingly fraught in a world of increased migration, economic interdependence, jurisdictional disputes over tax evasion, and the revitalization of ethnic and other identities. They are briefly addressed in the section on Emerging Themes in Political Geography.

From naturalized to critical knowledge

Political geography had a history before the term itself came into more widespread use in the 1890s. For example, the seventeenth-century Englishman William Petty’s idea of “political arithmetic” and his Political Anatomy of Ireland (1672) can be seen as historical precursors of late nineteenth-century political geography. In mid-eighteenth century France, Anne-Robert-Jacques Turgot used the term political geography to refer to the relationships between the facts of geography, seen as all physical and human features of spatial distribution, and the organization of politics. It is also apparent that many of the great figures in the history of political thought, from the ancient Greeks Aristotle and Thucydides to the early modern Florentine Machiavelli and later writers such as Hobbes, Locke, Montesquieu, Turgot, Madison, Rousseau, Hegel, and Marx, had ideas about political territoriality and the effects of geographical location and access to resources on conflict and war that can be regarded as basic elements of political geography. They picked up on the practical realities facing political elites and offered their solutions in the context of the historical periods in which they lived. Thucydides’ great work, The Peloponnesian War, concerns the two decades of war between Athens and Sparta (431–411 BCE) and forms the first example of use of the opposition between sea and land powers that later political geographers such as Halford Mackinder (1861–1947) in his famous work on control of the Eurasian Heartland used as a basic organizing principle of world politics.

The founders of modern political geography as such, therefore, could draw upon many centuries of relevant thought to inform their research and writing. But they were also creatures of their time. An important continuity across the early twentieth century is the naturalized understanding of knowledge that tended to dominate geography in general and political geography in particular. The university field of geography as a whole was invented in the late nineteenth
century in part as an offshoot of the growth of national geographical societies devoted to exploration, collecting information about exotic peoples, and the opening up of foreign lands to commerce and/or conquest. The other part of its origins lay in detailed mapping and portrayal of the regions and landscapes of national territories to communicate the material basis of national identity in the burgeoning elementary schools of the era. In this respect, of course, geography was one of a panoply of subjects with ancient roots that were reinvented under their old names to service the needs of statehood and empire-building: from anthropology’s measuring of physical differences between human groups and literature’s capture of national literary genius to history’s telling of distinctive and noble national histories. New fields such as sociology, economics, and political science acquired their own niches in the national service.

An increasingly prestigious and dominant thrust in all of the new “disciplines,” however, was toward a “naturalization” of knowledge claims. This is the tendency to want to explain human and social phenomena largely if not entirely in terms of natural processes, either physical or biological. In other words, they wanted to explain using processes assuredly not of mental construction that lay outside the questionable “human” realm in which values, interests, and identities were all subject to divergent interpretations and hence less amenable to “expert opinion.” The German thinkers who initially dominated the field, such as Friedrich Ratzel (1844–1904), were particularly given to this sort of approach.

Naturalization of knowledge claims had two vital intellectual preconditions. One was the separation of the scientific claim from the subject position of the particular writer (as in the “view from nowhere” mentioned previously). Claims were made to universal knowledge that transcended any particular national, class, gender, or ethnic standpoint. So even as a particular “national interest” was addressed, that focus was theoretically framed by a perspective that put it into the realm of nature rather than that of politics or society. This “view from nowhere” was by no means new, but it was very important to the new university fields in supporting their assertion of expertise and relevance to addressing the problems of the age. The second precondition was preference for the use of arguments drawn from the natural sciences to explain social and political phenomena. Thus, the principle of natural selection as proposed by Charles Darwin filtered down into popular culture and into fields such as geography largely in terms of the idea of survival of the fittest. This not only encouraged organic conceptions of nation-statehood (the state as a type of organism) but also stimulated ideas about racial competition, degradation, and dominion. Much of what passed for Social Darwinism, however, was inspired by the older evolutionary ideas of Jean-Baptiste Lamarck (1744–1829). These were both more open than Darwin’s reliance on variation over extended time periods to the immediate effects of the physical environment on social processes and, crucially, to the impact of “will” or intervention in creating more successful organisms. This allowed for the packaging of seemingly contradictory elements into a single study, such as races as biological categories arrayed according to their superior “consciousness” for which there was no natural basis whatsoever. Such ideas were widely shared among elites, not least the new academic ones, across all of the great powers.

After World War II, such ideas began to fall into disfavor, particularly in the United States. There had always been those who thought such logic limited or fallacious. But particularly in light of the expropriation of the term geopolitics
by supporters of German and Japanese expansionism in the interwar period, undoubtedly influenced in their reasoning by precursors such as Mackinder, political geography was tarred with the brush of a now defeated geographical determinism. Political geography went into something of a slump. It started to recover under two influences in the 1960s and early 1970s. One was the attempt to bring to bear classical concerns with territory back into political geography but without the biometaphysical bias. Crucial to this innovation were such figures as the French/American geographer Jean Gottmann (1915–1994) (e.g., *The Significance of Territory*, 1973) and the Norwegian political sociologist Stein Rokkan (1921–1979) (e.g., “Territories, Centers, and Peripheries,” 1980). The emphasis on state territories as the outcome of historically institutionalized and geographically variegated processes involving sovereignty claims and nationalism was a marked break with previous biological conceptions of territory. Later work, such as Robert Sack’s *Human Territoriality* (1986), both deepened appreciation for this contribution and extended it theoretically in new directions. Another influence came from a revival of electoral geography, first explored by Andre Siegfried in France in the early 1900s, with its focus on geographical patterns of election results and what they said about how people came to vote in the ways they did. Kevin Cox, Ron Johnston, and Peter Taylor were particularly influential in this regard (e.g., *Geography of Elections*, Taylor and Johnston 1979). This direction later developed into a more fully articulated linking of popular political views to the place settings or contexts in which people live (e.g., *Place and Politics*, Agnew 1987). If the approach of Sack and others tended to intersect heavily with positive political theory, electoral geography related more to research in fields such as political sociology and political science. In both cases, however, knowledge was seen as the outcome of human agency rather than of the direct effect of natural process.

Perhaps the most important theoretical departures, however, date from the 1980s when, respectively, Marxist ideas about statehood and capitalism and feminist and postmodern ideas about the discursive construction of geopolitics and political identities acquired increasing influence. In identifying the central role of the state in global capitalism and the social construction of political identities as a process beyond the realm of what was conventionally considered “politics,” these self-consciously critical approaches to knowledge called into question both the restriction of the “political” to a separate sphere and the independence of the state from broader economic and cultural considerations. As a result, political geographers referred to the limits of thinking about states in purely territorial terms (e.g., “The Territorial Trap,” Agnew 1994), argued for thinking about geopolitics in “critical” discursive terms (e.g., *Critical Geopolitics*, Ó Tuathail 1996), and refused to separate the economic from the political, although often with a tendency to privilege the former (e.g., *The Condition of Postmodernity*, Harvey 1989). Explicitly normative critiques of the modern state system and the competitive war machines that drive it, proposals for transnational democracy, and increased attention to looming global environmental disasters for which the geography of existing political arrangements seems ill prepared to respond, lay behind much of the renewal of political geography in the early twenty-first century.

**Theoretical approaches in contemporary political geography**

Three general approaches tend to dominate the field today, even though the lines between
them are not hard and fast. Indeed, more recent innovative research tends to work across them. The first, spatial analysis, involves the correlation of spatial patterns showing how a dependent variable, such as a vote for a specific political party, covaries geographically with various presumed independent or predictor variables such as class, ethnicity, religion, and age. In its stress on empirical data collection and analysis, this is akin to much of what goes for quantitative political science except, crucially, the emphasis is on how geographical variance fundamentally affects the nature of the correlations simply because closer locations are more highly related to one another than to more distant ones. Debates about important theoretical-methodological questions, such as the dependence of individual political preferences and behavior on spatial context (the local economy, whom you talk to, etc.), the “levels” or geographical scales at which variance is more or less concentrated (are differences local or regional?), and the clustering of different political phenomena (e.g., votes, riots, strikes, civil wars, territorial disputes, diffusion of different political institutions) in different places, tend to animate the approach (O’Loughlin 1986, 2003). The popular idea of a United States divided up into so-called red and blue states reflects a primitive version of the notion that where you live can have an independent effect on how you think and act politically separate from simple demographic indicators added up irrespective of how their effects intersect in people’s everyday lives in particular places.

The spatial-analytic approach is exemplified by the theoretical logic provided by Kevin R. Cox and David R. Reynolds in a book published in 1974. After a brief review of the neglect of geographical considerations in studies of power and conflict, the authors identify two factors that they see as leading to an increased concern for space in political studies: the increasing effect of externalities (effects on others who are not parties to a transaction) on people in industrial societies and the adoption of “systems” perspectives in political science that tend to increase the attention given to outcomes of the political process (who wins where) rather than just the political process itself. So, even if politics in the past could be thought of as “spaceless” this is no longer the case. The focus on urban settings and the spatial patterns produced by externalities (think of pollution plumes from factory chimneys and the benefits from living inside the catchment boundary of a high-quality high school) firmly distinguished the approach from previous ones. The logic, however, is not specific to either the urban scale or to such local external effects. It can be extended to interpret national and international relations in similar terms, as can be seen in Cox (1979).

During the 1970s geography experienced something of a turning away from the dominance of this spatial-analytic perspective. In the context of an extended period of political and economic crisis in many Western countries, many political geographers turned towards theoretical perspectives that could encompass the current situation as well as offer fresh understandings of old topics. A revived political economy proved especially attractive. Drawing in particular from Marxist and neo-Marxist writing in political economy, scholars framed political-geographical phenomena in terms of global patterns of uneven development and the processes that they claimed produce them. One variety of this approach that of the world-systems theory associated with Immanuel Wallerstein, proved particularly influential in political geography. This particular theoretical perspective was first popularized in Peter J. Taylor’s textbook (1989) and has led to numerous publications by Taylor and others, such as a paper showing how elections in a country such as Ghana have much to do

POLITICAL GEOGRAPHY
with not just that country’s but also different regions within that country’s commodity trade links to the world economy (Osei-Kwame and Taylor 1984). Theoretically eclectic, drawing its main tenets from such different thinkers as Fernand Braudel, Karl Marx, and Karl Polanyi, this perspective tends to explain most other phenomena with respect to where they are located within a global division of labor (core, periphery, semiperiphery) produced by the historical workings of the capitalist world economy. Under the political-economic rubric, however, can be found a range of perspectives, some adhering closely to an orthodox Marxism privileging the process of capital accumulation pure and simple and others exploring the autonomous powers of states. What joins them together is their view of space as a surface upon which political-economic processes (whatever the specifics) are inscribed and embedded but which is nevertheless essential to the outcome of the processes (e.g., providing the “spatial fix” to the declining rate of profit by moving investment from one place to another, defining the spatial limits to state autonomy, etc.).

This second approach is clearly committed to a political-economic analysis that foregrounds the geography of uneven development at a variety of geographical scales, from the global to the metropolitan. From this viewpoint, over time, the cycles of global economic expansion and contraction are seen as particularly influential in structurally shifting geographical patterns as new places are incorporated and old ones shed their historic roles. By way of example, political parties can be viewed as rising to represent distinctive political-economic interests that tend to cluster in different places because of the history of uneven development.

Finally, a third perspective tends to reject the overt rationalism of the first two modernist ones. In a register that emphasizes the role of the observer, the world is seen as written about rather than discovered or explored. Although writers under this rubric differ in the degree to which they see an “external world” as having an independent reality, the commonality is the rejection of the simple correlation and cause-effect relationships that are the basis for the other two. In a postmodern vein, language and discursive strategies become the focus. So-called critical geopolitics, for example, involves deconstructing the representational and communicative strategies employed by politicians in constructing foreign-policy crises, situations, and wars. From this viewpoint, these things never just “happen.” Some of the narratives help to anchor national identities, whereas others relate to the global agendas of elites in pursuit of this or that interest or policy (Campbell 1992; Sharp 2000).

Over the years many thinkers have questioned the pretensions of “grand theories” and “master narratives” in the social sciences, pointing to how they “over reached” the empirical evidence used to support them. Others have suggested that knowledge was more a product of language, conventions of study, and the relative power of different scholars than based on independent “facts” about the world. As a result, one critique, associated particularly with feminism and postcolonialism, came to emphasize the partiality or “situatedness” of knowing; knowledge is a function, at least in part, of the standpoint or subject position at which a scholar is located, particularly the historical experience of power relative to others and, thus, the capability to tell your story and those of others like you. Another critique came to play up the role of language and writing in offering meaning to readers. From this point of view, the world is entirely as it is written about. In other words, in this poststructuralist or deconstructionist view, writers recycle metaphors and tropes rather than discover new knowledge. Finally, some identified the tenuousness of all claims to tell “stories” about other
people and their places. Even “emancipatory” narratives, stories told to benefit the interests and identities of others, involve a quest for transcendence that disciplines and limits the aspirations of presumed beneficiaries. In this postmodernist view, respect for irony, ambiguity, and the paradoxes of existence remain as the only guarantees against imposing order on others. To the extent that it is possible, one looks for the stories that groups share to understand their self-constructions. By way of example, Sankaran Krishna (1994) uses the metaphor of “cartographic anxiety” to convey how discourses about an Indian “nation” are used to define the borders of contemporary India as a putative nation-state. The “body politic” of India is defined in terms of a physical map that tries to conjure up a “historical original,” a “homeland” that never existed prior to British colonial rule. So, not only are those at the borders of India caught up in an exercise in spatial self-definition that is the essence of nation-statehood: abstracting from history a set of stable, legitimate boundaries that fix the history of the state in place and guarantee it a place in future. The map, therefore, is an attempt at answering definitively the anxiety that comes from being “suspended forever in the space between the ‘former colony’ and the ‘not-yet-nation’” (Krishna 1994, 508).

There are signs of theoretical rapprochement, particularly in some research and writing on geopolitics and the rise of deterritorialized forms of power, such as those associated with so-called global cities and world-city networks. For example, Agnew and Corbridge (1995) attempted to bridge the divide between political-economic and postmodern perspectives by showing how “geopolitical order” – based on trends in the practical political economy of world politics – and “geopolitical discourse” – the ways of seeing and thinking about world politics – interrelate to produce the everyday practices of world politics. They identify different historical periods in which order and discourse relate to one another in distinctive ways to resolve the difficulty that arises in ahistorical accounts of giving priority to one over the other. Their historical geopolitics represents an attempt at engaging with both political-economic and postmodern perspectives rather than favoring only one of them.

In a different vein, an interesting combination of political-economic and spatial-analytic perspectives is apparent in the Beaverstock, Smith, and Taylor (2000) project on world-city networks. Criticizing the state-oriented understanding of the world that dominates both world politics and the social sciences, they propose instead a focus on the world of flows, linkages, and connections among the world’s cities. They bring together the explosive growth of service industries, the increased importance of information technology, and the tremendous development of worldwide direct investment to propose a theoretical framework for mapping what they call “the intercity global network.” Taking a roster of 55 world cities, they show how firms from some set up shop in the others. Empirical analysis of these linkages shows that there is a definite hierarchy to them, with some cities, such as London and New York, currently sitting on top. This pattern suggests that “networks” are beginning to challenge “territories,” if not for the first time, as an organizing principle of global geopolitics. Importantly, however, the authors note that “World cities are not eliminating the power of states; they are a part of a global restructuring which is ‘rescaling’ power relations, in which states will change and adapt as they have done many times in previous restructurings” (Beaverstock, Smith, and Taylor 2000, 132).
POLITICAL GEOGRAPHY

In the study of nationalism and ethnic conflict there has been a different rapprochement between spatial analysis, on the one hand, emphasizing the spatial patterning of conflicts and, on the other hand, postmodern approaches to interpreting the narratives or stories told by the combatants. Good examples come from the joint research of John O’Loughlin and Gearóid Ó Tuathail on ethnic conflicts in Bosnia and the Caucasus (2009) and Gerard Toal and Carl Dahlman (2011) on the return of displaced people to Bosnia in the aftermath of conflict. The latter study is an exemplary attempt at weaving together what can be termed “facts on the ground” about the geography of ethnic “cleansing” and the political debates and different stories of various parties to the resettlement of displaced people including foreign participants. Such research is not classifiable in terms of a single “approach” and is suggestive of future possibilities beyond the threefold categorization that tended to characterize political geography at least into the 1990s.

In the future more “violation” of the theoretical boundaries that have subdivided political geography in the recent past can be expected, if only because the world to which political geography is applied is changing rapidly and in ways that make the previous “intellectual division of labor” increasingly irrelevant. In particular, the emerging “geopolitical order” is one that challenges the fixed spatial claims of spatial-analytic perspectives, the unchanging political-economic imperatives of many political-economic perspectives, and the focus on dominant discursive representations of postmodern approaches.

Emerging themes in political geography

Trying to identify the emerging themes of political geography requires divining from recent trends those likely to emerge into prominence because of their fit with the developing geopolitical context. The purpose here is certainly not to exclude other topics from any future political geography or to offer an encyclopedic inventory of all contemporary trends in subject matter. Rather, drawing attention to the current “making” of political geography allows us to show how active the redefinition and reworking of the field actually is. This is not to simply endorse what we consider the avant-garde and disregard what has been emphasized in the past. The purpose is to illustrate the flow of influence between the contemporary geopolitical context, on the one hand, and the making of political geography, on the other.

In brief, three trends stand out. While the politics–environment nexus may have been disregarded within the geopolitical context of Cold War political geography, there are now significant examples of research that show how political geography can fruitfully engage with different aspects of the environment: from the analysis of how the uneven geographical distribution of resources could contribute to conflicts, to the politics of the environment, to the environmental connection to development issues. Moreover, the increasingly pervasive topic of climate change – perhaps as pervasive today in the public arena as security discourse – has opened multiple connections to questions of development, security, governmentality, scales of governance, and many other issues. Perhaps the possibility of resource wars, environmental security, and some of the many implications of climate security, in their relation to state sovereignty, violent conflicts, and human security stand out.

A second theme concerns the continuing debate about geographical scale and political analysis. The political-economic approach, for example, emphasizes scale as a social construct
incorporating and expressing power in terms of the dominance of one scale over the other, from the global to the local. The poststructuralist approach emphasizes the relational character of scale and how scales come to be represented and enter into different discourses. The two perspectives are not necessarily mutually exclusive in their understandings of scale (and space). As Anssi Paasi (2004) observed, relational networks and bounded territorial spaces may coexist. Therefore, the two approaches can actually complement each other, even if the former privileges direct and the latter intellectually mediated accounts of causation. Four examples can serve to illustrate the importance of considerations of geographical scale in contemporary political geography. The first is the rising role of cities and their transnational networks in climate governance. The second is the role of territorially embedded networks of power in world politics. One particular case is that of the Al-Qaeda network in its association with the September 11, 2001 attacks in the United States. The third is the changing “balance” of geographical scales in electoral politics, showing how “nationalization” is not the singular fate of electoral outcomes but can also involve localization (or fragmentation). The fourth example is of the emerging global system of finance linking major global cities and offshore banking centers in loosening the bonds of national financial regulation and currency markets and, consequently, undermining the close match between financial flows and national territories. In each case, however, it is the intersection of processes across scales rather the singular dominance of one scale (i.e., global networks versus states or the local) that is at work in the analysis.

Third, unlike mainstream political theory’s rigorous focus on concepts such as interests, power, and sovereignty, little or no attention has been paid until recently in political geography to critical analysis of the concepts that the field has been based on: territory and territoriality, space and place, nation-states and statehood, nationalism, sovereignty, and national identity, power and hegemony, geographical scale and networks, violence and boundaries, and so on. The theoretical aphasia finally began to dissipate in the 1970s with critiques of spatial analysis from broadly analytic-philosophical and Marxist perspectives. But only in the 1990s did a critical attitude towards normative assumptions begin to permeate the field as a whole, extending from analysis of conventional views of state territoriality to the language of foreign policy, understandings of power, the violence of national boundaries, and place and political identity in democratic practice (Elden 2013; Barnett and Low 2004). Particularly important in political geography have been deployments of the idea of “governmentality,” drawing from the writings of Michel Foucault. In this locution, power is seen as inherent in all relationships and institutions rather than being a singular property of states or other formal political entities (Allen 2003; Legg 2007). Currently, four areas seem particularly important for the further development of a normative political geography, engaging with debates about actual changes in the world of politics and with important normative aspects of political geography as a field as yet without the attention they deserve: transnational democracy, weapons and warfare, caring for distant strangers, and democratic states and intellectual freedom (Agnew and Muscarà 2012, Chapter 5). The future of political geography remains to be made.

Polycentricity

Christian Vandermotten
*Free University Brussels (ULB), Belgium*
*Belgian Royal Academy, Belgium*

The term “polycentricity” designates an urban system showing a more or less equilibrated functional, and possibly population, pattern. It is opposed to “monocentricity,” where one single city concentrates all the main functions, or at least to very pyramidal and hierarchical urban systems.

Monocentric urban systems are seen to engender such strong territorial disparities that they can even handicap overall national economic development, as was suggested in France by Jean-François Gravier in his book *Paris et le désert français* (Paris and the French desert) in 1947. In France, this was the basis of the policy of “métropoles d’équilibre” (equilibrium metropoles), the promotion of investment in big provincial cities to counteract the weight of Paris, from the 1960s onwards. In a sense, this policy anticipated the promotion of polycentrism, the term being then used not only as a description but as an aim. At another scale, in the Paris metropolitan area, the same concept has been used to found the policy of creating new towns around the French capital. The birth of the concept of polycentricity is thus implicitly embedded in the implementation of regional economic policies, as well as in suburbanization processes and the increased integration of cities and their surrounding hinterlands.

However, the concept remains polysemic, unsharp, multiscalar, and simultaneously descriptive (polycentricity) and normative (polycentrism).

As a descriptive tool, the concept is often used to describe, as more or less polycentric, the pattern of cities and their functional urban areas (FUAs) at the highest levels of the urban hierarchy, or even the business networks linking cities at a continental or worldwide scale. But it can also be used at larger scales for describing more local urban networks, metropolitan regions, or even intra-urban patterns, focusing on the location of business activities (one or more central business districts; possibly “edge cities”) or on retail patterns.

A lack of explicit definition of the scales (and the variables examined, morphological or functional) can lead to opposite conclusions: the German urban system is the archetype of a polycentric one, but considering for instance only northeastern Germany, it is strongly monocentric, centered on Berlin (which at the intra-urban level is a polycentric city); the French urban system is always presented as the archetype of a monocentric one, but it is very polycentric, considering, for instance, southeastern France. In a sense, Christaller’s and Lösch’s classical central places theories describe both monocentric and hierarchical structures as polycentric, depending on the scale at which the patterns are considered.

It also depends on the variables considered: if the United Kingdom is less monocentric than France when considering the population pattern, due to the importance of the conurbations linked to its coal mining and manufacturing past, concentration is at least as high as in France in terms of the location of company headquarters in the capital metropolitan region. Looking at
POLYCENTRICITY

population distribution patterns, Belgium, especially Flanders, presents a very polycentric urban network, but in terms of the functional hierarchy and the international links of the cities, and even the daily commuting pattern, it is much more monocentric, centered on the Brussels-Capital Region, which produces 20% of the Belgian gross domestic product (GDP), with the whole Brussels metropolitan area accounting for nearly one-third.

Different measures of polycentricity have been proposed: the share of the main city in the (population or economic) system; the ratio between the main city and the next cities in the rank order of cities, the slope of the line plotting the ranked distribution of cities, and so on. But, mainly in international comparisons, these measures can be strongly influenced by possible heterogeneities of the territorial definitions on which the data are based. The question arises as to whether the population considered is for the administrative units, for the morphological areas, or for the functional areas; and whether contiguous urban areas should be combined into one or not. Also the sizes of the countries have to be considered: a similar percentage of the population or of economic production or command in the main city of a small country doesn’t have the same meaning as in a large country.

At the metropolitan level, polycentricity can be described from a morphological point of view, characterized by different historical cores and major peaks of rent prices or population densities, or at a functional level, with several main employment cores, important multidirectional commuting flows, and possibly specialization and cooperation between these cores.

As a normative concept, the success of polycentrism grew dramatically during the past decades, in parallel with the development of network theories, in the context of the globalized post-Fordist economy.Implicitly, a polycentric urban system, with each city well related to the others by strong and complex material and immaterial links, is supposed to lead to better chances in the contemporary tertiarized economy. Through better networking in polycentric systems, smaller cities hope to get better opportunities. At the metropolitan scale, a multicore structure is supposed to avoid high congestion costs.

However, cooperation and specialization between cities in polycentric systems is far from being systematic. In many Marshallian industrial polycentric districts or areas, such as Silicon Valley, cities are not specialized but are inserted into specific proximity networks, enabling cross-individual relationships between enterprises. In the reverse case, cities located in polycentric urban areas, such as the early manufacturing or coal-mining basins, suffer generally from weak functional linkages, due to their similar obsolete economic structures: polycentricity is then only an “image on the map.” Cooperation links between cities are often not related to vicinity.

Even considering more or less homogenized scales, there is no clear empirical evidence that national polycentric patterns as such perform better or engender more interregional equity than more monocentric ones, either economically or even taking into consideration sustainable development criteria. It remains very unclear why regional morphological polycentric urban systems should imply more cooperation between cities inside the system, and consequently more economic growth. Linkages between polycentricity and the spatial scope of agglomeration externalities remain badly theorized.

At the metropolitan and intra-urban scale, the environmental situation is no worse in more monocentric systems, and public transport even appears to be better within the latter.
The question then arises: What explains the political success of the normative concept of polycentrism, largely promoted in European strategic planning documents, such as the European Strategic Development Plan (1999), the Territorial Agenda of the European Union (2011), and in the same way by many national planning authorities?

The promotion of polycentrism at European and national scales, on a par with the insistence on globalized networks, appears to be politically in line with the transition from priorities associated with Keynesian cohesion policies towards more neoliberal competitive ones. Such a transition is supposed to improve global economic growth, in terms of GDP, but instead concentrates it spatially. Through more polycentrism, implying a reinforcement of strong nodes within a national (or a European) system, each country or each part of a large country should thus be able to attract some profits from this more competitive (and concentrated) economy.

So, this vague concept allows a European consensus, with each region or big city, and even second-tier cities, hoping to benefit from strengthened competition, even if regional funding is in fact reduced. They then have good reasons for launching benchmarking studies, trying to improve their exogenous attractiveness in the framework of international business networks.

Despite this strategic promotion of polycentrism by the European (and national) authorities, the spatial concentration of economic command functions is not fading globally, nor at the international or national scales. More monocentric or more polycentric urban networks and patterns are historical products, reflecting long-term national and economic histories and associated spatial developments. It is doubtful that European or national public policies could strongly change these patterns, especially in a period of reduced funding for regional policies.

Finally, at the local scale, related to spatial planning, the idea of polycentrism can draw near to the one of “deconcentrated concentration,” referring to a better organization of suburban sprawl areas, for instance by concentrating residential areas around main railway stations. It can also refer to new towns or edge district developments, or even to the promotion of several new business or shopping districts and flagship projects inside the more or less central parts of the morphological area.

Popular culture

Thomas Stieve
Chris Lukinbeal
University of Arizona, USA

Marcel Danesi’s Dictionary of Media and Communications (2009) defines popular (pop) culture as cultural products such as television shows, pop music, fashion, shopping, comic books, and so on, that are geared toward mass consumption. Such different forms of culture and representation have offered fertile ground for new areas of investigation and theorization in geography. The history of geographic research in popular culture shows how paying attention to these cultural products has created different units of analysis and implications for the discipline. Starting in the 1960s with humanism and landscape studies, geographical inquiry started to include place experience in examining popular cultural forms, such as novels and music. Subsequently, in the 1970s and particularly the 1980s, philosophical and methodological debates also arose between those favoring behaviorist and those espousing Marxian interpretations of popular culture. By the 1990s, geographers were expanding their analysis to focus on still more diverse forms of media, and adopting different theoretical lenses in their analysis. Film was now used to analyze the crisis of representation, and television in the understanding of mediated places. The impacts of globalization and commodification have been examined in the new century. The effects of the international trade of cultural items and the influence of commodified music on space and time, for example, have drawn research attention.

J.K. Wright was one of the first geographers to focus attention on popular culture as a valid area of study. In his presidential address to the Association of American Geographers in 1947, he suggested that geographers should not only be concerned with the traditional formal or objective areas of studies, but also “peripheral areas,” such as travel books, magazines, newspapers, fiction, poetry, and paintings. Wright proposed the term “geosophy” to encompass this kind of study of geographic knowledge (Wright 1947). Although this concept was groundbreaking for its time, it took many decades before others would explore Wright’s terrae incognitae, or unknown lands.

Interest in popular culture emerged again in the 1960s–1980s, as humanist and landscape studies sought to move away from regional geographies and the quantitative revolution to the individual, the everyday, and popular culture. Relph (1976) suggested that popular culture affects how a person experiences place, and that popular culture via mass media encourages placelessness as it destroys authentic place experiences. Mass media suggest one way to experience place but are often equated with the dominant culture’s ideology. This theme was later addressed by researchers interested in globalization and the commodification of culture.

In the 1970s and 1980s popular culture was only selectively studied. Even with its rejection of positivistic investigation, the humanist movement’s study of popular culture concentrated only on literature and art. For example, Pocock (1981) pointed out that human geography is an art and social science, but the latter uses objective techniques. Authors in this collection of essays eschewed the positivistic framework.
and suggested approaches that engage the experience of region, place, and the environment through literary criticism. While analyzing the Sherlock Holmes series, Yi-Fu Tuan (1985) created a bridge between literature and popular culture by suggesting that research should focus on “nowness” and “permanence”: “nowness” means that a work of art reflects the social milieu of an era, while “permanence” questions a text’s impact based on its popularity within the era in which it was created, as well as its staying power. Continuing popularity occurs when a work of art speaks to what we call the human condition.

Burgess and Gold (1985) argued that geography does not value research on popular culture and the media because they are considered mere entertainment, and went on to suggest that existing research fell into two categories: those that adopted the American approach and those that privileged the European approach. Where the Americans use a behaviorist approach, the European approach favors a Marxist one. Geographers using a Marxist approach seek to uncover hidden ideologies written into mediated text, which naturalize class inequalities as well as other power relations that reinforce the status quo through popular culture. The authors’ type-casting of the two camps reflects a positivistic versus critical theory divide which, in practice, does not exist. This simplistic distinction ignores humanistic geography and its relationship with environmental perception and behavioral geography. While behavioral geography and environmental perception both use cognitive and social psychology theories, the former relies on the scientific method but the latter does not. This is a key distinction, as environmental perception, especially through transactional theory, was widely used in the 1990s to examine media. Transactionalism focuses on the person in the environment as a dialectic contingent on specific spatial and temporal contexts. In Place Images in the Media, Zonn (1990) used a transactional approach to situate the filmmaker, the medium, and the audience.

In 1994 Stuart Aitken and Leo Zonn coedited the first book about film by geographers. Place, Power, Situation, and Spectacle was published around the time that geography was going through the cultural turn and the crisis of representation. “The cultural turn” was an intellectual shift in which culture was not only brought to the forefront but also, through the crisis of representation, questioned the mimetic role of positivistic epistemologies. Aitken and Zonn (1994) pointed out that film, as a form of popular culture, has been neglected because geography emphasized material over nonmaterial culture studies. In their view, as a result of the postmodern condition, there is little difference between real and reel life, and film must therefore be central to geographic investigation. Cresswell and Dixon (2002) claimed that film is one of the most popular areas for geographic research and teaching.

While film has received lots of attention by geographers, television has not. Paul Adams (1992) argued that television can be considered a complex organization of people, technology, and symbols, where social practices overlap with television depictions. Like a monument that offers a focus to a community, it provides a gathering place for social life. Television also structures participation along a social division based on who can and who cannot appear within the monument. Those who appear on television have power conferred on them. In Place, Television, and the Real Orange County, Fletchall, Lukinbeal, and McHugh (2012) explored television place-making through a case study of three popular US television shows: The OC, Laguna Beach: The Real Orange County, and The Real Housewives of Orange County. More than just representations of reality, mediated places are an inextricable part of our daily lives and directly.
engage the processes of place-making by affecting our perception, senses, and subjectivity. This book showed that mediated places, especially as seen on television, matter.

More recently, geography has used popular culture to understand the commodification of culture. Rosati (2007) researched how the MTV network uses statisticians and psychologists to analyze audience reactions to songs. Like empires in the past, media enforce a monopoly on cultural life by destroying time with space: that is, the cultural product becomes so popular that it controls the time period of its airing and thus eliminates all other activities in space. Whereas Rosati’s focus was on music in the mass media, Miller (2014) analyzed how shopping malls in Argentina are engineered to create a certain affect for consumption by the playing of pop music. Music acts to encourage people to spend time in the mall and be a part of pop culture, regardless of purchases made.

The relationship of globalization to pop culture has become an area of interest to geographers in the past decade. Jakob Nobuoka (2010) studied how the Akihabara area of Tokyo, Japan, has had a worldwide influence. This small place, an area surrounding a railway station in the Japanese capital, is where many high-tech department and outlet stores offer Japanese cultural products: manga, anime, anime collectibles, video games, and so on. It also provides a space where fans and creators can come together to exchange ideas and knowledge about the meaning of these cultural items, which, in turn, influences their production. With this newly elaborated knowledge, new cultural products can be manufactured and sold globally to an ever-receptive market.

In addition to cultural products such as anime, globalization can be seen in music. Connell and Gibson’s Sound Tracks: Popular Music Identity and Place (2003) is often cited as the first book to deploy critical theory to engage music geography. For the authors, music is embedded in local practices that can transform social relations, as well as define and shape settings for social action and identity; however, music can also be thought of as a global commodity, a cultural product that is exchanged and used. Music allows popular culture to resonate through mobility, different scales, and transnational landscapes, for example Andean music played in Times Square in New York City. With new technological, cultural, and economic shifts, music is embedded in social networks as well as local–global exchanges of cultural products and practices. In another study of the globalization of popular culture, Stanley Waterman (2006) argued that, whereas European classical music has been considered the national music of Western-identifying Israel, globalization has also led to the importation of Western commercial music, causing many to worry about an Americanization of the country’s culture. Therefore, discourses of high and low culture (classical and commercial music, respectively) have been mobilized in globalization debates.

Popular geographics

Jerome E. Dobson  
*American Geographical Society, USA*

Geography and public education go hand in hand today as they have done for at least 2400 years. Even the earliest known attempt to write for the public lay firmly in the realm of geographic education. Ancient and modern scholars often credit Isocrates (436–338 BC) with being the first professional writer, founder of the modern approach to higher education, and the most successful teacher of classical rhetoric. What truly distinguishes his writing is that it was the first ever directed to the public … and his topic was urban geography (Marsh 2013).

Today, geography is taught from the kindergarten, through doctoral programs, and to the public at large, but its academic and public fortunes have waxed and waned wildly along the way. At times geography blossomed among scholars and the public as it had done in Greece and Rome during the classical age and in Europe and the Americas from the Renaissance to the mid-1900s. At times it lost favor and slipped into fantasy as in Europe during the Dark Ages and the United States today. There were always distinctions between what was taught in school and what was broadcast to the public, and there were always geographical patterns of where it was taught and where it wasn’t.

Among all disciplines, geography stands out for its vast bodies of phenomenological and methodological information. The amount of geographical information and data required to describe and explain a gargantuan Earth in all its complexity, covering all physical and human entities and processes, exceeds that of any other discipline. To convey even a generalized portion of that knowledge from one generation to the next requires the collective efforts of teachers at all levels of education, but that is not enough. Thankfully, society fills in with popular magazines, atlases, documentaries, and digital sources; some parents teach their children basic map and navigational skills; and other disciplines infuse geography into their own subject matter.

Likewise, the body of knowledge required to analyze all physical and human processes in their geographical contexts worldwide exceeds the phenomenological breadth of any other discipline and presents unique challenges due to geography’s insistence on spatial analysis, scientific integration, place-based research, and fieldwork. Throughout history, geographic methods have been taught almost exclusively in institutions of higher education, but certain exceptions among the public are conspicuous. We are currently witnessing a societal movement of massive proportions. Private individuals are using geographic technology, mapping geographic features of interest to themselves, volunteering to map information of great usefulness to other people in all sorts of crises, and building software for free and open use by vast segments of the public.

Many names – neogeography, GIS 2.0, FOSS4G – have been suggested for the nebulous collection of geographic technologies – popular computer mapping and imaging websites, volunteered geographic information (VGI), public domain software, spatially enabled social networking, crowdsourcing, and so on – that so excite the public today. It is, in fact, the

democratization of geography, automated geography, and geographic information science that has been advocated since 1983.

“Popular geographics” serves well as the covering term for all geographic information technologies that can be understood and employed at little or no cost and without much formal training, in the same sense as “popular science” and “popular mechanics.” Subsumed terms and definitions, gleaned from pertinent publications and websites, include the following.

• Neogeography: Literally, “new geography” is the use of geographic techniques and tools for personal and community activities or by a nonexpert group of users (Turner 2006).
• GIS 2.0, open GIS, open source geo: “a new generation of digital geographic tools … a converging set of technology trends including open source software, decreasing computation costs, ubiquitous data networks, mobile phones, location-based services, spatial database, and cloud computing … dramatically expanded access to geographic data and spatial analysis by lowering the barrier to entry into geographic computing. This expansion is leading to a new set of business models and organizations built around geographic data and analysis” (Disruptive Geo 2013).
• FOSS4G (www.foss4g.org): An organization called Free and Open Source Software for Geospatial (FOSS4G) holds a conference every year somewhere in the world. About 1000 individuals collaborate voluntarily to advance the cause of free and open software specifically for geographic applications. FOSS4G brings together a mix of developers, users, decision-makers, and observers from a broad spectrum of organizations and fields of operation for five days of workshops, presentations, and discussions under the theme of “Geo for All.” The 2015 meeting in Seoul, Korea, drew 562 attendees from 48 different countries.
• Volunteered geographic information (VGI): a georeferenced type of citizen science, a growing area of information gathering. The term was coined by geographer Michael F. Goodchild who, in exploring the world of user-generated content on the web, noted that “a remarkable phenomenon … has become evident in recent months: the widespread engagement of large numbers of private citizens, often with little in the way of formal qualifications, in the creation of geographic information, a function that for centuries has been reserved to official agencies. They are largely untrained and their actions are almost always voluntary, and the results may or may not be accurate. But, collectively, they represent a dramatic innovation that will certainly have profound impacts on geographic information systems (GIS) and more generally on the discipline of geography and its relationship to the general public. I term this volunteered geographic information (VGI), a special case of the more general Web phenomenon of user-generated content” (Goodchild 2007, 212).
• Public domain software: software in the public domain with absolutely no ownership such as copyright, trademark, or patent, often because it was generated through government-funded activities.
• Spatially enabled social networking: automatically adding geo-coordinates to messages generated by Facebook, Twitter, Instagram, Foursquare, and other social networking software.
• Crowdsourcing: According to Wired magazine’s Jeff Howe, who coined the word, “Simply defined, crowdsourcing represents the act of a company or institution taking
a function once performed by employees and outsourcing it to an undefined (and generally large) network of people in the form of an open call. This can take the form of peer-production (when the job is performed collaboratively), but is also often undertaken by sole individuals. The crucial prerequisite is the use of the open call format and the large network of potential laborers” (Howe 2006).

- Open publication: Open access (OA) means unrestricted online access to peer-reviewed scholarly research. Open access is primarily intended for scholarly journal articles, but is also provided for a growing number of theses, book chapters, and scholarly monographs.

- Participatory GIS: making geographic information technology available to disadvantaged groups in society to enhance their capacity for generating, managing, analyzing, and communicating their own geographic information (http://www.ppgis.net/). The American Geographical Society’s Bowman Expeditions, for example, provide equipment, training, and advice to indigenous communities so they can map their own lands and resources and thereby defend their ownership rights.

- Google Earth (www.google.com/earth): Google Earth is a virtual globe, map, and geographical information program, originally called EarthViewer 3D and created by Keyhole, Inc., a Central Intelligence Agency-funded company acquired by Google in 2004. It maps the Earth by the superimposition of images obtained from satellite imagery, aerial photography, and geographic information systems (GIS). The Google Earth Community, specifically those who register and add a location, consisted of approximately 160,000 individuals in April 2015, when the forum switched to even greater management by volunteers.

- Popular computer mapping and imaging websites and services: Many popular websites serve individuals wishing to locate or map Earth features of personal interest to them. Google Earth is by far the largest. Other sources include vast collections organized by the Federal Geographic Data Committee (www.fgdc.gov) and offered by various federal departments, plus many nongovernmental sites with data derived from them. Trails.com (www.trails.com), for example, offers digital topographic maps developed by the US Geological Survey. Many geographic databases are available for free, as well, from states and local governments throughout the United States. Worldwide, however, many governments insist on cost reimbursement for geographic data.

Today’s popular geographics movement is reminiscent of the eighteenth and nineteenth centuries when gentlemen scholars abounded and ladies of means hosted salons for debating the latest mysteries and discoveries of science, often including geography and Earth exploration. Now everyone can have a little or a lot of the globe to study and enjoy at leisure, earn a living, or help others. Significantly, both movements have included methods and techniques as well as information and data. Men and women often volunteer their time and talents to produce new geographic information, sometimes assembling this face to face, sometimes via Internet, and always digitally connected. The American Geographical Society (AGS), known since 1851 for advocating geography in government and industry, has adopted popular geographics as a major cause. Executives of organizations engaged in this burgeoning new industry now constitute nearly half of
its governing council. Not-for-profit volunteer mapping organizations, with snippets of description from their own websites, include the following.

- OpenStreetMap (www.openstreetmap.org): OpenStreetMap is a map of the world, created by people like you and free to use under an open license. Its 2014 workforce amounted to about 1.5 million volunteers.
- Crisis Mappers (http://crisismappers.net): The International Network of Crisis Mappers (Crisis Mappers Net) is the largest and most active international community of experts, practitioners, policymakers, technologists, researchers, journalists, scholars, hackers, and skilled volunteers engaged at the intersection of humanitarian crises, new technology, crowdsourcing, and crisis mapping, with 8000 members.
- MapGive (mapgive.state.gov): Map data are key to humanitarian and development missions. MapGive helps new volunteers learn to map and get involved in online tasks.
- MapStory (http://mapstory.org): MapStory empowers a global community to organize knowledge about the world spatially and temporally. With MapStory, people of all kinds turn into storytellers who can create, share, and collaborate on MapStories, and ultimately improve public understanding of global dynamics, worldwide, over the course of history.

Thus, large segments of the public are educating themselves earnestly and effectively in pursuit of multiple objectives, some altruistic and some commercial. For-profit companies dedicated to facilitating crowdsourcing and VGI include the ones listed below.

- Spatial Networks (http://spatialnetworks.com): According to its website, Spatial Networks build “geospatial technology products that solve real problems right now. Field data collection including crowdsourcing.”

Academic geographers have long been interested in promoting geographic literacy among the general public, but clearly a different force motivates geographic learning outside academia today. Indeed, this public movement seems to be driven by seething demand among consumers, not by supply offered from traditional producers of geographic knowledge. A nationwide survey administered by the AGS in 2011–2012 uncovered startling new evidence of a strong American constituency for geography. Compared to reading, writing, and mathematics, 66.8% of respondents felt that geography was just as important, an astounding affirmation of geography, considering the usual high regard the public has for “the 3 Rs.” (reading, writing, and arithmetic).

The AGS Geographic Knowledge and Values Survey found overwhelming public support for geography at all levels of education and widespread recognition of the discipline’s value in government and business (Kozak, Dobson, and Wood 2015). The results indicate that Americans predominantly want more geography education to be offered in schools, colleges, and universities throughout the United States. Approximately 9 out of 10 respondents wish they themselves had more geographic education and nearly all want more for their children. To meet this need, respondents favor offering geography courses at every education level, from elementary school to PhD programs in the most elite universities. And they insist that instructors should have formal training in geography. In
summary, geography’s problem is not with the American public but rather with the educational establishment itself, which has been killing academic geography programs relentlessly for seven decades.

Respondents recognize the importance of geography in today’s society. A large portion of respondents say they use geographic knowledge and skills in their everyday lives. They report using geographic concepts and spatial thinking when engaging with the world around them on local to global matters. Respondents correctly identify professions and government agencies in which geography and its skills would be highly useful.

Respondents know that geography is about far more than just knowing their states and capitals. They show sophisticated understanding of the purview of geography, which is defined not by content but rather by its emphasis on spatial reasoning, though many did not know to call it geography. They understand that the discipline covers a wide range of topics, methods, techniques, and technologies. However, their specific knowledge about real-world geography (places and processes) is no better than the dismal levels found routinely in other public surveys of geographic knowledge.

Surely normal human curiosity is a motivating factor for the kind of self-education we are seeing today. Undoubtedly, however, self-interest plays a key role, and nothing draws a crowd like jobs, jobs, jobs. The US Department of Labor, the Guardian newspaper, MSN, Money magazine, and PayScale all report higher salaries, lower unemployment, and faster industry growth for geography graduates compared to other disciplines (Dobson 2014).

Many academic geographers are responding to these issues by interacting with the public more intensely than ever through geographically enabled citizen science, variously called participatory GIS, participatory research mapping (PRM), or public participation in GIS. This movement, now about a quarter of a century old, follows the classic model of didactic geography, with geographers teaching and students eagerly learning. The classroom, however, is the field and the students are dedicated citizens seeking to map their own lands, understand their own resources, and defend their rights from encroachers. Most often, the goal is to help disadvantaged minorities or indigenous communities, but the model can work with any group that is eager to learn the knowledge and skills that geographers have to offer.

Geographers also continue to reach general audiences through their writing. Informative and instructional geographic writing for the public has a long history from Isocrates to today. In the West, for example, Herodotus (ca. 484–ca. 413/425 BCE), Plato (ca. 428–347 BCE), Strabo (ca. 64 BCE–24 CE), and Ptolemy (ca. 90–ca. 168 CE) wrote vividly about real-world phenomena, theoretical geography, cartography, and geographic investigations, and their works profoundly impacted subsequent generations both within and outside academia.

Marco Polo (1254–1324) wrote for the public, sometimes flavoring fact with fantasy. Indeed, fiction can be an effective medium for educating and informing the public. We tend to think of novels as pure fiction, but they can be a means of communicating geographic truths that otherwise may not reach audiences beyond academia. Charles Frazier’s historical novel Cold Mountain (1997) connects readers with the Appalachian Mountains, in a lilting fashion that matches the best writing of landscape geographers. James Michener’s Hawaii (1959) is a pageant of geomorphologic evolution and sequent occupancy, enchanting and informing at the same time. Jules Verne is known for using fiction to publicize his
predictions about the future. He wrote about airplanes, submarines, television, guided missiles, rocket ships, and satellites almost a century before their actual invention. But his writings were also thoroughly grounded in geography, and his first novel, *Five Weeks in a Balloon*, might be seen as the 1860s version of remote sensing, though he tried at first to publish his idea as a serious scientific essay.

Certain popular writers have a talent for writing about geography with a flavor of its own that doesn’t need fiction or fantasy to make it appealing. Harm de Blij, Jared Diamond, Barbara Tuchman, Timothy Egan, Erik Larson, Toby Lester, Charles Mann, V.S. Naipaul, Jan Morris, and John Noble Wilford are masters of this genre. Wilford’s *The Mapmakers* (1981) and Lester’s *Fourth Part of the World* (2009) were bestsellers as well as textbooks for the classroom.

Academic geographers who want to reach the public often favor short articles on timely topics. Not long ago, that meant op-eds in newspapers, and the American Geographical Society facilitated access by editing and distributing manuscripts to more than 1200 newspapers and magazines. Many individual op-eds were accepted and published by a dozen newspapers or more, including major market outlets such as the *Chicago Tribune*, the *San Francisco Chronicle*, and the *Guardian*. Now, it means blogs and tweets too, and a lot more competition in the world of ideas.

Last but not least is the medium of popular magazines. The National Geographic Society’s (NGS) flagship publication immediately comes to mind, but others are prominent around the world. Published in English and 40 local-language editions, *National Geographic* magazine, now majority-owned by 21st Century Fox, has a global circulation of about 6.8 million. Clearly it falls within the long-established public tradition of real-world geography, especially through exquisite photography and engaging writing, even though it doesn’t focus deeply on current geographical topics such as the explosive growth of geographic information systems, through which geography is dramatically transforming society. The NGS has movies, documentaries, books, and websites, and also uses social media and offers opportunities to teach geography to popular audiences on a deeper level. The Royal Geographical Society’s *Geographical* magazine and the Australian Geographic Society’s *Australian Geographic* fall between the popular emphasis of *National Geographic* and the academic tone of the American Geographical Society’s *Geographical Review*.

Looking ahead, popular geographics faces dramatic changes. New digital, network, social media, and geospatial technologies offer expansive opportunities to engage the public even as traditional media decline in impact. These opportunities hold all the traditional challenges of their predecessors but with a new twist. How can geographers keep geography alive and recognized in a web of communication, interaction, and movement they do not control? How can geographers simplify methods, techniques, and technologies to allow a broader public to use their innovations? How can participatory or crowdsourced geography involving hundreds or thousands of participants be designed and implemented with little centralized control? How can this work be pursued with the assurance that the privacy and personal rights of everyone involved will be respected? But perhaps the greatest challenge is how geographers can inspire the public with the same sense of wonder and curiosity, exploration and discovery, that lies at the heart of the discipline, and continue to make geography relevant to all audiences in today’s world.

The debate about population and natural resources refers to whether human population growth will increase consumption levels and lead to the ultimate exhaustion of natural resources. The discussion is usually divided between neo-Malthusians who believe that population increases will lead to a collapse in resource availability and market optimists who argue that human ingenuity and price mechanisms will allow societies to devise means to avoid collapse. A third group of analysts, however, is neither Malthusian nor market optimists, and instead look at how social factors control the ability to adapt to resource scarcity, or how scarcity is presented in order to justify different approaches to economic development. In turn, the debate about population and natural resources has also influenced parallel discussions about scarcity, adaptation to scarcity, and access to resources.

**Limits to growth?**

Most discussion about population and natural resources dates from essays written by the British cleric, Thomas Malthus (1766–1834), between 1798 and 1826. These essays outlined Malthus’s projections that population growth would lead to poverty through greater competition for wages and a decline in the availability of resources. At the heart of Malthus’s writings was the principle that agricultural production increases arithmetically (i.e., 1, 2, 3, 4) whereas population grows geometrically (i.e., 2, 4, 8, 16). Consequently, unchecked population growth could be predicted to lead to a sharp decline in population and human welfare as resources run out – often referred to in terms of the classical constraints of famine, pestilence, war, and death.

Malthus’s writings referred explicitly to population. When applied to natural resources, these ideas have been called neo-Malthusian. During the 1960s and 1970s, various influential books adopted this theme. *The Population Bomb* by Paul Ehrlich (1968), for example, predicted famines between 1970 and 1985 because of population growth outstripping food supply. The *Limits to Growth* report (Meadows et al. 1972) added to this concern. It presented detailed analysis of how current natural resources might remain available based on current known reserves, and estimates of resource use based on current growth in their use. Using this formula, the report predicted that natural resources would run out within specific estimates of time, such as, in the case of crude oil, by 1992 (later editions of the book adjusted this date). It concluded, “Short of a world effort, today’s already explosive gaps and inequalities will continue to grow larger. The outcome can only be disaster” (p. 195).

The implication of neo-Malthusian analysis is that human societies need to be aware that resources are ultimately finite, and that social and political unrest will become more common as resources become scarcer. Much research has sought to identify where and how...
local or global limits might be reached. For example, some analysts have argued that societies with scarce resources and poorly developed conflict-resolution mechanisms might be locations where population growth and competition for resources lead to violent conflict (Homer-Dixon 1994). Sub-Saharan Africa, for example, has been cited as a region where long-term environmental changes such as desertification or the emergence of refugees might lead to violence when different groups seek to access a dwindling supply of water or grazing land. Jared Diamond’s book, *Collapse* (Diamond 2005), identified various cases where human societies have, or have not, managed to avoid social breakdown as the result of controlling population growth – or the impacts of population on land cover such as forests in order to control erosion. Diamond, for example, reviewed evidence about the genocide in Rwanda (where ethnic Tutsis killed ethnic Hutus in 1994), and concluded that population growth, with its concurrent demand for land, was a key driving force.

In global terms, the concept of planetary boundaries (Rockström et al. 2009) has been used to identify ultimate limits to human productivity. This concept seeks to define safe operating spaces for humanity by identifying key tipping points of resource exhaustion after which environmental change will occur abruptly and will impact severely on human society. This type of analysis is different to earlier discussions of limits to growth because it reflects the spaces within which resources can be used, rather than focusing on resources alone. The proposed nine zones of planetary boundaries include climate change, biodiversity loss, biogeochemical changes (such as removal of nitrogen and phosphorous from ecosystems), ocean acidification, conversion of land to cropland, freshwater consumption, atmospheric ozone depletion, atmospheric aerosols (or particulates), and chemical pollution (including toxic substances).

**Challenges to limits to growth**

Various analysts, however, have questioned the appropriateness of limits to growth as a way of understanding the relationship of population and natural resources. The first, and most commonly heard, criticism is that the neo-Malthusian concerns about scarcity simplify the operations of markets and price mechanisms when competition for resources occurs. Consequently, so-called market optimists argue that scarcity will fix itself because goods that are in demand will become more expensive over time, and therefore competition for these goods will decrease. Perhaps the best example of this way of thinking was the famous wager undertaken between the Malthusian Paul Ehrlich and the market-optimist, Julian Simon, in 1980 when Ehrlich predicted that the price of chromium, copper, nickel, tin, and tungsten would increase by 1990, and Simon predicted the price would decrease. Ehrlich lost this bet – his presumed scarcity did not occur – in fact, there was a relative oversupply of these commodities during this period. Since 1990, commodity prices have risen, however.

In addition, market optimists have pointed out that demand for resources do not simply reflect demand and supply for known resources. Economic trends also determine which resources are valuable, and human ingenuity can create new responses to scarcity, or new trends in which resources are needed. Accordingly, a famous statement is that “resources are not; they become” – or that society should not focus explicitly on the commodity that offers an economic value, but instead seek which properties are offered by commodities, and
search for alternative sources for these properties. For example, copper wire used to be used for telecommunications. In time, this was replaced by fiber optics, and then again by wireless technology. Consequently, society should not look at the scarcity of current sources of resources, but at multifarious ways that social needs can be addressed. Another famous statement is that “the Stone Age did not come to an end because of a shortage of stone.”

Indeed, the work of Ester Boserup (1910–1999) provided a direct challenge to Malthusian notions of scarcity and collapse based on the transformation of agricultural production in developing countries (Boserup 1965). Boserup used the term adaptation to refer to how different societies regulate scarcity of resources by two key stages. First, societies identify and respond to the threat of scarcity proactively through practices, such as regulating resource consumption, or sharing resources such as agricultural fields. Second, societies can increase agricultural production in more than arithmetic ways through processes of innovation, such as converting sloping agricultural land to irrigated terraces. These forms of social organization and agricultural intensification are effectively different forms of technologies – both social and physical – that can allow societies to live with scarcity.

In response to these criticisms, Malthusian analysts have argued that debate about resource scarcity should focus mainly upon those commodities that are not substitutable. Another response is that the short-term adaptations to scarcity observed by people such as Boserup do not change the underlying reality that resources are finite, and that human societies will ultimately have to live within limits.

But the critics of the concept of limits to growth are not always analysts who believe in human ingenuity or the operation of market price mechanisms. Various analysts have instead looked at the political economy of which societies or individuals experience scarcity, or who can avoid scarcity through adaptive mechanisms and technologies. David Harvey (1974), for example, argued that the relationship of population and natural resources needs to be assessed through the lens of social class and the operation of capitalism. Rather than seeing scarcity in absolute terms (as proposed by Malthus), Harvey argued that questions of subsistence, or consumption, are also determined by the particular circumstances of the mode of production faced by working classes vis-à-vis higher classes. These distinctions can also be applied globally. For example, during the 1974 United Nations Bucharest Conference on Population, the United States proposed a population plan that sought to slow down population growth in rapidly growing developing countries. Developing countries, however, resisted these plans on the grounds that the focus on population numbers alone overlooked the social and economic context in which these numbers are considered problematic, and by whom.

Despite these international controversies, domestic policies in some countries sometimes introduced coercive population controls. In the early 1970s, the government of India introduced a program of forced sterilization that targeted men with two or more children. But the scheme also targeted many poorer, uneducated, men, and political opponents of the government. From 1976, the Indian government adopted a more persuasive approach based on propaganda, plus offers of money, housing, and land, aimed at both men and women. In 1979 China introduced a policy restricting urban populations to one child only, a policy that has been claimed to increase forced abortions and female infanticide where parents prefer sons. During the 1980s under the South African Apartheid regime, official family planning practices frequently injected...
the contraceptive Depo-Provera into women immediately after childbirth as the so-called fourth stage of labor – these injections generally targeted non-white African women, while other races were offered a choice of contraceptives. Concerns about the links between scarcity and population have therefore often been linked to human rights abuses, or opportunistic policies by specific governments (Mosher 2008).

Moreover, it is also clear that scarcity (and the ability to avoid scarcity) is also not uniform. Various analysts within international development have therefore proposed theories of access, or the means by which different societies or individuals benefit from resources or adaptive responses. Amartya Sen (1981) in particular provided a radically different perspective to Malthusianism by demonstrating how large famines during the twentieth century did not occur in democracies, and sometimes happened during times of national food surpluses. Sen used the term endowment to indicate direct access to resources such as food, and entitlements to refer to indirect access such as through family connections or employment. This “entitlements approach” was fundamental in changing thinking about international development away from questions of macro-economic food production alone, and toward an understanding of social vulnerability. For example, Sen pointed out that in India, the people most at risk from food insecurity were landless rural migrants, often of low caste, who lacked the social connections and assets to survive a period of food shortage. According to this approach, limits to growth are not simply driven by population growth or market forces, but by exclusionary social structures that make some sections of society more vulnerable than others. This point reiterates Harvey’s (1974) point above about the role of capitalism, but also acknowledges the role of other social influences such as caste, gender-relations, or other forms of social inequality that can influence vulnerability in association with market forces.

Representations of scarcity

The work of Harvey, Sen, and others showed that scarcity is neither universal, nor separate from social contexts. Consequently, these analysts have argued that there is a need to consider who experiences scarcity and why – plus there is a need to rethink what is meant by scarcity to begin with. Critics have therefore argued that social science needs to understand how definitions of scarcity are made, and how these can be used for political agendas. One paper (Taylor and Buttel 1992), for example, argued that the Limits to Growth report made the mistake of assuming that all individuals in different countries would respond to scarcity in the same way, or that scarcity would lead to social collapse. Instead, this paper argued that there was evidence from the work of Boserup and others that human societies respond to scarcity in different ways, including anticipating and responding to scarcity in adaptive ways. Consequently, this paper criticized the limits to growth model for projecting an image of immanent collapse when it was making unreliable assumptions about social behavior across the world. Scholars have therefore realized that models such as the limits to growth have the potential to represent society in a uniform or overly simplified manner, and that policies based on these models might therefore repeat these clumsy universal assumptions.

Another model of human behavior that illustrates this pattern is the so-called tragedy of the commons. This is another neo-Malthusian framework, which assumes that unregulated access to resources will lead to the degradation of the resource, as each individual will seek to
maximize their own benefits. The “tragedy” is often represented as an inevitable outcome, which should therefore justify the regulation of individualists. But analysts have also argued that this predefined vision of a tragedy is a development narrative – or more of an expectation than a reality – and there is a need to question why people believe in the tragedy rather than acknowledge diverse existing and informal regulations of resource use worldwide (Mehta 2010).

It is also important to ask whether causes of research degradation and scarcity under some circumstances are universally applicable. Diamond’s book *Collapse*, for example, identifies deforestation and soil erosion as key driving forces of societal decline, and that population growth is a key driving force behind both of these changes. Yet, this form of analysis simplifies the contexts in which erosion and deforestation might be problematic. Moreover, Diamond argues that population control is essential for international political order. He wrote: “People in the Third World can now, intentionally or unintentionally, send us their own bad things: their diseases like AIDS, SARS, cholera, and West Nile fever … unstoppable numbers of legal and illegal immigrants … terrorists; and other consequences of their Third World problems” (Diamond 2005, 518). He also suggests, “As a result of those problems [they] are also creating problems for us rich First World counties, which may end up having to provide foreign aid for them … or may decide to provide them with military assistance to deal with rebellions and terrorists, or even have to send in our own troops” (p. 516). Statements like these clearly reflect a worldview that minimizes development intervention or the creation of adaptive capacity in developing countries. They stand in contrast to discussions of scarcity by analysts such as Sen, who focus instead on how social deprivations drive scarcity, and which interventions might prevent scarcity. Consequently, there is a need to consider which political norms drive visions of resource scarcity, and vice versa.

**Governing population and scarcity**

Despite the popular debate about population growth and the possible exhaustion of natural resources, much international development policy in the twenty-first century tries to achieve equitable access to resources, rather than overall controls on population. This process is, however, far from easy. Both population planning and access to resources has to be undertaken sensitively and with regard to the vulnerabilities of different social sectors. For example, the United Nations International Conference on Population and Development in Cairo, 1994, emphasized reproductive rights – especially for women and girls – as a means to maximize individual choice in reproduction. This emphasis promotes individual empowerment and barriers to gender equality as part of the means of regulating population, rather than population control in Malthusian terms.

Similarly, international development programs seek to build institutions – or the shared rules and norms governing resource use – which can be considered part of adaptation to scarcity. These forms of adaptation, however, can be influenced by national priorities for development and controls on local participation. For example, in some countries of the Sahel, governments wish to control local livestock numbers and agriculture because of the feared impacts on desertification or forest loss, but development agencies wish to diversify access to resources and gain more empowerment for local actors or communities to take responsibility for governing resource use. Another area of uncertainty is in the potential role of migration as a way to regulate resource
use, or to adapt to local scarcity. Migration, sometimes across international borders, has been used as a means of responding to scarcity for centuries. But under international law, and under common uses of climate change policy, migration is often resisted and communities need to seek responses to scarcity where they stand.

Achieving successful governance of population and natural resources, therefore, requires flexibility in defining the problem of scarcity and in identifying who is vulnerable to it. This situation has become a lot more sophisticated since the generalized prediction of collapse by Malthus and his followers. But neo-Malthusian ideas still remain popular and often shape public debate about how population growth should be addressed by controlling population growth and movement, rather than the actual means by which vulnerable people might govern access to natural resources, achieve livelihoods, and avoid violent conflict.

Population geography

K. Bruce Newbold  
*McMaster University, Canada*

Population geography is a division of human geography that focuses on the study of people, their spatial distributions, their characteristics, and their density. It is the study of the ways in which spatial variations in births, deaths, and the distribution, composition, migration, and growth of populations are related to place. Population geographers seek to understand the society around them, the structure of a population, and how populations change through population movements and processes.

Despite its emphasis on location, place, and space, population geography is interdisciplinary and regularly draws upon related fields in economics, sociology, planning, and anthropology in order to understand population processes. It is also closely related to other disciplines, including demography, which is the study of population statistics and trends, spatial demography, which refers to the formal empirical tools to connect people and places and reflects the role and importance of geographic information systems (GIS) and spatial methods, and social demography, which seeks to explain population patterns based on different disciplinary perspectives.

While the disciplinary boundaries between demography, spatial demography, and population geography have become increasingly blurred, there remain important distinctions. Demography has been traditionally more interested in births, deaths, and marriage, and has typically had less interest in space and migration. Population geography, on the other hand, has taken greater interest in population movements, including residential mobility (which captures local moves), migration (crossing some administrative boundary such as a county or state), and international migration. Moreover, given geography’s emphasis on space, location is particularly important in population geography. But population geography is not just about population movement, and the subdiscipline has grown to encompass topics typically seen within demography, as well as other areas reflective of the diversity of geography. Indeed, the patterns of population growth and change through space and time are fundamental to understanding other processes that geographers frequently tackle, including urbanization, segregation, crime, and health. The study of population geography has influenced other geographic studies, including health, ethnicity, and economic geographies, as well as other disciplines.

Growth and diversity of population geography

Although early examples of population geography and thinking spatially about population processes could arguably include Ravenstein’s theory of migration from the 1880s and John Snow’s mapping of cholera deaths in London, population geography as a formal subdiscipline of geography dates from the early 1950s. Prior to this time, geography as a discipline was typically rooted in descriptive analyses of cultural and physical landscapes. The emergence and recognition of population geography have largely been attributed to Glen Trewartha’s presidential
speech at the 1953 meeting of the Association of American Geographers (AAG). Trewartha called for the increased study of population, arguing that geographical studies should be organized around the cultural landscape, the physical Earth, and population. As Trewartha (1953, 83) commented: “Population is the point of reference from which all other elements are observed and from which they all, singly and collectively, derive significance and meaning. It is population which furnishes the focus.” Following Trewartha’s call for population geography to assume greater prominence within the discipline, the study of population geography grew through the 1960s and 1970s. This growth corresponded to the growing interest in population issues more generally, along with the establishment of the Population Council and the first World Population Conference in 1954, held in Rome, Italy. Like geography more generally, population geography was initially largely descriptive in nature, content to describe a population through its characteristics, including density, distribution, and age structure. Following Trewartha, a number of geographers, including Torsten Hägerstrand and Wilbur Zelinsky, grew the field of population geography to include explanations for the spatial configuration of populations and the geographical analysis of population phenomena. Work by Hägerstrand in the 1970s, for example, situated people in time and space, a concept that population geographers continue to explore. Zelinsky (1966) further separated population geography from demography by highlighting the importance of space and time, and the influence of space on population processes.

Since Trewartha’s speech, geography has typically been divided into physical and human geography, with population geography a sub-discipline of human geography. By the 1980s, population geography had fully developed as an important subdiscipline, reflected in the participation of population geographers in a number of organizations such as the AAG, and particularly in the Population Specialty Group (see: https://popgeog.wordpress.com), the Canadian Association of Geographers (CAG), and the Royal Geographical Society–Institute of British Geographers in the United Kingdom (RGS–IBG). Further work continued both to refine and to expand the focus of population geography. Methodologically, it drew upon spatial analysis, logical positivism, and quantitative methods, reflecting its empirical origins and scope. In addition, population geography was increasingly linked to economic, cultural, and ethnic geographies, as well as regional science. Population geography and spatial demography were also increasingly cross-fertilized with the development of GIS and spatial econometrics, reflective of work by Luc Anselin and Michael Goodchild.

While population geography has not ascended to the importance envisioned in 1953 by Trewartha, and instead remains a subdiscipline of human geography, it has been an important influence upon other areas of geographic study as well as other disciplines. Not surprisingly, population geographers have actively published their work in journals including the AAG publications, the Annals of the Association of American Geographers and The Professional Geographer, as well as the CAG and the RGS–IBG publications, The Canadian Geographer and Transactions, respectively. Beyond geography journals, population geographers also regularly publish in journals including Demography, Papers in Regional Science, Annals of Regional Science, International Migration Review, and Environment and Planning A, reflecting the interdisciplinary nature of their work. As the subdiscipline grew and recognized the need for a more discipline-centered publishing outlet, the International Journal of Population Geography was established in 1994, the first journal to
POPULATION GEOGRAPHY

publish almost exclusively research by population geographers. While population geographers continue to publish in the journal, it changed its name in 2004 to *Population, Space and Place*, to reflect the diversity of disciplinary backgrounds and theoretical perspectives that were being published within the journal.

**Importance of geographic scale**

Scale is an important issue for population geographers. Population processes are influenced by individual preferences, local contexts such as the cost, age, and type of housing, neighborhood composition (race, income, education, age, etc.), employment opportunities, greenspace, and so on, as well as broader-scale processes and events such as the overall economic climate. The scale of the analysis influences the findings, such that conclusions reached at one scale of analysis may not be applicable at another scale. Identified as the modifiable areal unit problem (MAUP, Openshaw 1984), spatial units such as a neighborhood, census tract, county, or state that are used in many studies are often arbitrary and modifiable. More formally, MAUP represents a source of bias resulting from the aggregation of data from one scale to another, with results influenced by the choice of boundaries. Therefore, given that results can be influenced by the scale chosen for the analysis, it is typically more important to understand what scale is the most appropriate for the analysis than to assume one “correct” scale. The problem, however, is that geographic scale can run from the individual and household scale to the global, with all scales being potentially relevant. For example, population movement can occur across a number of scales, with an individual moving across the street, within the neighborhood, within the city, within a region (i.e., state, province), across regional (i.e., between states) lines, or internationally. In each case, the determinants of migration are different. In studying mobility and migration, the number of migrants moving across a comparatively small spatial scale, such as within a city, is always greater than the number moving across larger spatial scales, given that we are more likely to move short rather than longer distances. These differences reflect changes in housing preferences at small spatial scales, and the smaller number of individuals or families that are willing to invest in longer distance migrations that are often associated with changes in employment and labor markets.

But MAUP does not only affect the counting of migrants and the reasons for moving. Population geographers often explain differences in the behavior of populations in relation to local contexts (Entwisle 2007). Local spaces, such as neighborhoods, will have different contextual factors, such as local bylaws and different sociodemographic or socioeconomic profiles, with differences ultimately influencing behavior and outcomes. Fertility, for example, reflects choices made by the individual, but such choices are mediated by partner/family desires and the local community, as well as by broader economic conditions or state policies and programs that may discourage or encourage fertility. The role and importance of studying local contexts are found throughout the geographic literature, including health, crime, and segregation studies.

**Topics in population geography**

Societies are shaped by their populations, along with the processes and characteristics that define those populations. Population movement, for example, links people, countries, regions, and space, and it is not surprising that population
geographers have made substantial contributions to the mobility and migration literatures given the inherent spatial structure of population movements. Likewise, fertility and mortality processes, such as the generally higher levels of fertility and infant mortality in the developing world as compared to the developed world, influence security, economic growth, and politics.

While population geography has traditionally focused on fertility, mortality, and migration, the scope of research has expanded tremendously, with population issues underlying many of the challenges facing the world today, including resource and environmental issues, ethnic relations, politics, and power relations. Population geographers study a diverse range of subjects, including demographic phenomena (fertility, mortality, growth rates, etc.), population change, population mobility (including migration and immigration), occupation structure, and how places react to population change. In the 2006 publication Geography in America at the Dawn of the 21st Century, Patricia Gober and James Tyner authored an entry on “Population Geography,” and identified six research subdiscipline themes: (i) internal migration and residential mobility; (ii) international migration and transnationalism; (iii) immigrant assimilation and adjustment and the emergence of ethnic enclaves; (iv) regional demographic variation; (v) social theory and population processes; and (vi) public policy. Within these six broad themes, population geographers have contributed to migration studies by advancing understanding of direction and distance in migration, who moves (and who stays), net and gross flows at different scales, and modeling economic and social causes and consequences of migration, as well as the characteristics of domestic, international, and seasonal/cyclical movements. In addition, geographers have considered the wider implications of legal and illegal immigration, including the assimilation and adjustment of new arrivals to the destination country; economic, social, and political responses to population movement; and population ageing.

Population geographers continue to explore these themes, albeit with new methods or the addition of greater theoretical depth. Beyond these themes, Gober and Tyner noted additional opportunities for population geography to reach other subdisciplines in geography by engaging environmental geography and GIS. Indeed, since Gober and Tyner’s chapter was published, population geographers have extended their interests to include these realms, as well as other subdisciplines such as cultural or ethnic geography. The emergence or inclusion of new theories, data sources, methods, and tools, including GIS, remote sensing, and spatial analytical techniques, has increased the prominence of space and place in population and other studies, and these methodological and analytical tools are visible in the development of spatial demography, which is essentially a hybrid of population geography and demography. Concurrently, the work of some cultural, ethnic, rural, or economic geographers also constitutes population geography. Indeed, for geographers to consider issues such as the evolution of cities requires consideration of the population trends that accompany these shifts and the characteristics of the population within the city.

Research interests and methods of population geographers have shifted over the years, with such shifts chronicled in the chapter by Gober and Tyner, along with the review by Suzanne Withers (2010). Withers offers thoughts on research needs within population geography, including the need to consider the interdependencies between places and scales, human security issues, the population–health–environment nexus, economic development, and poverty issues. While mobility and migration studies
have remained a common topic among population geographers, they have been increasingly explored through life course and longitudinal analyses, gendered studies, and intergenerational studies. In particular, many population geographers have situated their work in a life course perspective, reflecting and linking events occurring over time related to someone’s life, and enabling the examination of the “careers” or trajectories of people’s lives (Bailey 2009). While life course analysis can be applied throughout population studies, it has been most readily applied to migration research, with work by Plane, Henrie, and Perry (2005) illustrating the diversity of motivations for migration and destination choice from this theoretical perspective, with the authors noting that many of the migrations across the metropolitan hierarchy in the United States are related to migrants in particular age groups, including the preference among 25- to 29-year-olds to migrate into the country’s largest urban areas, while retirees tend to move into nonmetropolitan areas, expressing preferences for lower cost of living or rural amenities (Plane, Henrie, and Perry 2005).

Data and methods in population geography

Reflecting the quantitative revolution that was sweeping geography in the 1960s, along with close ties to demography and the use of large datasets and an emphasis on spatial and quantitative analysis, population geography has been closely linked to logical positivism. Additionally, demography and social demography have also remained closely aligned with positivism and empirical analysis. Given the empirical scope of the subdiscipline, population geographers regularly use tools and measures such as population density, median age, sex ratios, migration rates, birth and death rates, population pyramids, labor force participation rates, and other measures to characterize populations. While many of these are descriptive measures, multivariate techniques including regression analysis, spatial econometrics, and GIS techniques are also frequently used by population geographers.

Population geography is traditionally data-rich. Most nations conduct national censuses containing information on housing, socioeconomic status, gender, age, education, and other attributes. Data sources such as the census or labor force surveys are typically representative of the total population, allowing generalized conclusions to be drawn. Beyond the census, population data are also found in other sources, including other government-run surveys such as the American Community Survey (ACS) or the Current Population Survey (CPS), as well as birth and death certificates or so-called vital statistics that are available through government agencies. In much of Europe, in particular, there is a strong reliance on these vital registry systems which record events such as births, deaths, cause of death, marriages, divorces, and moves/migrations.

Spatial demography and population geography more generally have benefited from the development of GIS and spatial analytical techniques that have offered new ways to view spatial population processes along with the opportunity to incorporate spatial relationships and interactions not available through aspatial analytical methods that had dominated the field for so long. Techniques, including network analysis, location optimization techniques, spatial interaction modeling, agent-based modeling, geodemographics, and spatial econometrics, have placed additional tools at the disposal of population geographers.
While quantitative analysis has not disappeared, it has faded along with the quantitative revolution elsewhere in geography and the social sciences. Instead, population geographers have increasingly turned to qualitative methods to provide new insights into and alternative understandings of population processes. This shift reflects a questioning of the reliance on traditional methods of inquiry, the reliance on positivism and empirical analysis, and the relevance and meaning of large, representative datasets. In particular, it has been argued that empirical techniques could not provide adequate explanations and representative datasets could not provide local or other details. Large datasets and statistical methods could not, for example, adequately capture the complexity of population processes, nor could they reveal the subtleties of individual (as opposed to collective) behaviors. Others, including White and Jackson (1995) argued that, given their dependence on data and processes, population geographers tended to overemphasize events without concern for longer biographical histories and the economic, social, or cultural context within which population processes occur. Moreover, the reliance on data such as the census tended to restrict understandings of the role of gender or age by confining these to specific categories such as male and female, or specific age groups. Other geographers have emphasized the need for ethnographic approaches to population processes in order to reflect on the broader set of features, including life histories and circumstances that could alter choices related to migration or fertility behavior.

Shifting analysis from quantitative to qualitative methods has revealed the details of social and cultural influences on population processes, while removing the emphasis on specific economic events and outcomes. Population geographers have increasingly embraced qualitative methods and regularly use a range of methods including document review, interviews, focus groups, or surveys to collect information. Population geographers have also embraced a range of theoretical perspectives to explore population processes, offering the ability to reveal the complexities of the locale and situate local knowledge. The greater complexity in population research has been revealed through an emphasis on people and their connections to multiple places, where it is argued that people on the move live in the present through reflections on their pasts and the potential of uncertain futures. Such work emphasizes the role of ties to place and the issues, concepts, and contexts that root an individual to a particular place or allow them to move.

Theory in population geography

Population geography’s link to demography has meant that it has long been associated with empirical, positivistic research and theoretical underpinnings, and it has historically drawn heavily on spatial choice theory, along with microeconomic and macroeconomic models. Premised on an assumption of individuals’ desire to better themselves, Ravenstein in the 1880s described the spatial, population, and economic determinants of migration. His work formed the basis for migration theories and analyses for decades. Among the more important generalizations, Ravenstein concluded that migration occurs in a “stepwise” manner; each migration stream tending to have a compensating counter stream; the majority of migrations are short-distance; and the major cause of migration is economic. These often quoted generalizations have stood the test of time and formed the basis of scientific discussion and theoretical development over the years. Lee (1966) advanced Ravenstein’s ideas, creating a framework for
migration analysis that involves the “pull” effects of the destination, the “push” effects of the origin, intervening opportunities, and personal characteristics. Several other theoretical perspectives have emerged within population geography to address questions of migration and mobility studies. These include Zelinsky’s mobility transition theory (1971), which links the types of migration with the development of a region or country; Sjaastad’s (1962) human capital theory, which sets migration as an investment in human capital whereby the costs of migration are balanced against future expected returns measured by lifetime earnings; and Rossi’s 1955 book, Why Families Move, which introduces concepts of the life cycle (now life course) and “residential stress” as primary motivators for migration.

All of these theories drew heavily from economic theories and were based on assumptions including economic rationality and utility theory. Starting in the 1990s, the emphasis on theories that reflected the empirical nature of the discipline drew criticism from population geographers, particularly as human geography more broadly reinvented itself by adopting various critical theoretical standpoints, including social theory, feminist theory, and cultural geography. Given theoretical advances in other fields, numerous calls emerged in the 1990s for population geographers to more directly engage in theory by placing it within population studies. Such calls included White and Jackson’s 1995 argument that the actions of individuals should be embedded within broader social, cultural, and economic contexts, so that population geography could benefit from new theoretical foundations that better situate population processes. Such calls reflected the introduction of critical perspectives across geography, including Marxist or feminist geographies in the 1970s. These interventions marked an important turning point for geography by enabling geographers to explain rather than just describe phenomena, in part by understanding how individuals make and perceive space and make locational decisions. For example, through these perspectives, the residential mobility literature turned its focus towards the impact of neighborhoods on peoples’ daily experiences and their opportunities.

Population geographers have been somewhat slow to incorporate critical perspectives. Population geography has retained its empirical and positivistic roots much longer than other subdisciplines. Despite calls for theory to inform the work of population geographers and some progress in incorporating theory within population geography, its empirical roots run deep and the inclusion of new theoretical insights has remained elusive. Elspeth Graham (2000) offered a number of reasons as to why population geography has been slower to adopt theory than have other areas in geography. For instance, the existence of large datasets continues to encourage empirical analyses with less attention to theory, particularly when the end result is policy engagement, where theoretical frameworks complicate the picture. That is, it is easier to base policy on empirical and generalizable results than to address underlying structural or ideological settings. Likewise, Graham suggests that the complexity and layers of theory complicate their application to population issues. Furthermore, spatial demography has also been largely atheoretical, limiting it to a largely analytical role within population studies.

At the same time, new and alternate theoretical viewpoints are increasingly being incorporated within the subdiscipline, deepening the understanding of human (population) behavior. In addition to life course theory, a wide range of critical theoretical frameworks have been incorporated within population geography studies, including feminist, gendered,
and transnational theories, both drawing from and contributing to other related fields. The use of theory is perhaps particularly evident in migration studies (i.e., Silvey 2004), although this may simply reflect the continued emphasis on migration-related research within population geography more generally. Moreover, other subdisciplines within geography may be better placed to theoretically inform the work of population geographers, resulting in greater collaboration across subdisciplines.

**Conclusion**

Although population geography has never attained the prominence and role suggested by Trewartha, its contributions to both geography and other disciplines have meant that it remains an important subdiscipline, valued for its emphasis on how place and space affect population processes. Population processes have continued significance for society, in terms of their connections to economic and livelihood systems, social structures, consumption, and cultural processes, or even geopolitics. Despite its relevance, there has also been critical discussion within the literature that a continued reliance on empirical and positivistic analyses, along with the failure by population geographers to engage more fully in theoretical developments, has meant that the discipline has become less engaged in geography’s mainstream (Graham 2004). Since these concerns were raised, in the 1990s and 2000s, there has been greater—but not complete—adoption of theory, particularly within migration research, although there is room for further developments as the discipline continues to evolve. As Paul Robbins argued in his Progress in Human Geography/CPESG Netting Lecture at the 2015 AAG meetings in Chicago, current population issues such as the implications of declining global fertility levels and population decline remind us of the continued relevance of geographical perspectives on population. They also provide an opportunity for the revitalization of population geography through the infusion of political economic theory to explain and solve such issues.

Echoing Trewartha’s call for increased attention to population issues, population geographers have also called for greater research in particular areas, leading to the evolution of the discipline, or more specifically the research areas that it touches upon, over time. The future topics of interest and research in population geography are just as critical as its theoretical expansion. This raises the question of what will be the next major area(s) of research for population geographers and whether this/these will reflect critical questions that are relevant to current events and issues. Emergent research has focused on links to environmental issues, including topics related to so-called environmental refugees. Other subdisciplines within geography, including health geography and economic geography, have also incorporated population geography within their research agendas.

While highlighting developing areas of research interest is always tricky, the coming years will offer new research opportunities for population geographers to expand the scope of their work beyond the traditional pillars of fertility, mortality, and migration. Issues such as environmental degradation, climate change, conflict, race/ethnic relations, and health care are potentially important areas for consideration by population geographers, given their inherently spatial implications. Moreover, there is the opportunity for both theoretical and policy development associated with these topics.

The journal Progress in Human Geography offers insight into topical issues tackled within the realm of population geography and the broader
discipline. Over the past decade, authors have identified a number of areas that could be further explored by population geographers. Writing in 2009, Adrian Bailey called for greater research into the role of the life course in population decisions and how population geographers could explore the interrelationships between population and climate change, including notions of vulnerabilities and vulnerable populations, risk, and policy discourse. Graeme Hugo (2007) argued for the need for population geographers to explore topics within the Southern Hemisphere, a geographic focus that has been less represented within the literature despite the size of its population, along with various fertility, mortality, and migration issues (i.e., international, rural–urban, population development). Hugo argued that there is substantial room for population geographers to add additional insights and policy discussion based upon population processes and phenomena in the Global South. More recently, James Tyner (2016) identified death, mortality, and vulnerable populations as areas that need additional attention from population geographers. Separately, Coulter, Van Ham, and Findlay (2015) identify the need to rethink short-distance mobility from a life course perspective, with an explicit focus on individual relations through time and space, while also considering the context and structure that define mobility.

It is interesting to note that the majority of these authors call for further work associated with mobility, migration, and immigration – the areas that population geography has typically focused upon – while there seemingly remains less interest in fertility and mortality. Given that population processes have implications for finance, property values, marketing, and other day-to-day events, population geography underlies many broad-based discussions, meaning that it remains a fertile area for study, research, and discussion.

POPULATION GEOGRAPHY

Further reading

Throughout much of humanity’s history, world population was small and it grew slowly. Although fertility rates (which express the average number of children born to a woman over her reproductive years) were high, unpredictable food supplies, short life expectancies, famine, war, and disease meant that the population grew slowly and the global population remained small. Even by the early 1700s, the estimated global population was just 500 million people. Yet, by mid-2015, it had exploded to nearly 7.3 billion, with ongoing growth assured (see Figure 1). These rapid changes raise a number of critical questions: How did the world’s population grow so quickly and in such a comparatively short period of time? How is the global population distributed? What are the implications of a large and growing population?

Beginning in the mid-1600s, the era of slow and stable population growth ended. Roughly corresponding to the start of the Industrial Revolution in Europe, death rates started to fall and life expectancy slowly increased with improvements in commerce, food security and production, and nutrition. At the same time, birth rates remained high, reflecting long-standing needs for larger families. This difference between birth and death rates allowed the population to grow, such that by 1800 the world’s population was approximately 1 billion, growing to 2 billion by 1930. The pace of growth continued to increase through the twentieth century, with global population passing 3 billion by 1960, 4 billion by the mid-1970s, and 5 billion in 1987. Just 12 years later, in 1999, global population reached 6 billion, and it surpassed 7 billion in 2011. Despite falling fertility rates and slowing population growth rates since the 1960s, current projections made by the Population Reference Bureau and other groups estimate the global population will reach 9.8 billion by 2050, with some projections estimating a total world population as large as 10.7 billion in the not too distant future beyond 2050.

Population growth patterns and rates are not the same across the globe, meaning that there is a clear geography to the world’s population growth both historically and in modern times. Many Western nations, including the United States, Canada, and several European countries, experienced their most rapid growth during the Industrial Revolution, with the population of Europe doubling between 1800 and 1900. Immigration to North America in the 1700s and 1800s resulted in rapid population growth during this same time. In the developing world, population growth was typically slower, although countries in the developing world already represented the largest proportion of the world’s population.

Much of the current population growth is occurring in the developing world where fertility rates and growth rates remain high, with its population projected to grow from 5.9 billion in 2015 to 8.2 billion in 2050. At the same time, the population of the developed world will be largely unchanged. Regions with rapid population growth include portions of Africa and Asia and countries with large populations or high fertility, including India, Indonesia, Pakistan, and the Philippines. Fertility rates in
India, the world’s second most populous country, remain high (2.3) and the population is growing at a rate of 1.2%, meaning India’s population continues to expand, with projections that India will overtake China as the world’s most populous country by 2028. Conversely, although China is currently the world’s most populous country with a 2015 population of 1.372 billion, it is growing at just 0.5%, reflecting government policies restricting the number of children per family. In sub-Saharan Africa, fertility rates remain high and average 5.0, resulting in a population growth rate of 2.7%. This means that its population can double in just 26 years.

Population growth rates are much lower in Central America, South America, and the Caribbean, although populations continue to grow because fertility rates remain in excess of 2.1, the “replacement rate” that is required to exactly replace the current generation. In comparison, the fertility rate in North America is just 1.8, combined with net migration gains this corresponds to a growth rate of just 1.0%, meaning the population will take 70 years to double. Europe has some of the lowest fertility rates and lowest growth rates, with some countries, including Germany and Portugal, experiencing population decline, while many other countries are experiencing negligible population growth.

The shift from slow and steady population growth to rapid population expansion can be largely explained by the demographic transition theory or the shift from high birth and death rates (pre-transition) to a low fertility and mortality regime. Initially, both birth and death rates are high and largely cancel each other, resulting in slow population growth. With development, modernization, and improved health care, death rates decline but fertility remains high, resulting in a period of rapid population growth given the difference between birth and death rates. Ultimately, birth rates decline as well, and population growth stabilizes. In the demographic transition theory, the two most important determinants of population growth are (i) level of fertility before the transition occurs, and (ii) the amount of time between the initial decline in mortality and the delayed decline in fertility. In other words, both higher initial fertility and/or increased time between the decline in mortality and the decline in fertility are associated with greater population growth.

Although the demographic transition theory can be applied globally, it is important to note that the timing, pace, and triggers of changes in fertility and mortality vary from country to country and region to region. The demographic transition theory has also been widely criticized for its Western focus. In the developed world, transitions to lower mortality and fertility occurred simultaneously with public health improvements that led to declines in infant mortality rates and increased life expectancy. The demographic transition has also not yet
completed in many parts of the developing world: mortality rates have generally fallen given improved nutrition and health care, yet fertility rates remain above replacement level in many locations in the developing world, averaging approximately 2.6 children per woman in the less developed world and 4.4 in the least developed world.

Consequently, population growth in the developing world has been aided by higher pre-transition fertility rates in the developing world and typically slower reductions in fertility relative to the developed world. This is because, in contrast to mortality, fertility choices are very personal decisions shaped by societal structures. Therefore, the pace and degree of declines in fertility will vary from country to country due to effects including different social, cultural, and religious expectations (for example around the number of children and the preference for male heirs), lower literacy rates, the likelihood that children will survive into adulthood, lower female participation rates in the workforce, and the availability, acceptability, and cost of family planning programs.

Although world population growth rates have started to decline, population growth remains a concern, in large part due to the continued population growth observed in Africa and other populous nations. Recognizing the potential for economic, social, and political problems of rapid population growth, some countries have moved to actively reduce fertility rates, with China being the most well-known. Beginning in the late 1970s, China’s leadership moved to drastically reduce population growth with its “one-child policy.” Although restrictions on family size were relaxed in 2015, families that participated in the program typically received cash bonuses, preferential school admission, and improved housing, while there were corresponding disincentives for families that had more than one child. While successful in reducing fertility rates that exceeded 7 at the start of the policy to just 1.7 today, the policy has been controversial given the state’s expectations that the policy would be followed and its use of coercion in ensuring that it was. China’s one-child policy has also led to an imbalance in the sex ratio at birth. Typically 105 males are born for every 100 females but the sex ratio in China has increased to 118 (Gilles and Feldman-Jacobs 2012), with even higher ratios in some parts of the country. The excess number of male births as compared to female births has been associated with the one-child policy and the preference amongst Chinese families to have a son (Hsu 2008), while the broad availability of ultrasound imaging to identify the sex of the child during pregnancy has facilitated selective abortion.

India has also pursued population programs aimed at reducing the country’s high fertility levels with a “two-child norm” policy. It has promoted lower fertility rates through family planning programs, economic incentives, increased accessibility to contraception, and sterilization. India’s program, like that of China, has been criticized for being heavy-handed and has resulted in skewed sex ratios (110), with more males than females, given similar preferences for male children (Gilles and Feldman-Jacobs 2012). In both India and China, the “missing women” problem is critical (Gilles and Feldman-Jacobs 2012), with potential implications for civil order if men are unable to find partners.

Many developed countries are faced with the opposite situation: low fertility rates, aging populations, and declining populations. Europe’s fertility rate is just 1.4, and its growth rate is stagnant (0.0%). Lower birth rates have meant an aging population: Germany’s share of people over 65 is 21%, and the proportion over 65 in Japan is 26%. Even in the United States, where the fertility rate is comparably high, the US
Population Growth

Census Bureau reports the population is aging. By 2030, over 20% of Americans will be over 65, compared with just 15% in 2015.

Concerns with housing, health, and the provision of other services for an aging population have prompted countries to promote fertility through pronatalist policies to increase fertility rates and ultimately population growth. Such policies often include financial incentives, such as paying women to have children, tax incentives, paid maternity or paternity leaves, free or reduced-cost childcare and/or restriction to contraception and abortion services in attempts to promote fertility. While several countries, including France, Australia, and Russia, have implemented pronatalist policies, there is typically only a small increase in fertility levels (Haub 2008). In Russia’s case, fertility rates had dipped as low as 1.2 in the late 1990s. Following the introduction of pronatalist policies, fertility rates had increased to 1.8 by 2015.

While population decline is cause for concern, the ongoing concern with high fertility (and consequently population growth) stems from discussions linking population growth with resource consumption and particularly food or the ability of the world to feed itself. Written in 1798, Thomas Malthus’s “Essay on the Principle of Population” has long shaped the discussion around population growth and food security. In his essay, Malthus argued that food supply would increase in a linear fashion (1, 2, 3 …) and that population would increase geometrically (2, 4, 8 …). In his scenario, population would ultimately exceed agricultural output unless population growth was “checked” by famine, plague, or war, which would ultimately decrease the population. Alternatively, population growth could be controlled through “preventative checks” with individuals imposing their own limits on reproduction. Given that Malthus saw little hope for preventative checks, he forecast a future of population decline and widespread poverty.

Malthus’s ideas have continued to generate discussion within the broader literature, and alternate viewpoints have emerged. Following Malthus, neo-Malthusians such as Paul Ehrlich have argued that limited resources place limits on the growth of the human population and consumption, and point to food shortages as evidence of the finite means to produce food. Murton’s 1999 analysis of population growth, poverty, and agriculture in Kenya demonstrated increasing disparities and a loss of self-sufficiency, particularly amongst those dependent on agricultural labor markets. Alternatively, “distributionists” such as Karl Marx argued that people were poor due to the organization of societies, and that an equitable distribution of resources aided by technology would allow unlimited population growth, meaning that societies needed to be reorganized (Harvey 1974). “Economic optimists,” including Ester Boserup, see few limits to population growth and prosperity, provided the economic system and market mechanisms work correctly. Boserup (1965), for example, argued agricultural methods depend on the size of the population, whereby a scarcity of cropland can stimulate labor specialization, increased productivity, and changes in agricultural practices. That is, larger and denser populations are associated with greater food supplies able to support a larger population.

Regardless of the standpoint, the basic question is whether the world has sufficient resources – including water and food – for a growing population. There is clearly anecdotal evidence that resources, including clean water and agricultural land, in areas with rapid population growth are stressed and limited (De Souza, Williams, and Frederick 2003). Likewise, there is mounting evidence that the global food
supply is precarious, with disruptions to supply chains, a poor growing season, or increasing fuel costs effectively reducing the food supply (De Souza, Williams and Frederick 2003). Climate change could further jeopardize global food security as rising temperatures and shifting precipitation patterns alter agricultural production. Moreover, there is emerging consensus that rapid population growth reduces economic growth, increases poverty, weakens investment in education, decreases household savings, and degrades resources. Population growth and limited economic growth also appear to be self-reinforcing (Homer-Dixon 1999), resulting in greater disparities across populations.

The broader concern associated with population growth is the potential for conflict over scarce resources, including water supplies. The threat is potentially the greatest in the developing world, where population growth is the greatest and resources are the scarcest. Homer-Dixon (1999), for example, argued that future conflicts are more likely to be related to environmental degradation, population displacement, or disruption to economic systems.

Given that population growth rates have been declining since the 1960s, some authors have argued that population growth is no longer a concern. It is argued instead that declining populations and population aging are the new population problems (Longman 2004). Yet, the young age profile of much of the less and least developed world means that their populations still have to enter their reproductive years. Even if fertility rates decline, population momentum will ensure the world’s population continues to grow, and failure to recognize the potential for future growth is problematic. As noted earlier, the global growth rate is 1.2%, meaning that the world’s population could double in just 58 years. While this scenario is unlikely, some growth is assured. Even as fertility rates have dropped in some regions, they remain high in the least developed countries, including much of sub-Saharan Africa where the 2015 fertility rate was 5.0. Moreover, young populations translate to a population that is entering or already in its prime reproductive years. Consequently, global population growth will continue, and it remains unclear whether the world can accommodate this growth.

Population mobility and regional development

Tony Fielding
University of Sussex, UK

This entry is about the many relationships that exist between regional economic development and population migration. At one level, these relationships are fairly straightforward—a region with high wages experiencing rapid growth is likely to attract migrants from regions that have low wages and are in decline. But, dig deeper, and one finds many unexpected outcomes—these relationships are often paradoxical and are not as simple as they seem.

Population mobility comes in many forms, only a minority of which will be covered here. Figure 1 shows some of these mobilities plotted on a graph with axes for distance moved and duration of stay. Broadly speaking, this entry will focus on those who move further than distances (often judged to be around one hour’s traveling time—say about 50 miles) over which people are likely to commute rather than move house, and on those who stay in the new location for longer than about six months, that is, longer than one would stay if the move were a regular seasonal migration such as for agricultural work or spending the winter months in a warm, sunny environment.

Figure 1 is, however, very useful in pointing out the fuzzy boundaries of migration between city-regions. On the lower boundary of the shaded area are the forms of mobility that lie on the border between definitive migration and temporary stay. Sometimes the intention of the person or household is to move permanently to a new city or region, but, in the event, things do not work out as expected, and the stay is cut short. More commonly, however, the shift is in the other direction. Without the intention to do so, a person’s temporary stay in a new place, perhaps to visit a relative or to do a temporary job, turns into a permanent move as friends are made, job opportunities realized, and an almost imperceptible embedding of the person in the new location occurs.

On the right-hand boundary of the shaded area in Figure 1 are the forms of mobility that lie at the border of internal (intranational) and international migration. Some countries are so large in population and area, and contain so many socially and culturally different city-regions, that an internal migration can take on the characteristics more typical of an international migration; this is especially true of China where the household registration (hukou) system means that a person’s social rights (to health, education, housing, etc.) are associated with their official place of residence, and changing that (e.g., by moving from a rural area to the provincial capital or to one of the larger cities in the country) has been difficult if not impossible for most people, especially in the past. Conversely, an international border quite frequently cuts through the territory of a functioning city-region; a striking example of this is Singapore, where the island-state of Singapore increasingly constitutes only the core section of the city-region, with the state of Johor in Malaysia and the province of Riau Islands in Indonesia forming the outer sections of that city-region.
Finally, on the left-hand boundary of the shaded area are forms of mobility that involve long-term but relatively short-distance moves. Many such moves combine housing and neighborhood considerations with those of employment location. For example, the solution to the problem of a long commute is, for some people, to move nearer to work; for others, especially those in a two- or multiple-job household, one person will work away from home, sometimes far away, coming home only at weekends or public holidays. Certain types of work tend to produce these kinds of arrangements (e.g., serving in the armed forces, working on construction sites or...
offshore, or working in domestic/care occupations), but dual-career professional households in high-income countries are also increasingly taking this form, resulting in the acronym LAT (living apart together).

The concept of regional development is taken to mean differential urban and regional economic change, measured by indicators such as gross national product (GNP) and GNP per capita, unemployment rates, and standardized mortality rates, at local, city-region, and subnational scales.

Absolutely central to an analysis of the relationships between population migration and regional development is the appreciation that the direction of causality can take place, and typically does, in both directions; that is, the rapid growth of a region’s economy will usually result in net in-migration, and high net migration gains will usually lead to rapid growth in a region’s economy. This creates the strong possibility that there will be positive feedback loops linking, for example, migration and employment, and that processes of circular and cumulative causation will be at work (Myrdal 1957). A more recent microeconomic version of the path dependency arguments developed by Myrdal is represented by evolutionary economic geography. A representation of this approach, when applied to migration, is provided by Figure 2.

Starting in the lower left-hand corner, regional economic growth will be largely determined by national forces such as technological change and changes in consumer behavior, mediated by both regional productivity change (investment and innovation) and the inherited regional employment structure. This employment structure, together with the volume and direction of employment change (new jobs created/jobs lost), will largely determine the region’s in- and out-migration flows (Boyle, Halfacree, and Robinson 1998). Interregional migration will affect population growth not only directly through the net migration balance, but also indirectly through the age composition (and other characteristics) of the migrants. As regional population growth (or decline) occurs, the region gains (or loses) critical mass for its selection as a suitable location for investments related to market size or labor pool size. Finally, interregional migration greatly influences regional economic growth through the selectivity of migration. Since migration is generally positively selective of people who have ambition and courage and qualifications and skills, possess social and cultural capital, tend to be flexible and adaptive, and are in the young adult age group when their economic potential is at its height, a net migration gain can bestow an enormous advantage to a region’s economy. Conversely, a net migration loss can have all the opposite effects—a brain drain, an aging population, and a loss of commitment to adjust or change. Interregional migration can also affect regional employment change; migrants may well only take up those jobs that are attractive—that are secure and that offer good pay and prospects. The rejection of the other jobs will lead to either the stemming of employment growth or the jobs being filled by foreign workers. This interdependence between domestic interregional migration and international migration has become of very great significance in high-income countries around the world (see, e.g., Fielding 2015, ch. 10, on the new immigration model applied to East Asia).

To emphasize in this way the bidirectional flow of causality between population migration and regional development, and its potential to result in patterns of cumulative growth and decline, is not to deny the strong logic of neoclassical economic approaches to these relationships. Regional income convergence in the United States, for example, has been explained as resulting from the combination of the migration
of labor from low-income, high-unemployment regions to high-income, low-unemployment ones (thereby raising the scarcity of labor and therefore wages in the former and reducing labor scarcity and wages in the latter) and of the flow of capital in the reverse direction (to take advantage, of course, of the lower costs of labor in the low-income region) (Borts and Stein 1964; for a useful survey of migration models in this tradition see Plane and Rogerson 1994). The problem is that many of the expectations about interregional migration based on the neoclassical economic approach are simply not borne out by the facts: paradoxically, the unemployed are, generally, rather immobile, whereas homeowners on the other hand are surprisingly mobile; on balance, high-income cities often lose interregional migrants rather than gain them, while low-income rural areas often gain migrants rather than lose them. More generally, those who have the greatest need to migrate (because they have the lowest incomes and live in places with the worst economic prospects) tend to migrate the least, while those who have the lowest need to migrate (because they are in secure, well-paid employment and live in places with the best prospects) tend to migrate the most.

Much of the remainder of this entry is concerned with providing explanations for these anomalies while focusing on just a small part of Figure 2 – the one-way causal link between regional economic growth and regional employment change on the one hand, and interregional migration on the other. But, before this, a note of caution is appropriate. In the past, say 50 years ago, the link between migration and
employment was exceedingly close – very few could afford to live away from where jobs were located. Today, there have been two changes, especially in high-income capitalist economies, which have weakened this link. The first is the decline in the returns to labor relative to the returns to capital. This means that a significant proportion of people – those living off their investments – can choose to live in places that are geographically distant from the places where the economic activities on which their wealth depends are located. Within countries, this can result in environmentally favored regions having wealthy in-migrants and net migration gains even though these regions are renowned for their low wages and high unemployment. In the United Kingdom, the classic example of this is the southwest region and, above all, the county of Cornwall (Fielding 2012). Internationally, the benefits of this separation favor Caribbean island countries, and cities like Dubai and London. The migration of wealthy foreigners to London has knock-on effects on internal migration within the United Kingdom. By raising housing and other prices in London, these migrants make it more difficult for ordinary families (such as those of teachers and nurses) to migrate to the capital region, and at the same time encourage others to cash in their London properties to enjoy a high standard of living elsewhere.

The second change that has weakened the link between migration and employment is communications technology. It has become possible to work physically apart from your work colleagues while remaining as much in contact with them as if they were in the office next door. As part of this tendency, web conferencing and online meetings have become a part of many people’s working lives. This facilitation of the physical separation of home and workplace is of great importance to professional men and women in dual-career households; it has the effect of injecting flexibility into situations that might otherwise threaten career development and relationship commitments.

We return to the economic drivers of interregional migration. The first step is to categorize the many economic processes that affect interregional migration on the basis of the time spans over which they operate. This step is essential; far too often one finds economic analyses of migration floundering due to the unproblematic conflation (e.g., in econometric models) of very different kinds of migration processes; specifically, business cycle-related processes are mixed up with regional economic restructuring processes, which in turn are mixed up with underlying and only very slowly changing patterns of regional inequality.

Figure 3 shows all the different economic processes affecting interregional migration. It has three layers or levels: the top layer consists of economic changes that occur frequently and quickly; these are typically related to the business cycle. The label adopted to describe these processes is “conjuncture”: this word was chosen because there is no term in English that matches exactly the economic use of the term conjuncture in French. Conjuncture means the economic circumstances of the moment, which, in turn, usually means the position of that moment within the business cycle.

We know that there are close connections between interregional migration flows and the business cycle; these links operate through both the labor market and the housing market. Four stages can be identified. In stage 1, the economy is in its “rise” phase: confidence is growing, firms are investing, people are moving to new jobs and are thinking about moving house. For a high-income region within a national space economy, the typical migration responses to this stage in the business cycle are: in-migration low but rising; out-migration high but falling; with
house prices rising, people put their houses on the market and plan to move to new places; with unemployment falling, people contemplate taking the risk of changing jobs, often with the implication that this will provoke moves to new places; the effect of these changes, which can happen quite suddenly, is a net migration gain for the high-income region.

In stage 2, the economy reaches the peak of the business cycle; investment levels and job opportunities remain high; there is a lot of construction of dwellings and of commercial property; and unemployment is low. Turnover in both the labor and housing markets is high. In-migration peaks high, out-migration bottoms out low, so a high net migration gain is the result.

In stage 3, the economy is in its “fall” phase: confidence is declining, firms are cutting back, people are reluctant to move to new jobs or to move house. House prices begin to fall and unemployment begins to rise. The migration responses in a high-income region are: in-migration is high but falling; out-migration is low but rising; and net migration shifts from net gain to net loss.

Finally, in stage 4, we reach the trough in the cycle – recession. Unemployment goes up sharply, house building grinds almost to a halt, and confidence in the economy plummets. People and firms tend in these circumstances to hunker down, that is, to reduce their activities, expenditures, overheads, and commitments so that they can weather the economic storm and be in a suitable position to benefit from the upturn when it comes. The migration responses to recession tend to reflect the low turnovers in both the labor and the housing markets, so rates of migration flow are at a very low level: in-migration bottoms out low; out-migration peaks high; and net migration loss is to be expected.

However, there is a contradiction in this account. During a recession mobility rates tend to be low, and yet high net out-migration is expected. In times past, when business cycles tended to be more local, perhaps even differing from one region of a country to another, it would

Figure 3  Population migration and regional development: the Fielding three-layer model (modified from Fielding 2012).
have been possible for the out-migrants from a region in recession to have gone to a region that was booming. But today, in general, that is not what happens; globalization tends to ensure that there is a synchronization of business cycles, so recession tends to affect a whole country, indeed many countries, at the same time. There is, therefore, nowhere that is booming where those who are adversely affected by recession can go.

Furthermore, in the real world, business cycle migration effects tend to be modified or even covered over by migrations that are obeying a different economic logic. This point can be illustrated by looking at the migrations to and from the London city-region (southeast England) since the mid-1970s. Migrations to and from London tend to reflect the business cycle in that they go up during boom times and down during a recession. But as a high-income region with low unemployment rates, London should logically be a region of net migration gain from the rest of the United Kingdom, and it should be gaining most by migration during the boom years. This is most assuredly not the case. Most of the time London is a net loser of population through its migration exchanges with the rest of the United Kingdom, and it tends to lose most during boom times and least during a recession (indeed, it has sometimes gained by migration during a recession). This paradox can be explained by focusing on the difference in the dominant stage in the life course of migrants toward the London region and those moving away from the region. Those coming to London from the rest of the United Kingdom are, of course, very diverse in qualifications and social backgrounds, but they tend to be young adults from middle-class backgrounds straight out of university; they are single and consume very little housing space. In boom years, they may go directly into well-paid employment; in a recession, they enter the same or similar jobs but at a much lower level (perhaps even as unpaid interns). In other words they come to London whatever the state of the economy – whatever stage in the business cycle the economy is in. Those leaving the London region tend to be older, often much older, and are, typically, partnered with children (so there are many of them), and they are also predominantly middle-class homeowners. During a recession, not only are house prices low, but it is also difficult to sell property. As the economy experiences an upturn, confidence in the housing market suddenly increases, houses become easier to sell, and the prices obtained are higher. Those migrating away from the metropolis can now “surf” the high house price wave as it spreads outward to the nearby regions and often, ultimately, to the whole country. They can sell high and buy low, thereby maximizing the value of the assets that they have stored up in their metropolitan properties. The implications are striking: many of those who leave the metropolitan region are responding very intimately to business cycle processes; in contrast, most of those who enter the region are indifferent to these processes.

The second layer in Figure 3 refers to economic processes that take place over a much longer time span, typically over a period long enough for three or four business cycles. These processes are called “economic restructuring” because they imply new ways of organizing what, how, and where goods and services are produced. In this author’s judgment, the best way to envisage them is through the concepts of changing spatial divisions of labor.

In the period 1950–1970 the dominant spatial division of labor was regional sectoral specialization. What is meant by this is, first, that the nation-state largely defined the limits of the economy – most economic transactions were internal to the national space economy; second, that regions specialized in the branches of
production for which their special endowments of physical and social resources (local climates, mineral resources, labor skills, work cultures, etc.) were best suited; third, that the incomes earned from the sale of these goods and services to people living in other regions of the country would be used to purchase the goods and services produced in those other regions; and, finally, that the agency for the exchange of these goods and services would be the market – this implies that the spatial or geographical division of labor would coincide with the social division of labor, that is, the distribution that would result from market exchange. The implications of this for migration were profound. If the specialization on which a region’s economy depended suffered decline, for example, through changing consumer preferences, technological change, or a low income elasticity of demand, then businesses would fail, jobs would disappear, and out-migration would follow. In the 1950s and 1960s most high-income countries experienced rapid rural depopulation. This came about because technological change was revolutionizing food production, leading to much lower labor inputs; food and agricultural products had a low income elasticity of demand (demand increased very little as incomes went up), and rural businesses in all three macrosectors (agriculture, etc.; manufacturing; and services) tended to be small, technically backward, labor-intensive, and uncompetitive. In contrast, large factory industrialization and services-based urbanization were making the cities rich in employment opportunities. The result was a mass movement from the countryside to the city. The classic study of this migration was Guy Pourcher’s (1964) account of the migration of men and women to the Paris region. However, rural depopulation was not the only migration pattern for this period. Old industrial areas built on coal and steel, shipbuilding and textiles, were also losing out economically to the centers of Fordist production. By Fordist production is meant the mass production of standardized goods for mass markets – products such as automobiles, white goods such as cookers and refrigerators, and electrical goods such as radios and televisions – goods that were very much in demand during this period. Fordist forms of production called for very large workforces and very large markets; these were to be found only in the largest and wealthiest of cities – the metropolitan conurbations and national capitals.

Connecting and, for a time, coexisting with regional sectoral specialization, the new spatial division of labor emerged in the 1970s, coinciding with a rapid growth in the size of both private sector firms and of public sector organizations. Instead of a region being defined by the sector of the economy that dominates its labor force, it was defined by the role that its labor force played in the production process – as headquarters staff managing the affairs of the whole company (located in the capital city-region and/or main financial center); as research and development staff bringing new products to market or evaluating new production technologies (located in urbanized countryside close to the metropolis or in a major university city); as skilled workers needed to produce those goods and services calling for particular knowledge or experience (located in provincial cities and in new industrial areas); and as raw labor engaged in routine unskilled production (located in regions with large labor surpluses such as agricultural regions and old industrial areas). The spatial division of labor now coincided with the technical division of labor – that is, a planned separation of tasks designed to maximize the efficiency and/or profit performance of the whole organization. Once again, the migration implications were profound. Since the new spatial division of labor brought the work to the workers (at the same time, incidentally, as
welfare payments helped unemployed people to survive in situ), working-class migration became much less important, and indeed in most high-income countries total interregional migration rates began to fall during this period. But, below the surface, two important new trends were developing. The first was the growth of intraorganizational transfers – as organizations managed their large and widely distributed workforces to achieve efficiency, they deployed their managerial, professional, and technical staffs to their various operations located in different regions of the country. So middle-class mobility was being boosted just at the time when working-class mobility was being suppressed. The occupational class compositions of interregional migration flows were being transformed (Stillwell, Rees and Boden 1992). Second, the labor and other costs incurred by companies in the metropolitan cities were too high to sustain the more routine parts of their production processes. As a result, there was a major decentralization of industrial and routine service sector employment away from the metropolitan city-regions toward small towns and rural areas where labor was cheap and plentiful. With this change in the geography of investment there was a migration “turnaround” – a shift from urbanization toward counterurbanization. This counterurban migration trend of the 1970s and early 1980s was found in all high-income countries (Champion 1989); in some, notably the United States, it was largely interpreted as a response to the changing place preferences of populations (favoring the rural over the urban), but in most cases it was seen as the result of shifts in the political economy of production, often combined with demographic factors (Ishikawa 2001).

From the late 1970s, and building up over the next 20 to 30 years, a further change in the spatial division of labor occurred. This time the driving force was not organizational change affecting firms operating within the national space economy, but the strong development of links external to the national territory – in short, globalization. The effect of this at the level of regions within a country was to produce regional functional disconnection (Dunford and Fielding 1997); this means that regions are not linked to each other through market mechanisms (exchanges of goods and services) or through the planned separation of tasks (as in the new spatial division of labor), but are instead disconnected from each other – each one linked independently through global connections of ownership, management, and the flows of goods, money, information, and people to places outside the national territory, that is, to other parts of the world. The London city-region represents, perhaps, an extreme version of this process; so seemingly cut off from the rest of the United Kingdom has it become as its global city character has displaced its national and regional economic roles that it is sometimes spoken of as if it were a “different country.”

Globalization also weakens labor’s relations with capital, allowing forms of flexible specialization to emerge along with new industrial districts and industrial clusters. As a result of these changes, regional functional disconnection has two major implications for migration. The first is that it further reduces the many economic connections between regions that have previously acted as conduits for migration (e.g., intraorganizational transfers). The second is that, by forging relationships at the global scale, it promotes international migration and thereby helps to bring about the new “superdiversity” of metropolitan cities in high-income countries. The social significance of these international migrations lies in the fact that they add populations at both ends of the social spectrum – at the top in the form of highly paid professionals and managers, and at the bottom in the form of gap-filling immigrants.
who do the jobs that the locals, including interregional migrants, cannot or will not do.

Since about the mid-1990s there has been another change in the political economy of advanced capitalist countries, a change that has again tended to focus net migration gains in the major metropolitan city-regions. This change does not involve the end of globalization but rather its transformation from being primarily about the integration of markets for the production and distribution of material goods to the establishment of global networks for the trading of immaterial goods and services – a shift to what is sometimes referred to as the “knowledge-based economy” or “cognitive capitalism.” This trend toward the financialization and commoditization of key social relationships, and the partial replacement of wealth creation by wealth capture, favors the regions that are the linchpins of the global economy, places where rent-seeking behaviors are most likely to be rewarded – New York, London, and Tokyo, of course, but also globally significant cities like Hong Kong, Singapore, Shanghai, and Mumbai.

The third layer in Figure 3 refers to economic processes that work themselves out extremely slowly, say over a person’s life span or over three or four economic restructurings, and are therefore called “deep structural” processes; this change is so slow that it is almost imperceptible. The underlying macrogeography of wealth and poverty, both within and between countries, is the kind of thing to which this label refers. At the global level, the deep structural processes include those that help to maintain the inequalities between developing and developed countries, and the slow but steady shift of wealth and power since the 1950s toward East Asia. At the regional (i.e., subnational) scale, certain metropolitan city regions seem to dominate the space economy in wealth and power from one generation to the next – Paris does so for France, and Beijing and Shanghai for China. One of the principal reasons for this stability of wealth concentration is interregional migration. These metropolitan city regions attract the brightest and the best from all over the country; they promote them socially at rates that are much higher than in other regions; and they lose them to other regions at later stages in their careers or at, or close to, retirement from the labor market. The metaphor of the escalator has been used to describe this process – hence these regions become “escalator regions” (Fielding 1992).

Conclusion: population mobility and regional development in Japan

It is sensible to draw some of these ideas together through the use of an empirical example, Japan. The focus will be on the net migration gains and losses of the three major metropolitan regions: Tokyo, composed of the four prefectures of the southern Kanto region; Osaka, composed of the four core prefectures of the Kansai region; and Nagoya, composed of the three core prefectures of the Chubu region (see Figure 4).

The first thing to notice is the variability of the net migration curves, and the tendency for the peaks to coincide with periods of business confidence and the troughs with periods of economic difficulty or recession. Second, the early 1970s, that is, before the oil crisis of 1974–1975, marks a turning point in the migration flows to Japanese cities. Before this, all three metropolitan regions were the beneficiaries of net migration from the rest of Japan, and the order was simple – the largest gained the most. The 1950s and 1960s were the peak years for rural depopulation in Japan, and hundreds of thousands of people, mostly young men and women from farming and small business backgrounds, were migrating
each year to the major industrial cities as regional sectoral specialization favored these centers of Fordist production over traditional provincial Japan. After the turning point, however, something very interesting happened – Tokyo took off on its own as a major destination for internal migration. This is largely explained by the transition to the new spatial division of labor; Tokyo is the corporate headquarters location for Japanese domestic and international business. The 1980s was a period when these major corporations were achieving astounding success both in Japan and elsewhere, and Tokyo, not Osaka or Nagoya, was the major beneficiary of that success. Tokyo’s global city success, however, suffered a severe blow during the Japanese financial crisis of the early 1990s; the net migration gain momentarily became a net migration loss as asset values tumbled and business confidence plummeted. Since that time, significant net migration gains have returned and held up until the current crisis which started in 2008.

But Figure 4 also shows us something else – the enduring attractiveness throughout business cycles and restructuring periods, of the Tokyo metropolitan region to internal migrants. Tokyo is the “one-point concentration” of the Japanese space economy. Where would an able, active,
and ambitious young person go? To the center of bureaucratic power and corporate wealth, of luxury consumption, artistic creativity, and celebrity success – they would go to Tokyo. Tokyo is itself a major hub for university education (Tokyo University being the most prestigious in the country), but it is also the destination for many students graduating from other university cities around the country. These other university cities, especially Kyoto, but also major provincial cities such as Osaka, Nagoya, Fukuoka, Sendai, and Hiroshima, act as “siphon cities,” recruiting bright students from nearby regions and from further afield and channeling them to Tokyo after graduation. And, when they get there, they benefit from the massive opportunities for upward social mobility that Tokyo offers relative to other places in Japan (especially, incidentally, for women). In the past, once a person had made it to Tokyo, they stayed there, but recent census results show that Tokyo is now joining many metropolitan cities around the world that lose older migrants to provincial, coastal, and rural areas as they enter retirement age groups.

In all these respects – stepping on, being taken up, and then stepping off – Tokyo displays the characteristics of an “escalator region,” a region that acts as a kind of permanent engine for upward social mobility within contemporary society.

Every country is unique, and Japan is arguably more unusual than most, and yet, using this example, most of the key theoretical relationships between population mobility and regional development outlined earlier in this entry have been exemplified.

Ports

Peter V. Hall
Simon Fraser University, Canada

Ports provide safe harbor for ships and boats so that goods and people can be transferred between water- and land-based transportation modes. This functional definition is complete, yet it obscures a fundamental global–local binary that makes ports a central and fascinating object of geographical inquiry. On one hand, ports are spaces situated in global transportation networks that connect widely dispersed points of production and consumption, and hence they are forged by the actions of steamship lines, railroads, cargo owners (shippers), workers, and governments. On the other hand, ports are places with distinctive local and site-specific characteristics, combining particular coastal morphologies and development histories, imbued with political and cultural meaning. Traditional geographical approaches focused on the conception of ports as places, while post-World War II analysts focused on ports as spaces; today, a more balanced appreciation of ports as multiscalar and multidimensional activity systems is emerging.

The simplest ways of classifying ports reference the physical characteristics that influence which vessels may call there: water depth and the width and other dimensions of the approach or shipping channel and berth limit the draft, beam, and length of ships. While natural characteristics of the waterways are important, often these are determined through dredging, the construction of coastal infrastructure, canals, locks, and berths. Hence the body of water on which a port is located provides one axis of classification: sea (or ocean or maritime), river, or lake ports. The ships which may call at these ports, and the cargos they will handle, are constrained in different ways: where seaports may face high and low tides, river ports may face seasonal flooding or drought, while lake ports may be constrained by ice during winter. Ports face other physical constraints – one of the most important is the availability and configuration of land for cargo-handling activity and expansion.

Ports are made up of one or more terminals, the term which describes the distinct combination of facilities for loading ships: wharf, storage yard, cranes, and other equipment. Different cargos require different terminal attributes. Hence categories of cargo also describe cargo-handling statistics and terminal types: container, ro-ro, and break-, liquid-, and dry-bulk. Containers, metal boxes which carry a huge variety of goods from manufactures to refrigerated foods, are lifted on and off ships with specialized cranes. Container terminals are prized because of the value and diversity of cargo moved in containers (see Figure 1). As container ship sizes have increased, container terminals have become larger and more mechanized (and increasingly, robotized) in order to achieve the desired economies of scale. Ro-ro (or roll-on, roll-off) cargos refer to automobiles and other self-propelled vehicles loaded via ramps. Break-bulk cargo is typically undifferentiated cargo loaded on pallets, in crates, or in bags; it is also increasingly common to distinguish neo-bulks, which refers to differentiated cargos such as steel, paper bales, and granite. Liquid-bulks such as oil and liquefied natural gas (LNG), and dry-bulks such as coal and grain are loaded unpackaged. Where
Figure 1  Millions of container units (twenty foot equivalent units, TEUs) per port, 2012. Most of the world’s largest container ports are located in East Asia. Adapted from Containerization International, port authorities and port associations, created by Jean-Paul Rodrigue.
liquid- and dry-bulk cargo may be poured or pumped onto ships, break- and neo-bulk cargo is typically lifted by crane. Most of the world’s largest ports have multiple terminals, and hence are multi-functional. Rotterdam, for example, is known as a container gateway to northern Europe, but it also handles huge volumes of bulk cargos. There are also non-cargo terminals and ports: cruise, ferry, fishing, and recreational.

Ports vary according to the inland and offshore location(s) they serve. Local ports serve the city and regional territories adjacent to the port area, while gateway ports serve more widely dispersed areas that could be continental in scale. The concept of the hinterland is fundamental to this distinction; local ports serve a captive hinterland in which they enjoy an effective monopoly, while gateway ports are likely competing with other ports to serve a contested hinterland. Of course, terminals within ports may also compete with each other to serve local and remote hinterlands; indeed, in a process called terminalization, the operators of port terminals today are asserting a more active role in value chains (see also Global commodity/value chains).

Ports may also be characterized according to their insertion into water-based transportation networks. The concept of the foreland describes this waterside or overseas trading territory of a port (Rodrigue and Notteboom 2010). Hub ports collect and redistribute cargo from multiple smaller feeder or peripheral ports located within the foreland of the dominant port. For example, containers from ports in the Pearl River Delta might be barged to Hong Kong and there loaded onto larger container ships. While transshipment occurs by definition at all hubs, ports such as Singapore which are specialized in this activity are known as transshipment ports. Also known as intermediate hubs, several of the world’s newest container terminals and ports have been built at locations which connect the major oceanic routes: for example, Algeciras and Tangier Med ports are located near the Strait of Gibraltar to connect Atlantic and Mediterranean–Indian ocean traffic. Hub and transshipment ports are most closely associated with containerized cargo.

Containerization is associated with other profound changes in the geography of ports. Traditional port locations were physically determined, sited at convenient river crossings (e.g., Paris), the head of a delta (Cairo) or estuary (Antwerp), on either side of an isthmus (Manila), or in a protected bay (Durban). These sites were important points in the “break of bulk,” hence there was a close historical relationship between ports and human settlements. Not only was lots of physical work and hence employment involved, but also warehousing and financial and legal administration to support trade. Merchants and traders left a distinctive impact on historic port cities in both metropolitan and colonial locations.

Industrialization heralded a change in the scale of shipping that was later greatly amplified in the container era. Fordist industrial ports were associated with processing imported raw materials for nearby assembly lines, and the export of manufactured products. Contemporary versions of such port-centric industrialization inform the widespread creation of export processing and Free trade zone around ports, notwithstanding concerns about whether the economic benefits will accrue to the port region (see Hall et al. 2011).

Changes in the relationship between ports and cities intensified with containerization. Larger ships require deeper water and more space for cargo operations. In his site-centric “anyport” model, Bird argued that ports would migrate downstream toward deeper water and away from the land-constrained port city, while Hayuth argued in his situation-centric “load center” model that a small number of ports would win out in the competition for the larger ships
PORTS (see Olivier and Slack 2006). In large measure, both predictions have been proven correct, but have also been surpassed by subsequent events. In many parts of the developed world ports, especially terminals and industrial sites in core urban areas, were abandoned. Some waterfronts have been redeveloped as sites of consumption, residence, and commerce (see Desfor et al. 2010; see also Urban redevelopment).

Yet the goods kept moving in ever more complex global supply chains. In order to secure the massive investments required to build and operate container terminals, port authorities, the government organizations which manage port lands, as well as terminal operating firms, have become increasingly active and strategic about their investments in both hinterlands and forelands. Notteboom and Rodrigue (2005) have termed this process “port regionalization.” The resulting changes in the relationship between ports and urban economies have been extensively documented (see Wang et al. 2007). In general the literature indicates that the relationship between ports and economic development today is positive at larger (continental, national, and mega-regional) spatial scales, but more uneven and even negative at smaller (neighborhood, port district, and city) scales. There are also differences in the port city economic relationship in different world regions, which relate to differences in colonial history and recent industrialization.

Such economic geographies are, of course, made by actors. Olivier and Slack (2006) draw attention to the increasingly important role played by transnational corporations (TNCs) in shaping patterns of port development: these TNCs include specialized global terminal operating firms, the major container steamship lines and their terminal operating divisions, as well as increasingly influential shippers such as the major North American and European retail chains. The entry of TNCs has been enabled by changes in the governance of ports, including privatization of some terminals, the corporatization of port authorities in formerly publicly owned and operated ports, and the financialization of the port industry.

All of these processes open up the possibility for new conversations between port and other human geographers around economic and urban development, institutions, and even culture and the health impacts of port activity. Terminalization, for instance, which involves the simultaneous fragmentation of ports as coherent places but also the opening up of new global and local connections to hinterlands and forelands, shares much with other Glocalization processes. Port geographers are also engaging more with physical geographers with ongoing attention to marine environments as well as to climate change and sea level rise and options for reducing transportation-based greenhouse gas emissions.

Portugal: Associação Portuguesa de Geógrafos (APG) (Portuguese Geographical Association)

Founded: 1988
Location of headquarters: Lisbon
Website: www.apgeo.pt
Membership: 800 (as of 2013)
President: Rui Pedro Julião
Contact: rpj@fcsh.unl.pt

Description and purpose

Associação Portuguesa de Geógrafos (APG) is the professional association for geographers in Portugal and it has just celebrated its 25th anniversary. The APG’s mission is to promote geography, supporting its professional development, and fostering the recognition of the geographers’ role in society.

Journals or major publication series

Current activities or projects

The APG organizes a congress every two years (odd years) where the broad field of geography and its major academic, research, and professional achievements are presented and discussed. This conference alternates every year with the Iberian conference (even years) as there is a strong liaison between the two countries. The APG also publishes Inforgeo, a magazine that is an open platform for paper publication.

The APG sends out electronic newsletter three times a week to all members and registered users with relevant news and the agenda for the upcoming period.

Brief history

APG was founded in 1988 by a group of academic and professional geographers and currently has about 800 members, most of them active as public servants at different levels of the public administration (municipalities, regional, and central administration) and working in a wide range of subjects.

The history of Portuguese geography is not confined to APG activities, but, undoubtedly, APG is now an important part of recent developments.

In 2012 the APG received a Public Interest Organization award from the Portuguese government.

Portugal: Sociedade de Geografia de Lisboa (SGL) (Geographical Society of Lisbon)

Founded: 1875
Location of headquarters: Lisbon
Website: www.socgeografialisboa.pt
Membership: 1280 (as of December 31, 2013)
President: Luís Aires-Barros
Contact: geral@socgeografialisboa.pt

Description and purpose

The Sociedade de Geografia de Lisboa (SGL) was created in 1875. Its origins and objectives were connected to the Portuguese and European contexts of that time and with problems in relation to Portugal’s position regarding its overseas colonies, especially in Africa. Currently its fundamental concerns are the maintenance and reinforcement of scientific and cultural connections with the countries in which Portuguese is the official language through conferences, seminars, books, and the systematic publication of the *Boletim* (Bulletin).

The SGL library is recognized nationally and internationally as a mandatory resource for all investigators dedicated not only to the study of the Portuguese expansion and history of discoveries but also to geography, history, and ethnography of the Portuguese speaking countries. It is used annually by students and researchers from all over the world.

The SGL has a museum rich in artifacts coming from Africa, Asia, and Australia.

Journals or major publication series

*Boletim da Sociedade de Geografia de Lisboa*
*Memórias da Sociedade de Geografia de Lisboa*

Current activities or projects

General cultural activities covering a great variety of subjects are carried out by about thirteen general commissions (such as the Africa Commission, Asian Commission, European Commission, Commission for International Relations) and by specific sections (such as Section of History, Section of Anthropology, Section of Ethnography, Section of Mathematical Geography and Cartography, Section of Ocean Geographic, Section of Literature and Fine Arts, Section for the Patrimony Studies, etc.). Many of the presentations made at the public sessions are organized by those commissions and are published in the *Boletim da Sociedade de Geografia de Lisboa*. Some workshops or colloquia publish their papers in special issues of *Memórias da Sociedade de Geografia de Lisboa*. Some special themes regarding our rich collections (at the library and/or museum) are developed as research projects supported by the National Foundation for Science (Ministry of Science) and normally involve university researchers.

Brief history

After the Berlin Conference (1840) organized by Bismarck, a rush of geographic exploration took place in Africa (the so called *Terra Incognita*), crossing this continent from the Atlantic Ocean to the Indian Ocean (e.g. Livingston, Stanley,
PORTUGAL

Cameron, Brazza). These geographical voyages were promoted by some recently founded geographical societies (such as those of Paris, London, and Berlin). It was thus considered mandatory for Portugal to have representation in that movement, leading to the birth of SGL in 1875 proposed by people interested in overseas matters. It received official support from the outset. Since then, the SGL has been sustained as has no other private institution specially connected to the national cultural life. It is alive and dynamic, in some cases taking initiative, in others coordinating activities with other national institutions.

A large number of congresses and colloquia, some promoted by SGL, same in cooperation with other institutions, have been held at SGL premises. It has created an ethnographic and historic museum in its headquarters. This museum has received not only documents and remainders of documents by Portuguese navigators from the fifteenth century in the African coast, but also donations to form an outstanding collection of artifacts from Africa, Asia, and Australia. No less important is SGL’s cartographic archive which offers the visitor a rich of variety of maps, atlas, plants, both Portuguese and foreign, and from all times in history.

Submitted by Luís Aires-Barros
The concept of positionality was introduced into human geography by way of feminist and poststructural interpretations in the early 1990s. Positionality highlights how people, including researchers, come to know and interpret the world from different social locations; positionality shapes research, and may inhibit or enable certain research insights. A person’s embodied subjectivity mediates the research process, including the relations with the people, places, and materials of the research project. Initially conceived in reference to face-to-face fieldwork, it was soon apparent that positionality had purchase in other sorts of research methods. As a concept, positionality raises important questions about the politics and ethics of research, and since the mid-1990s it has become highly influential in the design, conduct, and representation of research across human geography.

The roots of interrogating the impact of positionality on the research process date back to broader feminist challenges to the supposedly neutral, impartial claims and theories in the social sciences and the humanities. Also significant are contributions of feminist scholars of science studies who illuminated the ways in which scientific thought and practices are gendered. In brief, the critique is that seeking universal truths and all-encompassing knowledge (whether in the humanities or the social or natural sciences) constitutes what Donna Haraway (1991, 189) famously describes as an all-seeing “god trick … seeing everything from nowhere.” In short, all research is a view from somewhere and research is never value-free (even “hard science” research). Intellectual activities are shaped by the historical circumstances, normative expectations, and cultural beliefs of the time and place in which they are created. Knowledge is partial, situated, and power-laden.

The implication of situated knowledge for positionality is that both researchers and participants (and everyone else) are differently situated by their cultural, intellectual, and spatial locations, as well as their intellectual history and lived experience, all of which mediate our understandings of the world and the knowledge we produce. Thus research is created in a world already steeped in meanings and interpreted by people, including the researcher, who live their lives in it. When conducting research, our values and location in webs of power frame what we take to be “facts,” how we develop a particular research strategy, and what research questions we ask and what we “see” when exploring those questions. Researchers are a visible and integral part of the research encounter, and, as Liz Stanley and Sue Wise (1993, 157) put it, “researchers remain human beings complete with all the usual assembly of feelings, failings, and moods.”

As researchers are an embodied and integral part of the research process (rather than external, detached observers), positionality has been further extended to include considering others’ reactions to the researcher. Both our embodied presence as researchers and the participants’ response to them mediate the information collected in the research encounter. Moreover, subjectivities are contextual and shifting: different personas may be performed in particular
Positionality

circumstances and locations. In addition, positionality is a relational concept: the researched
are not passive; they are knowledgeable agents and, as such, the research encounter is structured
by both the researcher and the researched, both of whom construct “the data.”

Like most useful and robust concepts, positionality has been refined and adapted over
time. Two sets of theoretical, conceptual, and empirical interventions have been especially
significant: intersectionality and embodiment. Positionality became popular in the context of
the rise of identity politics and the early 1990s poststructural crisis of representation. Part of
that was also a challenge to white, Western feminists’ epistemic reliance on the universality
of a monolithic category of women as oppressed. Since then there has been growing literature
on the discourses, practices, and processes of systems of social difference and inequality (such
as gender, class, “race,” ethnicity, (dis)ability, and other social identities). Intersectionality involves
considerations of how systems of difference intersect differently in different places, times,
and situations. Positionality has and continues to be enriched by researchers paying attention
to how they are positioned (by the self, by others, by particular discourses) in relation to
multiple relational and intersectional processes of difference. Critical awareness involves addressing
how researchers are differently positioned in hierarchies of power and privilege from each
other and from those they engage in their research.

These more thorny issues have arisen particularly in the context of the positionality of those
wishing to address multiple and cross-cutting positions of privilege and oppression, and the
politics of white Westerners researching people from/in the Global South. Rather than avoid
such research encounters, Richa Nagar and Amanda Lock Swarr (2010) suggest building
cross-cultural collaborations and critically aware transnational praxis based on “alliances that are
created and sustained through deeply dialogic and critically self-reflexive processes of knowl-
edge production and dissemination” (2010, 3). One such example is Christine Schenk’s (2013)
discussion of her experience of doing fieldwork in the “antagonist context” of a non-Muslim
researcher in the province of Aceh in Indonesia. She argues for a psychoanalytically flavored
relational positionality that embraces a division of power through “cross-cultural collabora-
tion and a gender balanced team composition of researchers (that could) balance differences
arising from different backgrounds” (2013, 352).

Understandings of positionality are also being nuanced via provocative discussions of embodied
methodologies and fieldwork. The body was evident, but not marked as such in early discus-
sions of the feminist politics of both research and positionality. For example, in their influ-
cential mediation on the research process Liz Stanley and Sue Wise (1993, 157) pointed out
that our “consciousness is always the medium through which the research occurs; there is no
method or technique of doing research other than through the medium of the researcher.”
Since then theorizing of bodies, corporeality, and embodiment has propelled discussions of not
only the discursive constructions of bodies, but also the fleshy materiality of actual bodies. For
example, Longhurst, Ho, and Johnston (2008) reflect on their research on the role of making,
eating, and sharing food in the construction of home for migrants in Hamilton, Aotearoa/New
Zealand; and make the case for “our own bodies and our participants’ bodies as ‘instruments of
research’” (2008, 214).

It is now broadly accepted and indeed expected that human geographers will acknowledge their
positionality when constructing, analyzing, and writing up their research. It has become
commonplace for researchers to include a statement of self-representation explaining that they are writing as someone positioned within a particular set of subject positions. This is, of course, an important corrective to the trope of the omniscient, unmarked researcher. But a serious engagement with positionality requires more than this. Positionality is about being embodied and embedded in the shifting processes and practices of identity formation, affect, and power. Remaining at the category identification version of positionality may devolve into self-stereotyping by fixing the researcher’s subjectivity into generic categories, and further runs the risk of solipsistically placing the researcher at the center of the analysis (Robertson 2002; Kobayashi 2009). Positionality’s critical edge is that it is both a reflective and a political resource. The latter demands an accountable, politically aware progressive use of research to capture people’s everyday lives in all their shifting, messy complexities.

Postcolonial geographies

James D. Sidaway  
National University of Singapore

The department of geography at the University of British Columbia (UBC) in Vancouver has long been a key site for the discipline, with a community of scholars and generations of graduate students who have made significant inputs to its evolution over the last few decades. Directly opposite the four-story building that houses the department is another lower, longer building, UBC’s First Nations Longhouse (Figure 1). A relatively recent addition to the campus, the longhouse cites a presence on the land that long predates that of the modern university and its departments. Yet that history has only become visible to most visitors in recent years, through developments like the Long House and First Nations museum on campus and a series of art projects across the campus that signify indigenous presence (Figure 2). For decades, however, those histories were largely erased and overwritten as the structures that house UBC and their systems of knowledge and naming were established.

Today Vancouver sits at the intersections of imperial projects. Foremost for Canada and British Columbia has been the British empire, whose linguistic, legal, cultural, and political legacies deeply shape the landscape, nation, and city; however, that Canada accommodates two European settler projects (anglophone and francophone) is frequently visible, since Canada’s constitution requires that both European languages appear on official documents and signage. Moreover Canada is part of the military alliance structure in which its neighbor to the immediate south is the leading power (and, according to many observers, now acts as an empire). But Vancouver also faces west, across the Pacific where British and American power have clashed and melded with other empires in the twentieth century (chiefly that of Japan, but also those of France, Britain, Germany, the Netherlands, Portugal, and, in the century before, Spain) and where American power now faces the successor state to the Qing empire: the People’s Republic of China. China itself is both a successor state to a continental empire that became an object of foreign imperial colonization (chiefly by Britain, Germany, Portugal, and Japan). Elsewhere, Canada played a supporting role in the American-led invasions and occupations of Afghanistan and Iraq, whose course (together with Israeli policies in the West Bank territories it occupied in the 1967 war) led a UBC-based geographer to designate the early twenty-first century as “the colonial present” (Gregory 2004). For Gregory:

The colonial present is not produced through geopolitics and geoconomics alone, through foreign and economic policy set in motion by presidents, prime ministers and chief executives, the state, the military apparatus and transnational corporations. It is also set in motion through mundane cultural forms and cultural practices that mark other people as irredeemably “Other” and that license the unleashing of exemplary violence against them. This does not exempt the actions of presidents, prime minister, and chief executives from scrutiny (and, I hope, censure); but these imaginative geographies lodge many more of us in the same architectures of enmity. It is important not to allow the spectacular violence of September 11, or the wars in Afghanistan, Palestine, and Iraq, to blind
us to the banality of the colonial present and to our complicity in its horrors. (2004, 16)

More specifically however, geographical knowledge and geography as a discipline have long been deeply implicated in imperial projects. Mapping for nation and empire, imperial education, and the codification of strategic geographical knowledge offered much of the rationale for the nineteenth- and early twentieth-century establishment of geography as a formal discipline in many European states (Clayton 2011). Arguably, therefore, much geography was an expression of and was shaped by wider colonial discourses, frequently caught up with formations of “race” and the operation of racism. Awareness and critical scrutiny of these colonial discourses have developed since the 1970s in the wake of and accompanying formal decolonization in much of the Caribbean, Africa, and Asia and ongoing struggles for national liberation.

Orientalism and representation

The intellectual project of postcolonial geography was bolstered by the publication of Orientalism by the Palestinian-American literary scholar Edward Said (1978). For Said:

Orientalism is a style of thought based upon an ontological and epistemological distinction made between “the Orient” and (most of the time) “the Occident.” Thus a very large mass of writers, among whom are poets, novelists, philosophers, political theorists, economists, and imperial administrators, have accepted the basic distinction between East and West as the starting point for elaborate theories, epics, novels, social descriptions, and political accounts concerning the Orient, its people, customs, “mind,” destiny, and so on. (Said 1978, 2–3)

Not only that, for, according to Said, geography – though in a broader sense than the discipline alone, and therefore in the form of wider geographical imaginations—is at the heart of Orientalism and hence imperialism. So the “Orient” is not simply objectively there; it is represented as a historical and geographical object in Western discourses. In turn, those discourses are projected onto the Orient which is then cast and remade in an imperial light. The West is thereby defined vis-à-vis the Orient and vice versa. This process requires one side of the world (the West) to be represented as the source of civilization,
progress, and order, while the other side (the Eastern, non-Western, Oriental world) is represented as lacking these features and hence in need of Western stimulus to progress. For Said,

much as the West itself, the Orient is an idea that has a history and a tradition of thought, imagery, and vocabulary that have given it reality and presence in and for the West. The two geographical entities thus support and to an extent reflect each other. (Said 1978, 3)

While he focused in particular on European (and later American) representations of the Middle East, Said’s account of the power of imperial era definitions has been applied to other parts of the West/non-West binary, such as representations of East Asia, Africa, and Oceania and of labels such as the Balkans and Eastern Europe and “marginal,” “less developed,” and “backward” areas within continents and countries, such as the US South. In turn, the ways that such representations are internalized in the Orient, as well as the possibility of counternarratives and resistances, have meant that the critical study of Orientalism has thrived. This includes the study of a so-called “Orientalism in reverse” or “Occidentalism,” whereby the West is represented by non-Western thinkers as having characteristics (such as lack of religiosity) that invert the prior Orientalist notions about which side of the (imagined and preformed) East/West divide is superior.

Yet, despite this wealth of work, Orientalism was relatively slow to be cited by geographers and it was not until the early 1990s that it became a frequent reference point. It was first encountered through radical geography’s interrogation of the discipline’s intimate relationship to (especially European) imperialism. The history of academic geography, especially in the nineteenth and early twentieth centuries was thereby repositioned as part of a wider Orientalist narrative, complicit with racism and expressed through the discipline’s encounter with environmental determinism, as well as a corpus of colonial and allied geographies of the non-West. By the 1980s, radical geography sought to distance itself from these legacies and they were critically reassessed in subdisciplines such as historical geography (with its sensitivity to the representations and focus on empires), and development geography (in which the core object of study is the non-West). Subsequently, the advent of postmodernism and poststructuralism in human geography foregrounded the politics of representation in ways that Said and other literary theorists had forged. Postcolonial influences thereby became established within critical geography. While this happened, there was also what seemed to be a revival in Western imperial interventions in the form of the American-led wars in Yugoslavia, Iraq, and elsewhere, which led Derek Gregory to denote a colonial present and many others to reconsider the meaning and endurance of empire.

**Postcolonial geographies**

Today such debates continue against the backdrop of an array of theoretically sophisticated postcolonial readings of the spaces of past empires, including critical works on the intersections of sexuality, race, space, and empire (Phillips 2006; Legg 2014). In the meantime, moreover, literary studies have registered a wide broadening of the canon of texts worthy of study, to include postcolonial literature from former colonies or where colonial themes or power is foregrounded. More widely, literary studies were enlivened by the development of postcolonial approaches, inspired by Said and allied work that situated the canon vis-à-vis imperial cultures. These developing postcolonial approaches increasingly also impacted on academic geography through
the 1990s. Reflecting the richness and density of some of the key literary postcolonial theorists who emerged after Said (Homi K. Bhabha and Gayatri Chakrabarty Spivak in particular) some of this geographical work (for a recent example, see Jackson 2014) has been quite densely theoretical.

The publication of an edited collection of *Postcolonial Geographies* (Blunt and McEwan 2002) and a textbook on *Geographies of Postcolonialism* (Sharp 2009) signified the consolidation of postcolonial approaches in human geography. A few years earlier, Daniel Clayton (2001, 749–750) had suggested a series of departures for “postcolonial-geographical lines of enquiry that (variously and among other things)” seek to document and theorize multiple, contradictory, and fragmented identity spaces. He called for grounded work with postcolonial theory that was attuned to the discordant postcolonial politics of the places being studied. In turn, Clayton argued that all critiques of colonialism must recognize themselves as “situated knowledges,” bearing limits derived from their means and sites of study. For Clayton, colonialism needed to be examined at a range of scales, power intersections, and vantage points. He argued for serious study of the past and judicious use of archives, but that these needed also to transform understandings of the present and should have “an anti-colonial effect.” Clayton was wary, however, of a straightforward “postcolonial template for geography” (2001, 750), stressing that “the rudiments of a postcolonial-geographical way of thinking” required much further work, elaboration, and debate.

Analytically it can be useful to distinguish between postcolonialism as a condition, as in a postcolonial state or society that has been through a process of decolonization, and postcolonialism as an orientation, theory, or vantage point, although these postcolonialisms are frequently intertwined (Sidaway 2000). Moreover some geographers have criticized what they discern as a tendency for the discipline to focus on colonial discourse analysis of past colonial geographies at the expense of a focus on contemporary expressions and forms of colonial power. The historiography of the discipline has been greatly enriched by the impact of postcolonial approaches. Yet, according to Gilmartin and Berg (2007, 122), that focus has been “on faraway pasts and geographically distant spaces as the spatio-temporal containers of ‘postcolonial geographies’” comes at a cost:

As a consequence, British postcolonial geography is dominated by critiques of the discursive construction of historical colonialism, rather than focusing on the aftermath or continuation of colonialism. This effective hijacking of the postcolonial within geography means that it loses theoretical force, becomes one of a long list of “posts” that often alienate geographers who might like to, or already do, engage with the challenges posed by postcolonialism to the ways in which we construct knowledge. (Gilmartin and Berg 2007, 123)

While the social geography of migration and diaspora frequently registers postcolonial perspectives, more widely (reflecting postcolonial theory’s formation in literature and allied humanities), social, cultural, historical, and urban geography have registered the impacts of postcolonial perspectives to a greater degree than, for example, political or economic geography. The partial exception has been development geography, which as noted earlier, was an early domain for postcolonial perspectives. But the wider agenda for and possibility for other postcolonial geographies has been asserted by Pollard *et al*. (2009, 139), who argue

that postcolonialising economic geography is not confined to an engagement with the more obviously postcolonial worlds of diasporic communities and the global South. Nor are we suggesting
that it is only those who work in area studies who can practise a postcolonial economic geography. Far from it. The postcolonial economic geography we advocate is not a geography of “the South,” but an economic geography more conscious of its own perspectives and more open to embracing different perspectives through which to view economic practices. It is as important to turn these perspectives on the North to disruptive effect as it is to break the silences from the margins.

Future directions

Several decades on from postcolonialism’s arrival in human geography, what prospects loom now for further postcolonial geographies? Although the issue has become widely debated and contested, it is still the case that the parameters of disciplinary progress are largely defined from Britain and North America, whose relative hegemony (along with that of the English language) in setting agendas endures. That a discipline that was so implicated in colonial projects and therefore caught up with racism remains comparatively white in terms of faculty members at its core British and North American nodes has been flagged by critics. In respect of the opening themes of this entry, however, challenging questions about “indigenous geographies” have been raised by writers such as Panelli (2008, 802) who also draw attention to the relative lack of indigenous faculty in Aotearoa/New Zealand but also stress the ways that indigenous geographies “speak to many core interests in social geography: place, social power relations, and identity politics to name a few.” Subsequently Coombes, Johnson, and Howitt (2014) set out the ethical, epistemological, methodological, and political challenges arising from sustained engagement with and from indigenous geographies. They conclude that

The challenge is contextual, engaged and performative – it requires not just methods of research, but approaches to being-in-the-world. As feminist methodologies shifted the discipline’s view of its purpose a generation ago, debates about approaches, collaborations and ethics in Indigenous geographies unsettle our journey as researchers. They reset the compass by which we guide our endeavours and judge our achievements. (Coombes, Johnson, and Howitt 2014, 851)

In related terms, “decolonial” manifestos that have been elaborated by Latin American writers operate between recognition of the continued power of Eurocentrism and a refusal of its logics. Kiran Asher (2013) describes the premises of this literature, arguing that engaging further with them would be especially productive for the field of development geography. This begins with further study of how colonial conquest and racialized colonial practices constituted the modern world-system and how Western thought claims to be “universal and total,” placing “alternatives” as local and/or marginal. For Asher (2013, 832–833), “such decolonial alternatives or ‘non-Eurocentric’ forms of knowing and being in the world can emerge from the different wisdom and experiences of those who have been on the borders of colonial modernity,” and “Latin America and the past and present experiences of Latin Americans are a key, though not the only, loci of enunciation for decolonial thinking.” And, in a recent article, Jazeel (2014, 101) advocates “a postcolonial geographical research imagination to more effectively, and far less imperially, engage radical alterity.” His aim is to consider the analytical utility of “subalternity,” a category and style of analysis that developed first in critical historical writing on/from India. Indian subaltern studies sought to look beyond the power structures and discourses established there through empire and their categories of analysis that were arguably reproduced by
the successor states to the Raj. Subaltern has become a frequently used and contested term in postcolonial geography and wider postcolonial historical literary, cultural, and historical studies. In the same special issue of the *Singapore Journal of Tropical Geography* that contains Jazeel’s paper and another cited here, Sidaway, Woon, and Jacobs (2014) have suggested (rather like Asher, but without direct reference to her article) “five pathways for a postcolonial geography.”

The first of these (which draws on writing by postcolonial literary theorist Gayatri Chakravorty Spivak) they termed “narrating the planetary,” arguing that planetary thinking brought forth different conceptions (of human relations to nature, for example) to the more frequently used term “global,” which risked seeing the world as a grid, defined by universal systems of commerce and connection that relate to colonial visions and tend to overwrite diversity and difference. The second pathway required greater recognition of a diversity of postcolonial writings in languages other than English (they cited recent Portuguese work, for example) and in fields – such as postcolonial theology – that have hitherto not been widely drawn on by geographers but that are full of insights about categorizations that may inform postcolonial geography. A more central place for indigenous perspectives in postcolonial geography was their third pathway, one already being trodden by others but that required further thoughtful engagement with categories, movements, and epistemologies associated with indigenous peoples. Their fourth path stressed a broadening of one of the enduring strands of postcolonial geography, the critical study of “seeing like an empire,” requiring geographers to examine the presence and reproduction of imperial ways of thought and action. But they argued that this must not be confined to the West but should also scrutinize the legacy of empire among other powers, such as in China’s narratives about its place in the world-system. China’s empire was just one (though arguably the most prominent) among other non-Western empires, such as the Mughals, Japanese, Ottomans, and Safavids, suggesting that the scope for more diverse understanding of what falls under the remit of imperial discourses is in order, along with deeper historical geographies that study how empires, subalterns, and spaces intersected. Their final pathway is related. It stresses the complexity and importance of translation, signaling how the circulation and translation of geographical terms and categorizations have been mediated through colonialism, and may have their origins beyond the West, as well as arguing for a more nuanced recognition of how putative universals, like capital and the urban, internalize and disguise difference and need to be approached through diverse vernaculars and a historical-geographical sensitivity to their origins and uneven circulation.

As this entry has sketched, postcolonial perspectives have become part of a wider critical geography since the 1990s. This has followed an interrogation of geography’s past, specifically its relationship to racism and imperialism. It has also accompanied a developing debate about the geography of geography and theory, what places and cases set the parameters of theoretical debate in the discipline and how these need to be broadened beyond the metropolitan centers. Moreover, since neither racism nor imperialism is dead, the potential for postcolonial geography to elicit shifts in the geographical curriculum and to question who writes and delivers it remains. The decolonization of the discipline is incomplete. And the capacity for human geographers to contribute much more to wider developments in postcolonial theory remains. This contribution might include more careful tracing of the contemporary and historical geographies of postcolonial theory itself and its
relationship to allied fields, notably poststructuralism (Ahluwalia 2010), as well as connections with and contemporary reconfigurations of “nature” (Chakrabarty 2014), sovereignty, and security. There is much work to be done.

Postconflict geographies

Jon D. Unruh
McGill University, Canada

The powerful spatial aspects of armed conflict and its repercussions create the particular features that constitute postconflict geography. Wars are almost always about some form of spatial contest and control. While the focus of armed encounter on military objectives does influence the postconflict period, it is the profound disruption of economic, livelihood, ethnic, and identity-based attachments to, and dependencies on, particular landscapes that constitute the greater domain of postconflict geographies. The sociospatial repercussions of violence, dislocation, lack of access to and destruction of lands and properties, together with the breakdown of formal and customary institutions that manage land, property, and territory, have a much more pervasive and lasting impact on postconflict geography than the aggregate repercussions of battlefield encounter (Holbrooke 1998). Chronologically, these repercussions begin with the control and negotiation over the spatial spoils of war (landscape-based resources and locations that are or will become valuable), and continue with large-scale population return to areas of origin from which dislocation occurred, and the subsequent focus of war-affected populations on the pursuit of postwar livelihoods, including interaction with areas containing landmines.

How wars end can influence certain aspects of postconflict geography, but generally wars come to a close through either a peace accord or victory. As a civil war moves toward a ceasefire when negotiations for a peace accord are to begin, there is often increased battlefield activity as the different sides attempt to gain control over as much land, or over valuable areas, as possible before the ceasefire comes into effect, so as to have an advantageous position during negotiations or for future profit or administrative or population control. At the onset of a ceasefire, combatants then maintain their positions in the field and hence their control over specific areas, resources, and people. The result is often a spatial patchwork of control, along with a parallel patchwork of alliance and enmity with local populations. This then has a significant influence on postconflict geography, as positions and areas of control, alliance, and enmity harden, are negotiated away, or become contested again, sometimes even with a return to armed conflict. Control of specific areas, resources, and local populations can often be treated as spoils of war to be used in postconflict patronage politics. This control also influences the return of dislocatees, and can become volatile when the pre-war occupants of such areas return and attempt to reclaim lands. With the signing of a peace accord, international peacekeeping forces usually provide security, keep belligerent parties separated, and operate disarmament, demobilization, and reintegration programs, but can have little influence over the boundaries of areas of control by the opposing sides (Stedman, Rothchild, and Cousens 2002).

A war that ends with one side prevailing over another can take a postwar geography in a couple of possible directions. There can be a takeover of territory, lands, and land-based resources that were previously occupied by a population allied with the losing side, which usually then results in their resettlement elsewhere. This resettlement...
often involves impoverished livelihoods and may be where a subsequent insurgent movement emerges. A less common direction involves spatially based attempts at winning hearts and minds with the intention of reducing the prospects of future instability. Such measures can include the return of lands, assistance with reintegration, and support for livelihoods. What distinguishes a postconflict geography resulting from victory from a peace accord is that, with the former, there is no patchwork of control of territory, land, resources, and people, because all areas come under the control of the winning side. In addition, there is usually no allowance given to the losing side to form a political party as there often is where a peace accord has been reached. And there is much less of an international community presence because there is less desire by the victor to engage in disarmament, demobilization, and reintegation (Holbrooke 1998).

The forced dislocation of populations from pre-war livelihoods is one of the primary features of what becomes a postconflict landscape. Both refugees and internally dislocated persons (IDPs) often number in the hundreds of thousands and occasionally in the millions. The spatial repercussions involving the landscapes from which they depart, in which they arrive and stay for the duration of the war, and to which they then return are profound and long-lasting. Such forced dislocation, whether as a result of populations fleeing the effects of war or as part of purposeful military-on-civilian objectives of ethnic cleansing, secondary occupation, expropriation, emptying productive lands of their agricultural occupants so that opposing forces cannot resupply themselves, control over high-value resources, or the use of landmines, is a pervasive and acute aspect of today’s conflicts, their conclusion, and recovery (Fay and James 2009; Leckie 2009). International community participation in the return of IDPs and refugees to areas of origin after a war is a high-priority, costly, time-consuming, and complicated endeavor that puts great pressure on governments, donors, nongovernmental organizations (NGOs), and local communities (Leckie 2009).

An ability to return to predislocation livelihoods in a home area will depend on the length of the war, the degree of intactness of the return community, relationships between those who left and those who stayed, the scale of physical changes at the field, village, and landscape scales, and the degree to which individual and community changes during dislocation are still compatible with previous livelihood patterns. Also relevant to going back are the presence and activities of other actors, including squatters and commercial interests, who may seek access to lands thought to have been abandoned during the war (Holbrooke 1998).

Returning to areas of origin or elsewhere subsequent to the end of a war does not mean that populations will quickly re-engage in livelihoods that existed prior to dislocation. The productive landscape assets that would allow for resettlement in both rural and urban settings will have been destroyed, neglected, degraded, or taken over by others. The result for returnees is often the pursuit of a postconflict-specific set of livelihood activities that interact with the landscape in very short-term approaches to fulfilling the immediate needs of food, water, shelter, and security. While such approaches are usually not sustainable, even in the near term, they can nonetheless provide for survival. This form of landscape interaction includes the rapid overextraction and depletion of certain spatially based resources, such as overhunting, overfishing, freshwater resource depletion, destructive farming (i.e., no fallow period, quick farming with inappropriate crops, farming on unsuitable terrain), and the consumption or sale of reproductive livestock, along with the overextraction and sale
of timber and other plants, alluvial minerals, and wildlife parts. The pursuit of such postconflict livelihoods can be facilitated by incursions into national parks, commercial farms, and peri-urban areas. At the same time, however, a postconflict livelihood strategy also includes an attempt to reacquire or rebuild the landscape assets that allow for the (re)construction of a more durable livelihood strategy, such as (re)acquiring farmlands, grazing lands, farming implements, livestock, and so on. Essentially, then, postconflict livelihood strategies involve an attempt at the reacquisition of productive assets, together with the pursuit of a constantly changing menu of extractive, low-investment, opportunistic, short-term, and often dead end (resource-exhausted) activities which, taken as a broad set of pursuits, significantly alter both the human and physical geography in postconflict scenarios. Such strategies then influence the landscape constraints and opportunities of recovery and development. This point is significant because, subsequent to a war, the lack of food, jobs, markets, and infrastructure result in a much greater proportion of a national population living very close to the land in extractive and disrupted agricultural formats (Peluso and Watts 2001).

A further factor influencing postconflict geographies is the presence of landmines. The strategies for laying land mines highlights the highly spatial nature of violent conflict, particularly civil conflicts in developing countries. The legacy of landmines and other explosive remnants of war (ERWs), used offensively in area denial, social disruption, ethnic cleansing, and contests for high-value land resources such as diamonds, or defensively as a deterrent to enemy incursion and for the protection of specific locations, exerts considerable spatial influence on the recovering of livelihoods. The enormity of the ERW problem in war-affected countries is a primary, enduring obstacle to recovery and development. Apart from the highly visible impacts on mortality and morbidity, the presence of ERW alienates a population from important agricultural, forest, water, and pastoral resources. They also delay the return of displaced populations, thwart the reconstruction of infrastructure, and disrupt important fundamentals of peace building such as land and property restitution, investment, and personal security. The presence of ERWs not only leaves a profound social, economic, and physical footprint on specific areas, but has significant repercussions on larger adjacent areas where affected populations must reside in order to pursue farming and pastoralist livelihoods, in many cases coming into conflict with the original occupants of such areas (Unruh and Corriveau-Bourque 2011).

Postdevelopment

David Simon
Royal Holloway, University of London, UK

The shortcomings and failed promises of conventional or mainstream development have long spawned lively theoretical debates, attempted reforms, and alternative visions. Beyond the confines of particular groups or institutions, consensus has never existed in respect of development theory, policy, or practice and probably never will. Critical engagement should be regarded as healthy and debates have differed considerably in terms of the extent of problems identified and changes proposed by the protagonists. Postdevelopment is emblematic of approaches that reject not just the outcomes but also the fundamental assumptions and approaches of conventional development.

In terms of intellectual history, the watershed moment was the so-called impasse in development first identified in the mid-1980s and which has been characterized as a profound crisis of existence for the discipline. Its significance lay in the coincidence of several major trends or processes, including the widespread disillusionment at the failed promises or deleterious effects of developmentalism and many development projects, increasing recognition of the environmental costs of conventional development, and the need for greater sustainability. The impact of the debt crisis and reversal of major previous gains by the enforced curtailing of development expenditure, and the profound challenge to modernist ideologies and discourses (which encompassed the major contending development theories and approaches) posed by postmodernism were also important.

After some years of foment and ferment, a series of poststructural approaches emerged that reject the monolithic, universalizing, and totalizing approach of modernist discourses like modernization theory, dependency, and neoclassical and structural Marxism, all of which contended to be “the” single truth. Underpinning poststructuralism, by contrast, is the embracing of difference, diversity, polyvocality, hybridity, and some degree of cultural relativism. The best-known such approaches include postmodernism, postcolonialism, posttraditionalism, and anti- and postdevelopment. Conventional modernist approaches privilege Western ideas, norms, values, and prescriptions as embodied in the bulk of post–World War II development theory, policy, professional expertise and the interventions based on them. In contrast, poststructural perspectives reject such singularity and acknowledge multiple truths and knowledges, including indigenous traditions and systems, all of which have potential value. Accordingly, processes and projects need to be formulated inclusively, drawing appropriately from each according to the specific context, and perhaps with hybridized outcomes.

Understanding anti- and postdevelopment

Since postdevelopment is itself something of an umbrella for diverse interpretations, it is helpful to distinguish between those that constitute essentially rejectionist critiques of conventional development(alism), often termed antidevelopment(alism), and those seeking to envision or formulate
alternative approaches. Probably the most widely cited “foundational” antidevelopment texts are *The Development Dictionary* (Sachs 1992), especially Gustavo Esteva’s essay therein on “development,” and Arturo Escobar’s (1995) *Encountering Development*. Several other volumes from the early to mid-1990s contained more diverse perspectives that preclude simple categorization, for example *The Post-Development Reader* (Rahnema with Bawtree 1997). By the late 1990s, critiques of these perspectives began to appear, and debate continued through the 2000s, not so much among proponents of anti- or postdevelopment themselves as with progressive critics of these approaches.

That said, it would be inaccurate to suggest that anti- and postdevelopment were entirely original interpretations, born of the development impasse and poststructural turn. Similar concerns, objections and alternative formulations have abounded through most of the history of development as a worldview, discourse, discipline, and set of practices. They were expressed in terms of opposing theories (e.g., the variants of Marxism and political economy) and paradigms or initially radical propositions and approaches to tackle perceived problems, violations, and omissions. Such propositions have included meeting basic needs, bottom-up or grassroots development, feminism and gender mainstreaming, environmental sustainability, and participatory development.

The stimulus for all such critical engagements has been strong objections on philosophical, ethical, and/or practical grounds to the flawed nature of postwar developmentalism and its impacts. Had such interventions been overwhelmingly positive, the critical concerns would have been far smaller in scope and number. However, conventional development as espoused and practised by the principal international financial institutions, donor agencies, national elites, and middle classes in low- and middle-income countries has often distorted conditions on the ground, had unintended negative consequences, or actually failed. Lessons of experience are often not learned and mistakes are then repeated as a result of “institutional failure” of various kinds (including corruption) or deliberate ignoring of evidence and recommendations on account of inconvenience, additional cost, pressure of time, vested interests, and/or misplaced faith that the implementing “experts” know best. Examples range from large dams to overambitious integrated rural development schemes, industrial “white elephant” projects, inappropriate urban housing projects, and diverse “soft” programs ill-suited to local conditions and perceived needs.

From an anti- or postdevelopment perspective, the common feature of all these problems and examples is their underpinning by an absolutely or relatively uncritical Western-centric developmentalist worldview. This perceives the objective of development as being to bridge material and other gaps and through large-scale interventions and modern technology to enable poor countries and communities to “catch up” with rich countries. Such “modernization-as-development” is generally driven by economic and technological considerations in an ideological lineage stretching back through the Cold War to the Marshall Plan, in a complex mixture of altruism and material and geopolitical self-interest (Simon 1998). However, this frequently neglects or devalues local institutions, traditions, cultures, and practices, and transforms or undermines relative or absolute self-reliance, environmental sustainability, and collective senses of wellbeing and quality of life. As a result, supposed beneficiaries as well as those who are excluded and deprived of previous resources are often alienated. Moreover, from this perspective, not only are resource-intensive, consumption-oriented,
and individualistic Western lifestyles almost universally desired, but they would be unsustainable at present for all 7 billion people on Earth.

**Critiques of anti- and postdevelopment**

One of the most widely articulated criticisms, especially of antidevelopment, is that of oversimplification and exaggeration. In particular, the considerable diversity of visions and versions of development among official agencies and institutions, as well as of practice and outcomes, are elided into a monolithic and demonic stereotype of deliberate and even cynical exploitation. To argue that the World Bank and the United States Agency for International Development (USAID), for instance, are homogeneous bodies, let alone indistinguishable from other multilateral or bilateral agencies, is not credible. If nongovernmental organizations (NGOs) and other actors are included, the diversity on every variable is greater still.

A variant of this critique is that of unjustified extrapolation, in which particular case studies are used as the basis for global generalizations. A good example of this is the way in which Escobar's (1995) very detailed anthropological dissection of his native Colombia's development experience and the interventionist role of USAID, in particular, then forms the basis for globalized antidevelopment claims. This is doubly ironic because these claims constitute precisely the same homogenizing and universalizing discursive fallacy for which anti- and postdevelopment advocates castigate conventional developmentalists, and because it is probably mainly on the basis of this broader argument that the book has achieved its classic status. The principal reason for regarding this book as a canon of anti- rather than postdevelopment in terms of the distinction being made in this entry, despite Escobar (1995, 215) himself positioning it as post-, is that it constitutes overwhelmingly a critique of development; there is only a very preliminary attempt to consider alternative possibilities at the end. It is only fair to point out, however, that Escobar's subsequent writings reflect a moderation of this strident position as he engages more actively with the search and struggle for indigenous/local alternatives to development “from below.” He thus remains a leading postdevelopment voice.

The second major critique is that part of the oversimplification for which antidevelopmentalists are often taken to task is their overlooking or denial of the real gains achieved worldwide in terms of improved educational standards, health and welfare, and material standards of living that are reflected in widespread increases in life expectancy, improved public health, and reduced poverty. To be sure, this progress has been geographically and socially uneven but the Human Development Index and numerous other indicators bear this out. Moreover, the increased numbers of people worldwide living in absolute and relative poverty reflect growing populations rather more than people falling into poverty through development failures.

Third, as mentioned above, criticisms of development flaws and failings from within and beyond the ranks of conventional development organizations date back to the earliest overtly economic development initiatives. Some of these critiques have been far more than cosmetic and have generated entirely new understandings and approaches, the value of which has come to be widely understood to the point that they have been adopted or adapted by such agencies – the process often dubbed as “mainstreaming.” These provide evidence that institutions are not impervious to criticism or cynical and can “learn by doing,” to paraphrase an old World Bank motto.
Other radical and emancipator visions of development do not renounce development in its entirety but seek to harness appropriate elements in promoting positive, endogenously driven change. To this, postdevelopment proponents counter that reforming development is futile on account of its inappropriate (some would say objectionable) philosophical and ideological underpinnings and hence needs to be rejected or at the very least challenged fundamentally at that level. Essentially, it is the intellectual, philosophical, and/or political enterprise or “project” of development(alism), that is, the explicit intent to develop others and its underlying motives, that are fundamentally flawed rather than people’s or communities’ legitimate desire for and need of absolute and relative improvement in their material and psychological wellbeing. These latter constitute the basis of postdevelopment, starting with the experiences and aspirations of those “other(ed)” people and communities.

In addition and somewhat ironically in this sense, postdevelopment has been accused of reactionary or neopopulism in terms of a rather romantic and uncritical view of (particularly precolonial) local/indigenous traditions and cultures. Such positions avoid or ignore gender, caste, and other inequalities, exploitation, violence, and other ills in the implicit construct of indigenous cultural authenticity. This constitutes the fourth element of critique but, as Ziai’s nuanced assessments (2004, 1050; 2007) point out, this – like most other criticisms – is unfair in relation to many postdevelopment authors and highlights the dangers of generalization in relation to a very diverse and heterogeneous field. Indeed, even particular authors and individual works by an author reveal inconsistencies in terms of their vulnerability to the range of criticisms outlined here – for instance accepting the dynamic potential of cultural or biomedical hybridization while insisting on total rejection of development and all it stands for.

Fifth, some two decades since the emergence of identifiable anti- and postdevelopment critiques one might pose the question of what difference these dissident voices have made on the ground. In other words, how have they affected actual policy and practice in support of the aspirations and agendas of those at the bottom of the global pile? Undoubtedly some specific grassroots initiatives and NGO operations have been informed by such analysis and are operating more appropriately as partners and facilitators/advocates to people and communities. Despite many exhortations, however, very few published case studies exist to validate this assertion. Moreover, as with most of the poststructural perspectives and agendas, there is little evidence that anti- and postdevelopment have gained significant purchase within the larger development actors and agencies, where it appears to be business more or less as usual. Given the foundational principles of anti- and postdevelopment and the great momentum and vested interests behind such institutions, this is hardly surprising – indeed, anything else would be surprising. This in turn might be seen as at least partial validation of the common critique of anti- and postdevelopment as being more of an intellectual fashion than a practical guide and hence principally of value in academic debates and career promotion rather than being useful in the toolkit or field. Such criticisms emerged rapidly in the late 1990s and have also been leveled at most poststructural approaches (Simon 1998, 2006; Matthews 2008). It is also noteworthy that the leading postdevelopment voices have, with few exceptions, been academics or academic activists from or now based in wealthy countries. Whether the lack of purchase of these ideas in “southern” academia reflects perceptions that they have little relevance or
whether – as postdevelopment adherents would surely argue – such academics are themselves too intimately bound up with modernity and development, to abandon them is a moot point.

Transgressing boundaries in a globalized world

Such dilemmas are inevitable in the highly contested intellectual, policy, and project terrains constituted by development and no definitive resolution appears imminent or indeed feasible precisely because of the widely divergent perspectives, interests, and experiences. Beyond academia and some radical NGOs, it is likely that the principal recruits to agendas identifiable as substantively postdevelopmental will be individuals and groups (however defined) who feel irretrievably marginalized from the benefits of some form of development or who have been severely adversely affected by development schemes. Those who perceive some gains or hope of benefits are more likely to avoid the probable risks of total rejection, if indeed they even have any option. For instance, inhabitants of a river valley where a large hydropower dam is proposed and who will be displaced by the rising waters will surely oppose such a destructive scheme unless offered generous and appropriate compensation. In their struggle, they will probably seek support from civil society, NGOs, and internationally networked pressure groups. That does not mean, however, that they would reject or not appreciate access to reliable electricity (which such a scheme would be very unlikely to deliver them, even if they were relocated to safe ground nearby) and its potential benefits. Hence they would probably be far more positive about a meso- or micro-hydro scheme that would deliver them safe and sustainable water and electricity supplies without the massive capital cost and social, livelihood, and environmental destruction of a large scheme. Indeed, they might even lobby proactively for such a project to be commissioned. If it were undertaken as a genuinely participatory partnership between local communities and other partners (NGOs, private firms, official agencies) that ensured an appropriate degree of local “ownership” and output that was principally for local use in the first instance, all stakeholders would benefit. This would be a good example of appropriate and sustainable development and would address the objections raised by postdevelopment critics as outlined here, but whether it would qualify as being consistent with postdevelopment is a moot point.

Perhaps one lasting legacy of postdevelopment thinking will be a certain shift and sensitization of more critical thinking rather like that achieved by other poststructuralist approaches. In particular, as now acknowledged from different theoretical positions, ongoing globalization and progressively greater differentiation among countries between as well as within conventional “worlds” or other global categories have rendered such categories increasingly redundant except perhaps in world-system historico-evolutionary terms. That being so, persistent questions about why “development” is undertaken only in former colonial regions and not in some of the poorer countries of southern, central, or eastern Europe, for example, or in impoverished and deprived inner cities and peripheral regions of wealthy countries, become even more apposite. Historically, western Europe was the proving ground for postwar development efforts through the Marshall Plan; if semantic sensibilities nowadays preclude redeploying it in such contexts, perhaps it really is time to abandon this terminology and all it represents and to apply other, potentially less paternalistic or problematic vocabularies globally. Paradoxically
too, postdevelopment sensibilities suffuse the growing concern to develop “southern theory” as a counter to the traditional “northern” dominance of social theorization, although this self-ascribed label unhelpfully perpetuates the very dichotomous thinking that poststructural approaches supposedly eschew.

Posthumanism

Franklin Ginn
University of Bristol, UK

Posthumanism is a collection of diverse ways of thinking that are highly skeptical about the centrality of the “human” in Western philosophy and politics. Where humanism holds that unique properties such as language, tool use, culture, and so on enable humans to transcend nature, posthumanism emphasizes the different ways humans are continually produced through material forces, discursive regimes, and through nonhuman agencies. One of posthumanism’s key aims is to dissolve binary distinctions that characterize humanism, most notably culture/nature and self/world. Posthumanism is associated with the rise of poststructuralism through the latter half of the twentieth century, as well as struggles against hegemonic definitions of the human in feminist, postcolonial, anti-racist, and queer politics. It is also closely allied with philosophies that emphasize the embodied, material, and vital nature of human life. Within geography there has been some skepticism about whether posthumanism is any more than another episode in a procession of -isms. More receptive geographers have emphasized that posthumanism is broader in scope and in political and philosophical ambition, and captures many other -isms within its own orbit as ancillary concepts.

Posthumanism is in some sense easier to understand and identify due to recent changes in biological sciences that blur the boundaries of the human, such as genetic modification or xenotransplantation, as well as new technologies which can subvert or extend human agency in various ways, from electronic surveillance to unmanned military drones. Posthumanism is commonly identified therefore as both an epoch and a theoretical perspective. While the “post” in posthumanism may be taken to signal a transition to a new stage after humanism, many commentators argue any quantifiable historical shift is less important than the radical ethos of posthumanism’s attempt to deconstruct and move beyond a unitary, Western-specific idea of the human. Some scholars have argued that posthumanism is symbiotic with humanism, in that it relies on the figure of the human for a constituting other; from this perspective posthumanism risks reifying humanism as something grander than a historically and geographically located mix of practices, ideas, and technologies. Furthermore, some strains of posthumanism can often reproduce certain humanist commitments to ideals like freedom and democracy. In this sense posthumanism may present an evolution of humanist thinking, rather than a radical break. Others argue that posthumanism offers productive ways to move decisively beyond the human, but only if we reorient our horizons toward an ontology of life that is more radically open-ended, relational, and emergent.

Decentering the human

It is possible to identify a series of four logics through which posthumanism works to decenter the human. Each of these logics implies that the human should be taken neither as a common sense dogma, nor as an unproblematic grounding for ethics or politics, and works to replace the
human as the sole concern of analysis. Each has been influential in geography, the social sciences, and humanities.

The first is biological. Western Enlightenment thought enshrined a firm divide between humanity and the rest of nature. Advances in biological science have rendered such a view increasingly untenable, however. Beginning with Darwin, who placed humanity in a genealogical continuum with other species, research in diverse fields, including ethology, comparative genomics, and neurophysiology, has concluded that many other species share supposedly exclusively human characteristics, including language, tool use, and consciousness. Social theorists such as Donna Haraway have also emphasized the way the human body relies on alliances with other organisms, including slime, bacteria, or domesticated animals, for its continued operation. For these theorists, posthumanism involves tracing the ethical, political, and ontological implications of this biological decentering. Animal geographies have charted the constitutive inclusions and exclusions of nonhuman creatures for human culture and identity in varied settings. Eco-Marxism has, at a larger scale, shown how nature is not separate from society, but is produced by capitalism, demonstrated most spectacularly by the power of biotechnology to make new life. Others have pointed to shifts in governmentality wherein the object of intervention is no longer simply the traditional human subject, but aspects of human biology, including genes. Posthumanism therefore emphasizes distributed biological interdependencies and shared life, rather than a divide between nature and culture.

The second decentering concerns subjectivity. Where humanism posited an autonomous, rational being in charge of its own actions and destiny – the knowing subject – posthumanism emphasizes how the subject is given over to and produced by other forces beyond its own control. Around the turn of the twentieth century, the founder of psychoanalysis, Sigmund Freud, showed how much human behavior was driven by unconscious desires and fantasies. While psychoanalysis has had a modest impact on geography, recent theories have been more influential. Emerging from poststructuralism, Judith Butler’s notion of performativity was crucial in eroding the idea that a subject had any kind of essence at its core. Butler argued that gender difference was not a matter of nature, but of social performance. Performativity stresses the malleable, motile, and historically contingent character of subjectivity, in contrast to an essential human nature that takes the same basic form regardless of time and space. In geography, since the 1990s great attention has been paid to difference in the creation of subjectivity, both through discourse and representation, and also more recently through embodiment, materiality, and emotion. Far from being an autonomous, knowing subject, the human is seen by posthumanism as a process made through many more-than-human flows.

Third, technology has decentered the rational human. Karl Marx was one of the first commentators to write systematically about how technology and wider systems shape the conditions for human nature. Actor–network theory has also been deployed to show how technology is not a passive object operating at the behest of a potent human agent. Instead, actor–network theory exposes how agency circulates between heterogeneous actors, including technologies of all kinds, in complex, hybrid circuits. Posthumanism therefore stresses that technology is not something added to an already existing human, but is something that makes up humans. This is what Jacques Derrida called “originary technicity” and Graham Harman, building on Heidegger, calls “tool-being.” From a posthuman understanding, the human is always

---

POSTHUMANISM
POSTHUMANISM

a human-with-technology (and always has been). Indeed, posthumanism emphasizes that the human itself is a product of what Agamben (2004) called the “anthropological machine,” a system which produces self-recognition and partial differentiation of humans from other entities. Aspects of quantitative geography have also worked to decenter the dominant notion of the human. In the 1950s and 1960s, cybernetics conceptualized humans not as subjects of their own lifeworlds, but as nodes within a system that merely reacted to external forces. While cybernetics and systems theory were only models they were influential in producing ways of thought, for example in managing environmental and economic crises. More recently, advances in computational power and complexity theory have contributed to the rise of agent-based modeling in geography. Modeling human decision-making and behavior as part of emergent systems further decenters the idea of an independent, self-aware agent in favor of one reacting in complex ways to stimuli and feedback in sociotechnical systems. In addition, under the auspices of government and corporate surveillance a growing ecosystem of digital information, including self-replicating code, adaptive algorithms, and “big data,” increasingly shapes the way that humans think and react.

The fourth way in which the human is decentered is more recent, and can be termed “the planetary.” While the deleterious impact of human activities on Earth systems and other creatures has long been of concern to geographers and others, in recent years awareness of the unprecedented temporal and spatial scale of these impacts has led some to christen a new geological epoch, the Anthropocene. The Anthropocene remains contested. For some it represents the apoctheosis of humanism, with progress reaching a new level of intensity and extensiveness. For others, this new epoch firmly embeds humanity in the Earth’s material and energetic flows. This latter version of the Anthropocene shows the extent to which modern humans have internalized ecological and geological Earth forces, and also humanity’s differentiated vulnerability to such forces. This planetary decentering means the human is no longer an agent in charge of its own destiny: instead, the human is beholden to planetary forces beyond its control.

Each of these four logics of decentering has been influential in posthumanism. We can also discern three broad approaches to posthumanism: as epoch, as epistemological style, and as ontological condition.

Posthumanism as epoch

This populist strand of posthumanism takes the proliferation of new biotechnologies and technoscientific objects as a hallmark of a new historical epoch and a new stage of human evolution. Broadly speaking, much of what was previously limited to the realm of science fiction has come into being and changed the way many humans interact with the world. Such a list would include, but by no means be limited to: from William Gibson’s cyberspace to the pervasive chatter of social media; from cyborg military machines (the films RoboCop, Blade Runner) to unmanned drone warfare; from the paranoia of the cult 1990s television show The X-Files to the burgeoning discipline of exobiology; from speculative tales of colonizing other planets (Kim Stanley Robinson’s Mars Trilogy) to proposals by private corporations for extra-earth mining and space exploration ventures; from dreams of electric sheep (Phillip K. Dick’s Do Androids Dream of Electric Sheep?) to cloning Dolly the sheep and the creation of synthetic bacteria.

The list would encompass the breakdown of boundaries between flesh and information,
POSTHUMANISM

with genomics and bar-coding life for medical, scientific, and commercial purposes now part of biocapital enterprise across the world. These technological novelties are part of both spectacular and mundane processes changing the nature of everyday life for many. They each involve many “things” – DNA (deoxyribonucleic acid), images, bodies, instruments – that defy easy classification as natural/cultural or artefactual/given. Posthumanism as epoch suggests that all these processes have passed some threshold, putting the human in new terrain never before realized.

Optimists see this new horizon of humanity as an event to be celebrated. This position is popular among libertarian pro-technology and innovation groups, in particular certain science fiction writers or authors, in particular certain science fiction writers or authors in, for example, Wired magazine. They see playing with new ways of being human as exhilarating and technological creativity as something to be encouraged. They welcome boundary crossings between machine, human, and animal. They also inflate the potential for science and technology to make good on current speculative proposals, such as downloading human consciousness as software. This strain of posthumanism is also, however, ambivalent about inequalities, skeptical of state power, and welcoming of the creative destruction that capitalism brings. Instead, ingenuity is crucial, as amid an ever-faster pace of change the slow are left behind and the most adaptable posthumans thrive. This populist strain therefore in fact follows quite closely the established tenets of humanism: the potency and sovereignty of the individual; the march to ever-greater progress and prosperity; the promise of tomorrow to make good the problems of the present. Critics see this strain of posthumanism as an opportunistic attempt by advanced capitalist interests to graft a promissory posthumanism on to existing neoliberal subjectivities.

Pessimists agree that we have crossed a threshold into a posthuman era, but dispute that this is something to be celebrated. Rather, they see the proliferating evidence of posthumanity as deeply worrying. Pessimists include religious commentators, deep green environmentalists, and those who wish to defend the legacy of the European Enlightenment and its humanist commitments. They oppose, each for different reasons, genetic modification, nanotechnology, geoengineering, and other developments that they see as polluting the sacrosanct boundaries between humans and other creatures. Conservative thinkers like Jürgen Habermas and Francis Fukuyama, for example, argue that genetic manipulation and xenotransplantation are morally wrong on the grounds that they alter human nature. Deep greens oppose genetic modification because they believe that biotech corporations do not have the right to make new forms of life, and also because they worry about the unpredictable mixings that occur when new creatures are added to the Earth’s biodiversity. More broadly, mainstream environmentalists remain wedded to the idea of saving a transcendent nature, and erasing signs of human pollution of that separate realm. By contrast to the optimists’ desire for ever-faster change and ever-greater motility of human form, the pessimists want to halt current changes and where feasible turn back the clock to a time when categories were clear and the human was pure.

Posthumanism as epoch tends to describe hyperbolically new technological developments for rhetorical advantage to support existing ideological commitments. Both optimistic and pessimistic interpretations of posthumanism as epoch share a reliance on the figure of the human. For the optimists, the potency of posthumanism is to be measured by its distance from the historical figure of the human. For the pessimists, the dangers of posthumanism can be gauged from
the degree of deviation from the established norm of the rational human. Posthumanism as epoch is generally seen as the conceptually weakest of the three approaches to posthumanism.

Posthumanism as epistemological style

Feminist, postcolonial, disability, anti-racist, and queer studies have critiqued the normative assumptions at the heart of humanism. The central insight of this deconstructive stance is that “the human” acts with regulatory force as a standard of sameness to produce insider and outsider groups. This strand of posthumanism therefore interrogates different ways of knowing the human and their political effects.

Historically, a powerful standard of the human emerged from the Western Enlightenment and colonial encounters with various other peoples deemed by Europeans to be inferior in one way or another: due to their environment, physiology, innate intelligence, or distinct cultural evolution, for example. The figure of the white, male, full-bodied, and heterosexual human was deployed to justify a series of epistemic and physical violences against subaltern groups. Edward Said was one of the first thinkers to articulate a reasoned critique of the colonial experience and its injustices. Said’s Orientalism exposed how ideas of European exceptionality relied on a constitutive other, the Orient. Said argued that reason/enlightenment and violence/barbarism were not mutually exclusive, and that both could be found within humanism. Said turned Western, rational thought back against itself, critiquing humanism in the name of a more cosmopolitan humanism.

Michel Foucault’s ideas were another major force in anti-humanist critique from the 1960s on. Foucault argued against the autonomy and self-determination of the human subject, and against seeing the human at the center of history. Foucault’s work on madness, sexuality, and biopower showed how the production of difference was an internal dynamic within Enlightenment humanism. Instead of a dominant ideal human, Foucault emphasized how the human was socially constructed and power-laden. Posthumanism as epistemological style therefore replaces fixed identities with lines of difference that cut through gender, ethnicity, corporeality, race, sexuality, and so on.

One of posthumanism’s political aims is to enable people to decode, resist, and transgress their subjectification as certain kinds of subject. Feminist geography has examined the construction of gender and the inequalities that flow from the naturalization of rational man as the measure of all things. Feminist geography has been a particularly influential subdiscipline, with an important landmark being Gillian Rose’s Feminism and Geography (Rose 1993), which exposed the patriarchal assumptions inherent in the discipline. Postcolonial geography has brought self-critical awareness of how the discipline helped produce discourses of European exceptionalism, as well as to the political implications of how history is written. Postcolonialism critically engages with the continued legacies of colonialism, including how humanist ideals and their exclusionary universalism are written into social, cultural, architectural, and economic forms.

Posthumanism as epistemological style also encompasses the tenets of knowledge production dear to humanism. While the scientific method, steeped in empiricism and critical rationalism, was more a model of and less a rule book for scientific inquiry, science and technology studies (STS) has exposed the supposedly objective, disembodied, and universal idea of knowledge as a myth. STS emphasizes the role of culture, political economy, and the mobilization and alliance of myriad objects with
contextually specific procedures in producing and mobilizing knowledge. Scientific knowledge remains thoroughly marked by its geographic and historical context, rather than floating freely. Feminist epistemologies have taken the situatedness of knowledge as a methodological and ethical imperative. For instance, standpoint theory and situated knowledges both stress that knowledge production should acknowledge its partiality and locality, and that done well this produces more acceptable knowledge than false claims to universality. Posthumanism is closely allied with these ways of knowing, in which the subject is neither all-knowing nor transcendent of their particular circumstances.

Geographers have also deconstructed the divide between human and nonhuman, although not always under the banner of posthumanism. In the 1990s, animal geographies were reinvigorated by geographers drawing on animal philosophy and Foucauldian ideas of discipline and spatialized difference. This subdiscipline explored the subjugation and suffering of nonhuman creatures, which is often justified by the “great divide” (Latour 1993) between humans and all other animals. Animal geographies also exposed the ways in which representations of animals and other parts of nature provided ideological justification to naturalize certain forms of human behavior, such as heteronormative sexuality. Conceptually, animal geographies sought to deconstruct the nature/culture dualism not only in exterior space but also as it ran through the human, examining what Agamben called a great “caesura” at the heart of the human. Posthumanist animal studies therefore seek to account for the animal within as well as animals in diverse settings such as the city, the farm, and the laboratory. Feminist scholars have been among the foremost to point to the ethical implications of denying animality in favor of a constructed rational human. This denial has led to a “crisis of reason” and fuels environmentally destructive behavior (Plumwood 2002), so deconstructing ideologically charged human rationality became not just a matter of epistemology but also an ethical necessity.

Posthumanism as epistemological style maintains certain commitments to the importance of representation, and often works by deconstructing the self/other binaries at the heart of identity-making practices. This strand of posthumanism is therefore often concerned with denaturalizing nature, offering counter-readings to the messages encoded in nature and in representations of nature. The impact of posthumanism as epistemological style has been great. Replacing a pre-given, unitary standard of the human with the ongoing production of different subjects has enabled geographers to study the power relations of different processes of subjectification and has opened up important political spaces for anti-racist, anti-colonial, and anti-heteronormative politics. These perspectives emphasize the need to go beyond extending existing modes of representation to subaltern groups; they call for a deeper reassessment of the model of rational man as the foundation of modernity. The commitment to working at an epistemological level, however, means that this branch of posthumanism eschews the bodily, material dimensions of life. In other words, it is more concerned with the figure of a certain kind of human and posthuman than with the fleshy beings themselves. Therefore some scholars have pushed posthumanism to think of a more relational subject with embodiment, sexuality, affectivity, empathy, and desire as core qualities. Moreover, some critics have suggested that, ironically, posthumanism as epistemological style remains too reliant on humanism, not just as a necessary straw figure for criticism, but also because it usually ends up invoking humanist
POSTHUMANISM

ideas such as freedom, democracy, and progress to articulate its political goals.

Posthumanism as ontological condition

This final approach to posthumanism is rooted in anti-essentialist, process-oriented, and vitalist philosophies. It is associated with the ideas of Bruno Latour, Gilles Deleuze, and Isabelle Stengers, among many others. These thinkers emphasize dynamic processes of becoming instead of a world composed of discrete entities. In this ontology, human characteristics are merely temporary intensifications of matter and energy, indivisible from other agglomerations of matter. Accordingly, posthumanism as ontological condition is closely allied to geographic studies of embodiment, materiality, emotion, and the nonhuman.

Within geography the ideas of Bruno Latour and others associated with actor–network theory have been particularly influential. Latour argued that the modern settlement between nature and culture was merely an illusion and that the world was constituted through flows and connections between heterogeneous actants. Latour argued that the human was a result of purifying practices that worked constantly to separate a hybrid world into two realms, nature and culture. Actor–network theory therefore conceptualizes the human as an ongoing performance spun out of many different agents and agencies. Latour’s ideas have been recently supplemented by several other bodies of thought. First, concepts of multiplicity have augmented the flat ontology suggested by actor–network theory. Instead of one network, there is a multiplicity of overlapping networks, which create a denser, more complex sense of space. Second, geographers and others have drawn on the geophilosophy of Gilles Deleuze to produce assemblage theory, which accounts for conditions of multiplicity and describes open, emergent systems.

Critical of the text-bound excesses of postmodernity, scholars such as Nigel Thrift have highlighted the importance of forces that work on a pre-, ex-, or postrepresentational register in human becoming, formulating what has become known as nonrepresentational theory. Of particular importance has been the concept of affect, which is broadly defined as the capacity of a body to affect and be affected by other bodies through extralinguistic forces. Through ideas like affective atmosphere and affective politics, geographers are beginning to understand how life is shot through by transhuman energies. In related vein, cultural and historical geographers have reconsidered phenomenology, and in particular the philosophy of Merleau–Ponty, to explore how the world is brought into being through sense and experience, always in particular circumstances.

Feminist and postcolonial scholars have also cautiously brought the body back into their research agenda. While deconstructive posthumanism argued powerfully that race, gender, and sexuality were socially constructed rather than naturally given categories, scholars such as Rosi Braidotti have argued for re-ontologizing the body and examining the ways that difference is lived, felt, sensed, and performed. For this feminist perspective, bodily – and in particular sexual – difference becomes a political position from which to build alliances, rather than a problem to be overcome. Similarly, geographers have shown how race is materially produced through affective and bodily assemblages, as well as constructed through discourse. Both feminist and race scholars are mindful of the dangers in returning to the body, given the political effectiveness of constructivism and the dangers of naturalism. But the political message of such work is that a shift in focus from discursively
POSTHUMANISM

codified subject to processes of subjectification that encompasses body, technology, and the stuff of life generates a politics open to reappropriating the play of differentiation. Posthumanism emphasizes the mutability of being such that politics becomes a matter of interfering in flows of energy and matter to produce new possibilities for becoming otherwise.

This branch of posthumanism also brooks no ontological hygiene between humans and other species. Of particular resonance has been Donna Haraway’s material-semiotic cyborg and, more recently, companion species. Haraway argues that beings are a “knot of relationality” that draws in many species and many histories. Haraway’s work has also consistently reproached environmentalists for their anti-technological stance. Posthumanism as ontological condition draws on the concepts of originary technicity to argue against any possibility of human/technology purity, and instead argues for a critical appropriation of the technologies of capitalism.

There are several key differences between posthumanism as ontological condition and other forms of posthumanism. First, it denies that there has been any historical transition to a new, posthuman era. Instead, the argument is that we have never been human (Haraway 2008). In other words, the doctrine of humanism never fully encapsulated the condition of becoming human. This branch of posthumanism does recognize, however, that processes of mixing and decentering have accelerated in intensity in recent decades. Second, its vitalism – the notion that matter is agentic, self-organizing, and mutable – distinguishes this approach from the priority accorded to meaning, representation, and identity politics by the other forms of posthumanism. Third, its ethics and politics are less grounded in humanist commitments to universal justice, rights, freedom, and so on. Instead, the ethical-political commitments of ontological posthumanism are situated, context-specific, and open-ended. They exhibit a strong experimental flavor, and are organized through lines of connection and alliance which cut across national, species, and other traditional forms of difference. Often, research practice uses participatory methods and is aimed at encouraged resubjectification of both researcher and researched. Therefore much turns on an enlarged sense of embeddedness and awareness of relation to others, which creates new geographies of ethical response and responsibility. This posthumanist ethical-political project is generally underspecified, with speculative appeals to care and flourishing common but still not fully substantiated or worked through.

These ethical and political commitments mean that posthumanism has been met with some skepticism by geographers committed to more established forms of politics. Some critics point to the similarities between an open-ended, experimental, and context-bound ethical project and forms of uncertainty and precarity produced by neoliberalism. Others note that the posthuman possibilities presented by complexity and the mutability of matter have quickly lost their political potential as biocapital incorporates such resources into new regimes of accumulation. Eco-Marxists and political ecologists are debating the utility of posthuman immanent ontologies which do not use structure or meta-explanatory devices such as capital. Still others have identified a blind spot in posthumanism, in that it critiques humanism from the inside of Western thought. These critics have argued that there are plenty of human cultures that never shared Euro-American ideas of the human and its separation from nature and technology. They see the lack of attention to Indigenous knowledge and cosmography as extending the dangerous Euro-American exceptionalism of humanism. From such a perspective, while posthumanism as
ontological condition cleaves to posthumanism as a transhistorical theory rather than as an epoch, this maneuver still denies the way in which posthumanism has emerged from particular historical conditions and particular sites of privilege to become a key concern of our times.

Postmodernity

David B. Clarke
Swansea University, UK

On the face of it, postmodernity refers to a new historical epoch, beyond modernity. When it first rose to prominence in the 1980s, the idea was enthusiastically greeted by many geographers: the suggestion was that, whereas modernity privileged history and time, postmodernity privileged geography and space (Foucault 1986; Soja 1989). “The great obsession of the nineteenth century was … history,” wrote Foucault (1986, 22), “with its themes of development and of suspension, of crisis and cycle, themes of the ever-accumulating past” – whereas, Foucault declared, we now seem to have entered the “epoch of space … the epoch of juxtaposition, the epoch of the near and far, of the side-by-side, of the dispersed.”

Even without beginning to evaluate such a bold contention, the sense in which “postmodernity” defies easy comprehension may already be apparent. Since postmodern sensibilities regard “history” as itself a modern notion (not what actually happens out there in the world, but a particular human view of it), the end of modernity would also spell the end of history – which would seriously undermine the very idea that there can be a “next stage” of history such as “postmodernity.” If we are to avoid plunging into this kind of paradoxical tailspin, the implication must be that postmodernity, if it means anything, cannot refer to a new historical epoch. Rather than a periodizing concept, the alternative would be that postmodernity marks the realization that the modern sense of history as a chronological linear progression – onward and upward; destination Utopia – was always the hopeful vision of a particular kind of society. Modernity’s vain hope, the postmodern thesis contends, has revealed itself as supremely illusory. The specters of dystopia, ruination, the return of the repressed with a vengeance (fear, terror, risk, unreason) are once more on the prowl. “I define postmodern as incredulity towards metanarratives” (“big stories”), pronounced Lyotard (1984, xxiv), attesting to a loss of faith in the grand march of progress. Viewed in retrospect, the strikingly modern idea that reason, securely entrusted to the hands of the powerful – bureaucrats, scientists, politicians, industrialists, experts of all kinds – could deliver a utopian future for all has come to be recognized as a self-legitimating modern myth.

Although modernity’s penchant for imposing a rational order on an unruly world sounds superficially appealing, those on the receiving end – from nineteenth-century craft laborers, forced to adapt to the harsh regime of factory production, to those deemed genetically inferior and condemned to the Nazi gas chambers of the twentieth century – might offer a very different perspective. Tellingly, the most iconic of modern spaces is Bentham’s eighteenth-century design for an ideal prison, the Panopticon, which imposed order by actively soliciting the compliance of its inmates, placing them in a position where they were, at least potentially, perpetually subject to the gaze of the prison guards. Several centuries’ experience of modernity, the balance sheet of which is hardly limited to entries on the plus side alone, means that the promise of a final solution to the world’s ambivalence no longer
POSTMODERNITY

appears as either viable or, indeed, desirable: the twentieth century went down as the most violent in history. Released from the delusion that ambivalence and uncertainty are temporary irritants, set to be eradicated once and for all, we are finally in a position to realize not only that such qualities represent the world’s ineluctable condition (its “default setting,” so to speak), but also that they are not necessarily irritants. The idea that there might be something to celebrate in postmodernity resides precisely in this sense of release from the stranglehold of power-assisted “rationality.” To paraphrase Nietzsche, “the way does not exist,” and only by shattering the idols of modernity can new possibilities emerge. So what does “postmodernity” look like? All we may say with confidence is that it “means many different things to many different people:"

It may mean a building which arrogantly flaunts the “orders” prescribing what fits and what should be kept strictly out to preserve the functional logic of steel, glass and concrete. It means a work of imagination that defies the difference between painting and sculpture, styles and genres, gallery and street, art and everything else. It means a life that looks suspiciously like a TV serial, and a docudrama that ignores your worry about setting apart fantasy from what “really happened.” It means licence to do whatever one may fancy and advice not to take anything you or others do too seriously. It means the speed with which things change and the pace with which moods succeed each other so that they have no time to ossify into things. It means attention drawn in all directions at once so that it cannot stop on anything for long and nothing gets a really close look. It means a shopping mall overflowing with goods whose major use is the joy of purchasing them. It means the exhilarating freedom to pursue anything and the mind-boggling uncertainty as to what is worth pursuing and in the name of what one should pursue it. (Bauman 1992, vii)

None of this entails that postmodernity is some sort of panacea, allowing for the proliferation of spaces capable of accommodating life in all its infinite variety. If postmodernity is sometimes held up as the chance for difference to flourish, on other occasions it looks to be closer to the glossy, hyperreal, commodified world of the consumer society.

In this light, it is unsurprising that one of the most influential geographical contributions to the debate dismissed postmodernity as nothing more than the “cultural clothing” of late capitalism. For the Marxist geographer, David Harvey (1989), the fact that Lyotard (1984) sought to disqualify the insights of Marxism was enough to reveal postmodernism’s complicity with neoliberal ideology. A fundamental principle of historical materialism is that social consciousness (part of society’s “superstructure”) reflects society’s underlying mode of production (its “economic base”), and not the other way round. Adhering to this principle, Harvey sought to demonstrate that his alleged “metanarrative” was perfectly legitimate – and eminently capable of exposing the ideological basis of fashionable discourses pronouncing the “end of ideology.” To caricature, this was something of an “irresistible-force-meets-immovable-object” confrontation: for Lyotard, the distinction between “base” and “superstructure” no longer held; for Harvey, the economic base of late capitalism was responsible for generating precisely the illusion that the distinction was no longer operative. In toeing the Marxist line, however, Harvey created a backlash from feminist geographers, who saw in postmodernity the chance of an analysis of society and space that embraced more than class struggle. The idea that postmodernity represented a “merely cultural” phenomenon – signaling business as usual for Marxist theory – was more generally seen as inadequate. For Jameson (1984), another
Marxist, postmodernism represented the “cultural logic” of late capitalism: not simply its “cultural clothing” but a fully integral logic, as if base and superstructure had been fused by an unforeseen short-circuit. For Jameson (1984, 83), the vertiginous experience this engendered issued from the “latest mutation in space – postmodern hyperspace,” of which the disorienting interior of downtown Los Angeles’ Bonaventure Hotel provided an apt example: an appropriately commercial, pleasure-orientated postmodern counterpart to the iconic modern space of Bentham’s Panopticon.

Despite tendencies to associate postmodernity with particular spaces and places, of greater significance was the sense in which the changed view of knowledge ushered in by postmodernity pointed to a spatial analog. For Dear (2000, 140), a distinctively postmodern urbanism “is based on a simple premise: that just as the central tenets of modernist thought have been undermined, its core evacuated and replaced by a rush of competing epistemologies, so too have the traditional logics of earlier urbanisms evaporated, and in the absence of a single new imperative, multiple urban (ir)ratationalities are competing to fill the void.” But haven’t cities always been like this? As a number of commentators have shrewdly observed, “postmodernity” has been modernity’s indispensable alter ego from the start; the dissenting voice deflating its grand claims and exposing its illusions that drove it on. What has changed is the balance between the two. Postmodernity is the continuation of modernity by other means or, more accurately, the continuation of the means in the absence of the ends that provided its initial legitimation. Progress and history rumble on, leaving perpetual upheaval and transformation in their wake – but where they are heading has long since been forgotten. If the terminology of “postmodernity” has, after an initial wave of enthusiasm and contestation, by now been roundly abandoned, its disappearance may, paradoxically, signal its triumph rather than its demise: the situation it was meant to grasp having become generalized to the point where the need for specialist terminology has become redundant.

It is difficult to distinguish a specific “postsocialist” geography. The scale, the structure, and the level of geographical research and education in former socialist countries depended on their historical legacy and traditional schools created by leading geographers, and on a relative openness to the outside world and other factors. For instance, Polish geography was historically closely related with German anthropogeography, had a strong “natural” wing and developed landscape studies. Polish scholars had more opportunities to keep working contacts with Western partners than did their colleagues from the Soviet Union or Romania. Today, national geographical communities of former socialist countries are facing mostly the same problems as world geography as a whole; however, some common features inherited from the socialist past still can be observed.

From the institutional perspective, a common problem for postsocialist national geographical communities is, first, the decreasing importance of geography at school: it is often withdrawn from the curriculum of certain classes or replaced by a “general” discipline like “natural studies” embracing the elements of different sciences. This tendency undermines the positions of geography in pedagogic institutes/universities and partly the role of academic geography in society. Second, in the universities where geography was represented at the first-tier level (faculty), it is now often incorporated into new larger units with a wider focus (geosciences or natural sciences) or problem-oriented “institutes” (architecture, regional and urban planning, municipal economy, etc.).

On the positive side, in some countries, like Poland, geography remains a valued subject at high school and plays a decisive role when being enrolled in a university to study economics, finance and accountancy, management, tourism, and political science (Piróg 2012). The survival of specialized geographical institutes as parts of national academies of sciences should be particularly noticed. Such institutes play the leading role in geographical research in Hungary, Moldova, Poland, Romania, Russia, Slovakia, Ukraine, and other postsocialist countries where the academies were created or reshaped following the Soviet model, that is, directly run research institutes in different fields. After the collapse of communist regimes there were strong voices calling to relocate most research activities to universities or other institutions but the academies were kept. Even in Germany, where the academy of sciences of the former GDR was abolished after reunification, its geographical institute in Leipzig was transformed into the well-known Leibniz Institut für Länderkunde; however, in early 2014 the Russian Academy of Sciences was deprived of control of its research organizations, and the destinies of its geographical institutes in Moscow, Irkutsk, Vladivostok, Barnaul, and so on are still unknown.

As in other parts of the world, in the postsocialist countries the institutional position of
geography, combining the natural and human sides, is not easy. Usually, like in post-Soviet countries, Poland, Hungary, or Romania, geography is considered as part of the earth sciences but its position is weak compared with geology, geophysics, and so on. Human geographers have a particularly complicated status, as their field does not belong to either earth sciences or the humanities. But this model offers more opportunities for integration of natural and social approaches in studying the interaction between society and the environment, often not really used yet.

A common trend in the development of geography in postsocialist countries is its internationalization and Europeanization – a much wider involvement in the activity of international associations, research networks, and joint projects. The accession of Central European countries to the European Union (EU) allowed geographers to become fully-fledged partners of such programs as Erasmus or ESPON, the European Observation Network for Territorial Development and Cohesion. Together with specialists in regional economy, geographers play a central role in compiling comparable data bases on territorial development, mapping, and analyzing spatial structures of the enlarged EU, carrying out applied research which contributes to territorial cohesion and a harmonious development of the European territory – turning the boundaries between old and new EU members from dividing lines into seams between territorial structures of neighboring countries. Partners from post-Soviet countries can enter into consortiums applying for grants of European Framework Programs. There is also a great number of bilateral agreements between national foundations.

The creation of geographical journals in English is another manifestation of internationalization. For instance, in Russia there are now two new journals in English. The objective of Geography, Environment, Sustainability is first of all to publish papers written jointly by Russian and foreign authors that result from joint projects. Regional Research in Russia is focused primarily on the translation of the best papers that have recently appeared in Russian journals but also accepts original works.

Postsocialist geographical studies focus on a number of common main themes. First, geographers led the work on national atlases, which appeared or are being published in most postsocialist countries – Hungary, Slovakia, Slovenia, Romania, Russia, Ukraine, and so on. A good national atlas presenting a portrait of the country, an inventory of its potential and resources to its citizens, and “introducing” it to a foreign user is a question of prestige and an element of identity and state-building. The work on national atlases justified the geographers’ raison d’être and contributed to a better visibility of the discipline.

Second, the transition to market economy, the change of the political regime, and the accession to the EU have given rise to a great number of new themes and provoked important transformations in the structure of human geography. Economic reforms and European integration are related to growing territorial disparities, polarization of space – further concentration of economic activity around the largest cities usually in capital regions, and marginalization of the periphery, especially eastern regions – of Central-European countries. So, human geographers focused on new social mechanisms producing space, new methods and forms of spatial planning and regional policy, path dependence in regional development, assessment and mobilization of the regions’ endogenous potential, the impact of globalization and integration on different types of regions, and relocation of industry. Much attention is paid to border regions and cross-border cooperation. An important stream of projects and publications concerns...
urban geography: networking of urban systems at different levels and competitiveness of cities within the enlarged EU, metropolitanization, migration, social segregation and social exclusion; recovery of industrial cities and urban edges, and so on.

Both human and physical geography have faced the process of further differentiation and the rise of relatively new fields, such as the study of cultural landscapes, ethnic mapping, political geography, geographical images and representations, critical geopolitics, and so on.

Third, the traditional landscape analysis has been further developed and complemented by the study of the local impacts of global climate change. A strategic direction of physical geographical studies is also sustainable development and landscape management aimed at the improvement of the quality of life. Physical geographers continue to be involved in the selection, delimitation, mapping and management of protected areas, assessment of natural risks and hazards, particularly floods.

Fourth, a highly important new theme is geoinformatics – a tool of geographical analysis integrating natural processes and human activities.

In former socialist countries Russian geography has a place apart because of the size of the country and a relatively large number of geographical institutions, the duration of the socialist period, and specific academic legacy that was related to the original concept of territorial-productive complexes (TPC), or the economic regions as the basis of spatial planning and the administrative division. They were applied in national planning not only in the former Soviet Union but also in other socialist and third world countries.

In the early 1990s, the Soviet heritage in human geography was criticized. Yet in the postcrisis years geographers and economists, particularly from Siberia, found that the TPC theory had a lot to do with the cluster model developed by M. Porter and M. Enright, and some elements of this theory have maintained their relevance in the contemporary conditions. Some other studies pretend to modernize the Christaller–Lösch heritage, or generated some original ideas, such as the geo-evolutional concept of transportation networks, developed by S. Tarkhov.

Soviet/Russian physical geography was focused on the concepts of natural-territorial complexes (geosystems, landscapes) and studies of the relationships between their elements, their functioning, specific time, stability, and dynamics. Pioneering studies on the theory of rational use of natural resources, very close to the contemporary concept of sustainable development, were published as early as in the 1960s but unfortunately remained unknown in the West. Soviet/Russian physical geographers were among the founders of evolutionary geography and the authors of unique paleo-climatic reconstructions, which help to assess the impact of global climate change.

Physical geography traditionally dominates in terms of the number of laboratories, scholars, and papers. In 2008–2010, articles on physical geography made up 74.9% of all papers published in the main four national geographical journals – even more than in the 1980s–1990s (about 70%); however, as the increasing number of papers is now devoted to environment and sustainable development, it is sometimes difficult to separate publications in physical and human geography. The main journals are: Izvestia Rossiiskoi akademii nauk, seria geograficheskaya (News of the Russian Academy of Sciences, geographical series), Izvestia Russkogo geograficheskogo obschestva (News of the Russian Geographical Society), Vestnik Moskovskogo universiteta, seria geografia (Bulletin of Moscow
University, geographical series), and Geografia i prirodnye resursy (Geography and Natural Resources).

In human geography, an obvious shift from economic themes (geography of industry, agriculture, etc.) to social, cultural, ethnic, and political problems can be observed. During the period 2008–2010 these new themes accounted for 26.2% of papers that appeared in the same four journals (during 1980–1982: only 8.0% and during 1990–1992: 15.0%) (Kolosov and Treivish 2009). In the late 2000s the share of articles on economic geography increased again and in 2008–2010 reached 24.0%. This rise was related to the ongoing economic growth. The share of papers on population geography and urban geography, as well as on general, theoretical, and regional topics remains relatively stable—respectively, 13.8 and 22.2%. The interest in the geography of natural resources and environmental problems interpreted from the perspective of properly human geography seems to be declining (13.8% of papers). All in all, human geography has thus become more pluralistic, both theoretically and empirically.

Poststructuralism is a response to structuralism, a mid-twentieth century French intellectual movement dedicated to developing “scientific” approaches within the social sciences and humanities. The structuralists were organized against the abstractions of Western humanism. Poststructuralism addresses both movements with a range of critiques. It claims that the West’s traditional universal narratives about “mankind” invariably pushed many gendered, queer, raced, and non-Western “Others” to the margins. At the same time, it challenges structuralism’s binary abstractions – such as nature−culture, emotion−reason, space−time, nonhuman−human – that effectively reproduce past hierarchies of difference. In the place of binaries, poststructuralists offer a broad variety of perspectives and approaches for exploring difference both critically and productively. These include deconstruction and decentering, interrogations of discourse and power, and differential ontologies.

The history of geography’s encounter with poststructuralism is nonlinear. The discipline discovered these thinkers relatively late compared to other critically minded departments within the English-speaking academy, partly due to the nature of the publishing industry, which published translations (usually from French) out of historical order and in clusters that focused on one thinker while ignoring many of her or his contemporaries, creating a scene that was ripe for confusion and misinterpretation in early encounters with poststructuralism.

Geography’s engagement with poststructuralist thought began in the mid-1980s. Today, its influence can be seen in every area of “human geography.” Initially, poststructuralist geographies were fixated on critiquing representation, deconstructing disciplinary and ideological boundaries, and reading space as a complex plurality. Geographic interest turned to the porousness of identity categories and their performance and the agency of nonhuman objects. Later, geographers broached problems of nonrepresentation and affect. Today, poststructuralism and poststructuralist geographies are the subjects of numerous debates that have exposed certain theoretical limitations. It remains to be seen if these interventions will constitute a break from or an extension of poststructuralism.

Intellectual precursors

If poststructuralism is one of the most influential intellectual movements of the twentieth century, it is also one of the most complex. This complexity is lessened when poststructuralists are considered in the broader context of their precursors. As the name suggests, poststructuralism extends and responds to structuralism. Indeed, many celebrated poststructuralists initially contributed to the French structuralist movement. At the same time, structuralists and poststructuralists were influenced by earlier intellectual tendencies in French thought – most notably humanism, phenomenology, existentialism, and
Marxism. The following section offers a brief survey of these contexts before moving on to the turn to poststructuralism.

The three H’s

Starting in the 1930s, French intellectuals experienced renewed interest in German thought, which had been out of vogue since the Franco-Prussian War (1870–1871). The publication of Martin Heidegger’s *Being and Time* in 1927 attracted French students to Germany to study phenomenology – the study of human experience and consciousness – under Edmund Husserl and Heidegger. Neither had yet appeared in French translation. Instead, their thought filtered into France through the work of their French students. Most notable among these were Emmanuel Lévinas (who merged phenomenology with an ethical obligation to the Other), Jean-Paul Sartre (who explored it in the context of existentialism and free will), and Maurice Merleau-Ponty (whose phenomenology of bodily perception challenged the traditional separation of mind and body).

During roughly the same period, French intellectuals developed an interest in Hegel. Between 1933 and 1939, Marxist émigré Alexandre Kojéve delivered famous lectures on Hegel that were attended by Lévinas, Sartre, and Merleau-Ponty as well as Jacques Lacan and other future structuralist thinkers. Kojéve interpreted Hegel’s treatment of history anthropologically, correlating the “end of history” with the advent of the struggle between the United States and the Soviet Union. Kojéve’s thought influenced the official ideology of the French Communist Party – a mixture of Marxism and nationalism – which eagerly embraced a Hegelian interpretation of Marx. French Hegelianism hit its apex just after World War II. During this period, Jean Hyppolite (under whom poststructuralists Michel Foucault, Gilles Deleuze, and Jacques Derrida studied) published the first French translation of Hegel’s *Phenomenology of Spirit* (1939) along with key commentaries such as *Genesis and Structure in Hegel’s Phenomenology* (1946) that anticipated the structuralist movement. Hyppolite’s contributions cemented Hegel’s importance in France. Thus, by mid-century, French philosophy’s universalistic and human-centric obsessions with the “three H’s” – Hegel, Husserl, and Heidegger – had set the scene against which the poststructuralists would develop many of their best-known interventions.

Structuralism

The French structuralist movement broke with phenomenology and Hegelian humanism in favor of “scientific” approaches. During the early 1950s, anthropologist Claude Lévi-Strauss found an ideal figurehead in the early twentieth century semiotician Ferdinand de Saussure, whose “structural linguistics” employed “a scientific method rather than a philosophy or speculative thinking” to map the structure of signs and their creation of meaning (Dosse 1997, 115). Saussure’s structuralism distinguished abstract rules of language *système* (la langue) from individual speech *actes* (la parole). Studying the infinite variability of speech, he argued, reveals a finite, representable system – linguistic structure – capable of illuminating similar elements across multiple languages. Saussure divided the smallest unit of semiotic meaning – the “sign” – into two different elements: a “signifier” (for example, the word “cat”) and its “signified” (the idea that corresponds to that word). Saussure insisted that meaning is not a matter of a necessary relation between signifier and signified: the idea “cat” might just as easily have attached to the signifiers “schlemihl” or...
“schlemazl.” Rather, meaning emerges through the interaction of a series of signifiers. Structural linguistics studies meaning created through the play of signifiers. This dual concern with signs and structural abstraction became a definitive element in French structuralism.

If modernity had long obsessed over transcendent human “truths,” Saussure’s system offered many antihumanist escape routes for the humanities and social sciences. At the vanguard, Lévi-Strauss employed Saussure’s semiotic break to analyze different cultural practices and beliefs in terms of broader overarching systems. Like Saussure, he argued that broader transcultural structures rested behind apparent cultural differences. His *The Raw and the Cooked*, for example, describes disparate communities in terms of similar binary structural relations (nature—culture, feminine—masculine, and so on).

In psychoanalysis, Jacques Lacan repurposed the signifier (detached from its signified) as the germinal element of the “symbolic order” in the subconscious. He replaced Freud’s system of social taboos and repressed desires (for example, the Oedipal system of incestuous desire and the fear of castration) with a structure of signs (or exchanges of signs between subjects: for example, the Father’s “No”) that proceed one after another. The resulting “signifying chain,” in which signifiers are attached to each other and detached from their signifieds, is constitutive of the subconscious.

Finally, in the realm of Marxist political economy, Louis Althusser argued against the statist Hegelian argument that history is the manifestation of human reason. Taking a cue from Friedrich Engels, Althusser instead argued that in “the famous last instance” social relations are fundamentally determined by the economy. The state, he countered, was merely a structural effect of repressive and ideological “apparatuses.” These circulate through the practices of state agents such as police, bureaucrats, and professors. Althusser felt that autonomous subjectivity was a humanist specter. Rather, individuals are interpellated or “hailed” by ideological apparatuses (via police, school teachers) that *subjectivize* them: enlisting the individual to identify with a structural relation (e.g., to the state). Thus, too, structural class relations prevail over individual identities.

**The birth of poststructuralism: Johns Hopkins University, 1966**

Poststructuralism was born in Baltimore, Maryland, during autumn 1966. There, the Humanities Center at Johns Hopkins University hosted a conference on “The Languages of Criticism and the Sciences of Man: The Structural Controversy” that included several structuralist luminaries, including Roland Barthes and Lacan. Among them, a young philosopher named Jacques Derrida presented a talk entitled “Structure, Sign and Play in the Discourse of the Human Sciences” that took aim at Lévi-Strauss and structuralism’s sacred object: the sign. Derrida questioned structuralism’s tendency to maintain a “center” to which its structures were anchored (culture, ideology) and its conservative view on the play of signifiers within those structures. Both, he argued, are symptomatic of Western thought’s dependence upon a “metaphysics of presence”; that is, its insistence upon centering concepts (Being, existence, God, the sign) that stabilize a system but are invisible to it. Derrida appealed to a structuralism to come that would fully embrace the *play* of signs and discourses and their proper mode of analysis.

American academics heard Derrida’s call as a continuation of the structuralist project and the announcement of something entirely new.
For this, they invented the term poststructuralism. “What Americans call post-structuralism,” as Dosse explains, “existed even before the structuralist paradigm waned” (Dosse 1997, 17). Indeed, Althusser’s structuralist Marxism, for example, was not widely popular until after the worker-student revolts of May 1968. Thus, even the birth of poststructuralism (an appellation that its supposed members widely rejected) was marked by confusion.

Deconstruction and différence

Jacques Derrida (1930–2004) was born and raised in French colonial Algeria. The child of Jewish parents, he was expelled from lycée (French high school) due to the Vichy government’s anti-Semitic quotas. This seemingly paradoxical position—simultaneously one of privilege and one of marginality—anticipated a main concern of his work. Derrida’s philosophical project rejects the privileging of speech over writing (or logo centrism). Western thought has long preferred presence and existence to absence and inexistence. Following this tendency, structuralists favored speech (the present, the spoken, the witnessed) over writing (the removed, the disembodied, the recorded). Indeed, Saussure viewed writing as merely derivative or imitative of speech. Derrida’s famous invention “deconstruction” enabled him to disassemble and reverse (de-construct) uneven binary constructions.

For Derrida, writing does not follow from or represent speech. Indeed, he insists that, because it amplifies the polysemy of signs, writing is the more limber and playful of the modes of signification. This has to do with the way that we encounter writing (and it is here that Derrida merges his training in phenomenology and structuralism). Consider Derrida’s famous neologism différence, which plays on the French term différence, meaning both “to differ” and “to defer.” Différence introduces a “graphic intervention” (Derrida 1982, 3)—replacing the “e” with an “a”—that irreversibly entangles difference’s temporalization (to defer) with its spatialization (to differ). This space-time describes the way readers experience the emergence of meaning in writing. Words accrue meaning through their relation to other surrounding words (what Derrida calls “spacing”). But this means that, as we read, there are always “traces” of past words and more words to come that inform the meaning of any given word. The future and the past impinge on the present, multiplying rather than narrowing meaning. Thus, Derrida uses writing to deconstruct the binary of passive space and active time, rendering both dynamic in the process.

By the time Derridian poststructuralism arrived in British and American geography in the mid-1980s, it had already exerted a deep influence across the humanities. Geography was still in the thrall of debates over Marxist structuralism and humanist agency, and deconstruction was met with widespread confusion, suspicion, and accusations of relativism. Urban geographers such as Michael Dear cautiously introduced Derrida’s thought into journals, such as Society and Space, sometimes crowding many disparate thinkers under the umbrella of deconstruction. By the late 1980s, heated debates were flying between established Marxist geographers determined to organize the discipline around a common struggle and the poststructurally curious who are eager to experiment with critique. In many ways, these positions echoed the debates in 1970s France between the Maoists and the poststructuralists.

Geography’s first landmark poststructuralist intervention was cartographer Brian Harley’s “Deconstructing the Map” (1989). Blending
Derrida with Michel Foucault (see below), Harley interrogated cartography’s history of symbolic representation and its complicity in reproducing Western meaning systems. A decade later, deconstruction was sufficiently entrenched for Deborah Dixon and John Paul Jones III to broaden its focus to the intra-divisions that had arisen around differences in geography’s methodological ideologies. Written as a conversation between a Derridian and a spatial scientist, Dixon and Jones’s “My dinner with Derrida, or Spatial Analysis and Derrida Do Lunch” (1989) is poststructuralist geography par excellence. Through the use of literary dialogue, they offer glimpses of the interpretive gulfs between dominant discourses – a reminder that reading and writing are always confronted with the prospect of reconstructing or deconstructing structures of domination.

Drawing upon an old critique of Freud’s masculine bias (or, “phallocentrism”), Derrida invented the term “phallogocentrism” in the early 1970s to challenge the predominance of masculine perspectives in writing. Feminist thinkers had also deployed nuanced critiques against phallocentrism in Western representations and social institutions. During the 1970s, several poststructuralist feminists – such as Hélène Cixous, Julia Kristeva, and Luce Irigaray – merged these currents into the écriture féminine (“women’s writing”) movement, which sought to overturn phallogocentrism by writing bodily gendered difference into their texts. Within two decades, American feminist theorists such as Judith Butler and Eve Kosofsky Sedgwick would view gender and sexuality as something that was performed (rather than innate), leading them to consider the body itself to be a kind of text.

Such maneuvers were crucially important for cracking open the latent sexism in much of geography – even in the radical currents – in the 1970s, 1980s, and 1990s. An early chapter of David Harvey’s The Condition of Postmodernity (1989), for example, illustrates the cultural shift between modernity and postmodernity through a series of representative portraits and advertisements, each of which featured nude women. In an article entitled “Boy’s Town,” Rosalyn Deutsche critiqued Harvey’s use of the feminine body in a book that seemed otherwise oblivious to questions of gender or feminist politics. Harvey responded by adding a brief note to subsequent editions of Condition of Postmodernity that largely dismissed Deutsche’s critique as a product of postmodern feminism. His seeming blindness to his own phallogocentrism throughout the exchange was characteristic of the debates of the period.

Poststructuralist feminism insisted that, like texts, spaces are multiple and hybrid. Spatial experience is gendered. Thus, what might be a scene of abandon or enjoyment for men, can be a site of danger and terror for women. Gendered power is defined in part by the ability of the powerful to remain oblivious to spatialized differences. In geography, this myopia also surfaces when people of privilege (the discipline is disproportionately white and male) insist that their own spatial experience is universal. Antisexist geographers have responded by deconstructing geographic masculinism and, in the spirit of écriture féminine, creating new approaches to representing and narrating gendered spaces. Similarly, critical race theorists such as bell hooks, Gloria Anzaldua, and Katherine McKittrick speak back to white normativity by detailing marginalized raced spatialities. Finally, geographers J.K. Gibson-Graham (a portmanteau name for co-authors Kathy Gibson and Julie Graham) brought the attack on “centers” to bear upon political economy. Their critique of “capitalocentrism” blended feminist critique with an emerging interest in alternative economies.
Why, they asked, should political economy fixate on one mode of exchange – capitalism – to the exclusion of all others (such as cooperatives, gift economies)?

In the late 1990s, geographers unearthed the deconstructive kernel in postcolonial studies to critique Western constructions of nature. Bruce Braun’s “Buried Epistemologies” modeled this approach by examining wilderness preservation strategies by white Canadians that erased the indigenous communities living in and using the contested “natural” spaces. A decade later, Jake Kosek’s _Understories_ (2006) called for “new natures” after deconstructing the cultural politics surrounding dynamic forest spaces near Los Alamos National Laboratory in New Mexico. Kosek’s “understories” (a forestry term for leaf litter resting on the forest floor) are the many material and symbolic traces (names, mysteries, uses, and even radioactive isotopes) that expose the porous boundaries between nature, culture, and politics. We remain blind to these as long as we construct insurmountable differences between nature and culture. Other cultural geographers, such as Rich Schein and John Wylie, have recently deconstructed the “material semiotics” of vernacular landscapes. Schein, for example, critically dismantles the construction of a park built to celebrate horseracing in Lexington, Kentucky, that also erases from view a neglected African American enclave sitting just north of downtown. Meanwhile, Wylie reminds us that memorials make absence present in ways that ultimately exceed our capacity for representation.

**Discourse, power, and the body**

Michel Foucault (1926–1984) studied philosophy at the École Normale Supérieure under Hyppolite the Hegelian and Althusser the structuralist Marxist. In his early works, which many consider to be structuralist, he examined the underlying assumptions (or, _épistémé_) that enabled historic shifts in scientific knowledge during modernity. He argues that disciplinary and institutional knowledge (medicine, psychiatry) is a mode of power capable of inventing human subjectivities (the infirm, the abnormal) by introducing new categories and differences into social life.

Foucault broke with structuralism after 1968. His attention shifted to the complex relationship between power and “discourse,” a set of “utterances” – statements – that resonate across intellectual and institutional fields. To this end, he invented the “archeology of knowledge,” an archival research practice that seeks out the conditions of possibility (rather than the origins) of discourses. These tend to emerge across tangles of documents, appearing “sometimes as the general domain of all statements, sometimes as an individualizable group of statements, and sometimes as a regulated practice that accounts for a certain number of statements” (Foucault, quoted in Dosse 1997, 241). Rather than inscribing order upon this jumble, Foucault employed a “genealogical” reading strategy of “coupling together … scholarly erudition and local memories” (Foucault 2003, 8). This approach rendered a view of disciplinary power that, rather than being concentrated in a single point, was dispersed across various banal sites and statements.

Foucault and Derrida appeared on the Anglo American geographic scene during the same period, leading these very different thinkers to be sometimes confused with one another. Today, Foucault’s influence can be found in much of the discipline’s critical language. Like Derrida, his uptake by geographers was gradual. The earliest engagements in the mid-1980s focused on the “power/knowledge” relationship and its
implications for governmentality (the management of populations). This analysis also rounded out Harley’s deconstruction of mapping, which interpreted cartography’s semiotic complicity in state power. Other geographers, such as Chris Philo, took a page from Foucault’s histories of modern institutions by analyzing the institutional spaces of madness. Later, the genealogical strategy informed explorations of power, “expertise,” and the complex realities they manipulate. For example, Paul Robbins merged poststructuralism with Earth processes to track the paper trail of experts recommending invasive tree planting in deforested areas of Rajasthan, India, during the 1990s. His turn to the discourse of expertise helped initiate a new critical focus in political ecology on governmental structures’ imaginaries of ecosystems. Most recently, Stuart Elden’s *The Birth of Territory* (2013) employs genealogy on a grand scale to trace the shifts in the territory concept from antiquity to early modernity.

Poststructuralist geographers also celebrate Foucault for his nuanced engagements with metaphoric and material spaces, something he famously discussed with the editors of the French political geography journal *Hérodote* in 1976. Spatial metaphors figure prominently in his archeology and genealogy. Both reject linear historic perspectives in favor of spatial relations, such as the “proximity” of certain discourses within a tangled field of statements and documents. Foucault’s fascination with material spaces is evident from the opening lines of his *History of Madness* (1961), which invokes the “large, barren uninhabitable areas” left by recently vanquished leprosy “at the edges of the community, at town gates … where the disease no longer reigned but its ghost still hovered” (Foucault 2006, 3). By the 1970s, Foucault understood space as a dynamic power mechanism. In *Discipline and Punish* (1975), he famously analyzed British philosopher Jeremy Bentham’s “panopticon,” a circular prison surrounding a central surveillance tower. Believing themselves to be constantly under observation, prisoners would internalize self-discipline. Foucault described such spatial structures as power “diagrams,” arguing that the panopticon signals a particular disciplinary shift from central sovereignty to modern forms of dispersed self-government. His genealogy discovered the same “dispositif” (institutional power mechanism) in documents concerning army training, factory work, and schoolhouse discipline. All frame the body as a site for exercising not the power to oppress subjects, but the power to produce them: brave soldiers, fast workers, strong students. These “biopolitical” relations enroll components of human biology as elements of disciplinary “power strategies.”

Foucault’s conceptualizations of biopower and governmentality have influenced several approaches in critical geography. During the 1990s, some geographers explored the possibility for liberation from power relations via what he called “heterotopias,” complex sites that move out of phase with repressive structures. Meanwhile, studies of the government of bodies – particularly women’s bodies and reproductive labor – have gravitated toward the critical discourses of biopolitics. In the years since the start of the United States’ interminable “Global War on Terror,” Foucault figured prominently in critical geographies of surveillance, governmentality, and “necro-politics” (the power to determine who lives or dies). Important to these discussions are David Murakami Wood’s analyses of the globalization of surveillance and Ben Anderson’s work on emergency preparedness, which shifts biopolitical governmentality to the regime of anticipatory reflex. Derek Gregory’s study of Western geographical imaginaries of the Middle East, which help constitute the “colonial present,” shares much in common with Foucault’s lectures on governmentality, colonialism,
and race. Gregory is currently expanding this analysis through to the necropolitics of the US drone program in Iraq and Afghanistan.

**Difference, becoming, and ontology**

The French philosopher Gilles Deleuze (1925–1995) is best known for his collaborations with Félix Guattari (1930–1992), a trained philosopher and experimental psychotherapist. Together, they developed several important interventions in contemporary social theory that challenged Lacanian-Althusserian structuralism. Overturning psychoanalysis’ phallocentric “Oedipal” organization of sexual desire, their *Anti-Oedipus* (1972) invents a political psychology based on flows of “machinic desire” (bodily affections). According to Freudian psychoanalysis, personal desires are structured by innate drives that, when constrained by social taboos, fill the unconscious with anxiety. Deleuze and Guattari countered that unconscious desire is not pre-directed but rather operates upon a body organized by diverse social structures. A line of resistance seems to manifest in the “body without organs,” a body that shrugs off social dictates regarding the normal uses of its organs (e.g., the equation of sexuality exclusively with the genitals). Deleuze and Guattari saw a parallel between psychoanalysis and political ideologies that are prescriptive about what “counts” as legitimate objects of political struggle (a characteristic of the statist Marxism of the 1960s). Against this depiction, they introduced the notion of “micro-politics,” diverse, localized politics that emerge in minor ways from a wide range of social relations. These contributions have since been deeply influential for theorizing sexual liberation and other marginalized political movements.

Deleuze and Guattari later extended their interest in minor structures to systems as diverse as material processes, linguistics, social history, and perception. *A Thousand Plateaus* (1987) addresses these many fields and intertwines them with several others. Each system involves a dynamic relationship between “major” (dominant, normative, central) and “minor” (rebellious, abnormal, marginal) elements. Interacting major and minor elements transform one another in a process Deleuze and Guattari call “becoming”: the major enters a process of *becoming-minor* while the minor is enrolled in *becoming-major*. They become, in other words, decentered, emergent structures. In geography, Cindi Katz’s “Toward Minor Theory” (1996) uses minor theory to “scratch at major theory” (1996, 487) such as Marxism that continues to dominate and structure disciplinary debates on politics and relevance. Katz also interrogates the potential traps to discourses about becoming-minor, most notably the notion of “becoming-woman.” In this, she echoes many debates about the dangers of fetishizing the “minor” in social theory and social movements.

Deleuze and Guattari’s account of the minor is sometimes misread as a moral imperative, despite their warnings against this. For example, during the mid- to late 1990s, Nigel Thrift’s early nonrepresentational and affect theories tended to frame becoming-minor as a fundamentally liberatory activity that is easily accessed through activities such as dancing. Others objected that dance is a thoroughly representational activity. More to the point, any dance involves a variety of interacting major and minor elements. More recently, many affect theorists have been drawn to Deleuze’s use of seventeenth-century Dutch philosopher Baruch Spinoza to explore the dynamics of bodily capacities to affect and be affected by other bodies. These studies have inspired reconsiderations of working life, care labor, and human–nonhuman relations.
Because the elements of becoming are mutually transformed through interaction, Deleuze refers to such relations as “differential.” This is the fundamental component of Deleuze’s ontology (the study of what exists), which he defines as “pure difference.” Ontology speculates about the fundamental building blocks (or metaphysics) of the world. In the West, these have often been defined as things (or identities) such as “Being.” By defining ontology in terms of a relation rather than a thing, difference rather than identity, Deleuze created a picture of the world that emphasizes contingency and change rather than normativity and order. In the early 2000s, this emphasis would influence what is sometimes called the “ontological turn” in geographic theory. In their critique of the scale concept in geography Sallie Marston, John Paul Jones III, and Keith Woodward proposed that structural scalar concepts be replaced with a suppler notion of “site ontology.” They defined sites differentially, as the convergence of any number of disparate elements. Geographers do not prefigure the composition or character of such elements but rather describe them “immanently” from within the given spatial relations. Other geographers have been drawn to Deleuze and Guattari’s notion of “assemblages” (which, like Marston et al.’s sites, consist of disparate elements relating immanently) to explore the dynamics of urban and socio-natural spaces. Most recently, Deleuzian ontology has inspired an exploration of “new materialisms” that ask critical questions about the nature of material reality and seek to redefine its metaphysics and ethics.

The geography to come

Translations of French critiques of poststructuralism (some dating back to the 1970s) have appeared with greater regularity during the past decade. One longstanding critic is Alain Badiou (1937–), a former Maoist and student of Althusser, whose philosophy of events argues that mathematics is ontology. Although very critical of Derrida and Deleuze throughout their lives, his recent work has incorporated elements of their thought. Some key Marxist geographers involved in the 1990s debates on poststructuralist geography have begun to embrace fragments of Badiou’s earlier thought, along with that of fellow Althusser student, Jacques Rancière (1940–). Some geographers formerly associated with nonrepresentational theory have also embraced these thinkers. Currently, Badiou occupies a position in geography similar to that of Derrida and Foucault during the mid-1980s: the discipline does not yet seem to know where he fits.

François Laruelle’s (1937–) “non-philosophy” claims that several poststructuralists remain firmly situated within the “prior decisions” (presuppositions) of Western philosophy despite their decentering critiques. Nonphilosophy is a “science of philosophy” that Laruelle claims can interrogate such prior decisions from a nonphilosophical viewpoint outside the discipline. While geographers have yet to engage him, nonphilosophy presents a potentially interesting tool for interrogating the “prior decisions” of geographic social theory. Badiou and Laruelle lean heavily on science (mathematics and nonphilosophy), but it is not clear if this reflex heralds a return to structuralism of one form or another.

Quentin Meillassoux (1967–), a student of Alain Badiou, has introduced speculative questions about what it means to think what cannot be thought. This is an important question for nonrepresentational theorists; however, these thinkers have characteristically anchored their analysis to problems of the body, such as affect. Meillassoux’s project is much larger. He critiques the “correlationism” (the tendency to
define “truth” as a correlation between objects and thoughts) that has dominated Western thought since Kant. What are the implications of correlationism, Meillassoux asks, for something that preceded human existence and thus could not be correlated with thought? He calls this “something” the *arche-fossil* and uses it to develop an anticorrelationist philosophy grounded in contingency. Given geography’s reflexive empiricism and its tendency to demand that theory be met with practice, it seems unlikely that the critique of correlation can find much fertile ground in the discipline. As we move into the so-called Anthropocene, however, the Earth’s future state – which may or may not sustain human life – does suggest future states of the world that are essentially unthinkable. In this sense, Meillassoux might offer a fertile, antihumanist perspective to help frame this discussion.

Poverty

Lakshman Yapa
Pennsylvania State University, USA

Although poverty in the urban slums of South Asia, Africa, and Latin America is materially far more intense than poverty in any US inner city, there is no need for two different theories of poverty – one for poor countries and another for rich countries – as a single theory suffices. The United States is the greatest wealth-producing engine ever conceived in human history, but, nevertheless, the persistence of poverty amid great wealth remains a continuing paradox (Glasmeier 2006, 1). A discussion of poverty in the United States should therefore prove instructive for understanding poverty elsewhere in the world.

This entry contrasts an exchange-value approach to poverty with a use-value approach. Economics has always been central to the study of poverty, prioritizing exchange-value to increase income, employment, and economic growth. In contrast, the use-value approach looks at details of basic needs in complex substantive networks of food, health, energy, and so on, instead of subsuming everything under a single “income” rubric. The two views lead to very different outcomes and to the conclusion that poverty is a normal manifestation of an economy that has privileged exchange-value over basic use-values.

Persistence of poverty

Poverty has persisted, despite 60 years of initiatives from the World Bank and the United Nations and 50 years of the “War on Poverty” in the United States. Poverty status in the United States is determined through income thresholds that vary by family size. If a family’s total income is less than the family’s threshold, then that family and every individual in it is considered poor (US Census Bureau 2013). When official poverty calculations began in 1959, the poverty rate was 22%. The rate steadily declined through the 1960s, but since then has remained steady between 12% and 15%, despite trillions of dollars being spent on social welfare.

The World Bank defines extreme poverty as earnings of less than US$1.25 a day at 2005 prices. In 2008, 1.29 billion people lived on less than $1.25 a day, compared to 1.94 billion in 1981. These numbers represent a steady decline in poverty rates from 52% in 1981 to 22% in 2008. However, almost all of this poverty reduction came from China: between 1981 and 2008, the proportion of Chinese people living on less than $1.25 a day is said to have fallen from 85% to 15.9%; that is, by roughly 600 million people. But China achieved this poverty reduction with an unsustainable rate of economic growth of about 10% per year, which has come at an enormous cost to the environment. If the poverty line were increased to $2 a day, nearly 42% of the world’s population would be
POVERTY

deemed poor, and the World Bank itself admits that rates of poverty reduction at this threshold are not impressive (Chen and Ravillion 2010). The World Bank’s statistics on poverty reduction mask the stark reality that nearly 1 billion people live in slums, the fastest-growing human settlements in the world, in the megacities of poor countries (UN–Habitat 2003).

Why poverty persists

Conventional explanations of poverty such as lack of resources, lack of capital, and lack of economic growth are not helpful. Defining poverty as the lack of income privileges exchange-value over use-value. Modern economies systematically fail to produce the basic use-values needed by households. In fact, this can be used as an alternative definition of poverty: people are poor when the larger economy fails to produce basic use-values. There are four major reasons why poverty cannot be eradicated within an exchange-value framework: (i) failure to provide full employment; (ii) nonpayment of living wages; (iii) social construction of scarcity; and (iv) undertheorizing of use-value. Lack of full employment and low wages are well known as causes of poverty, but less recognized is the idea that these conditions are functional to the expansion of exchange-value. Another mechanism for expanding exchange-value is creating demand for high value-added goods through socially constructed scarcity. Finally, the exchange-value circuit is so hegemonic that it has created a condition that can be called “econo-normativity,” where it is almost impossible to visualize the production of goods outside that framework.

Nonpayment of living wages

Apart from unemployment, poverty also results from low wages, hence the presence of the working poor in the United States. According to the living wage calculator developed at MIT by Glasmeier (http://livingwage.mit.edu/), in every US state the poverty wage per hour is far less than what was calculated to be a living wage. The tertiary sector of the economy, which includes retail and food services, has been the principal job provider for the US economy since the 1960s, but this is also a sector where a disproportionate number in the workforce make very little money. Apart from the classic downward pressures on wages that Marx spoke of, neoliberal globalization has opened up whole new areas for the expansion of exchange-value. While globalization has broken down all national barriers to the movement of
capital, there is a veritable apartheid restricting the movement of labor from poor countries to rich countries. Whenever wage levels rise in a poor country global multinationals shift to other low-wage countries. The desperation of economic migrants from Central America to the United States, from North Africa to Europe, and from South and Southeast Asia to the Middle East is stark evidence that the model of development is not working for the poor.

Socially constructed scarcity

The claim that socially constructed scarcity is the leading cause of poverty needs a lengthy explanation as it is not a commonly held view (Yapa 1996, 2015). Resources such as arable land, oil, and food are indeed finite but, contrary to what economists claim, this is not the origin of scarcity, which is in fact socially constructed. Here is how it happens: the exchange-value of a commodity is usually a single definite amount of money, but the same commodity can have many use-values. For example, a meal at a given price can satisfy hunger, provide nutrients, express hospitality, or even confer social status. Most commodities have a range of use-values, with one or two being primary for the consumer. The primary uses can be described as “end use-values” – what we use the commodity for in the end. Once the primary end use-value of a commodity, say A, is specified, it can be seen that there are other ways of meeting that end use-value without consuming the commodity A. This is important to understand in order to see that scarcity is socially constructed. One way to increase the demand for commodity A is to remove all the other ways in which the end use of A can be met. The history of exchange-value is actually a history of how alternatives ways of meeting end uses have been eliminated, de-developed, or made unavailable. Many students of capitalism have observed that many needs appearing in a capitalist society are intentionally created to realize profits; that is, they are the needs of capital, not of people (Illich 1978).

The examples of socially constructed scarcity are legion in every sector of the economy throughout the history of the world. A most egregious example of this pattern is the increased demand for automobiles in the United States accompanying the elimination or de-development of alternative modes of transport such as public transit, carpooling, bicycling, and walking. Other examples include the increased demand created for infant formula caused by discouraging breast-feeding, the substitution of expensive meat protein for less expensive vegetable protein, the medicalization of health by discouraging preventive practices, and narrowing housing options by making the single family suburban home the most desirable; examples of socially constructed scarcity are everywhere.

The underlying mechanism for the social construction of scarcity can be represented through a simple demand and supply diagram. In economics scarcity is said to exist when the demand for a commodity exceeds its supply. In Figure 1a, when the demand curve moves to the right from D1 to D2, more of a commodity is demanded at each level of price, which increases the scarcity of that commodity. Scarcity is also increased when the supply curve of a commodity moves to the left from S1 to S2 as shown in Figure 1b. This is the case with the chronic underproduction of basic goods which, although essential to life, offer limited opportunity for extending commodity chains, adding value, and increasing profit, a situation clearly demonstrated by the nonavailability of fresh produce in contrast to the abundance of processed food in what are called “food deserts” in US inner cities.
Modern economies systematically *underproduce* basic use-values such as food, health, housing, energy, transport, and education. There are simply not enough of these goods available at affordable prices, yet there is simultaneously an overproduction of high-profit, high value-added goods. We can say, then, that the creation of the scarcity of basic use-values at affordable prices is a fundamental cause of poverty.

**Undertheorizing of use-value**

The exchange-value view of poverty is the dominant conventional view of poverty, and it enjoys support across a wide spectrum of political philosophy. At one end is the conservative view that poverty is a result of individual failure to adapt to unfettered markets. Liberals view household poverty as reflecting structural inequity, caused by class, race, and gender, that limits opportunity for social mobility, a matter that could be corrected through government regulation of the market (Krugman 2009). Inspired by the writings of Marx in *Capital* (1990/1867), geographers such as Harvey (2010) believe that poverty is an inevitable manifestation of capitalism’s inherent tendencies toward uneven development. Through this entire range of poverty philosophies, from individual failings to inherent tendencies of capitalism, one concept remains constant — people are poor because they have no money. This represents a classic instance of ideological hegemony: the power of ruling classes to convince not only the general public but also their formidable critics that poor people lack access to such things as food, health, and housing because of their marginal status in the formal economy. The net effect of the dominance of exchange-value in poverty knowledge is the complete absence of a discourse on use-values.

The historical movement of the household from the circuit of use-value to that of exchange-value, beginning with colonialism and continuing today with increased globalization, has had enormous consequences for the poor. First, the poor have been corralled into the formal economy, knowing that the

Figure 1  Shifts in demand and supply, end use-value, and constructed scarcity.
prospects of their full participation are dismal. Second, privileging gross national product (GNP) growth rates has prevented the critical examination of economic performance with respect to the production of affordable basic goods. Third, metanarratives of income poverty have disempowered the poor: a vast discourse has been generated that has invoked a raft of explanatory variables of poverty – lack of free markets, exploitation of labor, racial and gender discrimination, overpopulation, lack of natural resources, lack of investment capital, lack of education, the persistence of a culture of poverty, welfare dependence, and capitalist exploitation. By invoking these factors as causes of poverty, academics have created metanarratives at a discursive scale that are not correlated to the power of poor people, and that thereby rob them of agency. The poor have been acted upon through our agency – of corporate executives, development planners, state bureaucrats, and academics – because our theories don’t allow us to see the poor as potential agents of change.

A poverty discourse on use-values will be different from that of exchange-value because it will focus directly on subject-specific topics related to food, good nutrition, health of the body, and so on. The key claim is this: A large body of literature already exists that shows that resources such as land, labor, and capital are not limiting factors in the attainment of basic needs for the poor. A turn to a theory of the production of basic values is a good example of what Foucault (1990, 92–114) meant by “non-sovereign power”: power is the ability to solve our problems, and it does not always come from a single sovereign source, the state, or from above; power is resident in the multiplicity of force relations immanent in our daily lives. Knowledge of use-values exists to help ordinary people exercise power and agency at specific sites in specific fields at scales that are correlated to their power. The overwhelming presence of exchange-value in poverty knowledge has simultaneously led to the absence of its other: namely, use-value.

Use-value and the basic needs economy

The concept of use-value offers a very useful framework for thinking about solutions to poverty; however, as Marx himself noted, the concept of use-value does not lend itself to general theory. While the contradiction between use-value and exchange-value embodied in commodities is the source of all major contradictions of capitalist production, Marx believed that the proper object of study for political economy is the laws governing exchange-value (Marx 1990/1867, 138–154). It is not possible to make general claims about use-values as they are by necessity tied to specific physical, chemical, and locational properties of resources. A discussion of use-values involves subject-specific substantive literatures, so the claim that land, labor, and capital are not limiting factors for the production of basic use-values has to move forward through description of specific cases. The selected example here is food and agriculture.

An average person needs about 2000 calories of food energy, 50 g of protein, and some vitamins and trace elements in his or her diet each day. A perfectly healthy diet can be had from unprocessed whole grains, beans, vegetables, fruits, nuts, and modest amounts of fish and meat. The world as a whole produces enough calories for all human beings, but many do not have enough money to bid for foods that are also used as inputs for animals and automobiles. Since large numbers of people are, and will continue to be, marginalized by the formal economy, it
POVERTY

makes sense to develop an economy that focuses directly on basic use-values such as food.

Nearly 870 million of the 7.1 billion people in the world were suffering from undernourishment in 2010–2012 (FAO 2012). Almost all the hungry people live in developing countries, in areas that are tropical or subtropical. Plants that fix solar energy by means of photosynthesis are the sole source of food for humans and animals, and it is ironic that most of the hungry people in the world live in tropical and subtropical biomes that have the highest photosynthesis, and therefore the highest potential for producing food. The food and agriculture sectors of the United States economy generated about $1.3 trillion in 2010 (USDA 2014) and it is also one of the largest exporters of agricultural commodities. Nevertheless, the number of food-insecure individuals in the United States in 2010 was 48.8 million, 16.1% of the total population (Coleman-Jensen, Nord, and Singh 2013).

Mechanisms for the social construction of scarcity are at work in creating scarcity of nutritious food at affordable prices. For example, the average US diet is mostly made up of processed food, meat, and dairy with high levels of salt, sugar, and fat (Pollan 2006). Many observers believe the US food system promotes exchange-value by implicating food in long commodity chains between farm and household, a situation that can be described through the model of socially constructed scarcity presented earlier. Broadly speaking, nutrition can be obtained from two classes of food. Let us call whole foods and fresh produce class A foods, and processed foods with long commodity chains and value added at each step class B foods. For example, the profit margin for apple juice or a packaged apple tart (class B) is much greater than that of a fresh apple (class A). When supermarkets leave poor neighborhoods, they leave behind convenience stores selling class B goods. Thus the demand curve for processed food moves to the right (class B) and the supply curve of fresh produce (class A) moves to the left, aggravating food scarcity for poor people in the city (Figure 1).

Or consider sources of protein for human nutrition. For decades the idea that animal protein was superior to vegetable protein was official nutrition doctrine in the United States, but nutrition science now states that vegetables and beans can fulfill all our protein requirements, and, contrary to public perception, are not inferior sources of protein. The idea that vegetables are an incomplete or inferior protein removed vegetables as a source of protein supply, and thus increased the demand for meat. It is one thing to consume meat as a matter of taste and food preference, but to represent it in official government documents as an essential food group is an example of socially constructed scarcity (Pollan 2006). The mass production of animal protein creates additional scarcity, from the inputs needed to produce meat (Pimentel and Pimentel 2008, 67–75), and from high meat consumption, which is linked to poor health (Campbell and Campbell 2005).

Despite the “food deserts,” nutritious food can be produced in US cities at affordable prices because land, labor, and capital are not limiting factors. Methods of biointensive farming show that large quantities of food can be grown in very small spaces with few external inputs and little capital investment. The science is both new and old. Jeavons (2012) and many others have demonstrated that, compared to conventional agriculture, biointensive mini-farming can produce far more nutritious calories per unit area; use less water, energy, and fertilizer; increase soil fertility; and produce more income per unit area. Jeavons (2012, 215) also claims that it is possible to grow all the food for a person’s diet in as little
as 2000 ft², and that includes the area required for growing organic matter for producing compost to maintain soil fertility.

During the deindustrialization of Northern cities in the 1970s there was a mass movement of whites to the suburbs, leaving large areas of vacant land in the city. A survey of 70 cities in the United States (Pagano and Bowman 2000) revealed that on average 15% of urban land was vacant. Even these figures are gross underestimates as some cities do not have good records of vacant land parcels. Most urban farms in the United States grow crops on raised beds filled with compost made from readily available raw materials such as food waste, wood chips, and leaves. Often the compost is enriched with worm castings, a very low-cost method of using worms to break down organic waste into nutrient-rich soil amendments. Almost all poverty areas in US cities have very high unemployment rates and large numbers of previously incarcerated youth with limited job opportunities. Labor is not a limiting factor of production in urban agriculture. Biointensive urban agriculture requires little capital, uses little or no industrial inputs, and depends on the reproductive power of nature for growth and decomposition, rather than on the productive power of industry for inputs. Many urban farms, such as the ones run by Growing Power in Milwaukee and Chicago (Allen 2012), are not yet self-financing; their sales revenue is supplemented by modest grants from foundations and city governments. But it is too early to apply profit/loss calculations to urban mini-farms as they are an evolving technology in the stage of research and development. Moreover, urban farming has not received a fraction of the support that the federal government gives to conventional farming through crop subsidies, crop insurance, cooperative extension, and research from land grant universities. Urban farming exemplifies the use-value approach to the problem of poverty, and it also shows how each basic use-value draws on a specialized field of substantive knowledge.

Poverty and sites of agency

The most common definition of poverty – a lack of income – leads to the most conventional of solutions: increase employment in the corporate economy. This is the exchange-value view of poverty. But the economy does not produce full employment and does not pay living wages to even those who do find work. The economy systematically underproduces affordable basic use-values such as food, health, housing, energy, transport, and education. This is because the intentional construction of scarcity facilitates the expansion of exchange-value. Existing theories of poverty – conservative, liberal, and radical – fail to answer the question “What is to be done?” in a manner that confers agency on poor people. Conservatives point to welfare dependency and the need for unfettered markets. Liberals focus on race and gender as inhibiting social mobility. Radicals point to inherent tendencies in capitalism toward uneven development. These theories are not wrong; each emphasizes a particular root cause in what is a mutually constituted overdetermined system. Free markets, race, gender, and class are conceptual categories discursively aggregated at scales that are not correlated to the power of poor people. Existing theories of poverty have robbed generations of poor people of their agency. One solution to this problem is to explicate a use-value framework for poverty; it is a discourse that requires subject-specific information in the fields of food, health, housing, energy, transport, and education. Beyond the example of food production detailed earlier,
POVERTY

the use-value approach can be used to construct similar arguments in health (prevention of disease), housing (high-density living), energy (reduce entropy by matching energy sources to energy end uses), transport (decentering automobiles), and education (develop curricula to serve the sustainable production of use-values). The use-value framework turns away from the universalizing logic of economic growth and development to knowledge that is place-specific. In answering “What is to be done?” it produces knowledge that confers agency on place and community. Geography is central to the task of demonstrating how subject-and location-specific knowledge can be deployed to show that land, labor, and capital are not limiting factors for the production of basic use-values.

Power and development

Mary Lawhon
Joseph Pierce
Florida State University, USA

Development is, broadly speaking, the improvement of people’s wellbeing. Orthodox development thinking is often largely apolitical, despite the inclusion of vocabularies of power. The development community uses terms such as “empowerment,” “increasing capacities,” or the “ability to obtain resources” as key motivating vocabularies for the project. These terms are often used, however, without explicitly asking questions about how this increased power arises and where it comes from; what new relations are formed; which power relations have produced the existing patterns of capacity and resources; or how a redistribution of power might be necessary to achieve any form of improved wellbeing. Geographers have contributed to this depoliticized yet highly political development agenda both directly (by providing spatialized economic data to public and private actors) and analytically (by arguing for the benefits of well-executed development in the scholarly literature), and some continue to write in this vein.

Power is certainly a slippery concept, with diverse epistemological influences that shape how we understand its influence. The precise meaning of power in geographical writing on development is often implicit rather than explicit: most often, power has been transparently operationalized as the ability of some (usually Western/Northern/“developed”) actors to exert their will on other (typically Southern/“developing”) regions. This notion of power as the ability to force outcomes is often short-handed as “power-over,” as in “power over those with fewer resources.” However, over time geographers are becoming both increasingly explicit and more varied in their conceptualizations of power: some scholars argue that it can also be a means of enablement (“power-to” act and organize), and the distinction between power-over and power-to is increasingly important in understanding how geographers have used the concepts of development and power next to one another. Some of the specific treatments of power found in the literature on geography and development include power as an inscribed capacity which is located somewhere (a classical version); as relational and mobilized by groups towards specific outcomes; or as diffuse and mobilized through various processes.

This entry seeks to explicate the importance of power in development as well as how the concept of power is used in geographies of development. The development literature makes a distinction between immanent development (broad processes of structural or systematic change) and intentional development (specific interventions) (Corbridge 1998). This review discusses the role of power in both of these interrelated processes, with attention to different uses of the concept of power as well as key theoretical influences and epistemologies. It surveys significant trends in the discipline, while acknowledging that power/development is an important conjunction in the field and that there is wider geographical literature beyond this review.

One of the ways in which power has been exerted in the context of development is through language, and thus, before continuing, this entry...
briefly introduces some of the historically shifting regional terminology used, and its impact. The terms “First World,” “Second World,” and “Third World” emerged out of the Cold War context, in which the United States, the United Kingdom, and their allies were the First World, the Soviet Union and its allies were the Second World, and nonaligned countries were the Third World. Despite new geopolitical conditions, these terms remain in use today. While some consider the term “Third World” to be condescending, it is also used by progressive organizations such as the Third World Network. “Developed” and “developing” were subsequently popularized, although they have also been critiqued in turn for containing implicit normative assumptions and hierarchical power relations. More recently, the terms “Global North” and “Global South” have been increasingly used in an attempt to avoid the negative connotations typically associated with the Global South, although they are routinely critiqued for their geographical inadequacy/inaccuracy. Contemporary geographers have also sometimes opposed the underlying project of grouping of nations in its entirety, which inevitably essentializes diverse regions of the world and overlooks diversity at smaller scales. In the text below, the terms Global North and Global South are predominantly used, although alternative terms have been chosen where appropriate.

The powers behind development

Geographers (and the discipline of geography) were intimately involved in the expansion of Western/Northern power through the colonial project, as well as later expansionist American foreign policy. Throughout much of the nineteenth and twentieth centuries, geographers were complicit in the colonization of the Global South, contributing geographical data such as maps and regional studies. This era of scholarship began with the survey and publication of spatial data, but in later decades moved toward what are now seen as problematic efforts to explain spatial differentiation of privilege through race and climate. These now-discredited efforts helped to provide both an empirical basis and a theoretical justification for the exertion of what is typically described as power-over through colonialism, imperialism, and expansionism, as well as for later intentional development projects. Modernization became a critical aim, and development became central to global politics, particularly as the Cold War began to make international strategic allegiances increasingly important.

In this context, the World Bank (1944, originally known as the International Bank for Reconstruction and Development (IBRD)) and the International Monetary Fund (IMF, 1945) were founded in order to promote the internationalization of finance and support ongoing intentional development initiatives. Associated interventions sought to increase economic growth by bolstering the diffusion of technologies, markets, institutions, and practices from industrialized to developing contexts. However, optimistic projections of economic growth associated with development policies in the South often failed, leaving many countries (particularly in Africa and Latin America) unable to pay their debts. Geographers have demonstrated how this has shifted the site and scale of governance, giving international institutions power-over the governments in many nation states. Many countries in the Global South lost national autonomy as these international institutions pushed client nations into policies of “structural adjustment” which empower markets and private sector actors as key deliverers of development. Such programs generally reduce welfare support for lower-income citizens through market-centric programs, privatize state-owned enterprises
and public utilities, strengthen private property regimes, and reduce international trade barriers and tariffs. Collectively, these policies expose nations to the transfer of ownership of (and thus control over) key national industries to Global North actors, further reinforcing Northern decision-making prerogatives.

In addition to the IMF and World Bank, there has been a notable growth of nongovernmental organizations (NGOs) promoting intentional development, often through actions at a smaller scale aimed at improving wellbeing through specific projects. The power of NGOs is sometimes understood as “power-to” help Global South actors to achieve development. In this vein, a geographical lens can help us understand why NGOs in different contexts are comparatively more or less successful in achieving development outcomes; why NGOs are more present in some places than in others; and why their resources (human, financial, and other kinds of capital) flow to some places and not to others. Geographers have also attended to the shift in power relations between governments and NGOs: the growth of development NGOs means that these nonstate actors have moved to rival governments as the primary font of resource distribution (Bebbington, Hickey, and Mitlin 2008). This shift has rescaled the power relations of the aid community from that of various nation-states or NGOs toward internationalized systems and networks, largely understood as located in the Global North. More recent work has sought to move beyond individual case studies of organizations and towards understanding networks of social movements and the relationship between organizations, knowledge, and ideas. Taking this one step further, geographers have used the concept of assemblage, which promotes the understanding of social movements as performative and dynamic composites, rather than having distinct nodes between established entities (McFarlane 2009). McFarlane uses a case of Slum/Shack Dwellers International in Mumbai as an example of an NGO with international linkages, but not located in the North. The language of assemblage enables an understanding of power that is not about having power-over or power-to, but instead is a distributed, diffuse assemblage capable of mobilizing resources.

There has also been a significant reconfiguration of power relations that shape immanent development, or the broad processes of capitalist development. While trade has long been globalized, and economic relationships were a fundamental consideration of colonial geographers, increasing integration and new global production networks have shifted power. This includes a change from explicit and often violent power-over during the colonial era towards the greater importance of economic power-over, including transnational corporations which have in many cases become of greater significance in the development process than nation-states. New global production networks (GPNs) have become a focus of geographical examination, as geographers stress the need to move away from the typical focus of development studies on the state and towards the importance and cross-border activities of global firms. Geographical scholarship also seeks to move beyond the conceptualization of value chains towards understanding production and consumption as networked, nonlinear, and spread across space (Coe, Dicken, and Hess 2008). Economic and geopolitical power are also being simultaneously redrawn empirically and reworked conceptually as countries such as China, India, and Brazil, previously deemed part of the Third World, become increasingly central to production and consumption. Geographers have contributed overarching commentaries and theoretical developments as well as detailed localized examinations of the
POWER AND DEVELOPMENT

impact of such globalizations in the context of a capitalist economy, such as Hart’s work connecting South Africa with East Asia (Hart 2002).

Power as a lens of critique

While geographers have made important (and sometimes historically problematic) intellectual contributions to both the practice and our understanding of the shifting power relations associated with colonialism, globalization, and development, they have also been importantly involved in critiquing both their own intellectual history and international power relations. Critical scholars have suggested that the shift away from colonialism did not signal an historical shift away from the application of power in international politics, nor a move in the direction of international altruism. Rather, the rhetoric of power was transformed from one of political dominion to one of social and economic uplift in the orbit of successful examples in the Global North, while the practice of power shifted from an overt power-over to (neoliberal) economic and discursive expressions of power. Here are identified two key threads of critique, not entirely distinct from each other. The first emphasizes the need to understand and contest power in order to actually achieve development’s elusive ideal outcomes. The second questions the end goal, and suggests that the desire to achieve development itself is rooted in the imposition of power.

Analyzing power to better achieve development

Geographers have drawn on a number of different theoretical approaches to critique the dominant economic system, and most recently its neoliberal expressions, as well as that system’s impact on imminent development. In development studies generally and geography in particular, a number of these critiques begin with the articulation and rise of Marxist geographies from the 1960s onward. Questions of power slowly became central to understandings of development and underdevelopment; while the end goal of improved wellbeing remained relatively clear and uncontested, political-economic scholars began to question who gains and who loses in the development process, and whether development could ever be achieved through the actions being taken or processes being reinforced in the name of development. For example, drawing on dependency theory and world-systems theory, scholars have argued that historical power relations are merely reinforced through the subsequent efforts to develop. Increasing interconnectedness can, as Hart (2002) suggests, be disabling, reducing the autonomy of individual actors as well as nations in the context of established political economy. In short, macro-scale power relations established through colonialism and capitalism continue today, and must be recognized and contested in order to achieve development.

Economic geographers have also looked at the role of micro-scale power relations and the ways in which they constrain immanent development in the context of broad patterns of the contemporary capitalist economy. They have argued for the need to broaden scholars’ understanding of what constitutes the “economic” in order to see the networked, relational characteristics of development, and how power is enrolled in these relations. By emphasizing the roles that trust, associations, learning regions, institutional “thickness,” or placed networks may play in economic activity, these scholars offer ways of thinking about development that focus on its sociality and embeddedness, and how both power-over and power-to can be expressed through these
relations. In focusing on participants’ positionality, these scholars collectively provide a critique of development by suggesting that unless and until development attends to relationality and differences in power, it will fail to engender the improved wellbeing toward which it is nominally directed. As with Marxist scholarship noted above, such work typically implicitly retains a belief in the possibility of improving economic conditions and wellbeing through development.

Geographers have also critiqued the role of power in intentional development as it is conceptualized and performed by governments, donors, and NGOs. Some scholarship has been critical of the agendas of international government aid as well as that of NGOs, highlighting their tendency to reinforce the power relationship between donors and recipients and more generally their role in reinforcing broader international political economic relations. This includes the ways that government and non-government donors maintain their power to define agendas (a point geographers have particularly emphasized in research on the funding of conservation and sustainable development), have promoted particular technologies that increase dependency on donor economies, and promote export-oriented production to provide resources for more capital-intensive, profitable industries in the donor countries (Bebbington, Hickey, and Mitlin 2008). This critique has recently extended to include consideration of ethical consumption as a new funding mechanism through which intentional development occurs, and geographers have interrogated the use of development language as a marketing strategy that reinforces perceptions of difference and unequal power relations.

Another aspect of power relations that has been seen to shape international development is gender. One important insight that emerged from development theory, and continues to be significant in feminist development geography, is that women were typically overlooked in development plans and projects. Yet the decisions and activities of women are essential to the provision of everyday household livelihoods, and women often place greater emphasis on the wellbeing of the household (and particularly children) than men do. This insight and the associated critique have had practical outcomes, resulting in the allocation of funding and development of projects that sought to empower women by giving them power-to, both within the household and collectively. This included reconfiguring gendered power relations by increasing the decision-making and income-earning capacity of women in households and communities. This has had important consequences, not just in positive cases where changing the gendered power relations leads to improved wellbeing; it has also been noted to have threatened the empowered positionality of male household members, at times resulting in resistance, confrontation, and even violence within the household (Radcliffe 2006).

Development as the imposition of power/knowledge

Development has often been presented in both economic and specifically geographical scholarship as an unambiguously positive thing: surely no one would oppose improving wellbeing? In sites of development practice, however – largely in the Global South – the concept and its concomitant practices are much more contested. Resistance and opposition are as old as the concept, but critical geography was somewhat late in its engagement with postcolonial theory. Postcolonial theory suggests that the question of power is not just the contestation over resources or material, economic power; development is also about the power of ideas and the power to define norms and aspirations (Corbridge
1998; Crush 1995). Influenced by the work of Said, Spivak, and Escobar, but also drawing on Northern scholars such as Foucault, geographers have shown the discursive power of the development discourse. The aim here has been to problematize the self-evident; while it may surely be the case that improving wellbeing is desirable, geographers argue that there is much more to the practice and language of development, and a multiplicity of ways of understanding wellbeing (Crush 1995). The critique of the language and concepts is more than theoretical; it is rooted in a materialist desire, as so much is done in the name of development. This discursive critique seeks to show the connection between Western/Northern knowledge and power; power in this case is neither repressive power-over nor a liberatory power-to, but power as a universalizing discourse that shapes norms and desires.

An important locus of geographical scholarship has been the reconsideration of the aspiration of a single, unitary “modernity” that often underpins development theory and practice. Critical scholars suggest that modernization takes for granted that Northern economic patterns are “modern,” desirable, and beneficial for the residents of developing nations. Local case studies have been combined with broader theory to show how an understanding of geography helps to draw attention to the myriad networked influences on place, the diverse experiences of modernity, and the different possibilities and futures that may emerge. Geographers have also attended to the ways in which modernity is opposed, reappropriated, and reworked; Pred and Watts’s (1992) notable work examines wide-ranging examples, from technological changes in rice production in West Africa to labor conflicts at a steel mill in the United States, in the context of globalized ownership.

Geographical research drawing on postcolonialism and postdevelopment has also critiqued conventional development narratives (and previous scholarship) that treat recipients as objects of development. One of the consequences of this has, arguably, been the internalization of the development discourse by the people to be developed, thereby creating passive “objects” of development (Crush 1995). Instead, geographers and others argue for the need to recognize and respond to people as pluralistic, complex subjects with agency to resist, reappropriate, and subvert development projects and agendas (Crush 1995). Examining the power that these subjects have highlights another rescaling of analysis away from global/geopolitical outcomes of development (e.g., the degree to which development as a whole produces outcomes), as well as from the success or failure of individual plans and projects, and toward the networks of resistance and responses to development at the sites of investment or extraction.

Power

John Allen
The Open University, UK

Power, you would have thought, needs no introduction. A working definition captures its distinctive feature; namely, the ability to get people to do things that they would otherwise not have done. A long line of thinkers, from the political philosopher Thomas Hobbes, through Max Weber and Karl Marx, right up to present-day geographers David Harvey and Richard Peet, would have little difficulty in recognizing this definition of power. It is a definition of instrumental power; instrumental in the sense that it involves the exercise of power over others, whether through an ability to dominate, coerce, or subject someone to the rules of authority. Power, on this view, is a zero-sum game; it is always exercised at the expense of others.

Such a view chimes with the experience of imposition, of not being entirely in control when on the receiving end of an organized or institutional power. It is a view of power from which it is hard to digress. Yet for an equally long time, another less strident definition of power has run alongside it, in tandem, so to speak. Less instrumental in its force, it simply involves the power to make things happen, to make a difference, or to secure an outcome. Power, on this view, is a means to get things done, an enabling tool or facility, and has its historical roots in the statecraft of Niccolo Machiavelli. In more recent times, the legacy of this view is to be found in the work of such disparate figures as Hannah Arendt, Michel Foucault, and, Michael Mann.

Geographers have made their own use of these two different readings of power, often adapting them to their concerns and only showing fidelity to one or the other conception when it aligns with their particular interests. Such slippage arguably owes less to any profound eclecticism and rather more to the fact that when the likes of space, territory, and distance enter into the analysis they begin to trouble primary distinctions of power and authority.

“Power over” and “Power to”

It is possible to conceive of the “power to” act as a general precondition for all kinds of action, of which the power that is wielded at somebody else’s expense is a particular type of constraining action. On this view, the ability of the weighty institutions of the world to hold “power over” others reduces itself to one among other ways of acting in the world. Of late, however, the subsumption of instrumental power under a more general, catch-all, facilitative definition of power has given way to a more direct contrast between the two approaches. Whereas the ingrained idea of power as a force to be reckoned with, something which is held over others, speaks to domination and constraint; the looser notion that power is something that makes things happen, speaks to an enabling sense of action. Where the former accentuates the repressive side to power, the latter stresses its potential for empowerment. Where one is negative, the other is positive.
about the consequences of power and its actions. The distinction has hardened between the two senses of power and with it a gulf has opened up over what power is deemed to be for and how it works.

Instrumental power, or power over others

With only a slight hint of exaggeration, it is probably fair to say that an instrumental conception of power represents the default position within geography, especially political and economic geography. The ability to bend the will of others, to exercise power to get people to do things they otherwise would not have done, lends itself to questions of state rivalry and economic domination, as much as it does to issues of leaders and led, hierarchies, and the legitimation of authority. All of these characteristics imply that there is no “half-way” house about the distribution of power; either you have it or you don’t have it, and those that have it use it to further their objectives despite possible resistance from others.

What is also evident about this default position is that power is something that is “held” – it is held over others to gain advantage or to bring them into line. On this reasoning, power has something of a dispositional quality; that is, a capacity or disposition toward acting in certain ways, even if that potential is never actually realized. The capacity to do something, in this instance, is separate from the actual exercise of power. Such capabilities represent latent rather than observable qualities of power, so that the capacity for domination held by state agencies or economic corporations is conceived as present and capable of being exercised should the need arise or circumstances dictate. In practice, however, the possession of power and its exercise tend to be conflated, as if they were one and the same thing.

It is not uncommon, for example, to “read off” the power of an economic institution or governing body by the size of the resources at its disposal, regardless of how they may be used, or indeed misused. Size matters in this instance because it can be an indication of a concentration or “bloc” of power. The greater the resources concentrated at one location, the greater, it is often assumed, is the capacity for domination and control. Barry Hindess once described this as a quantitative conception of power, where more power prevails over less and it is possible to determine in advance who wins and who loses, regardless of context. In the “real world,” as he points out, one would expect a somewhat messier, qualified outcome, yet the obviousness of this zero-sum imagery underpins much of what is taken for granted when power is exercised over others in a hierarchical, top-down fashion.

The clue, perhaps, is in the instrumental language itself; when something is exercised “over” others it implies that power is located above the mainstream, at the apex of political organizations or economic enterprises. We owe it perhaps to Max Weber for this view of organizational domination, whereby those in authority attempt to order people’s lives through the bureaucratic character of rules and regulations which are more or less impartial. The removal of choice and the imposition of constraint lie at the heart of this process and institutional power is extended downwards through delegation with the attendant risk of losing authority or destabilizing the decision-making process. On this asymmetrical view of power then, effectiveness cannot be wholly guaranteed in advance and the pay-offs do not automatically sum to zero. Nonetheless, the zero-sum imagery holds, as does the spatial hierarchy of power. Weber’s legacy within geography is less clear than that
of Marx’s, but the more complex calculations of organizational power that he first outlined have left their mark, not least on those who have had to engage with the state’s territorial significance and the distribution of its authority.

Bob Jessop (2008), a contemporary political theorist, is one such figure whose work demonstrates a grasp of such complexity, although his account of the state’s instrumental use of power draws primarily from the Marxist tradition, in particular the writings of Nicos Poulantzas. For Jessop, the dispositional character of the state’s power is best spoken about in the plural, as a series of state capacities, not as a unitary subject in possession of preformed powers. On this view, the state is an ensemble of institutions made up of different interests with different capacities who influence and mediate the balance of class forces at large. The effectiveness of state power in this context is contingent upon the changing balance of political forces located both within and beyond the apparatus of the state itself. In place of a simple disposition or capacity to dominate, the political landscape is one of potential structural powers that may or may not be actualized depending upon the precise balance of forces in place.

If that sounds a little bit convoluted, that is precisely the message that Jessop wishes to convey. A crude instrumentalist approach is rejected in favor of a complex institutional system, one that nonetheless serves to reproduce capitalist social relations through the state’s ongoing political domination of society. If state power is institutionally mediated in such a complex, circuitous manner, however, it remains a hierarchical structure of potential powers, albeit embedded within a variety of “power centers.”

The importance of knowing where power is located is a constant in any instrumental treatment of power, Marxist-inspired or otherwise. One of the most influential treatments in this vein is David Harvey’s (2003) account of the workings of contemporary US power in The New Imperialism, in which he identifies two key axes, one political, the other economic. Taking his cue from Giovanni Arrighi, he outlines two logics of power, one territorially based, which involves the state as the main political actor orchestrating its powers to control the often highly charged landscapes in which capital accumulation takes place and a second capitalist logic predicated upon flows of economic power across territorial boundaries in the endless pursuit of capital accumulation. The two logics combine, yet each has a life of its own, one awkwardly fixed in territorial space, the other highly mobile, a fact which builds into the system the likelihood of antagonism and their volatility and unpredictability.

Political power, on this view, thus acts as the stabilizing force in the system, in much the same way as in Jessop’s analysis, as it works to balance the haphazard movements of capital and its aligned forces. For all its built-in tensions, however, power operates along familiar hierarchical lines with a Wall Street–Treasury–IMF complex situated at its apex. The concentration of capabilities at this one location tells you all that you need to know about the disposition of US power. Where the analysis departs from that mold, however, is through the recognition that the rest of the world is not so much under the command of this power center as “networked and successfully hooked into (and effectively ‘hooked on’ usually by way of credit arrangements) a structured framework of interlocking financial and governmental (including supranational) institutions” (Harvey 2003, 134).

Such slippage in the language of instrumental power is itself indicative of the troubling effect that geography can have upon more well-worn treatments of power. We return to such matters after first considering a different understanding of
power; one that focuses on power as a means of enablement rather than a capacity for domination and control.

Enabling power, or power to make things happen

If instrumental power represents the default position within geography, something that is adopted for want of an obvious alternative, enabling power has made its way into the discipline by a more roundabout route. The looser sense of the “power to” act can be spun out in a range of different directions, designed to secure mutually beneficial ends as much as far-flung goals of a more normative persuasion. Here, the clue is in the word itself – enabling – in that power can be made to “work” for a variety of ends in what can amount to a positive, rather than a zero-sum, game. As a means to an end, power as such does not have to serve any particular interest or be tied to practices of domination and control. It can be designed to further common purposes or to foster transformation, in so far as it can “make a difference” to eventual outcomes. That does not mean to say that such outcomes are always benign, however, only that they may be so.

With this more nebulous conception of power, it is harder not only to pin down, but also to locate. In contrast to an instrumental view of power, when power is conceived as a medium there are no readily identifiable concentrations of power, only a sense of how it is generated through the mobilization of collective or individual resources. On this view, it makes little sense to talk about “blocs” of power when the means itself can expand in line with the resources available or contract once collaborative, short-term goals have been achieved. Rather, it is sustained through patterns of association that bind people together in the pursuit of particular ends. As such, its geography is less centered and more dispersed over tracts of space and time, in line with the forms of social interaction generated.

It is perhaps not that surprising then that one distinctive twist to this account comes through the recognition that the mobilization and control of resources takes place through networks of social interaction. The work of Manuel Castells is probably among the best known for such an orientation. In Communication Power (2011), drawing upon his earlier account of networks as means to overcome the barriers of distance to secure outcomes, he focuses explicitly upon what he calls “network-making power”; that is, the ability to program the content of networks in line with specific goals as well as ensure a unity of purpose through the control of the points where different networks connect. Programmers and switchers are said to shape the communication content of networks that connect the local with the global and give them extensive reach. Different types of networks – political, financial, military – interact, although each is programmed to achieve its specific goals across a range of interfaces. This understanding of power networks, however, only really comes to fruition in the detailed treatment it receives at the hands of Michael Mann.

In his magisterial four-volume work on the sources of social power, he sets out a notion of power resources as something which, historically, have been organized and extended over space in loose or tightly orchestrated ways to achieve identifiable goals. The expansion of power and its consolidation are said to take their shape from a series of networks organized over space which overlap one another, of which the most significant in terms of power resources are economic, ideological, political, and military. Differences in the makeup and dynamism between the networks ensure that they reach out across
space in different ways and to varying extents, but the most effective networked practices, for Mann, are those which blend different forms of organizational reach. In his account of the makings of power in the twenty-first century (Mann 2011), political relations are presumed to channel and institutionalize each of the other power resources, although in practice he details how powers are often poorly organized, uneven and incoherent, especially when it comes to the manner in which US power has been extended across the globe in the contemporary period. Nonetheless, power for Mann is the product of pooled resources that are used to fuse and modify patterns of interaction to achieve far-flung goals.

As a fluid medium, power in this pooled sense has also been interpreted in at least two different ways to give a more associational spin to networked power. The first draws inspiration from actor-network theory, principally the contributions of Bruno Latour (2005) and Michel Callon (1998), and the second, from a different angle, is rooted in the mutuality of Hannah Arendt’s thinking (1958).

In the former set of hands, the “work” of the network is stressed; that is, the “power to” bridge, broker, and connect people and things together to bring about some form of alignment. The ability to forge associations by enrolling, translating, and channeling others into networks of meaning in such a way that they extend and reproduce themselves through space and time represents a mediated exercise of power; one where distances are overcome by the successive enrolment of others to form what amounts to a single will across the network. Leverage, on this account, is achieved through association rather than simply domination. The same associational tone is evident in Arendt’s understanding of power, but for her the formation of a common will is less something forged and more the product of mutual action, of people acting together to pursue common, agreed goals. The powers of association, on this interpretation, are thus something that is experienced through other people. As such, it is more about exercising power with others where the power to act is empowering in and of itself.

Power, on this view, has a positive side, one that can open up possibilities rather than simply close them down. This positive side to power was also pointed out by Michel Foucault (1984), where the emphasis upon people being free to govern themselves works through a kind of normalizing force. On this view, there are no direct constraints on behavior, no overt sanctions, only indirect techniques of regulation through which people freely fashion their sense of self. Subjects are constituted by the spacing and timing of their own activities as much as they are by those seeking to influence their behavior. As such, their conduct is said to be shaped as much by what they absorb and imagine the “truth” of their circumstances to be as it is by the spatial layout, distribution, and organization of their surroundings.

Foucault’s account of dispersed government and his later concerns with biopolitics and liberalism have had a significant influence on geographers, most notably in the ongoing body of work which falls under the heading of critical geopolitics and, more generally, through those more concerned with the technologies and rationalities of government. The former, although less concerned with the relationship between politics and space, has moved beyond a concern with the power/knowledge of statecraft to embrace a wider cultural and political agenda, while the latter has found a renewed significance with the publication of Foucault’s lecture series. On both counts, though, the power that is brought to bear upon people’s actions is often more about closing down rather than opening up possibilities. It is at this point that the “power to” provoke can fold over into the “power over” others. Such
ambiguity is plainly evident in the writings of Foucault, but when geographers introduce space and territory more centrally into the analysis the notion of how power actually works out in practice seems to become more troubled.

**Powerful geographies**

It would be false to say that instrumental and enabling notions of power have developed without taking geography into consideration, but for the most part the actors involved have been sketched against a given spatial backdrop. Even Harvey’s account of US power has an implicit geometry that rarely troubles the operation of power itself and makes for easy distributions. Since the publication of John Agnew’s seminal work on “the territorial trap” (1994), however, which highlighted the strain between how state power is practiced and the inability of bounded territories to contain the relationships involved, it has been harder to ignore the fact that spatiality itself can make a difference. Indeed, there is now a greater willingness among geographers to problematize power and spatiality, and also to question the place of instrumental power as the default option.

**Territory in question**

Neil Brenner (2004), following Bob Jessop, is perhaps the most consistent exponent of the view that state power has been liberated from the idea of containment and contiguity, in terms of units of spatial authority seemingly piled one on top of the other. States increasingly face pressures from both “above” and “below,” which have resulted in the displacement of their authority. Administrative and regulatory functions have, as it were, moved “upwards, downwards, and sideways” (Jessop 2008, 196) as national states find themselves destabilized from above by the growth of supranational institutions and undermined from below by the devolution and decentralization of decision-making powers to subnational institutions. On this view, the larger number of institutional interests on the political landscape, in particular the multiple sites of authority, from numerous quangos and private agencies to local administrative units, have undermined the notion that the central state apparatus is the prime locus of political power. In place of the conventional assumption that the central state is the only actor of any real import, the institutional playing field is now shared with nongovernmental organizations, multinational enterprises, and other supranational as well as interstate organizations. At any one point in time, the relative significance of each scale may change in that the power can be scaled up or down through the different units of spatial authority both transnational and subnational. This is an altogether different arrangement of powers from one that considers regulatory or devolved authority as something which is slotted into pregiven spaces, be it local, urban, regional, or national. In recognizing that space is not simply “filled out” by power relationships or acts merely as a container within which things happen, the geography itself becomes pliable, open to manipulation and modification. The lines of authority, as much as where the edges are drawn, and the scales of regulation, as much where their extension halts, are themselves the subject of political construction, relative rather than absolute in their geographical form. Multicentric, multiform, and multiscale are among the descriptors used to capture this new found spatial complexity as the coordinates of power lose their territorial fixity.

An equally nuanced use of the notion of territory is to be found in Stuart Elden’s
Terror and Territory: The Spatial Extent of Sovereignty, which attempts to work through why territory matters in an age when boundaries have not only become more porous, but state territorial sovereignty itself is increasingly under threat. Territory, or more specifically the connection between the state and its territory, is for him one of the key sites of struggle in the contemporary geopolitical moment. In line with Brenner, territory is not seen as a static backdrop with fixed coordinates, but as an arena through which particular geographies of fear, threat, and division are played out. Elden’s prime concern is with territorial integrity: the spatial extent of a state’s sovereignty, that is, its effective political control over a given territory. Such integrity, he argues, has been fractured, as more or less failed states have had their sovereignty undermined by the international community in the name of security and the “war on terror.” Yet, at the same time, that very same community has worked hard to defend territorial integrity in the interest of preserving stability and the right of states to exercise power legitimately within their borders. On the one hand, the sovereignty of states has been drawn into question when they are deemed a threat to the vital interest of others, yet, on the other hand, the spatial extent of their powers has been defended and their borders deemed inviolable.

The image is one of territorial political actors, the more dominant of which extend their powers over the territory of others when “global” danger threatens. There is no pre-giveness to territorial power and, as with Brenner, territory is conceived as an achievement, something that is actively produced. Unlike Brenner, however, there is less of a preoccupation with the redrawing of bounded spaces, of the need to continuously recalibrate spatial units of authority or, in Elden’s case, territorial boundaries. Rather, the focus is more about the ability of certain powerful states to curb the powers of other states elsewhere and, in so doing, throw into sharp relief the making and remaking of territories.

A similar concern with the making of territory is at the heart of Saskia Sassen’s (2006) Territory, Authority, Rights: From Medieval to Global Assemblages. For her, the mix of spaces and times that inhabit the national setting defines a new, overlapping geography of power within which different actors – state authorities and jurisdictional agencies, corporate firms and supranational institution, civil society movements, and transnational activists – jostle, co-exist, and interrupt one another to gain advantage. As she sees it, the disembedding of state functions and the growing authority of nonstate actors in the public realm that Brenner also describes opens up spaces within the formally exclusive territory of nation-states where global firms are increasingly subject to extraterritorial forms of authority. Parts of global cities like New York and London, for instance, predominantly their corporate finance sectors, are seen to be partially detached from the geographically circumscribed authority of the state. This, however, is not a geography where some parts of national territory are said to hover or float above it; rather, such economic spaces remain firmly embedded in national territories, yet are subject to wider geographical authorities when it comes to regulation and control.

The detachment of authority from territory also brings into question the idea that borders are always at the edges of any given territory. For Sassen, such is clearly not the case, as borders are not so much redrawn as re-embedded within national territory, in line with the form of authority under consideration. The disruption to a fixed geometry that such insights presuppose, however, does not lead her to problematize the notion of extraterritoriality, nor question
instrumental power, in particular authority, as the only relation that really matters.

Far-reaching power

Extraterritorial power can be translated literally as an addition to a state’s territorial powers, but to do so offers little insight as to how such spatial reach is obtained. For geographers more concerned with such questions, the ability of the state or any institution for that matter, to exercise power at-a-distance is more often than not a work of associational or networked power, although an alternative immanent form of reach is evident in the work of Hardt and Negri, which had an impact within geography. Their debt to Foucault (and Deleuze) is evident from the manner in which power is said to take its shape from the simple act of people living out their lives in circumstances that mold their behavior and actions. Unlike associational or networked accounts of power, however, the mediated nature of reach is largely absent when immanence comes to the fore.

For that, we have to turn to the work of Joe Painter (2006) who has shown how everyday life is suffused by state practices in a rather mundane, prosaic manner. Rather than try to identify the actions of the state from above, he argues that, following Timothy Mitchell, there is an element of reification to the power of the state as something separate from civil society. Both the state’s power and its territorial base, in his view, are best understood as an effect of networked practices within and outside of state institutions. In line with Latour and Callon, the “work” of the bureaucratic apparatus relies, in the main, upon routine certification, registration, and licensing practices that reach directly into people’s daily lives and serve to both shape as well as enable their behavior. The enabling side to such practices is clearly in direct contrast to structuralist accounts of state power, exemplified in the work of Jessop.

The focus upon state practices as ordinary, often tending to pass unnoticed, draws attention to the agency involved and leads quite naturally to accounts of state power which point up its hegemonic qualities. Among the most prominent within geography is Agnew’s (2005) Hegemony: The New Shape of Global Power, which is an attempt to show just how much state power relies upon both consent and cooperation. On this view, the ability to persuade and induce is as much in evidence as coercion and constraint. Such work chimes with Joseph Nye’s influential (2004) Soft Power, where the stress upon cultural as well as political values as a source of attraction and desire for others is said to form part of an exercise in molding people’s expectations about what it is that they want and aspire to. The eventual outcome of such practices may be instrumental in shape, favoring one set of interests at the expense of another, but the routine nature of their exercise relies upon people buying into those interests rather than having them imposed upon them. Indeed, the employment of possibly more artful practices by state agencies which may mask their actual intent draws attention to the slippage that can take place between instrumental and enabling conceptions of power, where the gains of a cultural positive-sum game, for instance, may turn out to be illusory.

Such hegemonic accounts tend to rest upon the assumption that power is capable of extensive spatial reach; that is, an ability to permeate daily life in such ways that people bring themselves to order. Painter, however, is hinting that power is more than simply an extensive force. For him, the ability of the state to become present in the here and now of daily life suggests a more intensive reach where the barriers of physical distance are not at issue. When the “reach of government” is understood as intensive, such
actions are said to be topological, in that the reach of government bodies enables them to make their presence felt in more or less pervasive ways by cutting across proximity and distance (Allen 2003). It is not just the reach of the state that can be viewed in this manner, however, so too can the actions of far-flung corporations in making their presence felt at close quarters, or the ability with which social movements are able to fold distant harms into local campaigns. Such power-topologies are said to transcend a landscape of fixed distances and well-defined proximities and pose a challenge to conventional territorial accounts of geography and power.

Conclusion

The two main readings of power, instrumental and enabling, have had an uneven yet influential presence across the social sciences. Among geographers, they have been adopted and troubled in roughly equal measure. The subjection of power to a spatial agenda, whether that be through the production of territory, the mobilization of networks, or through a more topological register have, in their own ways, brought conventional accounts of power into question. But the challenge of geography today is not only spatial, the natural or environmental also has a part to play in the figure of the more-than-human. The inspiration for thinking more broadly about the powers of life, rather than simply power over life, largely comes from Foucault’s biopolitical critique, but it is extended further when the question of power relates to the powers in and of things. How geography engages with the provocations of vital materialism, the powers of the nonhuman, especially the powerful physical forces that work themselves out on a planetary scale, has the potential to trouble mainstream accounts of power even further.

Precarious work

Kendra Strauss
Simon Fraser University, Canada

Precarious work (also called precarious employment) is a relatively recent addition to the conceptual toolkit of economic and labor geographers. Developed by labor scholars to describe what was understood, conceptually and empirically, as a significant shift in the nature of employment in the advanced industrial economies after the 1970s, the concept encompasses several processes and dimensions. These include the rise of temporary and intermediated forms of employment, the changing nature and allocation of social and economic risks, the feminization of paid work, and the experiences of migrant workers at the “bottom end” of the labor market. In this sense research on precarious work in other disciplines overlaps with evolving preoccupations of labor geographers (Coe 2013) and economic geographers interested in subcontracted and temporary work and migrant labor (McDowell, Batnitzky, and Dyer 2009; Wills et al. 2009). Not solely confined to low-paid work, however, geographers have also identified precarious employment relations among workers in the creative and knowledge economies (see e.g., Hracs and Leslie 2014; Sanchez-Moral, Mendez, and Arellano 2014).

At the same time, work by geographers such as Louise Waite, Gill Valentine, and Hannah Lewis (2014) has explored the precarity experienced by asylum seekers and refugees in the United Kingdom across multiple dimensions. Here, precarious work – in some cases forced labor – interacts with precarious legal status in a more generalized way. This approach aligns with broader currents in political and cultural geography, which build on theorizations of the condition of precarity and which understand vulnerability as socially and politically constructed and combine different scales of analysis – including the microscale of the body.

The concept of precarious work

Precarious work is a concept that has developed to describe changes in labor markets, especially but not exclusively in the Global North, from the late 1970s. The development of the notion of precarious work aligns with a broader set of debates about political economic and social shifts described by neoliberalism, post-Fordism, and the rise of the service economy. A diverse range of geographers have written about these trends, with work by inter alia David Harvey, Jamie Peck, Ash Amin, Allen J. Scott, and Doreen Massey examining the changing organization of production, the globalization of labor markets, deindustrialization, and the forms of technological change associated with the knowledge economy. In relation to the last mentioned, economic geographers have examined the expansion of high tech industries and associated forms of geographical concentration (agglomeration, clusters) with ambivalent outcomes for labor; the extensification of production has been explored via the frameworks of global value or commodity chains, and global production networks.

The picture that has emerged in many economies is one of increasing polarization.
between highly remunerated workers in professional services at the top end of the labor market, and low-paid insecure conditions for workers in food services, hospitality, agriculture, care, and domestic work at the “bottom end.” Associated with the creation of “flexible” labor markets, the political economic shifts that have underpinned this polarization include legal and regulatory changes to systems of labor law, employment standards, and occupational welfare (pensions, unemployment insurance). These shifts have in many cases been designed to reduce what orthodox economists refer to as rigidities: the protections (e.g., associated with hiring and firing workers) that, in their school of thought, interfere with the efficient functioning of labor markets. The abandonment after the 1970s, with Keynesian macro-economic policy, of the goal of full employment also allowed governments to deal in very different discursive and policy terms with the unemployment created by industrial restructuring and deindustrialization.

These trends have produced a hollowing out of the occupational structure of labor markets, with formerly middle-income jobs – from unionized blue collar to clerical and lower level white-collar work – becoming either professionalized or more precarious. Privatization and subcontracting in public service professions like health and education have reduced pay, benefits, and security for those in previously solid middle-class jobs. While these trends have been uneven and contested, like other dimensions of neoliberal de- and re-regulation, labor market insecurity and polarization have increased in almost all countries, including the formerly social democratic Scandinavian states – albeit from a much lower level. There is also variability within what Gosta Esping-Anderson described as the three worlds of welfare capitalism, so countries with some similar characteristics (like Sweden and Norway) have taken different paths to labor market reform. Declining unionization in many countries has compounded, and been exacerbated by, these changes, and in the Global South structural adjustment policies have also been significant. Labor geographers like Andrew Herod, Andrew Cumbers, and Danny Mackinnon have explored these trends in relation to traditional unionized sectors, emphasizing that workers have not been passive victims of the processes that have increased precariousness for many.

Yet, despite many common themes in these accounts of political economic change, the idea of precarious work is not a straightforward one. As Linda McDowell and Susan Christopherson (2009) have noted, precariousness and precarity have different meanings, grounded in different intellectual and political genealogies. If the former is associated with the political economy of work and employment, the latter is grounded more directly in Marxist approaches and political mobilizations in France (around the concept of precarité) and Italy (the San Pracario movement). In France, the idea of precarity was first associated with Pierre Bourdieu’s work on contingent and nonstandard forms of employment. In France and Italy, however, and arguably in Europe more broadly, an initial focus on wage work and employment shifted to a wider political concern with, and mobilization around, generalized conditions of insecurity across – and connecting – the domains of production and social reproduction. Some commentators have noted that direct political action under the rubric of precarity seems to have peaked in countries like Italy around 2004–2005, while academic work on precarity and precariousness (still relatively rare at that time) has since proliferated.

In the Anglo-American nations, however, explorations of precariousness have been more directly associated with academic research on the changing nature of employment in the
post-Fordist period. The concept of precarious work emerged out of research by theorists of labor market segmentation and “nonstandard” work in disciplines such as sociology, political science, and feminist legal studies. Influential studies by Leah Vosko, Judy Fudge, and Arne Kallenberg built on earlier research by Gerry Rodgers that identified four key dimensions that could indicate insecurity in an employment relation, and hence the condition of precarious work (also called by Vosko the “precarious employment relationship”). These are uncertainty about the continuation of employment, lack of control over the labor process (related to the presence or absence of employee voice), the absence of regulatory protection, and low pay. Rodgers emphasized, however, that the concept of precarious work encompasses more than just the form of employment and recognizes wider conditions of insecurity including a lack of legal and union protection and forms of social and economic vulnerability. This approach is related to theories and studies of labor market segmentation and forms of social stratification which, like Jamie Peck’s work in the mid-1990s, also built on earlier models, for example, of the dual labor market with primary and secondary sectors.

A key focus of theorizations of precarious work, however, has been the decline of the standard employment relationship (SER) and related standard employment contract in the advanced industrial economies in the Global North. The SER was understood as representing, in a sense, the mirror image of the conditions of insecurity identified by Rodgers. It encompassed full-time, relatively secure, continuous, direct employment, often with a single employer over the life course, and was associated with both industrial and white-collar jobs in the “golden age” of industrial citizenship after World War II. It was also associated with both the male breadwinner model and family wage, and with the social wage (into which occupational welfare benefits like health, disability and unemployment insurance, and pensions were enfolded). As feminists and critical race scholars have long highlighted, the SER was always only a reality for some: women, workers of color, and immigrants were fully or partially excluded from its protections, which in any case varied spatially and temporally. Others, like Neilson and Rossiter (2008), argue that Fordism’s “golden age” was not only partial but also exceptional and that capitalism has always been characterized by precarious work. What labor market restructuring, flexibilization, and re-regulation in the post-Fordist (or neoliberal) period thus represent, according to them, is a return to longer term historical trends.

In terms of reproduction, too, it has been argued that the male breadwinner model associated with the SER was not only normative and aspirational for many (rather than descriptive), but also exceptional. Certainly, changes in relations and institutions of societal reproduction have also occurred in the period that has seen the rise (or resurgence) of precarious employment. On one hand, women’s increasing educational attainment and entry into the labor market in large numbers has been of huge significance in relation to the changing composition of the workforce over the last half-century. The composition of the household, from falling birthrates to increased divorce, unmarried co-habitation, and single parenthood, has changed enormously. Thus wage stagnation in the middle and lower income brackets in, for example, the United States has been offset by the rise of the dual-earner household. On the other hand, however, state decommodification of services like childcare, education, and health has been impacted by welfare state retrenchment in relation to what feminist political economists have characterized as the re-privatization of
social reproduction. As women often depend upon these services and sectors for support and paid employment, such changes have gendered implications for both paid and unpaid work, making life more precarious across these dimensions. In Asia and Latin America, capital has sought the “nimble fingers” of young women for its new manufacturing workforce, while states like the Philippines and Indonesia depend on remittances from women who migrate to perform domestic and care work in the homes of middle-class and wealthy women.

Thus not all workers have experienced the trend toward increased precarious work in the same way, or to the same extent, since the late 1970s. Vosko, in her theorization of precarious work, highlighted the importance of social location and social context. She defined precarious employment as “work for remuneration characterized by uncertainty, low income, limited social benefits, and statutory entitlements,” but went on to argue that precarious employment is shaped by the relationship between employment status, form of employment, dimensions of labor market insecurity, and social context and social location (Vosko 2010, 2). While social context signifies characteristics like occupation, industry, and geographical location, social location relates to the interaction of social relations and categories, like gender, with legal and political categories, like citizenship. From a geographical perspective, social location has distinctly spatial and scalar dimensions. The role of place in the social construction of local labor markets, the interrelationship of spaces and places of work (and home) through varying and evolving types of linkages, and the increasingly “glocal” nature of economic activity all relate to the highly uneven nature of the restructuring of employment relations. At the same time these processes shape, and are shaped by, the social construction of categories of difference like gender, race, and class.

Much work on precarious employment thus overlaps with and incorporates concepts like feminization: the idea that “mainstream” employment relations increasingly resemble conditions in the secondary sector in general, and women’s employment in particular. Part-time, temporary, contract, and agency work do not figure in the SER. Historically these forms of employment were associated with women and racialized workers who, because of caring responsibilities or their subordinate labor market position, were unable to secure full-time permanent wage work. Geographical research, like the work of Susan Hanson and Geraldine Pratt, has shown both how the spatial distribution of home and work sites affect women’s choices and opportunities for paid employment, and how (in Pratt’s work on live-in caregivers in Canada) middle-class women’s labor market participation often depends on the availability of low-paid racialized domestic workers to “replace” their labor in the home. Subordinate labor market position and caring responsibilities are thus often connected, but subordination is not uniform among women. Many women of color held down full-time jobs doing paid reproductive labor in homes and public institutions, as well as having caring responsibilities in their own households — which often went unrecognized in accounts of women’s work.

Vosko’s argument was that the kinds of insecure employment conditions experienced by women temporary agency workers in clerical occupations, previously the exception, are coming to look more like the norm. Like geographers including Jamie Peck, Nik Theodore, Neil Coe, and Kevin Ward, Vosko is particularly interested in labor market intermediaries and how they function within labor markets. Intermediaries include temporary employment agencies, labor brokers, labor dispatch operators and labor contractors. While temporary agency
work was previously limited in its scope, and confined to the secondary sector (pink collar clerical work in Canada was the example used by Vosko, but other sectors like agriculture are also characterized by the presence of labor brokers), it has now permeated all sectors. Heightened precariousness in employment is directly related to increased intermediation in the employment relation. In other words, although historically particular to marginalized groups, many workers are no longer hired directly by the firm or individual on whose worksite they labor. Moreover, such intermediated employment relations often involve short-term and/or temporary job placements, fluctuating and irregular hours of work, lower levels of pay than those earned by permanent employees in the same job, and low levels of job security (Strauss and Fudge 2014). Again, however, not all workers experience precariousness associated with intermediation in the same ways. Higher skilled workers in sectors like IT, while precarious across several domains, need to be distinguished from workers in low-wage occupations with little mobility, power, or discretion in the employment relation. However, Peck and Theodore (2007) have demonstrated that labor intermediaries now play a key role in providing numerical flexibility not only at the firm level, but in the macro-context of overall labor market adjustment during periods of crisis and recession. Temporary workers are increasingly the buffer that firms and sectors use to smooth business cycle adjustments.

Two additional trends related to the rise of precarious work are political-legal and institutional in nature: changing regimes of labor law and employment regulation, and changing immigration regimes. Kallenberg has argued that the decline of the SER indicates the decline of “good jobs” relative to “bad jobs.” The prevalence of “bad jobs” in the US labor market is associated with changing labor market regulation, which in turn relates to the changing balance of employer and employee power. These trends are uneven; research has highlighted polarization in incomes and access of occupational benefits, but less of a direct shift to insecure job tenure. These outcomes, however, need to be put in the context of an already highly flexible labor market. In parts of Europe, where employment protections (so-called labor market rigidities) are stronger, the proportion of temporary workers is higher but so are the regulations protecting core workers.

In a more generalized sense, the norms underpinning both employment policies and protections, and related welfare models, are shifting to what Dyer, McDowell, and Batnitzky (2011) call the “adult worker” model. This means that the insecurity associated with precarious work overlaps with changing norms that cast both men and women, regardless of their caring responsibilities, as labor market participants. Changes to legal and regulatory frameworks governing employment thus emphasize procedural equality (equality of opportunity), and greater flexibility, while simultaneously rolling back substantive protections in the areas of job security, health and safety, and right to collective action. Research in Canada, for example, has shown how employment standard regimes have shifted toward complaint driven models with little proactive enforcement (Gellatly et al. 2011). Workfare regimes increasingly require people to engage in the labor market in return for welfare benefits, at the same time that the spread of precarious work means that paid employment provides less security and social mobility than before. For some workers, the discourse of work–life balance has produced advances in the ability to (at least request) flexible working arrangements, but such benefits are often available only to higher paid and higher skilled workers, while low-paid workers may
precarious work

struggle with too much flexibility, as in the case of zero hours contracts in the United Kingdom.

Finally, precarious work is increasingly associated with changing migration dynamics in many labor markets. Bridget Anderson, a migration scholar, has noted the ways in which governments use immigration controls like a tap to regulate the flow of labor and control the type of worker that can enter the local labor “pool” – and under what conditions. Points-based systems pioneered in countries like Canada are increasingly being adopted elsewhere to establish channels of entry for skilled workers. At the same time, temporary migration (guest worker) programs often attach highly restrictive conditions to “low-skilled” workers who are granted visas to work in areas such as domestic service, agriculture, hospitality, and food services. As mentioned above, migration makes “work–life balance” possible for many in the Global North, but migrants and racialized workers are employed in the most flexible and low-paid jobs of the postindustrial economy. Precarious employment conditions thus create a fragile work–life balance for many migrants, especially those who leave families behind to migrate with no route to settlement and family reunion in the host country.

Scholars have thus coined the term “precarious migrant status” to describe the condition of migrants whose precariousness is constructed in and through the legal and political regimes that structure their entry, and continued presence, in “host” countries. They argue that, in relation to migration status, dichotomous approaches (legal–illegal) do not capture variable forms of illegality and irregularity, therefore precarious status helps draw attention to blurred boundaries between citizenship and illegality where the policy context (alliances between the state and capital) create pathways to precariousness (Goldring, Berinstein, and Bernhard 2009).

Precarious migrant status again signals the ways in which precarious work is mediated by institutional contexts beyond the labor market and economy proper.

Much of the research on precarious work, tied to the concept of the SER, has focused on the Global North. It remains an open question the extent to which the concept can be profitably deployed in contexts where informalit is the norm. In countries like India, for example, the vast majority of the population has never had access to a bundle of employment rights and conditions resembling the standard employment relationship. Yet at the same time, processes of casualization, outsourcing, and subcontracting in those parts of the public and private sectors where formal employment had been institutionalized do suggest parallels with forms of labor market restructuring in the advanced industrial economies. Both local and transnational firms and factions of capital are identified with these processes, as in the Global North. In China, the destruction of the “iron rice bowl” – a set of rights to employment and occupational welfare benefits associated with urban, mostly industrial employment in state enterprises – has created new groups of precarious workers. Many workers in formerly state-owned enterprises are now subcontracted by labor dispatch companies. Internal migrants from rural areas are, because of the hukou system of household registration, subject to precarious employment conditions that are compounded by a lack of access (and rights) to services like housing and healthcare.

Similarities and differences between labor market realities in different places have left theorists searching for ways of linking up processes that share common characteristics but play out in a variety of ways in different places and at different scales. European policymakers have sought to extend Scandinavian and Dutch models of “flexi-curity” to create social safety
nets (encompassing unemployment benefits, but also robust training and skills upgrading programs) to facilitate labor market flexibility and mobility in ways that do not create social and economic insecurity. Applied outside the relatively generous welfare states in which they were first designed, however, flexi-curity policies have been critiqued for emphasizing flexibility over security. At the other end of the spectrum Guy Standing, formerly of the International Labour Organisation (ILO), has coined the term precariat to describe a “new class” of workers defined not by traditional class relations but by their shared experience of precarious employment. Standing’s concept of the precariat is broad enough to encompass highly skilled and well-paid workers on temporary contracts in the creative industries, migrant workers doing the “dirty, dangerous, and degrading” labor at the bottom end of the labor market in advanced industrial economies, and workers in the informal sector in the Global South (from rag pickers in India to petty traders in Lagos to migrant construction workers in Dubai). This opens Standing up to the critique that describing the precariat as a class ignores the very limited points of intersection of the positions and experiences of such diverse workers – or, at the very least, downplays the differences in labor market power, income, and social and cultural context among them. Academics remain divided on its utility and the concept has been little discussed in geography despite garnering widespread attention in other disciplines and beyond academia.

Precarity and precarious life

It is in relation to geographies of migration, and political geography, that the concepts of precarious work come into conversation with concepts of precarity and precarious life. Drawing heavily on the work of the feminist philosopher and gender theorist Judith Butler, geographers have utilized her articulation of a social ontology of precarity to explore how bodies and communities experience precariousness across a range of dimensions. Butler’s notion of precarity draws attention to the forms of mutual dependency that are the condition of human life. In Butler’s conceptualization we all depend on each other in various ways, but precarity is also unequally distributed: certain populations are rendered precarious through the allocation of social, economic, and political risks. Waite, for example, examined political, social, and spatial dimensions of precarity in the lives of asylum seekers and refugees in the United Kingdom for whom precarious work (asylum seekers are prevented from seeking formal paid work) interlocks with generalized precarity (Waite 2009). Asylum seekers in particular endure “hyper-precarious” conditions because of their precarious legal status and vulnerability to precarious, and sometimes unfree, conditions of work in their desperation to secure the conditions of everyday life.

Another theoretical influence on geographers theorizing precarity is Michel Foucault. Nancy Ettlinger (2007) argued for an expansive conception across time and space, using Foucault’s concepts of biopower and governmentality to examine how the US government’s attempts to create illusions of security and certainty after the attacks of September 11, 2001, instead recreated and concentrated precarity in certain populations. This approach has resonances with other work in political geography on vulnerability and insecurity, including at the scale of the body. Feminist geopolitics have long argued for understandings of the body as a gendered, racialized, and classed site through which norms of nationhood, citizenship, and exclusion are rendered visible. The body is likewise the field through
which imperatives of capitalist accumulation in the organization of the labor process are materialized and labor control exercised.

The concepts of precarious work and precarity thus resonate, but are also informed by quite different intellectual and political traditions, especially in the Anglo-American world. In geography, in recent work on migrants, asylum seekers, and refugees, political economic, and political philosophical traditions are being explored in ways that amplify those resonances, exploring precariousness across economic, sociocultural, and political dimensions. These approaches are in keeping with geographical traditions of social constructivism, for example, in understandings of scale and of labor markets, but also with poststructuralist-influenced approaches to ontologies of vulnerability and insecurity. At the same time, political economic understandings of precarious work remain important in relation to epistemologies of labor market change, new geographies of paid and unpaid work, and economic and social polarization in increasingly unequal societies.

Precipitation describes hydrometeors that fall from the Earth’s atmosphere to its surface (American Meteorological Society 2012). Rain, snow, sleet, glaze, and hail are all common forms of precipitation. Often the general term is used because it can be difficult differentiating between the liquid and solid phases of water when making forecasts or remote sensing observations. The field of “precipitation research” can be divided into four main themes: precipitation physics, quantitative precipitation estimation (QPE), quantitative precipitation forecasting (QPF), and the climatology of precipitation.

Precipitation physics

Not all clouds form precipitation, which is not surprising considering millions of cloud droplets must somehow coalesce to form a raindrop. For clouds that are entirely above freezing (>0°C), known as warm clouds, precipitation formation occurs through the collision-coalescence process. Large cloud droplets, having a greater terminal fall speed, collect small cloud droplets much like a bulldozer. The efficiency of this process varies. Clouds with a diversity of droplet radii and strong vertical winds will be more likely to form precipitation. However, collision is also limited by small droplets being repelled by the airstream around large droplets. Another process aids collision-coalescence in clouds that contain ice crystals (cold clouds). The “ice crystal theory” or “Bergeron theory” was proposed in a series of papers by Wegener (1911), Bergeron (1935), and Findeisen (1938). It states that when ice crystals and supercooled (liquid below freezing) cloud droplets coexist, the deposition phase change will overwhelm condensation and the ice crystals will grow at the expense of the liquid droplets. However, this vapor deposition mechanism depends on the humidity of the atmosphere, and in many cases both ice crystals and supercooled water droplets will grow or shrink simultaneously (Korolev 2007).

Further growth is achieved through accretion, where supercooled droplets freeze onto ice crystals to form graupel (small snow pellets), or aggregation, where ice crystals clump together to form large snowflakes. These larger hydrometeors precipitate but will often melt into raindrops, where the collision-coalescence process takes over. The melting at the 0°C isotherm in the atmosphere is clearly evidenced by large reflectances within vertical profiling radar images, the so-called bright band.

In a cold cloud, the type of precipitation that eventually reaches the ground depends largely on the vertical temperature profile. Snow falls if the atmosphere is below freezing at all levels. All other precipitation types go through the melting process. If the atmosphere is sufficiently warm rain falls. However, sometimes graupel will circulate within a thunderstorm cloud sustained by strong updrafts. The graupel will grow when it is below freezing, as supercooled droplets freeze on the exterior, or when it is above freezing, when the pores of the ice stone soak up liquid water like a sponge. When the hydrometeor is sufficiently heavy or enters a region of downdrafts, it will...
fall as hail. Detailed physics on hailstone growth can be found elsewhere (List 2014a, 2014b).

Near the surface, raindrops will freeze and become ice (sleet) if there is a deep enough layer of below-freezing temperatures. Glaze or freezing rain requires a strong temperature change close to the surface, with temperatures dropping quickly to well below freezing. In this case rain will become supercooled and freeze upon impact with the ground. Sleet and glaze can lead to treacherous driving conditions and the riming of ice can down trees and power lines. These societal hazards motivate the forecasting of winter precipitation types. However, predicting the temperature profile of the lower troposphere remains a significant challenge.

**Quantitative precipitation estimation**

Precipitation is easy to measure; the earliest records can be traced back to India in the fourth century BCE (Strangeways 2010). All that is necessary is a container to collect precipitation. Rain gauges have become more sophisticated over time, including the popular automated tipping bucket gauge. Rain or melted snow enters a collection funnel and is directed into a seesaw apparatus. A cup at one end of the seesaw is filled (usually 0.01 inch or 0.25 mm) and then tips under the weight of the water, pivoting the second cup upward to collect more precipitation. Each “tip” is automatically recorded. Other gauges measure the size distribution and fall speed of precipitation (called distrometers); they are useful for understanding the microphysical processes involved and can distinguish among different types of precipitation.

Paradoxically, even though precipitation is easy to measure, it is very difficult to adequately quantify the total amount falling from any particular cloud or storm. This is due to precipitation being highly variable in time and space. Precipitation collected in one gauge is not necessarily representative of neighboring areas and depends on storm motion and size, and moisture flux (Hendrick and Comer 1970). This issue has implications in hydrology and has led to concerted efforts in deploying new rain gauges (e.g., The Community Collaborative Rain, Hail, and Snow Network), compiling existing rain gauge information (e.g., The Global Precipitation Climatology Centre), and data rescue operations. In addition, meteorologists have turned to the development of remote sensing estimates of precipitation and research in quantitative precipitation estimation (QPE).

Radar is one means for estimating precipitation. Microwave pulses are emitted from a weather radar. When a radiation pulse intercepts a hydrometeor, it reflects back to the radar dish. After correcting for range and calibrating the equipment, the strength of the reflectance value (Z) can be converted to the intensity of rainfall (R). Very large reflectances are associated with hail, but otherwise scientists have developed empirical “Z–R” curves to estimate rain rates. The Z–R curves continue to be refined by relating echoes to physical measurements of rainfall from gauges.

Satellites can also infer precipitation at the ground by sensing radiation coming from the atmosphere. Infrared radiation or “thermal energy” is detected from cloud tops. The lower the infrared temperature, the higher the cloud top must be in the atmosphere. Studies have shown that thick clouds produce more precipitation than low, thin clouds, and that the infrared technique is most appropriate in the tropics. Microwave energy is more directly related to precipitation as low-frequency microwave channels are emitted from liquid hydrometeors and high-frequency channels are scattered by solid hydrometeors within the cloud. The first
NASA mission dedicated to the estimation of precipitation from space was the tropical rainfall measuring mission (TRMM). The core satellite was launched in 1997 and included microwave sounders and the first space-based radar platform. The active microwave instrument greatly advanced QPE and paved the way for the follow-on global precipitation measurement (GPM) mission. The core satellite was launched on February 27, 2014, orbiting at a more inclined angle relative to TRMM, and thus covering the mid to high latitudes. Advances in instrumentation will allow for the retrieval of light rain and snow. The most exciting advances in QPE research are those that take advantage of all available estimates of rainfall – gauges, radar, and satellites – to produce accurate and timely global precipitation datasets.

Quantitative precipitation forecasting

One of the biggest forecasting challenges is correctly predicting precipitation amount. Therefore, in concert with QPE, quantitative precipitation forecasting (QPF) has evolved as an important research agenda item. Currently, precipitation forecasts are given as a percent chance of rain, or the probability that 0.01 inches (0.25 mm) of rain will fall somewhere in the forecast area during the period of forecast. Numerical models produce grid-scale precipitation as a function of hydrometeor size distributions over the cell. Subgrid-scale precipitation is parameterized through a number of convective schemes. In the United States, QPF is performed operationally by the Weather Prediction Center (WPC), formerly the Hydrometeorological Prediction Center. In general, QPF starts with an ensemble of model output and then determines which models are producing reasonable quantities of precipitation in time and space. Estimates are then extended into the future, after being adjusted manually by forecaster experience. QPF skill decreases with lead time, and is generally not performed past five days, but WPC verification shows greater skill compared to individual model runs.

Precipitation climatology

The distribution of plants, animals, and people on this planet (its habitability) is strongly dependent on amounts and extremes of precipitation. Precipitation is one component of the overall hydrologic cycle – comprised of water evaporating from oceans, rivers, and lakes, condensing into clouds, and then returning to the surface as precipitation. The exchange of precipitation in this cycle has recently been estimated at $486,000 \text{ km}^3 \text{ year}^{-1}$, with 23% falling over land and 77% over the oceans (Trenberth et al. 2007). Of course, the distribution of precipitation on the planet varies greatly (Figure 1). The wettest place on Earth according to the Guinness Book of World Records is Mawsynram, India, which receives an average of nearly 40 feet (12 m) of rain in a year, while some areas of Antarctica have not seen rain (or snow) in two million years.

The history of geography includes the classification of Earth’s climates based partly on precipitation. In fact, in most of the tropics the annual cycle is marked by variations in precipitation, and not temperature. To understand Earth’s precipitation climatology it is important to recognize that rainfall is primarily dependent upon two things: (i) a humidity source and (ii) uplift. The presence of moisture is insufficient if the atmosphere is stable or the air is subsiding. Some of the driest regions on Earth are over the oceans (Figure 1). Air rises because of orography, surface convergence, frontal boundaries, and convection. Some of the wettest (driest) areas in
the world are on the windward (leeward) sides of mountains. The intertropical convergence zone (ITCZ) is where the trade winds converge and coincide with copious clouds and precipitation (Figure 1). The South Atlantic Convergence Zone and the South Pacific Convergence Zone act in a similar way and are easily recognizable in global maps of rainfall (Figure 1). The east coasts of Asia and North America receive consistent amounts of rainfall throughout the year due to the baroclinic zone that naturally occurs between land and ocean. Extratropical storms generate and intensify in these coastal environments, and the tracks of storms across the North Pacific and Atlantic and encircling Antarctica can be identified in satellite-based precipitation climatologies (Figure 1). Finally, convection is a type of energy transfer in the atmosphere, where air rises from a warm surface. The Earth’s dominant convection centers are over the tropical landmasses of South America, Africa, and the Indonesian archipelago (Figure 1). Each of these areas receives abundant precipitation, thus supporting the biologically diverse rainforest ecosystem. However, convection can also lead to severe thunderstorms, hurricanes, and extreme rainfall. It was found in a recent study that the most intense thunderstorms are not located within the climatological convection centers or oceanic convergence zones but in semi-arid regions of the world such as northern Argentina and the south central United States (Zipser et al. 2006). The combination of insolation and a nearby water source lead to strong convective updrafts.

Earth’s precipitation climatology cannot be discussed without mentioning the monsoon. While “monsoon” is technically defined as a reversal of planetary-scale winds, monsoons are associated with copious amounts of rainfall. In particular, the southwest monsoon, when the
wind blows from the Indian Ocean into the Indian subcontinent, brings rains from May to October and is the main reason for the rainfall record in Mawsynram, mentioned earlier. The opposite northeast monsoon brings rains from November to April to portions of the southern hemisphere, such as northern Australia. Other areas of the world also experience monsoonal rains but to a lesser extent, such as West Africa and southwestern North America.

It should be noted that Earth’s precipitation climatology is not static, but can undergo variations on many timescales. Changes in expected rainfall can lead to societal disruption, with an excess of rain resulting in floods and too little rain leading to drought. So it is not surprising then that the rise and fall of civilizations have been linked to these extremes. People have attempted to mitigate the drought disaster by trying to control the weather, and make it rain. While history is teeming with stories of medicine men performing rain dances, modern techniques have primarily focused on cloud seeding, where aerosol particles, like silver iodide, are released at the top of clouds to initiate the growth of ice crystals and thus kick start the Bergeron precipitation process. However, cloud seeding has met with limited success and, thus, is not routinely practiced.

One of the biggest contributors in disrupting global precipitation patterns is the El Niño Southern Oscillation (ENSO). The periodic warming of the eastern equatorial Pacific disrupts the convection cell (also known as the Walker circulation) that would normally bring about abundant precipitation in the western Pacific (tied to the Indonesian convection center) and a deficit of precipitation in the eastern Pacific. During El Niño the most intense precipitation shifts eastward across the basin causing the western Pacific to dry out. The new distribution of rainfall affects the amount of latent heating in the atmosphere, which subsequently has a ripple effect on the rest of the world by altering the major pressure centers and jet streams. Impacts of the ENSO on global precipitation are reviewed in Curtis (2008). Other climate phenomena, such as the North Atlantic Oscillation, can cause changes in climatological precipitation as well, but to a lesser extent than the ENSO and usually only over limited regions and seasons.

Long-term trends in precipitation are not as readily apparent as interannual variations or the anthropogenic global warming signal. The Clausius–Clapeyron relationship directly relates temperature with atmospheric moisture. Warming of 1°C equates to an approximately 7% increase in total water vapor (Allen and Ingram 2002). However, global climate models also predict that the convection cell in the equatorial zone (i.e., Walker circulation) will also weaken. Since, as stated earlier, rainfall is dependent on humidity and uplift, the net result is little to no change in global precipitation. Most observations from the satellite record have corroborated this theory (Adler et al. 2008), although some would suggest that global precipitation is increasing and the hydrologic cycle is accelerating (Wentz et al. 2007). The contradictory findings, lack of long-term reliable datasets, and the small signal-to-noise ratio, all lead the scientific community to having a low-to-medium confidence in global trends in precipitation.

Observations have shown, and climate models project, an increase in precipitation extremes, due to the availability of moisture. If, in general, the frequency of storms decreases due to a background environment that inhibits vertical motion, storms that do spawn will be laden with water vapor and produce heavy precipitation – often coined as the “more bang for your buck” theory. Regarding global patterns of precipitation, climate models also suggest that wet regions (e.g., the ITCZ) will become wetter

**PRECIPI TATION**
and dry regions (e.g., subtropical desert belts) will become drier with the warming (“the rich get richer” theory). This is likely due to an expansion and intensification of the Hadley circulation cell (Held and Soden 2006). Finally, it should be noted that other changes in the atmosphere caused by humans, such as the addition of aerosols, can have equally strong, and sometimes contradictory, impacts on precipitation when compared to global warming.

Pre-Quaternary landforms and landscapes

C.R. Twidale
University of Adelaide, Australia

Convention

Common sense suggests that land surfaces exposed to the elements surely must be worn away. The concept finds support in the sediments eroded and transported by rivers, glaciers, and waves and on the wind, and in measurements of contemporary erosion. With the exception of exhumed forms, most landscapes are perceived as of Quaternary age. True, some may date from the Pliocene but continuous chemical weathering arguably has ensured that few older features could have survived. And enormous tracts of the Earth’s land surfaces, including the mid-latitude deserts and continental areas of the Northern Hemisphere that were occupied by ice sheets or glaciers during the Pleistocene, manifestly are youthful. Similarly, the many fluvial plains, some local features but others of regional extent, like the erosional and depositional plains of the Lake Eyre catchment of central Australia, which occupies about 22% of the continent, are of Quaternary age.

Yet the basic argument propounded by Hutton, Lyell, and Davis, that weathering and erosion continually and rapidly destroy and renew land surfaces, is flawed. This is demonstrated by the existence of pre-Quaternary landscape elements not only in uplands but also in the midst of youthful plains. In northwest Queensland, Australia, for example, laterite-capped plateaus of Miocene age survive on the divides between major river valleys eroded in Cretaceous strata.

Moreover, exhumed landforms – some of them of great antiquity – are widely distributed in both space and time. The age of the resurrected surface is bracketed by the age of the youngest rock exposed in the buried surface and the oldest of the cover material, but it most likely immediately predates the cover.

Paleoforms of epigene-etch origin

In addition to such relics of past land surfaces, very old forms that have never been protected by burial also persist in the contemporary landscape. They are overwhelmingly of etch type. They are two-stage forms that have been shaped at the weathering front or lower limit of discernible alteration, and then exposed as landforms by the stripping of the regolith or weathered mantle. They are not untouched by weathering and erosion, but their essential characteristics survive.

Thus, some 70 million years ago, what is now the steep-sided inselberg known as Uluru was a low soil-covered rise located in the Amadeus Basin of central Australia. Differential weathering by moisture retained in the regolith caused the weathering front to become dimpled and grooved. As the bed of Lake Eyre subsided, the rivers flowing to it, including those draining the Amadeus Basin, incised their valleys. The regolith on the rise was stripped away...
and the rocks around it were further weathered and eroded by the waters flowing from higher ground. A siliceous duricrust was widely developed on the lowered plains during the Eocene (Figure 1).

Once standing in relief, the hill that was to become Uluru continued to shed water and was little changed. By contrast, the surrounding plains were lowered and the bounding slopes of the residual were steepened to produce the present well-known monolith rising abruptly from the desert plains. The dimpled and grooved bedrock crest of the inselberg came to stand high in the local landscape and was, as such, a dry site. It has stood basically unchanged throughout the Cenozoic.

Figure 1  Dissected plateau capped by Eocene silcrete, southwest Queensland.

Examples of very old Australian paleoforms

No direct method of determining the age of pre-Quaternary land surfaces has yet been discovered. Physical dating procedures have been applied in some areas but with confusing and in some instances widely different results that are moreover at variance with dates produced by a consideration of stratigraphic/topographic criteria.

Plateau remnants are typical of central and northern Australia. Those capped by laterite stratigraphically determined to be of Miocene or Oligocene–Miocene age occur throughout the monsoonal tropics of Australia, from north
Queensland in the east to the Carnarvon Basin of Western Australia. In the lower Lake Eyre topographic basin plateaus associated with Eocene silcrete are widely developed and conserved (Figure 1), but in southwest Queensland the silcrete has been folded, giving rise to cuestas that serve as a reminder that old surfaces survive despite virtually continuous and continuing minor tectonic disruption.

Using stratigraphic data – later confirmed by numerical dating – Hills (1955a, 1955b) showed that summit bevels developed in Paleozoic strata and preserved in the ranges of eastern Victoria are separated by valleys floored by lava flows, some of them of Eocene age. The lavas postdate the valleys, which are younger than the summit surface into which they are incised. Thus, the lavas provide a minimum age for the summit bevels. Similar features preserved in southeastern New South Wales were initially ascribed to the Pliocene but dated valley lavas later showed them to be older and comparable to their Victorian counterparts. Later regional mapping suggests that throughout southeastern Australia the higher bevels may be as old as Triassic, with the Permian glaciation a useful back-marker for landscape development here and in other parts of the former Gondwana.

The method of dating articulated by Hills (1955a, 1955b) is based in topographic relationships: in an undisturbed landscape the older surfaces persist high in the relief, whereas younger forms are found lower in the topography and the most recent are in valley floors. This relationship is illustrated by the stepped morphology characteristic of the many inselbergs that have been shaped during periods of subsurface weathering and intervening phases of erosion and lowering of the surrounding plains. Such episodic exposure caused the residuals to become more and more prominent features of the local topography. The crests of some of the inselbergs are of considerable antiquity.

In southeastern Australia, lavas provide numerical age control, but elsewhere, dated sediments and duricrusts serve the same purpose. The southern Flinders Ranges in South Australia is a region of ridge and valley. During the Middle Eocene the pre-existing westerly drainage of the intermontane northern Willochra Basin was blocked, forming a lake. Silicified lacustrine sediments extend up adjacent valleys. Thus, the ridge-and-valley assemblage was in existence some 60 million years ago. The beveled crests of the quartzite/sandstone ridges probably date from the Cretaceous and may be relics of a planate surface shaped by rivers graded to an Early Cretaceous marine shoreline. The stratigraphy of Triassic intermontane basin deposits hints at regional planation during that Period, but no landforms demonstrably associated with that event have been located.

To the west of the Flinders Ranges the prominent summit surface of the Arcoona Plateau transects various gently dipping Proterozoic quartzites. Early Cretaceous marine beds (and Eocene silcrete) are preserved in valleys cut into the surface, which therefore predates the marine transgression.

In the arid interior of Australia, the beveled bornhardts of the Everard Ranges apparently stood as islands in the Jurassic seas, for in eastern sectors of the upland tongues of Late Jurassic sediments extend up the intervening valleys. Similarly, the quartzitic Kakadu massif of Arnhem Land is bordered by marine beds and shorelines of Early Cretaceous age, showing that 120–130 million years ago it stood as an island in the then seas.

Dissection of the east–west trending Macdonnell Ranges developed in Proterozoic strata and folded in the later Paleozoic has produced a ridge-and-valley assemblage that existed prior
to the Eocene, as indicated by silcrete-capped mesas in valley floors and the southern piedmont. Remnants of a much higher and hence older bevel are evident in the Ranges and have tentatively been construed as having been shaped by streams graded to a Cretaceous shoreline.

Though some of the laterites of the southwest of Western Australia are of Late Cenozoic age, others appear to be older. Jutson noted that the so-called New Plateau or high plain of the Yilgarn Craton of Western Australia is an etch surface resulting from the dissection and partial stripping of the lateritic duricrust that forms and underlies the Old Plateau (Figure 2). The topographically lower New Plateau is an etch surface eroded by rivers and streams initiated during the Eocene and still extending inland. This evidence indicates a pre-Eocene or Mesozoic age for the lateritized Old Plateau. The regional setting also suggests a pre-Eocene age for the laterite but later Cenozoic paleomagnetic ages complicate interpretation.

In any event, stepped residuals protrude above the lateritic surface. Their beveled crests are even older than the duricrusted high plain. The Humps and other stepped forms display a dome-on-dome morphology, some with flared sidewalls associated with former piedmonts and, possibly, planate surfaces that predate the Old Plateau (Figure 3).

The laterite that forms plateaus in southern Eyre Peninsula, Kangaroo Island, and southern Mt Lofty Ranges – the Gulfs region of South Australia – appears to predate the Middle Eocene, as indicated by lateritic debris recorded from the basal Middle Eocene beds in one of the fault-angle depressions. Stratigraphic evidence from Kangaroo Island points to an even earlier
Triassic age. This interpretation is based on potassium–argon (K–Ar) dating of basalt that appears to overlie the laterite, but other dating methods (particularly paleomagnetism) indicate a Miocene or even Pliocene age for the duricrust, the former consistent with the high Miocene sea level noted in the area. However, whether the laterite developed on a pre-existing surface or planation and pedogenesis were concurrent remains to be determined. Suffice it to state that regional stratigraphic and topographic evidence favors a Mesozoic age for the duricrust. For example, the early Tertiary sediments deposited in southern Eyre Peninsula are not lateritized as they ought to be, had the intense humid tropical alteration occurred in the later Tertiary as suggested by paleomagnetic analysis.

In some instances, fossiliferous deposits provide evidence of the age of landscape of the source area from which the sediments were derived. Thus, the summit bevel preserved on the bornhardt massif of the Gawler Ranges is an etch surface. During the earlier Mesozoic the area was reduced to a planate surface underlain by a regolith of variable thickness, thick over fracture-controlled bedrock valleys, but thin over bedrock highs. Uplift of the southern margin of what is now the upland caused rejuvenation of streams flowing north to the Cretaceous seas that occupied what is now the Eromanga Basin. The fluvial deposits, including cobbles of Gawler Range Volcanics – corestones derived from the previously developed regolith that covered the whole of the Ranges – were laid down as the Mt Anna Sandstone. Thickness variations and cross-bedding also indicate a southerly provenance for the formation. It was interbedded with fossiliferous marine beds of the Cadna-Owie Formation that show the Sandstone to be of Early Cretaceous (Neocomian–Aptian) age. As
deposition implies erosion, this age determination applies also to the exposed bornhardt landscape. Silcrete of probable Eocene age preserved in the piedmont and within the upland suggests that, apart from marginal valley floor dissection, no later comparable stripping of the upland is in evidence.

**Paleosurfaces in other parts of Pangea**

Very old landscape elements are not confined either to Australia or to the oldlands of cratonic regions. Thus, and like the Kakadu massif, the various uplands of the Roraima Plateau of northern South America may have stood as islands in the Cretaceous ocean. The beveled upper surface must be considerably older. The uplands defined by the Great Escarpment of southern Africa also are bordered by coastal and offshore plains underlain by Cretaceous and younger sediments. In the interior, very old Gondwanan plateau remnants that transect Jurassic basalt flows and Late Cretaceous kimberlite pipes survive on uplands such as the Drakensberg (Figure 4).

But, by contrast with the subsiding crust and interior drainage of central Australia, southern Africa has experienced recurrent uplifts that induced repeated phases of stream rejuvenation and landscape revival. Older and older surfaces separated by more-or-less prominent scarps form concentric zones, decreasing in age-range from the interior toward the coast.

In Zimbabwe, for instance, extensive plains of Pliocene age occupy the lower reaches of major catchments, such as those of the Limpopo and the Zambezi rivers. They are succeeded inland by the regionally dominant post-African Miocene plains, which in turn give way to the landscapes of African, that is, mid-Cretaceous to Oligocene, derivation. This stepped landscape is protected by its interior location but each surface is being reduced as the younger scarps and surfaces migrate inland. Stepped landscapes with bauxitic and ferruginous cappings of Jurassic, Cretaceous, and various Tertiary ages are prominent in several parts of West Africa (Niger, Cameroon), and to the east in Kenya, Uganda, and Tanzania.

In Britain, and citing stratigraphic indicators, Jones speculated that the summit surface preserved in the uplands of central Wales is of Triassic age. The upland bevel preserved on monzonite in the western Sierra Nevada of California has been linked to Cretaceous age.
deposition in the adjacent Great Valley. But correlations are not everywhere simple and obvious: four prominent planation surfaces have long been recognized in the Appalachian Upland of eastern North America but only three phases of rapid weathering and planation (earlier Jurassic, mid-early Cretaceous, and Middle Miocene) are identified in the record preserved in the strata beneath the adjacent continental shelf. Double planation associated with etching may account for this discrepancy. Alternatively, it may further confuse the issue.

**Reality**

Common sense and field observations point to the ever-changing youthfulness of the Earth’s land surfaces. However, several very old surfaces have been recognized based on a range of evidence and argument based in topography and stratigraphy. Ages derived from physical procedures and at variance with these results are cause for concern and call for explanation. Yet stratigraphy cannot be denied. As to survival, as they exist, the very old paleosurfaces cited here must be possible. The structural factor is vital to concatenation: structural contrasts have led to the development of an unequal distribution of weathering and erosion that has in turn induced positive feedback, episodic exposure, and stepped forms and terrains. This complex of factors may, in part at least, account for the persistence of landscape elements that are relics of the former Pangea.

Definitions and conceptual traditions: geographies of personal privacy

Personal privacy is multifaceted, not amenable to simple definition, and subject to diverse and wide-ranging categorization across the social sciences. Dictionary definitions focus on being alone or free from public attention. Recent papers have identified three persuasive taxonomies, outlined in Table 1. The majority of these definitions cluster around a person’s ability to be alone, to control information about oneself, and to freely behave in a manner consistent with religious, sexual, and so forth, practices and beliefs. Privacy in this sense has strong links to individual freedoms, and links between personal privacy and rights of the person and individual are hence emphasized in some disciplines.

Concern with personal data, personal communications, and autonomy of association, beliefs, and practices is writ large in geographical thought. This is especially the case methodologically. The methodological implications of personal privacy, especially as they relate to research ethics, have been one focus of geographical research on personal privacy (Dowling 2005). The collection of information by researchers (or other agencies) can involve “invading” someone’s privacy. Geographical research may entail recording information considered private, or observing interactions in people’s homes that are customarily considered private. Geographical research, and university

Human ethics boards, thus develop and follow guidelines about not releasing such private details into the public domain. This includes protocols about the storage of data and ways to ensure that research participants are not identified. The rise of the Internet has transformed geographical research, opening up a plethora of new sources of data such as social media, new ways of collecting qualitative data like online surveys, and new ways of recruiting research participants. These methods and sources pose myriad challenges to research ethics, especially to informed consent, privacy, and confidentiality. Using online questionnaires brings confidentiality to the fore. Online surveys are often conducted using commercial software and web-hosting services, which means that the researcher doesn’t have complete control over protecting participants’ identities. The web service, for example, may track IP (Internet Protocol) addresses and hence enable the identification of participants. Using the various elements of Web 2.0 as sources of qualitative data is even more contentious in terms of privacy and informed consent.

Geographical scholarship on personal privacy, however, tends not to produce or work with taxonomies such as those contained in Table 1. Geographers accept the existence of multiple dimensions of personal privacy and acknowledge that they are complexly interrelated. As such, the multiple definitions of personal privacy in Table 1 infuse rather than direct geographical engagement with the concept. Though it recognizes that privacy is a phenomenon experienced by an individual, geographical analysis does not focus solely on the individual or on individual experiences. Rather, personal privacy is understood as a social construct: the ability, characteristics, and places of personal privacy are determined by the social and political context. Geographical attention is hence more regularly turned to the production of personal privacy: the conditions under which it is enabled and experienced. More specifically, understanding personal privacy geographically has focused on whether, how, and where personal privacy is experienced by an individual, and is influenced by power relations, social positioning, and discursive framings.

Taking power relations first: personal privacy is strongly influenced by a powerfully reproduced dichotomy of public and private. In this dichotomy (see Blunt and Dowling 2006) the private is defined in opposition to the public: personal privacy is created and experienced in retreat from, and separation of, the public sphere – of work, politics, and the street, to name just three examples. Privacy here takes on a particular meaning because of its political-economic context. And it is used to define and discipline
populations. Feminists have long argued, for instance, that privacy, and in particular the perceived sanctity of home, have been one means through which the oppression of women has been reproduced. Privacy as a social construct also entails attention to sociopolitical framings. The meaning and shape of personal privacy is produced through discourses of the state, of economy. In legal geography, for example, the ways in which laws and regulations enable, constrain, and spatialize personal privacy are highlighted.

A second point, which also draws from feminist analyses, is that personal privacy is socially differentiated. For example, the ability to keep information about oneself secret is dependent on the degree of autonomy that an individual has. Likewise, being able to claim a space for privacy is highly dependent on access to physical, psychological, and financial resources. Even within private spheres like the home, women’s ability to claim independence can be curtailed by patriarchal relations that involve surveillance by men. The question for geographers is typically to examine the ways in which social and geographical contexts circumscribe and shape experiences of privacy.

A final point is a discursive and cultural analysis of privacy as a social construct. This means that definitions of what privacy means are historically and geographically specific. In many Western societies, for example, privacy is thought of as a virtue, something to aspire to and defend. Indeed, some legal scholars speak of a “right” to privacy. Yet, in other cultural or historical contexts, the propensity to be alone and the ability to control information about oneself are not highly valued in comparison with shared knowledge and understanding. For example, in communities in the West developed with the intention that they be shared – with communal housing and activities like cooking and child care collectively rather than individually undertaken – different expectations and characteristics of personal privacy are expected and enacted.

Human geographers translate this understanding of personal privacy as a dynamic and context-specific experience into a concern with the relations of personal privacy and place. As Somerville (2009, 532) observes, privacy requires “the possession of a certain territory with the power to exclude persons from the territory and prohibit surveillance by others.” Securing personal privacy is a geographical process. In the process of seeking to be, and being, undisturbed and free from public attention, geographical barriers are assumed, made, and remade. Three geographical implications of personal privacy are commonly excavated. The first is that there is a rightful place for privacy, that certain places are constructed as obvious places of privacy. Here, geographers examine how such places come to be sites of personal privacy, how they are experienced by diverse social groups, and how they are contested and remade. A second strand focuses on the experiences of personal privacy on the move, especially, but not exclusively, in public. Here, the focus is on the ways such places are created as private, and the forms of personal privacy they support. This strand directly challenges the public/privatedichotomy by considering the experiences of privacy in public spaces like town squares, streets, and public buildings. A third strand considers privacy at a distance. Here, the focus is on the ways in which privacy is being transformed in the contemporary world. This entry outlines each of these in turn.

**Personal privacy in the private sphere: home**

Privacy in geographical terms is conceived of as a spatial location, secured by the policing of
boundaries around a territory (Squires 1994). Given the strong associations between privacy and private property, home is considered the quintessential private space. Home is not the state or government, home is not work, home is not the church, home is not the realm of politics, and home does not encompass commercial activities. Rather, home is separate from and outside of the collective institutions of public life and, as such, is the primary site through which personal privacy is enacted. It is a space for intimate, confidential relationships and a space beyond the gaze of the state and other institutions. In Blomley’s (2005, 619) terms, “in our home we are, supposedly, able to shield ourselves from the views of others, whether our neighbors or the state.” Home, and the relations within, foster personal privacy. Home offers a space of freedom and control for the individual, and for intimate, caring relationships. Home as haven or sanctuary is a central idea in the privacy of home. While public space outside the home is seen as imposing and dangerous, home space is inside, enclosed, and safe. It is a sanctuary, a place to retreat into, to be oneself, away from the gaze of others, and to freely express one’s beliefs. Home also facilitates the notion of privacy as familial intimacy. The activities of caring for family members, caring for the self (washing, dressing, grooming), engaging in intimacy with others and in related “private” emotions like love and desire, occur within, and are associated with, home spaces. Indeed, the emergence and consolidation of the nuclear family as the idealized family formation coincided with the delineation of home as a private space. Home is assumed to be, and is constructed as, the natural place for personal privacy.

In geographical work on privacy and home, multiple definitions and contestations of privacy are highlighted. One important dimension is the social and geographical specificity of the personal privacy afforded through home. Feminists ask whether home as sanctuary is pertinent to the lives of many women. In the context of domestic violence and emotional abuse, for many women home is certainly not a haven or a foundation for autonomy, but a site and source of alienation and upheaval. Gendered experiences of privacy are culturally specific. In Qatar, for example, privacy at home is especially significant for women in that it “reduces or eliminates the need for covering and modest self-presentation and conduct that is required of them in public” (Sobh and Belk 2011, 130). The class specificity of home as a sanctuary is equally important. The privacy of home is similarly never completely available. It is, for example, not an opportunity for many who rely on state-provided housing. In jurisdictions like Australia and the United Kingdom, for example, state housing authorities have established standards of cleanliness and occupancy which they often enforce by entering an individual’s home without warning. Home as sanctuary is hence an ideal and a practice connected to both class and social differentiation. A final instance of complicating home as private is what privacy means for those who do not have a home. Again returning to the discursive and legal associations of personal privacy with private property, it has been shown that homeless people not only lack the privacy afforded by home, but that this lack also functions to reproduce the political marginalization associated with homelessness (Sparks 2010). Personal privacy at home is politically produced and socially differentiated.

A second theme is the porosity of public and private boundaries, both material and metaphorical. Privacy at home is at once enabled because of the symbolic and physical boundaries around the house that deter and prevent the entry of uninvited others. Yet these are also fictitious boundaries. For example, the concerns of the state and economy are writ large in home-based
experiences of personal privacy. Building regulations, home energy and appliance standards, sanitation policies, to name a few, shape, and indeed make possible, experiences of solitude. This porosity similarly applies to the privacy experienced by families within the home. Technology, and in particular television, has long been responsible for bringing the “outside” worlds of politics, war, and popular culture into the home (Silverstone 1994). Personal computers and other devices connected to the Internet challenge the solitude and independence of individual activities at home. The World Wide Web enables constant connection between home and beyond in historically unprecedented ways. Privacy at home is being transformed.

A final geographical concept is that there are multiple experiences and forms of privacy in the private sphere. The notion of home as private implies that all members of a family do not desire privacy from each other; indeed, the ideal of familial togetherness requires that family members embrace the sharing of space within the home. A geographical, dynamic conception of personal privacy leads to a questioning of the totality of home as private. Family members seek sanctuary from each other, a respite within the home. Munro and Madigan (1993) aptly term this “privacy in the private sphere.” In this construction of privacy, the ability of individual family members to secure and maintain a sense of physical or social separation from other members is equally important. Such privacy is also secured through social negotiation between inhabitants, whether through formally agreed scheduling of activities within a shared space or through informal negotiations as occasions demand. These social negotiations are arguably gendered, with men having greater freedom to achieve privacy and independence within the home than women (especially those who are mothers), who more often fit their own needs and work requirements around the activity, space, and time demands of children. Thus we see separate areas for children (rumpus rooms, play rooms) and parents (parents’ retreats), multiple bathrooms to accommodate the individual desire for privacy, and multiple electronic devices (televisions, computers) scattered throughout the home to facilitate the fulfillment of each family member’s individual aspirations. Through these, privacy in the private sphere is both sought and achieved.

Thus far this section has presented a quite conventional geographical understanding of privacy and home. There is a further complication to this description that draws on recent concerns with sensory geographies. Privacy is also an olfactory experience, as illustrated in Sobh and Belk’s (2011) analysis of homes in Qatar. There, before guests arrive, homes are scented to create a different, nonprivate smell, and after guests leave homes are treated to return them to their original, private smell. Privacy at home can also be auditory – keeping unwanted sounds out.

Creating privacy in public

While personal privacy at home is the predominant focus of geographical scholarship, it by no means exhausts the spatialities of privacy. Indeed this possibility is implicit in the conception of privacy operationalized in the previous section, namely privacy as an accomplishment shaped by social, political, and cultural framings, and imbued with both porous and fixed relations to the public sphere. The seeking of personal privacy transforms public spaces into private spaces, illustrated through the following two examples.

Cars dominate cities around the world. While they are often associated with traffic, movement, and road infrastructure, geographers also point out that cars are spaces of personal intimacy.
They are physical cocoons. Within them drivers are strapped into seats and afforded some protection from surrounding objects and people by metal and locks. This material cocooning is correlated with a sense that cars are also individual, providing a space to relax, be alone, and be oneself. According to Kent (2014), “the car is explicitly perceived and felt as a very personal and private space. It is a place where the body is shielded from others, and from the biophysical environment.” Kent’s work also highlights car drivers’ use of the car as much more than a means of traveling from A to B. Cars facilitate time to zone out and “me time.” Cars are spaces that are personal and personalized, in which individuals can choose to interact. The car is also a site for familial privacy and intimacy. As with the home, it is in the car (sometimes through information and communications technology (ICT), sometimes through the thinking space it provides) that family arrangements are made. For women who are mothers, the car becomes a site valued for its facilitation of private domestic conversations. In this respect, cars are mobile sites of personal privacy that are private in the way they are experienced, and public in that occupants are visible to outsiders and traveling through public space.

A second example is also of privacy in public: mobile privacy. Hatuka and Toch (2014, 3) have articulated the concept of “portable private-personal territory” which they define as “a personal space that individuals develop and that is characterized by a multi-dimensional set of social and spatial relationships.” This form of personal privacy on the go is facilitated by the proliferation of communication technologies, in particular mobile phones. These allow people to be private in public, bringing ostensibly private activities like chatting and watching television into new spaces. Smartphones, in other words, provide personal visual and audio spaces regardless of a person’s location, and allow users to ignore the presence and actions of people around them. Personal privacy is, thus, becoming disconnected from the physicality of space.

Personal privacy in the twenty-first century

The twenty-first century has heralded significant shifts in the meaning of, and the influences on, personal privacy, especially in relation to information about the person that may be deemed private. These shifts have occurred partly because of new roles and relationships among privacy actors. First, there has been an explosion of social media platforms – Twitter and Facebook being the most well-known examples – designed solely for sharing personal information. Second, individuals are more likely to reveal highly personal details online, such as in blogs. The first two points converge to create a third – an explosion of personal information outside the control of the individual and often in the hands of corporations (Elwood and Leszczynski 2011). In essence, personal privacy in terms of information about the person has become more public and less private.

Smartphones and other locative (GPS-enabled) devices bring to the fore questions of locational privacy – the ability of a person to move about without being tracked or monitored (see de Souza and Frith 2012). For example, when it was discovered that users of some smartphones were being tracked in 2011, ostensibly without their permission, and that this data was available to others, public consternation and discussion ensued (see Kumpu 2012). Likewise, the geotagging of online content, or technologies like Google Street View, are provoking public debate about what personal privacy means. Moreover, as Elwood and Leszczynski (2011, 7) argue, these
debates are conceptually important for the ways they “reconstitute the objects and practices of privacy concern, and in so doing alter the roles and relationships of state, civil and corporate actors in the constructions of privacy.” In sum, geographers are interested in these privacy violations not just for their detail, but for what they reveal about transforming the spatialities of privacy.

Processing LiDAR data

Maria Antonia Brovelli
Carolina Arias Muñoz
Politecnico di Milano, Italy

Processing of Light Detection and Ranging (LiDAR) data can vary depending on the different technologies used for data collection and on the desired output mapping products. One thing that is common for all technologies and mapping products is the generation of digital terrain models (DTMs) – bare earth – and digital surface models (DSMs), which are the most used and fastest growing LiDAR observations products. In almost all LiDAR applications, point cloud filtering, or ground filtering, is a necessary step in LiDAR data processing to determine which LiDAR returns are ground surface features, and which are nonground surface features. The former are used to generate DTMs, while the latter are used to extract DSMs. DSMs are surfaces containing features that reflect the first return of each laser pulse (e.g., trees, buildings, or towers), while DTMs are surfaces representing the bare ground without any objects like vegetation or buildings (see Figure 1).

The general procedure to generate a DTM from a point cloud, as described in Meng, Currit, and Zhao (2010), can be summarized in four steps: (i) Error filtering; (ii) Interpolation, resampling, or reorganization; (iii) Ground filtering; and (iv) DTM generation. Error filtering consists of the elimination of outliers which normally have excessively high or low elevation values. To identify these outliers an analysis of the elevation value’s frequency distribution can be done, as well as a comparison of each point to a local elevation reference, a residuals analysis after interpolation, or simply a manual examination of the dataset. After error filtering, some interpolation, resampling, or reorganization is needed to create raster datasets from the point cloud. This procedure could be necessary because certain ground filtering algorithms depend on raster-based neighborhood search logic. Methods for point cloud rasterization assign to the pixel value the lowest or nearest point within an area, or interpolate the pixel value using kernel functions. Ground filtering, as previously mentioned, is the process of separating ground and nonground points or pixels. Finally, to generate a DTM, the ground points identified after ground filtering have to be interpolated to produce a continuous surface. The interpolation methods include inverse distance weighting, splines functions with regularization, absolutely minimizing Lipschitz extension (AMLE), kriging, and other hybrid methods that combine linear and non-linear interpolation. Steps i, ii, and iv are common to all field measurements; ground filtering, meanwhile, is specific to LiDAR observations.

In order to select a ground filtering method, several aspects have to be considered: the terrain characteristics, the number and type of LiDAR returns, and the definition of neighborhoods, among others. Concerning the number of LiDAR returns, first and last returns are used for ground filtering; intermediate returns are mostly used for separating vegetation from solid objects. The definition of neighborhoods is essential to describe the height context of ground features. The height context is defined by a local neighborhood function which assigns weights to each point within that neighborhood. The function...
could also be performed as a series of linear, circular, or rectangular windows. Furthermore, most filtering algorithms iteratively modify the neighborhood size to improve filtering accuracy.

Though filtering algorithms can be differentiated on the basis of different operative characteristics, the more interesting distinction can be made upon the assumptions on which the different filters work.

Tóvári and Pfeifer (2005) point out four distinct algorithm types: morphological or slope-based, progressive densification, surface-based, and clustering/segmentation algorithms. Other less commonly used methods include block-minimum and multiscale (Lee et al. 2013).

*Morphological or slope-based algorithms* use height differences to recognize points belonging to objects. The classification is performed using a threshold that determines the admissible height difference between two neighboring points such that one can be considered as bare earth. This approach can also use fixed slope or gradient threshold values instead of height differences. *Progressive densification algorithms* are filters that at first identify some points belonging to the ground and then, depending on those, classify more points as ground. Usually the points used as seed are the ones with lower height. Additional ground points are determined by investigating their neighbor on the reference surface. *Surface-based algorithms* are filters that use a parametric surface that iteratively approaches hypothetical bare earth. The surface is modified depending on the influence of the individual input points. Common interpolation methods include: hierarchical robust interpolation; bilinear/bicubic spline functions with Tychonov regularization in least squares approach; thin-plate spline (TPS); the facet model; and statistics methods such as minimum values. *Clustering/segmentation algorithms* are filters that are based on the idea that a cluster of
points belong to an object if it has height values greater than its neighbors. In these cases the classification is performed in two steps: first, a segmentation is carried out, and then the segments are divided into different classes depending on the differences in height between segments (Sithole and Vosselman 2003). Block-minimum filters search the minimum value in a given spatial extent within neighboring points. Multi-scale filters are based on the fact that surface properties are scale dependent: feature variations exist at a smaller-scale range than terrain variations. The point cloud is interpolated into multiresolution grids, and points are then classified based on a threshold that varies according to the procedure used. Decision algorithms include: multiscale Hermite transform (MHT) filter; multiscale curvature classification (MCC); and multidirectional ground filtering (MGF).

Automated filter algorithms are built into LiDAR software tools. These tools have several data-processing and information-extraction functions, with ground filtering as their core function. Among the most widely adopted proprietary software is TerraScan, which is the most complete, advanced, and powerful software available for LiDAR data processing and analysis. It has the capability of handling big datasets by creating projects and breaking the big datasets into smaller tiles that can be processed individually. LAStools Software Suite is a collection of highly efficient, batch-scriptable, multithreaded command-line tools for LiDAR data processing, which can be run via a graphical user interface and are available as a LiDAR processing toolbox for ArcGIS versions 9.3, 10.0, and 10.1 of the Environmental Systems Research Institute’s (ESRI) mapping software. General tools such as those for data format conversion, header information extraction, or data precision are free, but more sophisticated tools for filtering, classification, and interpolation require licensing.

Free and Open Source Software (FOSS) offers alternatives for LiDAR tools, and some of these suites have the same processing capacity as proprietary ones. Among the FOSS alternatives, GRASS GIS includes a suite of tools related to processing LiDAR data (Brovelli and Lucca 2011) as described on the GRASS LiDAR wiki (https://grasswiki.osgeo.org/wiki/LIDAR). It has a series of commands to perform DEM/DSM separation: v.lidar.edgedetection detects edges from last return data; v.lidar.growing generates buildings from detected edges; v.lidar.correction postprocesses data; and finally v.surf.bspline computes DTMs and DSMs. BCAL Lidar Tools is another FOSS tool, developed by the Idaho State University Boise Center Aerospace Lab as a plug-in for the ENVI (ENvironment for Visualizing Images) software package. It is written in IDL (Interactive Data Language) programming language and includes a bare-earth digital elevation model (DEM) creation and a height filtering tool optimized for open rangeland (sagebrush) vegetation. SAGA GIS is an open source geographic information system (GIS) package that includes tools to work with point clouds, like reclassifier, attribute calculator, subset extractor or gridding, and interpolation. FUSION is a LiDAR/IFSAR (interferometric synthetic aperture radar) data conversion, processing, and display FOSS suite. It processes raw LiDAR data into a number of vegetation metrics; and it has a processing tool called Canopy Fuel Estimator (CFE) that uses LiDAR data to characterize canopy fuels over a landscape. MCC-LiDAR is also an open source command-line tool for processing discrete-return LiDAR data; it is used especially for forested environments, with the MCC algorithm for ground filtering.

In the future, LiDAR studies for data processing need to focus on large LiDAR datasets processing optimization, full waveform LiDAR data analysis, and integrated analysis of LiDAR data.
and other remote sensing products, like multispectral image data. Until now, ground filtering algorithms have had performance problems with surfaces with irregular terrain or discontinuous slope, low vegetation regions – often ignored by many ground filters – and dense forest canopies that reduce the penetration of laser beams. This means that ground filtering algorithms research is far from being over.

Producer services and trade liberalization

Holger Breinlich
University of Nottingham, UK

Trade liberalization and recent advances in communication and information technologies have increasingly permitted the trade of services, including producer services, across borders. This entry discusses recent research on the nature and importance of such trade, on existing trade barriers, and on the progress and consequences of services trade liberalization. The concept of trade liberalization is broadly interpreted here to refer to the elimination or reduction of any policy measure which explicitly or implicitly discriminates against foreign providers of a service relative to the domestic providers of the same or related services. The analysis will focus on the economic consequences of services trade liberalization and look at the impact of liberalization on variables such as firm- or sector-level output and productivity. The entry presents the historical context of this research; describes the most common definitions of trade in producer services and the forms it can take, and briefly looks at issues of measurement and data quality; discusses trends in aggregate services trade flows and summarizes recent findings on transactions at the firm level underlying these aggregate flows; and provides an overview of existing restrictions on services trade, attempts to liberalize trade, and the economic consequences of such liberalizations.

Historical context

Research on services trade has a relatively short intellectual history. This is in stark contrast to the much older research efforts related to goods trade which go back to at least the works of Adam Smith in the late eighteenth century. While there were some important early contributions in the 1960s and 1970s, a broader research program on services trade was established only in the 1980s, largely in reaction to the trade negotiations during the Uruguay Round that resulted in the General Agreement on Trade in Services (GATS) in 1994 (see Francois and Hoekman 2010). Since then, the research agenda has evolved to span a wide range of issues such as the nature, definition, and measurement of services trade, the collection of comprehensive international statistics on trade flows and barriers to services trade, and the evaluation of the consequences of trade liberalization. While initial research has concentrated mainly on insights into broad trade flow patterns and the aggregate consequences of trade liberalization, more recent research has focused on the firm-level decisions underlying these aggregate trends.

Trade in producer services: definitions and measurement problems

The provision of producer services across borders is in many ways fundamentally different from the trading of physical goods. For example, Hill (1977) notes that an important characteristic of most services is a “joint production requirement.” As services often
PRODUCER SERVICES AND TRADE LIBERALIZATION

cannot be stored, both producer and consumer need to be present at the same time, and possibly in the same location, for a service transaction to take place. This means that services trade often requires a combination of direct cross-border transactions as well as a local presence through the movement of persons and the establishment of foreign affiliates.

The two most common definitions of services trade reflect these peculiarities. First, the residential or balance-of-payment definition of services trade defines it as service transactions between the residents and nonresidents of an economy. For example, the provision of call center services from India to customers in the United States is such a transaction. A presentation given by a London-based consultant to clients in Paris, or the attendance of the same clients at a training course in London, also represent services trade. Note that, while these last two examples do not involve cross-border transactions, the producers and consumers remain residents of their respective countries; thus, their interaction represents transactions between residents and nonresidents.

Second, an often used alternative definition focuses on the modes through which services transactions take place. This GATS definition classifies services trade into four modes. Mode 1 (“cross-border supply”) comprises transactions in which the producer and consumer of a service remain in their respective countries. The provision of call center services mentioned earlier would be a mode 1 transaction. For transactions in mode 2 (“consumption abroad”), the consumer moves to the country of the producer (the Paris-based clients attending a training course in London), while in mode 4 transactions (“presence of natural persons”) the producer moves abroad to provide the service (the London-based consultant giving a presentation in Paris). While these three modes overlap closely with the residential definition, the GATS definition also includes mode 3 (“commercial presence”), where companies supply services internationally through the establishment of foreign affiliates that are legally resident in the host country, and their transactions with local consumers do not count as services trade according to the residential definition.

The discussion of these two definitions illustrates that the measurement of services trade is substantially more complicated than that of goods trade. The shipment of physical goods across borders can be monitored with relative ease, and a long tradition of levying customs duties has led to the establishment of sophisticated statistical systems in most countries. In contrast, services are intangible and much harder to record (World Trade Organization 2013, 202). Many countries rely on surveys in which the coverage of service-producing establishments is often incomplete. If central bank records are used instead, transactions that do not use financial intermediaries go unobserved. Services that are transmitted electronically or between the establishments of individual multinational enterprises are frequently not registered at all. Also, while substantial progress has been made in setting up internationally comparable methodologies for data collection, there remain important gaps in terms of coverage, in particular for developing countries. As a consequence, data on services trade is much less complete than data on goods trade and is generally assumed to be of inferior quality (Lipsey 2006).

Overview of recent trends in services trade

Figure 1 shows the evolution of aggregate world exports for the principal categories of international trade. Trade in commercial services, of which producer services are the
dominant category, stood at US$4.35 trillion in 2012. Since 1980, nominal yearly growth rates have averaged 11.9%. Despite this strong growth, the share of commercial services in total world exports has increased only slowly over the last 30 years, from 16% in 1980 to 19% in 1990 and 20% in 2012. As seen in Figure 1, this is because other categories of international trade (manufactures, in particular) have been growing quickly. Nevertheless, trade in commercial services has been the fastest-growing component of international trade since 1980.

The subcategories of commercial services do not neatly subdivide into producer and consumer services (i.e., services for intermediate use and for final consumption), but Table 1 shows that categories that mostly incorporate producer services (transportation, computer and information services, royalties, construction, and business services) accounted for 62% of the total value of commercial services trade in 2012. Those comprising a mixture of consumer and producer services (insurance, finance, and communications) accounted for 12%, and categories dominated by consumer services (travel, and personal, cultural, and recreational) for 26%.

The most important type of producer services in 2012 were business services which consist mainly of professional and technical services such as legal, accounting, management consulting,

The information in Figure 1 and Table 1 excludes an important channel through which providers of producer services can access foreign markets: the establishment of a commercial presence through foreign direct investment (mode 3 in the GATS definition of services trade). Data on the activities of such local affiliates is much less comprehensive and mainly available only for OECD (Organisation for Economic Co-operation and Development) countries. However, it shows that local affiliate sales exceed the combined value of trade through GATS modes 1, 2, and 4 in many services sectors. For example, Oldenski (2012) estimates that mode 3 sales of US multinationals were on average twice as large as their sales through all the other modes put together in 2005. In contrast, US multinationals sold as much manufactured goods through direct exports as through local affiliate sales. Similar findings hold true across a range of OECD countries (WTO 2013) and further highlight the fact that, despite substantial progress in communications technology, proximity to customers remains of paramount importance for services providers (Oldenski 2012).

Research on trade in producer services also increasingly makes use of the firm-level data used to construct balance of payments aggregates. Such data have recently become available in a number of countries. Using British data, Breinlich and Criscuolo (2011) show that only around 6% of firms export producer services, but that these exporters show a number of positive performance characteristics, such as higher sales and productivity than nonexporters. Exports of producer services are also concentrated among architectural, or engineering services. The overall share of producer services has also increased markedly since 2000, the first year for which disaggregated data are available. Particularly striking is the rise of computer and information (IT) and business services, which by 2012 accounted for a third of all services trade. Explanations often advanced for this trend include technological progress that has made the cross-border transmission of information easier, as well as changes in organizational practices such as outsourcing and offshoring.

The information in Figure 1 and Table 1 excludes an important channel through which providers of producer services can access foreign markets: the establishment of a commercial presence through foreign direct investment (mode 3 in the GATS definition of services trade). Data on the activities of such local affiliates is much less comprehensive and mainly available only for OECD (Organisation for Economic Co-operation and Development) countries. However, it shows that local affiliate sales exceed the combined value of trade through GATS modes 1, 2, and 4 in many services sectors. For example, Oldenski (2012) estimates that mode 3 sales of US multinationals were on average twice as large as their sales through all the other modes put together in 2005. In contrast, US multinationals sold as much manufactured goods through direct exports as through local affiliate sales. Similar findings hold true across a range of OECD countries (WTO 2013) and further highlight the fact that, despite substantial progress in communications technology, proximity to customers remains of paramount importance for services providers (Oldenski 2012).

a small number of firms; 50% of the total is accounted for by fewer than 15% of exporters. Similar results have been found for a number of other countries such as Italy, Germany, France, and Turkey.

Trade barriers and trade liberalization

Some characteristics, such as the need for proximity to customers, make trade in producer services inherently difficult, but there are also a large number of policy measures that prevent firms from accessing foreign markets. Prominent barriers include limits on foreign ownership of local affiliates, licensing requirements for foreign firms and professionals, aspects of domestic regulatory regimes, or visa restrictions (relevant for mode 4 transactions).

While the variety and complexity of these barriers make measurement difficult, most forms of trade restrictions fall into one of three categories (Borchert, Gootiiz, and Mattoo 2014). The first consists of measures that explicitly discriminate against foreign service providers, such as restrictions on foreign ownership of domestic firms. The second consists of policies that do not explicitly discriminate but may still disproportionately affect foreign providers; for example, domestic qualification requirements to practice professional services such as law, auditing, and accounting impose an additional burden on foreign professionals who have already met requirements in their home countries but whose qualifications are not recognized abroad. Finally, an absence of regulation can also represent de facto barriers to foreign services producers. This is the case, for example, if regulation fails to ensure equal access for all providers to essential infrastructure such as telecommunication networks.

Even when the complexities of measuring services trade barriers are taken into account, the availability of data on such barriers can only be described as poor. This is the case even though the share of producer services in world trade is rising and services trade barriers are increasingly important in bilateral and multilateral trade negotiations. Initially, research in this area focused on attempts to quantify the services trade commitments made by members of the World Trade Organization (WTO) as part of the GATS negotiations in the 1990s (Hoekman 1996). However, subsequent work has established that actual services trade policy is much more liberal than countries’ WTO commitments would suggest (Borchert, Gootiiz, and Mattoo 2014). Put differently, it seems that services trade commitments only guarantee a minimum level of openness which is usually surpassed in actual policy.

More recent research has tried to provide better measures of the de facto openness of countries to services trade. This is usually done by surveying private sector representatives, local law firms, and government officials to obtain information on the most relevant barriers for each sector and GATS mode across different countries. Indicators of the presence of individual policies are then aggregated to the sectoral or country level, using subjective weights of the importance of individual measures.

One challenge any such aggregation faces is to take account of possible substitution between GATS modes. For example, if a given producer service can be delivered either cross-border (mode 1) or through the movement of professionals to the other country (mode 4), substantial trade barriers in only one mode need not imply high effective barriers – producers can simply switch to service delivery via another mode. On the other hand, if service delivery requires a combination of modes, such as a
local commercial presence (mode 3) combined with cross-border trade (mode 1), the higher of the two trade barriers will be relevant for a producer trying to access the market in question. To some extent, the use of subjective weights in the construction of restrictiveness indices allows such issues to be addressed, although extensive validation exercises have not been carried out so far. It is also unclear whether the use of fixed weights can really adequately capture the complex substitution patterns between modes.

A number of studies have tried to quantify the barriers affecting individual sectors or countries, but there are currently only two databases that aim at providing a more comprehensive picture. The Product Market Regulation Index of the OECD provides data on all the important types of producer services for OECD countries for 1998–2013. The World Bank’s Services Trade Restrictions Database (STRD) offers more limited time coverage but also includes information for 79 developing countries. Both databases use the combination of survey data and aggregation via subjective weights discussed earlier.

The picture that emerges from these data is one of substantial heterogeneity across countries, types of services, and GATS modes. Using the STRD, Borchert, Gootiiz, and Mattoo (2014) show that there is a negative correlation between the restrictiveness of a country’s policy regime and its per capita income. By and large, developing countries impose higher services trade barriers than high-income countries (Figure 2). However, there are important exceptions to this general pattern. For example, the Gulf Cooperation Council (GCC) countries – Bahrain, Kuwait, Oman, Qatar, and Saudi Arabia – are high-income but exhibit some of the most restrictive policy regimes. There are also developing countries such as Rwanda, Madagascar, Senegal, and Mongolia that are quite open to services trade, while some of the most rapidly growing Asian economies (China, India, Indonesia, Malaysia, the Philippines, and Thailand) impose above average trade barriers.

In terms of types of services, professional services (here accounting, auditing, and legal services) encounter the highest barriers to trade (Figure 2). This is also true for OECD economies, which maintain substantial immigration restrictions and licensing and qualification requirements, making the delivery of such services by foreign professionals exceedingly difficult. Substantial barriers remain in transportation services as well, whereas access in banking, insurance, and telecommunication services is relatively unrestricted, at least in high-income OECD countries. However, Borchert, Gootiiz, and Mattoo (2014) caution that a high degree of market access uncertainty remains in most countries, even if formal services trade barriers are low. For example, the allocation of licenses is often opaque and highly discretionary; regulators in some countries do not have to provide justifications for rejecting license applications; and foreign service providers do not always have a right of appeal against unfavorable regulatory decisions.

To date, attempts to liberalize trade in producer services have taken a number of forms. Best known are the multilateral negotiations leading to the implementation of the GATS at the end of the Uruguay Round in 1994. More recently, services trade liberalization has also played an important role in a number of regional trade agreements. Since the 1980s, in parallel with these multilateral and bilateral initiatives, countries have undertaken unilateral liberalizations in a range of sectors such as telecommunication and transportation.

Services trade liberalization in the GATS takes the form of so-called commitments, whereby countries guarantee market access and national treatment (i.e., the nondiscriminatory application of domestic regulation and taxation to both
Figure 2  Trade barriers for producer services, 2008–2011. Horizontal axis denotes country groups categorized by income level; STRS measures the overall restrictiveness of a country’s policies on services trade (0 = open without restrictions; 100 = completely closed) (author’s calculations derived from Services Trade Restrictions Database; Borchert, Gootiiz, and Mattoo 2014).

foreign and domestic providers) for specified sectors and modes of supply. The degree of commitment is codified in a country’s schedule of commitments and can vary across modes for the same service activity. For example, a country may guarantee market access and national treatment for cross-border service provision (mode 1) while imposing restrictions on the establishment of a commercial presence (mode 3).

Countries can also choose not to commit themselves by writing “unbound” in their schedule for a given service type. This does not mean that market access will be necessarily restricted, only that the country does not guarantee access and national treatment. As a consequence, the GATS schedules only provide an incomplete listing of policies that are actually applied. This is known as a “positive list” approach because only unrestricted service types and modes are explicitly enumerated. More recent regional trade agreements have generally followed the commitment approach of the GATS and have also relied on positive-list schedules. An exception is the North American Free Trade Agreement (NAFTA) where the
presumption is that market access and national treatment are guaranteed unless restrictions for a sector or service type are explicitly mentioned (a “negative list” approach).

How successful have multilateral and bilateral trade liberalization initiatives been in reducing services trade barriers? The general view in the literature is that, with some exceptions, they have not been effective, and that most meaningful liberalizations have taken place on a unilateral basis (Francois and Hoekman 2010). As mentioned earlier, analysis of GATS commitment schedules has revealed that actual policies are often substantially more liberal, and that this was the case even before the implementation of the GATS (Borchert, Gootiiz, and Mattoo 2014). Even the European Union, the deepest regional integration initiative at present, has encountered serious resistance to attempts at services trade liberalization such as the Services Directive.

Why bilateral and multilateral liberalization initiatives have been mostly unsuccessful is still not fully understood. Possible explanations include conflicting regulatory objectives of national regulators, weak exporter lobbies, and a lack of suitable reciprocal offers (Francois and Hoekman 2010). Many service sectors, such as professional services, are subject to substantial regulation, and it is often impossible to agree common minimum standards across countries. Because services sectors tend to be less export-oriented than manufacturing, exporter lobbies seeking market access abroad may also not be sufficiently strong to initiate liberalization initiatives. Finally, while service providers in developing countries would stand to benefit most from the liberalization of immigration regimes that would allow easier market access through mode 4, such access is strongly opposed in most developed economies, reducing the scope for meaningful exchanges of concessions between countries.

Given the lack of success of bilateral and multilateral negotiations, most of the evidence regarding the effects of services trade liberalization comes from unilateral liberalizations. One strand of this literature relies on cross-country panel data and tries to link sector-specific liberalization initiatives to performance measures such as sector-level output and productivity. The findings of these studies are generally supportive of a positive economic impact of services trade liberalization. For example, Fink, Mattoo, and Rathindran (2003) analyze the impact of policy changes relating to ownership and competition in the telecommunications sector in 86 developing countries in the period 1985–1999. They find that these reforms led to better sectoral performance, measured as increases in fixed line communication connections and in labor productivity (i.e., production per employee). However, a common problem encountered by Fink, Mattoo, and Rathindran and similar cross-country studies is the difficulty of disentangling the effects of specific policy changes from the myriad of confounding factors that also impact sectoral economic performance, an issue reminiscent of the cross-country literature on (goods) trade and growth.

More recently, a number of papers have used firm-level data and focused on liberalization episodes in individual countries. For example, Arnold, Javorcik, and Mattoo (2011), in a study of services liberalization in the Czech Republic, find that foreign entry into producer services contributed to improved productivity of downstream domestic manufacturing firms that used the inputs produced by the foreign-owned service providers. Similar results have been obtained for India (Arnold et al. 2010) and Chile (Fernandes and Paunov 2012). Given the greater ability of firm-level studies to disentangle channels of influence and to pinpoint specific mechanisms, this latest research provides more convincing
evidence for the beneficial effects of services liberalization on economic activity. It remains to be seen, however, to what extent these findings can be generalized to other countries and to the liberalization of GATS modes other than mode 3.

Conclusions

Trade liberalization and recent advances in communication and information technologies increasingly permit the trade of producer services across borders. Trade in producer services has been growing rapidly since the 1980s and now accounts for close to 70% of services trade and 14% of total world trade. Services trade liberalization has featured prominently in multilateral negotiations in the World Trade Organization and in many regional trade agreements. However, progress in liberalizing services trade has been slow and has been achieved mainly via unilateral initiatives. As a consequence, important barriers remain between many countries and across types of services, despite the fact that a small but growing body of research has shown that trade liberalization in producer services can have substantial positive economic effects.

Over the past century, the Western world has experienced significant economic restructuring, from manufacturing to services and then to producer services, which is depicted as a “quiet revolution.” In contrast with consumer services, which are primarily consumed by individuals and households, producer services are intermediate-demand inputs supplied to enterprises or public institutions for the production of goods or other services, including economic activities as diverse as finance, insurance, real estate, business services, and transportation and communication services. Intensively involved in the production process and providing state-of-the-art knowledge and expertise, producer services not only generate direct economic benefits as a substantial source of output and job creation, but also significantly contribute to regional economic performance as a catalyst of technological and organizational change.

The move from Fordism to post-Fordism and the “global shift” of industrial production since the 1970s has given rise to a world economy characterized by “flexible specialization” in production and “vertical disintegration” in organization. As an outcome of the deepened division of labor, producer services have undergone a dramatic expansion in response to recent changes in the economy, and as a consequence, replaced the manufacturing sector as the principal engine of urban and regional development. Producer services exhibit “a geographical logic” of location different from that of the manufacturing sector. The location of manufacturing activities is influenced primarily by production and delivery costs, such as transport, labor, and land. Producer services, however, reveal a strong tendency to concentrate in certain places that provide access to the benefits arising from spatial agglomeration, such as a reduction in transaction costs and a localized process of “collective learning” (Coe and Townsend 1998). From the urban system perspective, producer services are more likely to locate in large metropolitan areas. Within such cities, these service activities display a strong clustering propensity in the form of agglomeration in central business districts (CBDs) (Illeris 1996).

Thus, the rise of producer services has dramatically reorganized urban and regional economies, the structure of the urban hierarchy, interactions between cities, and urban form and landscape. In the “transnational urban system,” “world cities” or “global cities” have emerged to dominate the system as the strategic sites for producer services. In subsystems at the national and regional levels, cities that were not able to successfully transform from manufacturing-based to service-based economies have been downgraded. In recent years, an outward movement of producer services from large to medium and small cities at the urban system level and from cities proper to suburban areas at the city level has been observed (Coffey and Shearmur 2002). Advances in telecommunications and transportation enable producer service suppliers to enjoy lower wages, lower rents, and a better living environment in small cities and suburban areas.
areas, while still retaining their economic and social contacts with clients in large cities and elsewhere. The decentralization of producer services does not reduce the importance of large cities and downtown areas for attracting producer services; rather, it gives rise to inter- and intra-city functional specialization, leading to the emergence of specialized service centers in the urban system and new suburban centers within cities.

The phenomenon of producer service growth and its impacts on urban and regional development are not confined to developed economies. Over the past two decades, even though a degree of “catch-up” with the West is still required, producer services in developing countries have undergone rapid expansion and become an increasingly important force driving economic, urban, and social change (Daniels 1998). For example, the development of the Asia-Pacific region into a “workshop to the world” has enabled it to be one of the fastest-growing global regions. Although specializing in manufacturing, the region is increasingly dependent on recent producer service growth and its “strategic” impacts in order to retain its competitive advantage. The growth of producer services in the Asia-Pacific demonstrates an uneven pattern similar to that of its Western counterpart but, because it is embedded in a different economic and political context, it also shows attributes distinctive from Western experiences. As Daniels, Ho, and Hutton (2005) argue, service development in the Asia-Pacific is characterized by rapid tertiarization, parallel development with manufacturing, and strong state intervention.

China, the second-largest economy in the world, is one example. It has undergone a profound economic transition based on the implementation of reforms and an open-door policy towards investment and trade since the late 1970s. The rapid economic growth and the acceleration of industrialization that has followed, especially since the mid-1990s, has driven up demand for producer services, leading to their rapid expansion. In 2011, producer services generated US$1618.2 billion (10 032.8 billion RMB) in gross domestic product (GDP) and created 22.15 million jobs, accounting for 21.2% of total GDP and 15.4% of total employment, respectively. Some of the general attributes of service development in the Asia-Pacific, as identified in the existing literature, are certainly replicated in China. However, a history of central planning and the recent transition of the country to a socialist market economy have complicated the use of existing theories derived from the experiences of Western and other Asia-Pacific economies.

It is widely known that China adopted the planned economy framework during the Maoist era. The central government was the sole agent in allocating resources and arranging production. Although a market economy has been actively developed since the economic reforms in 1978, the Chinese state has adopted a gradual mode of market transition, which has resulted in distinctive state–market relations that affect the growth of producer services and, consequently, their role in economic and urban development. Indeed, the Chinese party-state still plays a crucial role in shaping the growth trajectory of producer services (Yeh and Yang 2013). Prior to the economic reforms, when production and distribution were arranged within the “plan,” demand for producer services was rare. While economic reform started to remove obstacles and provide opportunities for the growth of producer services, their dramatic expansion did not happen until the Chinese government recognized their importance in the economy and adopted a series of policies and approaches to facilitate their growth from the mid-2000s onwards, such as the emphasis of producer services in the two
recent Five-Year Plans (eleventh and twelfth). Producer services in China are still relatively less developed than those in Western economies, even though they show a higher growth rate. Nonetheless, they have contributed significantly to changes in the Chinese urban system and within Chinese cities in the past two decades.

First, in contradistinction to most developed and developing countries, industrialization in China did not only occur in urban areas, but also occurred in the countryside, giving rise to a large number of small and medium-sized cities. But producer services show a strong inclination to locate in large metropolitan areas to enjoy the advantages of agglomeration economies. It is also the case that the recent decentralization of producer services in Western countries has yet to become evident in China (Yang and Yeh 2013). The net effect is a significant reinforcement of the role and significance of extra-large cities in the urban hierarchy, leading to significant reorganization of the Chinese urban system. The growth of producer services is thus an important underlying process that has ushered in a new wave of urbanization in China since the 2000s. Second, the boom in producer services has underpinned the emergence of “new urban spaces” such as CBDs that have substantially reconfigured the internal structure of Chinese cities. As the “natural habitats” for producer services, CBDs are a common feature of Western cities, but before the rapid growth of producer services in the 1990s they were absent from Chinese cities. More significantly, rather than being a spontaneous form of development, the growth of CBDs in China reflects active state action in urban planning and land leasing. The distinctive state–market relationship and its interplay with the forces of globalization mean that the theoretical basis for understanding the relationship between producer services and economic development in China requires some reconstruction.

Because producer services deliver strategic benefits to the economy, they are increasingly regarded as an important determinant in the formulation of urban and regional policies. However, as noted earlier, producer services demonstrate an uneven pattern of growth in favor of certain cities and locations. The locational attributes of producer services should be seriously considered in order to formulate appropriate policies for promoting urban and regional economic and spatial transformation.

PRODUCER SERVICES AND ECONOMIC DEVELOPMENT

Further reading

Based on which economic activities use them, services are often classified into those used mainly by other businesses and those primarily used by households for final consumption. The former are classified as producer services and the latter as consumer services. Producer services are “part of the supply capacity of an economy; they influence its adjustment to changing economic circumstances [by enabling users] to adapt skills, attitudes, products, and processes to changes, or to reduce the structural, organizational, managerial, and informational barriers to adjustment” (Marshall et al. 1988, 13). The OECD (2000, 83) defines producer services as “intermediate inputs to further production activities that are sold to other firms, although households are also important consumers in some cases. They typically have a high information content and often reflect a ‘contracting out’ of support services that could be provided in-house.” Producer services serve markets that are internal as well as external to individual firms and those that are involved with external markets may only have transactions with intermediate users while others may also supply services for final consumption. These are sometimes described as “mixed services.”

Producer services are therefore intermediate inputs to the production of goods as well as other services, including public institutions that also purchase producer services as inputs. This reflects the way in which most producer services activities provide specialist knowledge and expertise to their clients that might be required infrequently or for only limited periods each day (such as office cleaning services); this does not justify the cost of retaining their own staff to fulfill their requirements. Indeed, a rapid expansion of the range and specialization of producer services over the last 30 years, with information and communications technology playing an important role, has been encouraged by a tendency for many firms to “contract out” or to outsource to other providers all but their core business functions. Such externalization is not only about potential cost savings for firms but also about gaining access to the most up-to-date information and expertise at the time and place when they really need it in order to ensure, for example, that their products retain a competitive edge, incorporate the latest innovations in their product lines, or utilize the most advanced marketing techniques to reach their customers.

There are variations in the statistical classification of producer services that depend on the resources available to national statistical institutions and the length of time that they have been collecting appropriate information. Most, such as the North American Industrial Classification System (NAICS), will attempt to conform to the International Standard Industrial Classification of All Economic Activities (ISIC) (United Nations 1989). Using Rev. 3 of the ISIC, producer services comprise the following:

Tabulation Category: J – Financial intermediation
Division: 65 – Financial intermediation, except insurance and pension funding
Group: 651 – Monetary intermediation
The classification is organized as a hierarchy, starting with the highest order Tabulation Categories (J and K) and gradually introducing increasing levels of detail down to the four-digit classes. It will be apparent that the range of activities identified as producer services is considerable and it is necessary to drill down to the lowest levels in the classification hierarchy to achieve a satisfactory level of detail. Note that the most populated groups and classes are “other business activities”; there the ongoing challenges associated with placing producer service activities into specific categories, not least the fact that new types of these services are continually emerging and, until they are represented in sufficient critical mass or have a clear identity, they will invariably be placed in the catch-all “other business services n.e.c.”

It should also be acknowledged that researchers rarely adopt a consistent classification of producer services. For some the above classification is too narrow. There are other types of services with intermediate markets, including real estate, finance, insurance, or parts of transportation services such as air and sea freight. Some are not unambiguously producer or consumer services, rather they are “mixed” services: accountancy, tax, or banking services are examples of mixed services.

Production of nature

Alex Loftus
King’s College London, UK

The “production of nature” refers to the historically and geographically specific practices through which humans “make” their environments. This making should be viewed as a coevolutionary or metabolic process in which “nature” and “society” – categories that lose their meaning within the production of nature thesis – are mutually transformed. As a thesis, it represents a profound, perhaps scandalous, challenge to the belief that nature is a pristine realm, free from human influence. Most studies have focused on the production of nature within capitalist societies. As such, the production of nature thesis, first advanced by Neil Smith (1984) in his landmark book *Uneven Development*, has come to be closely associated with a critique of nature–society relationships under capitalism and a simultaneous critique of the commodification of nature.

Smith’s original formulation is framed as a reconstruction of Marx’s concept of nature and is juxtaposed with “a bourgeois” or ideological conception of nature (Smith 1984, 15). Smith revels in the perverse claim that nature is produced, a claim that appears no less quixotic when one realizes that Smith constructs the argument as a means of better understanding processes of uneven development and gentrification. Although building on a thorough reading of Marx, Smith’s thesis goes against the grain of almost all Marxist conceptualizations of the environment: he therefore produces one of the most brilliantly original readings of a range of geographical processes.

The success of Smith’s approach lies, in part, in the relative failings of earlier theorizations of nature. *Uneven Development* was published at a moment when Marxism was characterized by a strongly urban focus and an apparent inability to speak to a growing environmental consciousness. The production of nature thesis intervened in this moment and preceded several key debates on the relevance of Marxism to environmental questions (Benton 1989; Grundmann 1991) while exploring fundamentally different ground from previous writings on Marx and nature (Engels 1976; Lukács 1971; Schmidt 1971). The thesis simultaneously chimed with the growing emphasis on anti-essentialist readings of nature that emerged in the late 1980s and early 1990s: it thus became one part of a new constellation of ideas seeking to challenge dominant readings of nature–society relations. The production of nature thesis, perhaps inevitably, came to be read alongside William Cronon’s (1991) *Nature’s Metropolis* as the theoretical counterpart to Cronon’s more empirically grounded and liberally oriented effort to read nature in the city.

The approach

The concept of nature, Smith argues, is predominantly ideological. Taking his cue from Lefebvre, Smith describes this ideology as “an inverted, truncated, distorted reflection of reality” (Lefebvre, quoted in Smith 1984, 15). This distorted worldview has changed depending on the context in which ideas about nature are developed. Although it is not an example that Smith draws
PRODUCTION OF NATURE

on, we might think of the framing of nature within apartheid South Africa. The main environmental debates under apartheid concerned wilderness conservation, often through excluding those who had a justified claim to using that land for agriculture and settlement. With the end of apartheid, environmental justice activists sought to reframe nature as a lived, practiced, and embodied realm. Challenging the ideology of nature that had existed previously, the key environmental question became how best to provide basic services for those most in need. Nature is thus recast.

For Smith an essential dualism has come to dominate the social concept of nature. Understood simultaneously as that which remains outside of human practice (an external conception) and that which is essential to the human subject (a universal conception), interpretations of nature throughout Western philosophical and scientific traditions have been plagued with the fundamental contradiction between these two understandings. Marx, Smith claims, pioneered a fundamentally different approach that liberates his writings from such contradictions; nevertheless, how one gets to grips with Marx's approach is not an easy task, given that the latter never laid out any separate treatises on “nature.” Having dispensed with Alfred Schmidt's The Concept of Nature in Marx, a book that had come to be regarded as the “definitive” account of Marx's concept of nature (Smith 1984, 18), Smith then seeks to reconstruct, largely from the Grundrisse, The German Ideology, and Capital, a fundamentally different approach.

Smith’s strategy is to reconstruct the methodological coordinates of Marx’s approach:

Marx nowhere talked explicitly about the production of nature. But in his work there is implied an understanding of nature which leads firmly in this direction … The first major task has been to detect these clues; the second is to lay them out and complete the jigsaw puzzle. Marx has given us the four corners and most of the straight edges; he has also given us most of the common pieces necessary to complete the picture, but these pieces are presented in the context of wholly different analyses. What must be done in order to recognize their significance is to turn these pieces over and, as it were, to reveal their nature face. (1984, 32–33)

The first step is to historicize nature–society relations. From the beginnings of human history, acts of production have served to break down the perceived divide between nature and society which is held to be sacrosanct within the philosophy that runs alongside it. Building on such an approach, Harvey (1996) challenges his readers to try and separate out their own lives into that which is natural and that which is social. The task quickly becomes impossible, as we consume, breathe, walk, type into a computer, and so on. Human relations with nature are, as Marx writes, metabolic. Against both environmental determinism and socialized conceptions of nature, Marx and Smith (and Harvey) see “nature” and “society” as code-determining. Capitalism establishes important sets of social relations in this process. Numerous examples of such a produced nature abound. William Cronon’s Nature’s Metropolis (1991) is one example where an environmental historian has sought to demonstrate how the emergence of a city like Chicago is dependent on a symbiotic relationship with its hinterland, and how nature is progressively transformed through this symbiosis. To take a somewhat more banal example, when an individual wakes up in the morning (in an “environment” owned by a landlord to whom he or she pays a monthly rent), the organic oatmeal and fairtrade coffee that he or she first consumes are all transformed aspects of “nature” mediated through a set of colonial, gendered, and capitalist relations of production and exchange. Although
the individual’s metropolitan life seems utterly divorced from nature, it is, in reality, entirely dependent on “nature’s” bounty. Swyngedouw and Kaika (2000) similarly recount a tale of standing on Piccadilly Circus while tracing the socio-natural connections that produce that specific place: music floats from the Rainforest Cafe, high roast coffee fills the air with its pungent odor, and the vast TV screens selling new commodities are fueled by the transformation of oil resources drawn from disparate locations.

If Smith’s work (and Kaika and Swyngedouw’s) contrasts with that of Cronon’s, it is in the greater influence accorded to capitalist relations of production and exchange. (Cronon was roundly critiqued by geographers in an entire issue of Antipode (26(2)) dedicated to Nature’s Metropolis for failing to emphasize the importance of capitalism.) Nevertheless, far from a narrowly deterministic reading of capitalism as the sole influence on nature in the present moment (a critique that Cronon seems to level at some of his own critics), Smith sees human activity (not capital, money, or capitalists) as having forged this coevolutionary relationship throughout history. Smith quotes the Grundrisse, in which Marx writes “some determinations belong to all epochs, others only to a few,” before re-emphasizing the point that the need to produce means of existence is a transhistorical act: without production, humans would, quite simply, starve, freeze, or expire. However, in tarrying with this notion of transhistoricity, Smith inadvertently replicates the dualistic conception of nature that he is seeking to refute. Thus, “Human beings are born with certain natural [universal conception] needs – food, sex, warmth, social interaction – and they are born into a world where nature [external conception] provides, either directly or indirectly, the means for fulfilling needs” (Smith 2010, 54). This brief dalliance with a dualistic conception is then quickly dispensed with, and, instead, Smith considers, albeit at an abstract level, the practices through which metabolic relations have been forged. Practical activity and the natures produced out of such practical activity shift according to a variety of determinations (the new needs that are created out of fulfilling original needs; the conceptions of the world that circulate within particular societies; and emerging divisions of labor).

Although attentive to the changes in nature’s production, Smith’s thesis can be contrasted with epochal arguments that detect a blurring of the nature–society relation within the contemporary moment. (In many respects, discussions of the Anthropocene can be read as one more recent manifestation of such an epochal argument, against which the production of nature thesis would, quite rightly, present a more historically and geographically specific reading of what has always been a metabolic process.) Challenging shallow, and often apocalyptic, claims about the death of nature, Smith is quite explicit in stating that “production in general is the production of nature” (1984, 53). Nevertheless, some confusion has emerged around the relationship between the transhistorical (the production of nature) and the historically specific (the capitalist production of nature), leading to Castree’s (2000a, 643) claim that Smith “used Marxian economics to argue that capitalism has replaced a non-human ‘first nature’ with a socially produced ‘second nature.’” Nowhere does Smith make such an argument, even if he appears to come close to doing so. Much of the confusion arises from Smith’s idiosyncratic reading of “first” and “second” nature in Uneven Development. Although they have some historical purchase in their reference to the human and nonhuman, first and second nature acquire a qualitatively different meaning in the present moment. Thus, against the
PRODUCTION OF NATURE

commonsense reading of first (nonproduced) and second (produced) nature (as interpreted by Castree), Smith (1984, 55) claims:

This distinction ceases to have real meaning … the distinction is now between a first nature that is concrete and material, the nature of use values in general, and a second nature which is abstract, and derivative of the abstraction from use value that is inherent in exchange value.

Reception

In the first readings of Uneven Development, the production of nature thesis was often overlooked. Even now there seems to be a reluctance to see Smith’s theorization of the production of nature as fundamental to the production of space. Nevertheless, by the late 1980s and early 1990s the production of nature thesis had become a fundamental influence on the fast-moving tide that sought to retheorize nature in nonessentialist ways (Braun and Castree 1998; Castree and Braun 2001). Elsewhere, Castree has noted the distinctiveness of the production of nature thesis within Marxist readings of socio-natures. He argues that Smith’s work, although much less known, avoids the pitfalls of other theorizations such as O’Connor’s and Benton’s. Writing in 2000, Castree offered

a long overdue presentation of an alternative tradition of Marxist work on the capitalist production of nature … It thus promises to take us beyond the Nature–Society dualism organising both previous Marxian work on nature and versions of bourgeois technocentrism and radical ecocentrism. (2000b, 10)

If Castree gave a long overdue presentation of the production of nature thesis in 2000 (and was in many respects fundamental to the revival of the fortunes of the production of nature thesis within and outside geographical scholarship), Smith’s work has been engaged with more readily since then; however, it has still perhaps not quite achieved the status of a “classic” thesis within Marxist debates.

Perhaps the main subfield to explore the production of nature thesis has been urban political ecology; thus, in the writings of Swyngedouw, Heynen, Kaika, and others, the production of nature has been seen as the starting point for an analysis of the power-laden ways in which nature comes to be urbanized (Heynen, Kaika, and Swyngedouw 2006). Loftus (2012) places the production of nature thesis in conversation with an immanent critique of everyday life and thereby seeks to position the thesis more centrally within the Marxist tradition. However, elsewhere the sources turned to for an analysis of Marx’s approach to nature remain works produced by sociologists, economists, and political scientists.

Several engagements with the production of nature thesis have, unsurprisingly, taken offense at the stark, and seemingly paradoxical, claim that nature is produced. For both Marxists (Benton, personal communication) and non-Marxists (Lorimer 2009), this assertion is one step too far; the thesis appears to place too much agency on humans and quickly lapses into dualisms. The production of nature is portrayed as hubristic, insensitive to nonhuman agency, and even dangerous. The normative implications are then read as the demands of a demagogue whose wish to fully “humanize” nature will be frustrated by nature’s own “liveliness.” Whatmore (1999) has taken issue with the dialectical framework. Thus, against Castree’s claim that the production of nature thesis is nondualistic, and against the clear overall intent of the production of nature thesis, Whatmore mistakenly writes: “far from challenging this a priori categorization of the things of the world, dialectics can be seen to raise its binary logic to the level of a contradiction and
engine of history” (1999, 25). These criticisms are perhaps to be expected from a thesis that is so deliberately provocative. To place labor squarely within an environmental politics was always likely to raise the ire of those who would seek to defend nature’s beauty, its vitality, and the agency of nonhuman over human. However, beneath the provocations and the aggressive prose, the production of nature thesis is acutely sensitive to nonhuman difference, to the interrelationships between human and nonhuman, while it also remains profoundly open to nuanced readings of coproduction and nonlinear science.

Future directions

Given the mass of scholarship now accumulating on nonhuman agency, it seems likely that such themes will be explored further within work on the production of nature. Donna Haraway, whose writings on the figure of the cyborg and on companion species chime rather beautifully with Smith’s ideas, would seem one of the most brilliant of fellow travelers on such a journey. Indeed, the relational approach to socio-natures developed by Haraway (2008) has many similarities to that of Smith: one can sense how indebted Smith, Hartsock, and Haraway might have been to one another in their initial shared readings of Marx and also in their collective efforts to elucidate a nondeterministic understanding of the socionatural. Hartsock’s writings on feminist standpoint theory may well provide another valuable source of inspiration for future work, enabling a more thorough exploration not only of the gendered division of labor out of which “produced natures” emerge, but also of the conditions of possibility for nonbourgeois conceptions of nature (see Loftus 2007). These conditions of possibility are enabled by the practical acts of those working within capitalist patriarchy.

Such an emphasis on the gendered division of labor suggests another crucial area for development. Abstract labor and the role of the exchange abstraction are crucial to the kinds of nature that Smith sees being produced and reproduced within capitalist societies. Nevertheless, acts of laboring simultaneously exist as concrete practices: labor under capitalism is a differentiated unity of both the concrete and the abstract. By neglecting concrete practices and the multiple relationships out of which workers are not only classed, but raced, gendered, and sexed, the production of nature thesis risks assuming a white working-class laborer as the subject of history. Better historicizing the concrete acts out of which historically and geographically specific natures are produced would not only enable the thesis to speak more directly to a range of concerns outside of the Marxist canon but also open up conditions of possibility for thinking beyond abstract natures to other more democratic environments. Ekers and Loftus (2013) have suggested that Antonio Gramsci’s absolute historicism provides valuable conceptual resources for rethinking such a position.

Opening up the labor process to a broader range of determinants also necessitates a deeper consideration of mental, affective, and immaterial laboring practices, in addition to, while not excluding, the manual labor which is often prioritized within secondary writings on the production of nature. Smith discusses the importance of these emerging divisions of labor and their influence on the production of nature and associated conceptions of nature (1984, 52–53). As elsewhere, one of the primary inspirations for his discussion is Sohn–Rethel’s (1982) discussion of intellectual and manual labor and the real and conceptual abstractions that emerge from such concrete practices. However, in subsequent discussions little sense has been given of the kinds of nature produced through the laboring
practices of the call center worker, the caregiver, or the artist. As these forms of laboring have gained greater prominence within late capitalist societies, the production of nature thesis can seem a somewhat redundant basis for considering produced environments and conceptions of the world. However, the greatest advantage of the production of nature thesis in being able to respond to such questions is the way it is framed not as a doctrine but rather as an approach through which historically and geographically specific practices might be better understood and critiqued. The production of nature thesis thus encompasses a flexibility to accommodate other modes of working and an openness to a wide range of historical and geographical practices.

Productivity

Andrés Maroto-Sánchez
Universidad Autónoma de Madrid and Instituto Universitario de Análisis Económico y Social (IAES), Spain

Productivity is commonly defined as a ratio of a volume measure of output to a volume measure of input use. While there is no disagreement on this general notion, a look at the specialized literature and its various applications reveals very quickly that there is neither a unique purpose for, nor a single indicator of, productivity.

Despite these controversies over its particular definitions and different uses, “productivity” is probably one of the most widely used terms by economists and noneconomists alike. Political leaders use it in their electoral programs and proposals. The media refer to it when they discuss economic performance. Trade unions and business leaders use it in wage negotiations and demands. But productivity tends to get the most attention when it is poor. That is, when one of the indicators that are normally used to analyze productivity shows very low or negative growth. Productivity is a concern because, as Krugman (1990) said, “productivity isn’t everything, but in the long run it is almost everything.” Productivity affects a country’s capacity for economic growth and its global competitiveness, as well as the standard of living of its citizens. In the long term, whether or not the welfare of an economy improves depends essentially on improving productivity.

Within the ongoing debate around productivity, the case of the services sector is particularly important, both in terms of the theory and of its political and economic applications. The developed economies are clearly service economies. Most of the production structure, in terms of both employment and added value, is directly attributable to activity in the services sector. As a result, in the long term the aggregate productivity of these economies should converge toward the rates registered by the services sector. However, not only is the productivity of the services sector important in itself, but it is also important indirectly because of the strategic effect of intermediate services – mostly producer services such as transport, financial services, communications, and certain business services – on the improvement in productivity in other economic sectors.

One problem that always arises when writing about productivity is that the concept itself is often confused. The notion of productivity has been approached from various angles and has been used for a range of purposes. This has given rise to significant ambiguity. First, the term “productivity” is not univocal. It can refer to the economy as a whole but also to a particular sector or activity, or to a specific company. Second, it can be measured based on one factor of production or on a combination of them all. It is also important to bear in mind that other terms, such as “efficiency,” “efficacy,” “competitiveness,” and “effectiveness” are sometimes used incorrectly to denote productivity.

Rethinking the concept of productivity

It is therefore necessary to clarify the different definitions that have been formulated for the
concept of productivity throughout the history of economic thought. The first to approach the subject of productivity were eighteenth-century physiocrats who referred to it as the capacity to produce. Over the years, its meaning has gradually been refined and by the twentieth century economists were referring to productivity as the relationship between the end product and the factors required for its production. This definition has been accepted for several decades: first, because it evokes what productivity is considered to be in the context of a company, an economic sector, and the economy as a whole; and, second, because it does not vary depending on the kind of production or socioeconomic system being analyzed. According to this definition, productivity is simply an arithmetical quotient that can be understood as the efficiency with which factors are used in the production process.

Based on this definition of the term, “productivity” is understood as the ability of an economic player to convert inputs into finished goods. It is therefore a relative concept, that depends on whether comparisons are made between time periods or between different units of production, or whether it is used to refer to a unit within a company, a company, an area of activity, an economic sector, or the aggregate economy.

However, the socioeconomic reality – increasingly deregulated, globalized markets; constant changes in consumer preferences and expectations; a reduction in the life cycle of services; new structures and work organization systems – is leading us to reconsider the notion of productivity. Traditionally, the term was related to productive efficiency – insofar as it analyzes to what extent the use of resources to create a particular end product is optimal – but the concept of effectiveness or efficacy is gradually being incorporated into this definition, understood as the way in which companies dynamically adapt to the needs and demands of consumers. Productivity, therefore, depends intrinsically on the value of products and services – which is why terms like usefulness, quality, convenience, availability, and originality arise – and on the efficiency with which they are produced and supplied. Consequently, this far broader definition of productivity calls for a broader, clearer set of indicators that embrace these new elements, as well as those related to processes and methods that improve productivity, to the environment and sustainable development (with the emergence of concepts like green productivity), to the management of value and supply chains, or directly to the human factor as a key element.

**Measuring productivity**

However, the description of the concept of productivity thus far does not allow for the difficulties that arise when this concept is applied to the economic reality. For this reason, the problems and biases that arise when measuring productivity have received a great deal of attention in recent years. Most current research seeks to improve the quality and quantity of existing estimates, or to present and develop new methods that overcome the biases and errors. The main elements when measuring and analyzing productivity, especially in the services sector, are those related to output estimates: adjustments deriving from improvements in the quality of the services offered and their effect on the price of the product; estimates of activities that operate outside the market, such as certain public services, or in underground (or informal) economies; international comparisons based on common terms; and problems stemming from the aggregation of factors and prices, both in terms of time and space, among others.

Productivity can be measured using various approximations, indicators, and methodological
PRODUCTIVITY

Deciding which of these to use falls to the analyst, who usually makes a decision based on the objective of the study and the availability of data with which to undertake the research. If we take productivity as an economy’s capacity to convert inputs into end products and services, it is a relative concept. Different productivity indicators will arise depending on the different kinds of productive factors analyzed.

Measurements such as **apparent labor productivity** or **apparent capital productivity**, where only one input is analyzed, are known as **partial productivity indicators**. Despite the potential problems with these – such as the fact that a change in the proportions of the composition of factors affects productivity – these measurements are useful for analyzing potential growth, so whether they are used will depend on the time frame of the study in question. In the case of services, the indicator traditionally used to measure productivity has been the relationship between production – measured through value added – and the work factor – whether that be total workers or total hours worked (OECD 2001). Nonetheless, when we try to apply this indicator to some services, its significance is questionable since the added value of many services, especially those that are not destined for sale, is practically equivalent to the work factor cost. This means that there is a direct link between the evolution of production and productivity in these activities.

Due to the limitations of these partial productivity measurements, the concepts of **total factor productivity** (TFP) and **multifactorial productivity** (MFP) have been introduced for cases where all factors of production (TFP) or more than one factor of production (MFP), respectively, are included in the indicator. These multifactorial measurements are not, however, independent of the partial measurements; they form part of the sources of growth of the apparent labor productivity. When all factors of production are included, the growth in TFP can be conceived residually as the growth in output that cannot be explained by the growth in inputs. It is in the estimation of these multifactorial indicators that most innovations have taken place in recent decades. Multifactorial productivity can be estimated through frontier analyses using both parametric techniques, such as stochastic frontiers and Bayesian estimations, and nonparametric techniques, such as data envelopment analysis. Likewise, other kinds of analysis have been introduced, such as the average response function and the use of index number theories.

Once we have overcome the problem of choosing the right indicator with which to measure productivity, further problems and issues arise. These become more significant still when we attempt to analyze the services sector generally and some producer services specifically (Maroto 2011). This has led to an intense debate in recent decades and to a case-by-case analysis of the different types of services, in an attempt to identify potential biases or errors when it comes to measurement of their productivity.

The traditional estimation technique used for other economic activities, based on double deflation, is not the most appropriate for service activities. The use of double deflation incorporates various problems that would be inconsequential or nonexistent in the production of manufactured goods. But, in the case of services, one of the main problems is how to account for intensity or quality. To account for these within the productivity indicator, we would have to add two more indices to the index of services production: one related to the complexity of the set of services and another related to their intensity. Another aspect to bear in mind for many services, especially those related to the transfer of knowledge such as education, health care, research and development, and some business services, is that their provision gives rise
to a series of results in the medium and long term. For example, a lawyer could charge for his or her services based on direct output (legal work undertaken as reflected by the services provided and the time taken), but also on the basis of the results of his or her output (a proportion of the payout obtained by the client through the lawsuit). It is often difficult, however, to distinguish between direct output and medium- and long-term effects.

Traditional view of services and low productivity

Regardless of the indicator used to measure productivity and the aforementioned issues with these indicators, the literature traditionally cites the relatively low productivity of the services sector as one of the key factors behind its growth in modern economies. This idea is fundamentally based on analyses developed from the seminal work of Baumol (1967). These attribute the differences in productivity in services to the role played by labor. Baumol’s cost disease, as this phenomenon is widely known, if it were to take place, would result in a slowdown in economic activity and the aggregate productivity of the advanced economies, along with an increase in service prices.

The empirical evidence at an international level for the developed economies for different time periods appears to indicate a negative relationship between the size of the tertiary sector – both in terms of occupation and of production – and the growth of aggregate productivity. Therefore, for the services sector as a whole, this would appear to confirm conventional thinking about its relatively low productivity. However, the different ways in which services are defined and measured and how they are included in the productive process could have an impact on the results. Some of the effects many services have on aggregate productivity are undervalued, especially for producer services such as communications, transport, and financial and business services.

More positive perspectives on services and productivity

Since the mid-1990s there has been progress toward a less negative view of services and productivity. This been driven fundamentally by two elements. First, traditional theses have been adapted to take account of the kinds of service being analyzed. Many authors state that the aggregate nature of some studies leads to the real productivity of tertiary activities being undervalued. A microeconomic analysis would therefore be the most appropriate option. Second, new ideas have been introduced that contradict, or at least limit, the traditional theories. Some authors even go so far as to state that Baumol’s cost disease has been cured (Triplett and Bosworth 2004).

One of these new ideas is to incorporate the role of innovation in services productivity, especially in some high-growth activities. In addition, related innovation, the role of knowledge, and human capital have been emphasized, as they facilitate significant increases in productivity in many tertiary activities, especially knowledge-intensive business services (KIBS). Another important factor helping to revise the image of many services is the positive indirect effects they have on other productive sectors. This is the case for activities that are aimed at intermediate demand and are highly weighted within the intermediate consumption of other highly productive sectors, such as logistics services and transport, telecommunications, information technology (IT), many advanced business services, research and development (R&D), and design services. All these services, which are also
closely linked to information and communications technologies (ICTs) and the new economy, have productivity levels and rates that are not only comparable with, but even higher than, those observed in some of the most dynamic manufacturing industries (Maroto and Rubalcaba 2008).

Finally, another of the strongest lines of revision in recent years is the idea that the low productivity of many services is merely a measurement issue; the data for many service productivity analyses is simply undervalued. The effect of this bias will depend on the weight that poorly measured tertiary activities have in the productive landscape as a whole. Among the best examples are the many producer services whose real effect on the aggregate productivity of the advanced economies is far greater than that expressed by traditional statistics, owing to not only progress in innovation and knowledge in those services, but also the indirect stimulation they provide for other productive sectors.

Conclusion

In summary, the problems of measuring the productivity of services stem from two sources. First, there is an issue around how to estimate inputs. For example, it is important to measure the work factor through the number of hours worked, especially in those services where there has been a reduction in the number of hours per worker or where part-time or seasonal work accounts for a substantial proportion. Likewise, it is important to bear in mind the relationship between the work factor and other intermediate consumption, especially in services such as commercial retail services or financial services, where outsourcing and offshoring have become more widespread in recent years. Second, output estimates could also be improved. In the case of services, for example those related to ICTs, these improvements would stem from a differentiation in the calculation of constant prices, between price increases derived from purely inflationary processes, and between price increases that are attributable to improvements in the quality of services. However, not all of these are easy to analyze. There are therefore very few studies that comprehensively examine all of these measurement biases. For this reason, work is currently under way on alternative measurement procedures or improvements to the existing statistics on the productivity of services.

However, the evidence to date can only give an initial indication of the extent of the measurement biases and their effect on the calculation of productivity variations. It does not resolve many of the doubts about the reliability of measures of productivity in services. Possible channels for future improvements could arise from the wider application of the best practices developed by some countries (such as Canada, the Netherlands, and some Scandinavian countries) for the measurement of services productivity, and from a stricter and more careful application of existing production models to some service activities such as health care, transport and communications, and business. Some countries have begun to take steps to improve these measurements and international organizations are working – along with their member states – on various specific sectors, such as finance, insurance, and IT services. Nonetheless, it is clear that much more effort is required if we are to achieve accurate measurements of productivity for the services sector in general and for producer services in particular. Only then will we reach a better understanding of the factors that drive services productivity and the differences that exist at an international level.

Property and environment

Nicole G. Graham
University of Technology Sydney, Australia

Definitions

The property regime of a human society is the regulatory mechanism that controls the distribution of real and abstract things both within and beyond that society. Consequently, concepts of property profoundly affect, and are affected by, the culture and the environment of a society. Property regimes are arguably the most important of all regulatory mechanisms with regard to the environment because they articulate and actualize culturally acknowledged principles of, and processes for, the human use and disposal of various environmental elements and processes. The specific character of a property regime, its method of distribution, is determined in part by political models and in part by environmental conditions. Property, from the broadest view, also necessarily implies and requires corresponding corrective processes (redistributive and/or punitive) for instances of improper distribution, access, use, and disposal of the environment. The numerous histories, philosophies, and geographies of property are so fundamental to human economies and cultures that they encompass the entire history of the relationship between human societies and the environment.

Ideas of property create, protect, and defend culturally specific environmental epistemologies. For example, cultures in which the environment is regarded principally as a set of economic resources have property regimes that position humans as separate and superior to the environment. These property regimes articulate property primarily (but not exclusively) in terms of entitlement (rights). In contrast, cultures in which the environment is regarded partly as a set of economic resources and partly as objects and processes invested with noneconomic cultural, ecological, and/or metaphysical significance have property regimes that position humans both within and connected to the environment. These property regimes articulate property primarily (but not exclusively) in terms of obligations (responsibilities).

In comparative legal terms, property is understood as a set of principles concerning access to and disposal of things. Access to environmental things, as objects of property, is described variously in terms of inclusion, exclusion, and possession (contingent on the status, permissions, transactions, and privileges of social membership), rights (actual, future, potential, mediated, presumptive, subsidiary, individual, familial, tribal, communal, sovereign, sui generis), responsibilities (customs, duties, and obligations), and security of tenure (relation to other property interests). Disposal of property is described variously in terms of alienability (transferability, assignment, sale, and gift) and waste (permissive, voluntary, and externalities).

Categories of property

There are many different kinds and categories of property across time and place, more than can be described here. The following familiar categories are neither exhaustive nor mutually
exclusive. However, they do provide a helpful basis on which to consider some key features of property regimes generally and in relation to the environment specifically.

Open access

An open-access regime is not properly a property regime because it is characterized by the absence of regulation. Open access is in fact an unregulated regime in which a thing is regarded as being simultaneously the property of everyone and no one, that is, a thing to which all may have access but for which none bears responsibility. The reason that a thing is so regarded is that it is an abundant and inevitable geographical feature of living in that particular place (for example, snow in Alaska), or that human society has yet to successfully remove it from this category and place it a different category with restrictions of access and use. In legal terms, there are no rules (of exclusion and alienability, for example) regarding the access, distribution, use, and disposal of environmental resources within an open-access regime. In political terms, open-access regimes can be the source of intense and ongoing political conflict due to competition for the resource in circumstances where the resource becomes scarce (seasonally or permanently) and no responsibility is taken for the health of the resource base and/or for social stability.

Historically, human societies have determined open access to (and use of) parts of their own (or another community’s) local habitat for food and fuel which were believed to be, but were not in fact, infinitely abundant and inevitable geographical features of their environment. It is thus often the case that things that were once regarded as objects of an open-access regime were so regarded on the basis of ecological misunderstandings and attendant economic miscalculations, or political immaturity (through which ongoing social conflicts over the objects remained unresolved). For this reason, open access is increasingly regarded as a regulatory failure rather than as an evidence-based economically sustainable property regime. Another, longer-term view is that because human knowledge of certain environmental resources is acquired through economic experience with those resources and because that knowledge necessarily develops over time, open-access regimes may be more generously regarded as indicative of immature or developing knowledge bases rather than regulatory failures per se.

Once an environmental resource is recognized as no longer being (or never having been) abundant, renewable, or easily reproduced, it is common for societies to remove that resource from this category and thereafter restrict and regulate access and use of the object. For example, marine resources (fisheries) beyond the jurisdiction of individual states are no longer regarded as an open-access environmental resource. Modern laws of the sea with regard to the distribution and use of marine resources have replaced open-access regimes whereby societies depleted and/or exhausted fish (including whale) stocks.

The property regimes of nations and communities colonized by Western European imperial forces since the sixteenth century were often mistakenly regarded as open-access regimes. Indeed, it was often precisely on the basis of this erroneous classification and the corresponding international law doctrine of *terra nullius* that those nations and communities were colonized.

Common property

Common property regimes, also known as “the commons” and “community commons” are those in which entitlement to and responsibility for certain environmental resources are held in common by members of a certain society.
Common property is determined in part by the agreement of a society (with a defined membership) to both enable (entitle) and restrict (prohibit) its members to access, use/consumption, and disposal of certain environmental resources at certain times and under certain conditions. Common property is determined in part also by the geographical conditions and limits of those resources. Common property is thus a regime that can control the allocation and distribution of environmental resources effectively over long periods of time (for example, centuries) because it combines (evidence-based or experience-based) human knowledge of environmental resources with locally adapted and highly particular prescriptions of access, use, and disposal of those resources. For this reason, common property is often regarded as suitable for environmental resources that are less abundant than open-access resources, or less resilient to unregulated access and use. For example, in parts of pre-Enclosure England, the timber branches, sticks, and twigs of certain species of tree already fallen to the ground or easily pulled down by a simple hook were regarded as common property. The corresponding corrective rule applicable to the same context prohibited the taking of branches of certain trees if that involved using a sharp utensil such as an axe (Bellamy and Williamson 1987).

However, while common property regimes often share the quality of providing environmentally sustainable regulatory practices, there is a wide diversity of sociopolitical structures at their foundation. For example, some common property regimes are characterized by egalitarian structures while others are hierarchically structured. Successful common property regimes (those that have endured over the longest periods of time) have been associated with small human populations and/or strict administration. For example, the violation of common property laws regarding the killing or taking of a certain animal, or the use of freshwater outside the fixed (and sometimes biologically determined) rules of membership or outside the appropriate (seasonal or cultural) timing, have in some regimes been severely punished. Rules of exclusion and alienability are central to common property regimes. The access to and use of common property is restricted to the members of the society owning the resource and excludes all others (noting certain exceptions for cultural purposes including hospitality and economic exchange with other societies). Common property is by definition not individualistic and so the alienation (transfer through gift, trade, or sale) of common property by individual members of that society is therefore generally prohibited by its operation.

The property regimes of nations and communities that were colonized by Western European imperial forces were often held in low esteem, maligned, or not recognized at all for predominantly colonial purposes (for example, the doctrine of *terra nullius* was the basis for the assertion of British sovereignty in the colony of New South Wales in the eighteenth century). However, since then, many of those property regimes have been belatedly recognized, and some have been classified as common property regimes. Owing to the association of successful common property regimes with environmentally sustainable economic practices, indigenous property regimes in former colonies are occasionally conflated with environmental knowledge that is regarded as somehow inherent to an indigenous society on the basis of race, rather than on long-standing experience and evidence-based economic expertise with certain environmental resources in particular places. The tendency to essentialize and conflate indigenous property regimes and environmental knowledge (and to identify indigenous peoples with nature in
the Enlightenment’s nature/culture paradigm) arguably perpetuates the misunderstanding and misdescription of indigenous laws particular to the “other” of colonial discourse (Fitzpatrick 1992; Krech 1999).

Common property regimes can be used to resolve persistent tensions and dilemmas about the access to and use of critical environmental resources, and have been used in hybrid forms within capitalist economies. For example, in the Murray–Darling Basin of Australia, irrigation cooperatives and corporations were established by the New South Wales government in 1994 to transfer the ownership and management of irrigation schemes in the Basin from the state to the irrigators themselves. Where once farmers were water entitlements holders under a state-owned irrigation scheme, now they are shareholders owning and operating cooperatives and corporations. Water-sharing plans regulate the distribution (including the trade) of the water in the catchment to and between the members of the cooperative or corporation.

Crown, state, and public property

Crown, state, and public property regimes include a broad category of different interests in land and environmental resources that are defined by the fact that they are controlled by the sovereign of a given jurisdiction (whether monarchy, presidential systems, parliamentary republics, theocracies, or one-party states). Indeed, these property regimes do not exist in the absence of a legally constituted and observed sovereign power. Most property interests within this category exist within hierarchical political structures and are abstract rather than material (environmental) in origin, logic, and extent. Public property, unlike open-access and common property regimes, has been said to be nonrivalous because the resource base is not diminished by the use of others. For example, whereas the taking of 20 fish (from an open-access or a common property regime) by one person will decrease the fish stock available for others, the walk through a national park by one person does not decrease the quantity or quality of walks available for others. However, even public property (beaches, parks, rivers, and state-owned mines) is subject to diminishment of the quality and quantity of resources through human use over time.

In England and in Commonwealth countries, the feudal doctrines of tenures and estates determined that the ownership of all land was vested ultimately in the Crown through whom smaller private tenures (landholdings) and estates (interests defined by time) were created and distributed to the Crown’s subjects. In addition to being the ultimate “owner” and “radical title holder” of all land within the jurisdiction, the Crown also reserves land to itself called Crown Land. Crown Lands are now administered by legislation which determines access, use, and disposal of these lands and the resources therein. For example, in (the Commonwealth of) Australia, extensive leasehold interests in Crown Land include mining leases and pastoral leases to facilitate and control specific land uses. Crown Land includes but is not limited to public property. Public property in monarchical societies owes its origins in part to common property as after the enclosure of common property (the Enclosure of the Commons), land and resources that remained in common usage, such as parks, became regarded and eventually regulated (through the local municipal government, for example) as public property. Crown land is inalienable (it cannot be transferred by gift or sale other than by the Crown itself). Access to and use of the various kinds of Crown Land depend on the relevant governing legislation and so the
Crown ultimately determines whether, when, and who to exclude from that access and use.

Unlike the tenurial system of Commonwealth jurisdictions, the property regimes of presidential systems and parliamentary republics are allodial (land without a lord). Allodial land interests are the interests of a private citizen (rather than a subject) and are not derived from the Crown. As such, they are regarded as a form of absolute ownership. However, such private property interests, while enjoying legal and cultural protection through constitutional law and powerful political lobby groups (property rights movements), are ultimately creatures of political hierarchies and are accordingly subject to acquisition by the state from time to time. In recent years the extent to which the state does compulsorily acquire or “take” the private property of its citizens for broader environmental benefits has become the subject of significant debate. State property includes property that was never successfully claimed by private interest holders and property that has been acquired compulsorily (or was never available to the private sphere) by the state. This is called compulsory acquisition or takings. State property includes but is not limited to public property. Public property in presidential systems and parliamentary republics is similar to public property in monarchies in that it is state lands and environmental resources that are reserved for public access and direct use (such as national parks and cultural heritage sites). State property that excludes, prohibits, or strictly limits public access and uses, such as military bases and nuclear power plants, is invariably rationalized by the state in terms of the ultimate benefit (economic or security, for example) to and on behalf of the public, its citizens.

Private property

Private property is a regime in which the access, use, distribution, and disposal of land and environmental resources is controlled not by the Crown/state, a community, or a collective, but by individual entities (which can be natural persons or legal persons such as a company) through the notion of an entitlement or “right.” The twin rights that characterize private property are the right to exclude all others from the land or resource, known as “exclusive possession,” and the right to alienate (to transfer by gift or sale) the land or resource.

Because private property consists in multiple rights (the right to possess, the right to exclude all others, the right to alienate), it is common for private property rights to be shared between different individuals. For example, the ownership of a parcel of land may be shared between co-owners in various proportions and under various conditions; or the right to exclusive possession may be sold temporarily to other individuals through lease arrangements or permanently through easements of different kinds. There are many other ways in which private property in a single parcel of land or resource is fragmented through legal mechanisms so that the “ownership” of something becomes complex and complicated for those wishing to interact with, experience, or impose conditions on its access and use. In theoretical terms (to be explored in more detail below), this complexity is referred to as a “bundle of rights” in which each “stick” within the bundle indicates a different right or interest in the object of property. Some interests pertain to the abstract dimension of time (such as future, current, reversionary, and redemption interests) while others pertain to the more material dimensions of space or place (such as easements of right of way, or covenants to not build something, or licenses to use or take certain things from the land).
The legal apparatuses of private property regimes regulate the normative and discursive conditions through which objects are commodified, exchanged, and accumulated as wealth. Private property is therefore a category of property that is indispensable to the purpose and operation of capitalist economies. Accordingly, private property rights have been afforded strong legal protection and legal priority within the overarching hierarchy of legal rights and obligations in a given legal order, thus stabilizing and then entrenching the normative dimensions of private property. For a long time, private property rights were regarded as absolute rights free from external (usually government) interference and unshackled by obligations to the object of property as well as to all other non-owners of that object of property. However, in practice, private property rights are not absolute as they have always been subject to the demands of social and technological change. The acquisition of private property by the state or Crown is enshrined in the constitutions and conventions of several jurisdictions and has been long practiced to achieve, for example, improvements in infrastructure (through the construction of railways, freeways, airports, etc.) and the realization of mineral wealth beneath the land’s surface (through the legal fragmentation of land ownership into state and private strata).

Since the late twentieth century, private property has been used as an instrument of public environmental protection policy through the extension of the concept of private (and therefore tradable) property rights to environmental phenomena such as biodiversity (bio-banking and offsetting), pollution (carbon credits), water, and genetic material, for example. The extensive use and strong policy preference for the abstraction of environmental phenomena into environmental assets, environmental services, and environmental markets is consistent with the logic of commodification within capitalist economic theory. However, private property regimes have also been identified as a major legal and cultural agent of adverse anthropogenic environmental change (Sax 2008; Graham 2011). It is in this context that the use of private property rights in environmental policy is the subject of strong debate, and the extent to which environmental policy can further develop without evaluating the fundamental role of private property in environmental change (for both sustainable and unsustainable outcomes) is unclear.

Private property regimes have been closely related to the forceful termination of the property regimes of indigenous nations and communities through acts of dispossession and declarations of imperial sovereignty. The expansion of the British Empire throughout the seventeenth and eighteenth centuries depended heavily on private property concepts, including the notion of exclusive possession, which were applied in non-British jurisdictions against the different property regimes in operation. The notion of exclusive possession, that is, that land cannot be shared, is central to the operation of private property, and it was this way of thinking about property that made it possible for imperial forces to justify to themselves the dispossession of First Peoples from their lands physically and in abstract legal terms. In the twentieth century, private property regimes were radically challenged by native title claims. However, invariably native title has been regarded as incompatible with private property rights due to the right of exclusive possession, and private property is therefore legally immune from native title claims, which can only be made over nonprivate property.

Private property in the environment can logically include any and all of the components and processes of all of the Earth’s systems even prior to any necessary technological innovations designed specifically to capture or harness them.
This is because, owing to the abstractness of the notion of a private property “right,” it is possible to create property interests in abstract things, including things that (may) exist in the future, ideas, and innovations. Similarly, property in the environment is not limited to property in the elements and processes of the Earth, but may extend (subject to technological possibilities) to the Earth’s solar system and beyond. It is important to acknowledge also that broader definitions of environment, including contemporary ecocentric definitions that situate humans within the environment, and anachronistic colonialist definitions that conflate colonized peoples with “nature,” have facilitated private property in human beings (alive, deceased; fluids, cells, tissue, and body parts). Private property in the environment can mean therefore property in almost anything.

Stewardship and custodianship

Beyond the categories of property described above, there are also property regimes known as land or country stewardship and custodianship. Western property regimes articulate property in terms of “rights” (entitlements) and “negative duties” (to avoid certain behaviors, for example, restrictive covenants in private property regimes; prohibitions of access to and use of certain species of plants and animals in common property regimes). However, the property regimes of custodians and stewards articulate property in terms of “caring for country” through locally particular land-use practices such as fire-stick farming (Altman and Kerins 2012) and responsibilities (Lucy and Mitchell 1996). Western legal discourse would translate “caring for country” as “positive duties.” Stewardship and custodianship property regimes are highly culturally and geographically particular and their legal apparatuses vary significantly across time and place. However, both share long histories and similar environmental philosophies of a nonhierarchically structured connection between humans and the environment. Indeed, the characteristic intellectual premise of these regimes is that humans and the environment are epistemologically and ecologically integrated, rather than separate. This philosophy is sometimes apparent in the religious and spiritual discourses of societies with stewardship and custodianship property regimes which anthropomorphize environmental elements and process, and which adopt totemic systems and embed totems with enduring economic, social, and spiritual significance.

Theories and critiques of property

Overview

Owing to the broad reach of property as a key concept in cultural and legal discourses and as a powerful social institution and regulatory mechanism, it has been the subject of the research of scholars from multiple disciplinary backgrounds. Conventionally, theories and critiques of property have been anthropocentric in focus, emphasizing the role and means through which property organizes the structure, quality, meaning, and experience of human life and human society (Davies 2007). Such work can be found largely within and across economic, sociological, anthropological, political, geographical, and legal scholarship. Given the predominance of capitalist economies in the anglophone world, a great deal of property theory written in the English language deals with questions of distributive justice, economic efficiency, and personal liberty arising from the ubiquity of private property regimes.

However, property theory of the late twentieth and early twenty-first century has increasingly broadened its scope beyond the human world, to include a focus on the relationship between
property and the environment. Such scholarship considers the environmental potential of extending the concept of rights at law to things in nature (Stone 1972; Burdon 2014) and of redeveloping the current model of private property as a “bundle of rights” into a more environmentally sustainable “web of interests” (Arnold 2002). It also critiques the adverse environmental legacy of the dominant paradigm of private property as a legal institution designed to incentivize limitless growth (Sax 2008; Alexander 2011). Contemporary property scholarship has also pointed to the ways in which private property regimes have been based more on abstract principles than on material conditions, which adversely affects the viability and durability of those regimes (Sherman 2008; Graham 2011).

### Labor, improvement, and growth

Theories of private property broadly classified as liberal have presented rationales for and defenses of private property regimes. However, despite the predominance of the anthropocentric lens throughout this theoretical tradition, the environment, referred to as “nature,” constituted the intellectual and material basis of these ideas. The gradual transition from feudalism to capitalism in England depended heavily on the rise and acceptance of a new concept of property, which in turn was based on a new concept of nature. Consequently, liberal property theories date back to these profound theoretical changes. The work of John Locke in the seventeenth century captures the broader socioeconomic and political debates of his time relating to the enclosure of the English commons and the colonization of North American lands and peoples. These debates were articulated through the discourses of improvement and progress, both of which carried aspirational sentiments regarding the place of humans in the world and particularly of (certain kinds of) people transcending nature, becoming cultivated and cultured in contradistinction to their primitive counterparts (Fitzpatrick 1992; Brace 2001).

John Locke’s theory of property was premised on the idea that the environment, as “nature,” was without inherent value, chaotic and disordered, from which state human intervention would improve and order it through cultivation. From this premise, Locke argued that improving land (through certain kinds of agricultural land use) provided the moral basis for a claim to private entitlement to that land. His “labor theory” of property was used to defend the enclosure of the commons and the dispossession of First Peoples and the colonization of their lands. The nexus between humans and the environment in the “labor theory” of property is the greatly increased quantum of agricultural land use. It is precisely this point that links the labor theory of property with the idea of a growth economy. Locke’s property theory explicitly advances the idea that land should be used to exceed economic need rather than to meet it, so that profits become available. There is a large literature defending and critiquing Lockean property theory, most of which relates to questions of distributive justice and political and economic philosophies. However, more recently scholars have revisited Locke’s provisos on waste, in particular to examine what restrictions, if any, there are in his original work regarding the environmental limits of property and environmental protections. Economic theorists critiquing the current growth economy are concerned to question its intellectual origins and for this reason it is important to review the work of Locke and his contemporaries.

Locke has cast a long shadow over property theory. It has been 400 years since he anonymously published his justification for the dispossession and enclosure of the then common and community property regimes in place.
in England and North America. Despite this, the idea that the labor and cultivation of land improves both the environment and the society in which those land-use practices are adopted prevails. Even up to the early twenty-first century the case for economic growth and development has been so long advocated as to have become normalized. Theories of property that question this orthodoxy are either part of, or at least perceived to be, the counterargument of antiliberalism known better as Marxism, socialism, and materialism. However, it is important to note that environmental critiques of liberal theories of property are not always, or even predominantly, concerned with this classical framing of the property debate in exclusively political terms. Environmental critiques may or may not be also concerned with distributive justice and other political issues at the heart of critiques of liberal property theory. What is radical about some environmental critiques of liberal property theory is that their various degrees of nonanthropocentrism (from ecocentrism to network and relational theories) indicate a shift away from debating property in the exclusive terms of human experience towards debating property in broader ecological terms that include humans but do not place them at the center of the epistemological model on which the debate is founded.

Materiality, sustainability, and connectivity

Since Locke’s advocacy and justification of private property regimes, and since their proliferation within and for capital-growth economies, property theory has become increasingly and remarkably abstract and detached from material and, especially, environmental concerns. Some property theorists’ work deals directly with the abstractness of the dominant private property regime. In legal scholarship, this abstractness is referred to sometimes as “dephysicalized” property. The origins of dephysicalization are traced back to Locke, although more commonly it is the work of English lawyer Jeremy Bentham in the eighteenth century and American lawyer Wesley Hohfeld in the early twentieth century that is cited in scholarly enquiries into the nature of property’s dephysicalization. The perspective of proponents and analysts of dephysicalized property alike is that private property relations are not about real things in the environment, but about abstract legal rights between people. The emphasis on rights and on the abstractness of property relations has been the source of much scholarly analysis, with some theorists arguing that dephysicalized property is politically unstable and others arguing that the emphasis itself is misplaced. Nineteenth-century German economist Karl Marx and twentieth-century American philosopher Hannah Arendt insist that private property regimes are certainly framed within the discourse of abstract rights, but that their conditions and effects are inevitably material and specifically environmental (in which they include humans). Both Marx and Arendt caution against forgetting the materiality of real property as things in the world in the interests of sustainable economies.

However, beyond the original writings of Marx and Arendt, and like liberal theories of property, Marxist critiques of liberal property theories are largely anthropocentric in focus, and deal mostly with the distributive justice questions of political theory (liberty and individual personhood) and economic theory (the efficiency of natural resource use). Some of this theoretical work examines directly the material conditions and effects of private property in human terms such as social inequality, poverty, homelessness, and diaspora linked to the privatization of lands and environmental resources. More recent attention to questions of distributive justice has also included consideration of the impact of climate
change on developing countries and island states, referred to as environmental justice. A distinctive recent trend in this literature has begun to deal directly with material conditions and effects of private property with specific regard to environmental considerations. Interestingly, much of this emerging literature is produced not by legal theorists but by human geographers, anthropologists, and environmental economists whose work is influenced directly and indirectly by Marxism and the philosophy of materialism generally.

Since the 1970s, environmental law and environmental governance scholarship have also contributed substantially to property theory directly through sustained and rigorous attention to the potential and effects of adopting market mechanisms in environmental regulation methodology (Freyfogle 2003). Most of this literature frames the discussion in terms of property rights and environmental sustainability. However, while some of this literature promotes the use of private property rights to enhance greater natural resource-use efficiencies (for example water trading for irrigated agriculture) and to resolve environmental problems (internalizing the previously regarded “externality” of industrial pollution through pricing units of atmospheric carbon), other literature concerned with the use of property rights for environmental sustainability outcomes critiques the logic and/or the outcomes of this increasingly common policy approach.

Both the supporting and the critical literature on property rights and sustainability from an environmental perspective engage explicitly or implicitly with the issues raised nearly 50 years ago in Garret Hardin’s 1968 essay “Tragedy of the Commons.” That essay incorrectly refers to an open-access regime as a common property regime (an error which several legal, economic, and geography scholars have discussed at length). Putting aside this error of classification, the issue Hardin identified remains that anthropogenic environmental problems are indeed created by regulatory failure and almost always by inappropriate property frameworks. While Hardin’s essay contended that the use of private property regimes offered the most environmentally sustainable outcomes, almost any property theorist and environmental researcher would agree that any property regime providing natural resource access and use restrictions and prohibitions is superior to an open-access regime. The conventional political analysis that compares private, common, and public regimes has tended to overshadow some of the more complex environmental management questions raised in Hardin’s essay, which remain as urgent today as they were then.

What Hardin’s essay has shown, in addition to the significance of property to anthropogenic environmental crises generally, is, inadvertently, the importance of transdisciplinary education and integrative thinking. Indeed, theoretical and critical property scholarship that is transdisciplinary has revealed the environmental potential of redirecting property research from its predominantly anthropocentric focus towards an alternative approach that is significantly decentered. Network theory and the ideas of relationality and connectivity appear increasingly relevant to this most recent body of research concerned with the intersection of property and environment. Some of this work derives from in-depth analyses of the property regimes of indigenous peoples and links the notion of custodianship with connectivity between peoples and places (Weir 2009). Other work derives from discursive analyses of regulatory frameworks constructed on the premises of individualism and the precept of autonomy, advocating greater attention to relationality and responsibility (Nedelsky 2011). Much of this work
emphasizes the intellectual and practical possibilities of rethinking the human experience (with each other and in the world) beyond the terms of Enlightenment philosophy (progress, improvement, growth, autonomy, possessive individualism).

This growing trend in recent property theory suggests that the incorporation of geographical knowledge, and specifically of environmental conditions and limits, into property laws, and the alignment of property and environmental laws rather than their taxonomic separation, could address some of the current challenges to private property regimes – for example, the inadequacy of the abstractness of private property rights to helpfully contribute to the pressing environmental policy issue of the physical erosion of coastal lands. Given the strong influence of private property regimes (and the attendant ideas of progress and growth) on natural resource management and policy, it is likely that environmental problems will continue to be examined by reference to the relationship between property and the environment. Indeed, it is likely that new categories of property will emerge to replace those described above through unilateral and multilateral efforts to adapt to changing climatic circumstances in particular. The role of integrative transdisciplinary innovations of both the cultural discourses and regulatory institutions of property cannot be underestimated to this effect.

PROPERTY AND ENVIRONMENT

Psychoanalysis is a form of inquiry about society, a therapeutic practice, and a theory of personality emanating from the work of Sigmund Freud (1856–1939). The legacy of Freud’s ideas, which developed throughout his lifetime, has been hugely influential on modern thought and the ways in which we understand contemporary society, our relationships with each other, and human mental functioning. Since the publishing of his work, which spans nearly 50 years, Freud’s theories have been enthusiastically embraced, refuted, rejected outright, molded, and reshaped by many including Carl Jung, Melanie Klein, and Jacques Lacan. The results can be seen in different regional, national, and cultural settings across the world where distinct (re)interpretations and forms of psychoanalysis have emerged – from the British Kleinian and object relations school of thought and the (French) Lacanian linguistic formulation, to the American ego–psychological paradigm, the Latin American Kleinian and Bionian perspective, the Franco–German philosophical and hermeneutical contingent, and so on.

While each school of thought may have its own theoretical and professional foci, one thing that unites these different traditions is a convergence on the existence of the unconscious. This dynamic part of the mind strongly influences our conscious lives and our sense of identity and how we become aware of ourselves and, as a consequence, of who we are. For Freud, this part of the mind lay outside the boundaries of consciousness and was constructed in part by the repression of ideas and thoughts that were too painful or dangerous to be allowed to enter the conscious mind. Some of his earliest works examined how the unconscious, memories, and “phantasies” were indistinguishable. He soon realized that not everything in the unconscious was repressed, but that these things were just not expressed at the time.

In 1923 Freud published a book on a new dynamic model of the mind, known as the structural theory of the mind. Although it did not contradict or exclude his earlier topographical descriptions, this work was an attempt to describe the way in which the whole mind system determines personality and its main motives, drives, and desires. According to Freud, the mind is made up of three parts: the id, ego, and superego. The ego is the mediating part of the psyche that reacts to external reality and that which a person sees as “self”; the id is the unconscious part of the psyche that is concerned with inherited, instinctive (primitive) impulses; and the superego is the part of the mind that acts like an “inner parent,” acting as a social conscience that reflects society’s cultural norms and values. The ego and superego are essential for keeping the id in check.

For those curious about psychoanalysis an obvious question follows: How do we know that the unconscious exists? While there are some differing understandings, evidence of the unconscious can be experienced and felt through dreams, slips of the tongue (parapraxis), Einfall (the German word for mental content that simply drops into conversation but is not necessarily invited), and our “gut feelings” or intuition.
about situations, people, and places. Sometimes we may do something that is out of character, that is not entirely expected of us or “rational.” We may, in conversation, intuit how somebody else is feeling (maybe even finish their sentence), subtly building our unconscious communication with one another. Sometimes our feelings of envy, guilt, aggression, rivalry, and so on may seem incomprehensible or appear from out of the blue. Phenomena may occur that cannot be explained by rational knowledge, highlighting theoretical contradictions that, according to Thomas Kuhn and Karl Popper, indicate the extent to which our existing knowledge is always probabilistic and provisional. The way we make decisions and navigate our lives, therefore, intrinsically connects to the kaleidoscope of our inner worlds. This process does not happen by simple cause and effect, from inside to outside, but through a number of complex processes such as projection, denial, resistance, splitting, and so on (Kingsbury 2009). These psychoanalytic terms attempt to give a name to what is really going on for us, and to explain how our behavior is rooted in deeper unconscious communications.

In a clinical setting, psychoanalysis has been fundamental to the development of a number of psychological therapies. Psychotherapy, coined an “old art and a new science,” is one treatment and method (among many) that is directed toward the psyche. While analysis does not purport to be a quick fix (it can take years), the framework for therapy is rooted in the relationship between patient and therapist. It uses the most pragmatic form of material available – communication – both spoken and somatic. In other words, it is not just what is said by the patient but how it is conveyed (including body language, silences, hesitations, and repetitions). The therapist and patient attempt to unravel and untangle the unconscious workings in the consulting room as a microcosm of the patient’s world. In this therapeutic setting the patient may play out his or her concerns, feelings, thoughts, and wishes, which the therapist in turn holds, listens to, and re-presents in a manageable form. While there are considerable divergences in theory and approach, it is through this complex interaction that analysis purports to bring unconscious material to light and to help relieve the patient’s problems.

One might argue that, by understanding and making sense of the patient’s world, therapists become well versed in geography (Kingsbury and Pile 2014). The experiences, coincidences, and everyday narratives retold in the therapeutic encounter are (slowly) unfolded and mapped by therapist and patient together. Creating a space in which both therapist and patient are allowed to think is of central importance to the psychoanalytic endeavor. Geographers, in turn, have found psychoanalysis to be a rich resource, despite the different aims of each profession (Kingsbury and Pile 2014). While much controversy exists about Freud’s topology of the mind, the idea that the unconscious destabilizes human agency as rational, knowing, and predictable can be very useful to human geographers. Geographers have engaged with psychoanalytic theories since the 1930s, although it was during the late 1990s that psychoanalytic ideas in geography became more prominent, leading to the inaugural entry of psychoanalytic geography in the *Dictionary of Human Geography* in 2000.

Geographic engagement with psychoanalysis has not always been a comfortable journey. As Chris Philo and Hester Parr (2003) once remarked, geographers are “squeamish” about concepts such as sexuality, threat, desire, repression, and abuse, as well as cautious about the unconscious as “raw material” for geographical inquiry. The task of assimilating psychoanalytical concepts and ideas into geographical inquiry
PSYCHOANALYSIS/PSYCHOANALYTIC GEOGRAPHY

presents a challenge when developing understandings of spatialities and subjectivities that do not necessarily fit together neatly. In addition, Liz Bondi highlights how there is much confusion about different approaches: psychology, psychotherapy, and psychoanalysis have often been equated unproblematically, without recognizing their respective diversifications (as well as similarities) between and within theory and practice.

Concerns and critiques have been valuable, however, in developing psychoanalytic geographies. Geographers have continued to ask what the unconscious might mean for geographical inquiry, coupled with how psychoanalytical “material” may be used in geography. Conversely, geography is currently recasting psychoanalytic concerns by working with active therapists to think through spaces of trauma and distress, and notions of therapeutic space. Such collaborations indicate that geographers are also having an impact on psychoanalysis, including in the domains of neuropsychoanalysis and psychiatry (Callard 2014).

Building on earlier feminist work in human geography, a rethinking of the politics of positionality in geographical research has raised important (ontological and epistemological) questions about the production of knowledge. Through a psychoanalytic lens, the ontology of the subject is somewhat unknowable and requires new thinking (Thomas 2010). If we acknowledge the unconscious, then our knowledge about the world and of thoughts is not transparent and straightforward: the unconscious processes of the research encounter (of subjects and ourselves) create a number of epistemological issues, raising questions about truth claims, relationships between data and theory, and how to appropriate subjects’ narratives. There are no easy answers. Nonetheless, psychoanalytic geographers continue to formulate practical resources in response, advocating a research alliance that has “intimate distance” between participant and researcher and that draws on earlier formulations in psychoanalysis (Pile 2010); and providing a framework to conceptualize narratives rather than inferring personalized unconscious workings (Thomas 2010).

Liz Bondi has emphasized how empathy and identification can enhance geographical understandings of fieldwork. Drawing on Winnicott, Bondi explores the differences between empathy and identification and how reflecting on these can enrich existing methodologies. For example, empathy involves a capacity to think about and be engaged in responses while not being incapacitated by such responses, something which she acknowledges is not easy. Empathy is different from identification (which draws on projection and introjections of bad and good objects) because empathy for a researcher involves offering, rather than expelling, unconscious material in a way that can be handled by the participant. Recently, Bondi has further discussed the ways in which we can better understand the emotional dynamics of interviewees’ accounts by developing our own “receptive unconscious.” Research is replete with unconscious processes and “transmissions” that require us to think about positionality, trust, and rapport in fieldwork (see Bondi 2014).

Moreover, there are a number of applications of psychoanalytic thinking that have provided critical analyses of contemporary social problems or issues. Steve Pile, one of the earliest proponents of the subdiscipline, suggested that some geographers (erroneously) assume that psychoanalysis is preoccupied with the person(al) and that the unconscious is somewhat fixed, meaning it is thus unable to inform critical analyses of social power relations. Classic work in the subdiscipline by David Sibley and Robert Wilton drew on the works of Freud, Klein, and Kristeva, however, to address critical questions of exclusion, difference,
and marginalization. Paul Kingsbury notes how, by producing discursive and stimulating accounts, psychoanalytic geographic research can illustrate the political psychospatialities of issues such as sex(uality), racism, exclusion, embodiment, and community. More recently, conversations between psychoanalysis and other areas in human geography have drawn on affect and emotions as well as intersubjectivities and the nonhuman.

The breadth and depth of psychoanalytic geographies continues to gain critical mass. Research (and the list here is not exhaustive) has engaged with mental health and health geographies as well as psychiatry and neuroscience (Callard 2014); the politics of global warming and the Anthropocene (Healy 2014); industrial capitalism, masculinity, and the geographies of the machine (Nast 2014). Further, Mary Thomas (2010) has delved into the spaces of girls’ identities and daily practices in schools in the United States, marked by racial segregation and violence. Using a psychoanalytic lens, she examines the psychic investments and identification practices that actually serve to maintain (rather than resist) racist, sexist, and heteronormative relations. While feminist geographers have been critical of alliances between psychoanalysis and feminism, particularly Freud’s (early) formulations of women, psychoanalysis has been used as a resource in challenging normative gender roles. For example, the use of psychoanalytic concepts such as splitting and conflict are central to gendered discourses on young women’s alcohol consumption (Stepney 2014). Here, the contradictions and ambivalences in young women’s own narratives about their drinking behavior relate dialectically to neoliberal negotiation and the ordering of social space.

As Liz Bondi notes, applications of psychoanalytic theory offer powerful ways of understanding how unconscious aspects of human life are manifest in the social world. More widely, the transmigration of people, the social tra7uma of conflict, the rise of far right movements in several parts of the world, the fear of terrorism, and the re- enactment of imperialism, along with all the joys and ecstasies of life, are all in some way underscored, internalized, and remade by our inner dynamic worlds. In other words, the outer world becomes internalized, while our inner workings are a microcosmic mediation of the whole world, or at least our world. It is often at points of crisis or in times of conflict that our inner worlds reveal themselves. Connecting worlds, geographers have found psychoanalytic theory to be wholly social, relational, and spatial.

Public health activities focus on any source of ill-health that an individual cannot fully control by their own actions, but which can be more effectively controlled by a larger entity, often, but not always, a government entity. Through time, the common sources of ill-health in a population change, primarily as a result of new knowledge, as well as by acceptance by the public of the need for actions to prevent, control, or eradicate the effects of a disease. As this knowledge changes, so does the scope for public health activities. Omran (1971) influenced the thinking of many people when he introduced the concept of “the epidemiologic transition.” This transition described how the typical causes of death changed as societies developed and the proportion of deaths from communicable diseases declined while the proportion of deaths attributable to diseases of the aging process increased. During this time, the average years of life expected at birth increased. He noted that the role of public health changed as the prevention, control, and treatment of the diseases that caused death changed. Along with this transition came the increased realization by the public that different societal behaviors were necessary to reduce the burden of these “new” diseases. Thus the human dynamics of public health also needed to change.

Human dynamics enter this discussion at several levels. First, knowledge of the mechanisms by which a disease develops in any population follows a path of knowledge acquisition and diffusion. Second, pathways through which diseases spread among a population change as typical behaviors of populations change. Finally, the types of diseases that cause death change through time from diseases that spread from human contacts to diseases that develop in populations from the ageing process. Concerns about the health of the public change and more of the activities of public health focus on regulating the exposure of people to broader environmental conditions that, individually, they cannot control.

The focus of this entry on human dynamics concerns the different behaviors in societies involved in these processes, and the different outcomes that occur as a result. The entry distinguishes between two types of human dynamics that affect public health: first, the everyday behaviors of individuals that affect their health, and second, the behaviors of societies who act in the broader general interest. These behaviors are often different between individuals and between societies. The entry begins with a consideration of two notable diseases that have ravaged societies through time, cholera and smallpox. Then, it turns to a consideration of principles surrounding these two types of behaviors, particularly in the context of how they operate differently through time, and throughout the world. The results are complex differences in the geography of public health throughout the world.

Cholera is a disease which illustrates the different kinds of human dynamics that have affected...
the burden it has brought to human populations over long periods of time. The disease “is a severe bacterial infection of the intestine that results in watery diarrhea, vomiting, and when not treated, may lead to death within less than a day. The illness in humans is by ingestion of various species from the genus *Vibrio*,” (Collins 2003). One of the most important public health discoveries of the nineteenth century was that the disease of cholera was transmitted among people by their exposure to organisms in fecal matter in the environment. These vibrios flourish in warm alkaline mediums, such as are found in the brackish waters in estuaries in tropical and subtropical environments (May 1958). After 1854, consensus rapidly developed in societies in North America and Western Europe and most other temperate areas of the world that the spread of these contaminants could be arrested by constructing sanitation systems in which the sources and distribution of fresh water were separated from the collection and dispersal of public waste. To control the importation of cholera from the areas where the disease was endemic, these temperate areas focused on the quarantine system in which the health status of people who reached them, usually by ship, was tracked and, if there was any suspicion that they may have the disease, any contact between them and the local population was prevented for a sufficient length of time that the chain of transmission of the disease from person to person was broken. In many tropical and semitropical areas, however, the cholera bacillus was endemic and this disease was virtually constantly found in local populations. Later, the focus changed to eradicating the disease in areas in which it was always found.

Three different methods of control were available (see May 1958, 56): attacking the causative agent in nature (Collins 2003); changing the susceptibility of the potential hosts, for example, by inoculating travelers; and lessening the opportunity for contact between agent and host. The disease is most often fatal in young children and, for much of the twentieth century, it accounted for a large number of deaths in developing countries. An important medical discovery of the 1960s was that many children could be saved from death by receiving a package of salts that replenished the loss of body fluid from dehydration, thus enabling many young bodies to escape death through rehydration. Thus, the story of the control of cholera in the nineteenth and twentieth centuries is a complex story of advances in biological, medical, and civil engineering knowledge and changes in individual and societal behavior. The story is typical of many other public health problems that rely for their solution on regulating and controlling human dynamics in a population. To be specific, in the case of cholera, regulations related to human behavior began in the 1850s and were so successful that Jacques May, often called the father of medical geography, could conclude, prematurely as it turned out to be, that the last worldwide epidemic of cholera was in the past. The disease was now, on a worldwide scale, “effectively contained.” The reason May’s conclusion proved to be premature is that he did not envision that the regulation of cholera would relapse as societies increasingly relied for their health on vaccinations of the population that traveled in these areas of the world where cholera existed. Experiences with cholera epidemics were largely forgotten and controls, such as requiring vaccinations among those traveling in areas where cholera was endemic, ceased. It was now possible for an immigrant from a cholera-endemic area to travel to other areas of the world without requiring proof of a currently active vaccination, as would have been required 30 years before. Collins (2003) reported that during the late 1990s more than 74 countries
reported cases of cholera. Recently, Richardson et al. (2013) have referred to “the spatial turn in health research.” They note the increased use of geographical information systems to study and monitor the status of such diseases as cholera, where many geographic layers of data interact and where “overlay analysis” increasingly sheds light on the effectiveness of public health efforts to control the spread of the disease.

Not all efforts to control the spread of diseases were without success. Notable was the decision by the World Health Organization (WHO) and by a Cold War agreement between the Soviet Union and the United States in 1958 to cooperate in the goal of stopping the transmission of smallpox throughout the world. Under the auspices of the WHO, many countries participated in a “surveillance and containment strategy” that eventually stopped the person-to-person transmission of smallpox. Surveillance meant prompt and accurate reporting of cases of the disease; containment meant the isolation and vaccination of all persons who had contact with persons known to have the disease. This geographically inspired strategy replaced the older strategy of attempting to vaccinate a very large proportion of all people at risk of the disease. Since May 1970, when the WHO declared that smallpox was eliminated as a disease everywhere in the world, other diseases that depend on the chain of human-to–human transmissions have been targeted for elimination.

The disease that currently appears to be tantalizingly close to elimination is polio, and for more than a decade the WHO has declared its imminent demise. Since polio is spread by interpersonal contacts, and since an effective vaccine is now available to prevent its transmission to protected individuals, polio has, for many years, been a candidate for worldwide eradication. In 2014, the WHO (see WHO 2015) declared a “Polio Public Health Emergency” with temporary recommendations aimed at reducing the international spread of the polio virus. By May 2015, only two countries remained on their endemic list for the polio virus: Nigeria and Pakistan. Several other countries remain under watch. The reason that the worldwide eradication of polio has not yet been achieved is a breakdown in accepted protocols for vaccination in the affected regions and disruptions in implementing these protocols caused by civil wars and the flow of refugees. Each year new cases are found and new steps are taken to contain its spread beyond the geographical area in which it has been found. The question remains as to why it is not possible today to eliminate a disease with largely the same person-to-person transmission characteristics as smallpox. The answer has two elements: first, there have been changes in cultural views about the efficacy of vaccines or the motivations of health workers in areas in which they are sometimes regarded as not working in the interests of local populations; second, there have been increases in the spatial mobility of persons enabling them to move large distances without being required by authorities to show health vaccinations in the areas to which they have moved. In short, the human environment of prevention and control of communicable diseases has changed at the same time as the numbers of people and distances over which they move have increased by many orders of magnitude. The environment of poverty, warfare, and malnutrition, and the absence of a public health infrastructure, also contributes to an environment in which many communicable diseases flourish. More recently, the outbreaks of Ebola in several West African countries have reminded the world of the jeopardy that all may experience as new diseases arise in remote corners of the world.

With cholera and smallpox as illustrations of two diseases in which public health has played
PUBLIC HEALTH: HUMAN DYNAMICS

a notable role in their eradication or control, the roles played by individual behaviors and public behaviors can be discussed. In the age of communicable diseases, individual health behaviors conducive to controlling ill-health differed according to the specific process by which particular diseases spread. Tuberculosis accounted for a very large proportion of deaths during the age of rapid industrialization in parts of Europe and America. The disease is spread through close interpersonal contact, especially within populations who are already weakened by poverty and ill-health. The high density of populations in work areas and residential areas provided fertile ground for human interaction that led to the spread of the disease. Before the discovery and use of drug therapies in the 1950s, however, the proportion of the population with tuberculosis plummeted in many areas of the world as society regulated these conditions by reducing the opportunities for close contact between members of poor populations. This experience is noted because it is emblematic of many other diseases that thrived in certain environmental and medical conditions. These examples led many to discuss the role of society itself in controlling the conditions in which diseases flourish. Many countries decided that there was a distinct role for public health to play to reduce the burden of ill-health on defined populations. Thus was born a concern over “health disparities” and “health inequalities.” This concern, found in many societies, is to find the causes of these disparities. Evidence shows that the health of poorer populations, and other disadvantaged groups, is distinctly poorer than of that of more advantaged groups. Consequently, many countries are trying to identify the causes of these health inequalities and to provide these populations with services that will improve their health. Some of the inequalities are shown to be found in specific areas and some conclusions spread to spatial interventions to reduce inequalities.

Human behaviors, which are the core of public health, operate at both individual and group levels. Noteworthy in the nineteenth century were behaviors related to personal and public hygiene. These activities followed new understandings of how many diseases involved person-to-person disease transmissions and that personal and public hygiene protected the individual from acquiring many diseases. Civil engineering was the key intervention as the wastes of urban living were collected, conveyed, and disposed of separately from the collection and distribution of potable water. The degree to which a person could protect themselves differed markedly from one disease to the other. With the development of vaccines, many of these transmissions could be avoided, and protective methods became available to the public. Not all vaccinations were 100% effective, and not all protections were permanent. A large literature on this subject exists (Rosen 1958).

A second area of focus in human dynamics and public health is the idea that the diseases from which many current populations die can be attributed to behaviors in which individuals choose to engage. Many diseases now can be traced to patterns of eating and drinking that often lead to obesity. Fewer people engage in day-to-day activities of movement and exercise. Instead, far more people are sedentary. Many people smoke tobacco or consume other drugs with harmful health effects. People sometimes drive after drinking alcohol, leading to deaths from vehicular homicide. By the 1960s, major causes of death in the developed world were cardiovascular disease and stroke, cancer, pulmonary disease, and injuries. Vallin and Meslé (2004) show how some countries in Europe were successful in reducing rates of death from cardiovascular disease while others were not.
They show that a group of countries in Western Europe were able to focus on changing behaviors that increased the risk of individuals developing cardiovascular disease and worked to accelerate the development of medical treatments which, to a large degree, reduced these risks and reduced the rate of death due to these causes.

Determining the behaviors in question that needed to be regulated and controlled involved research, education, and changes in public policies that many people disputed were issues for the public to decide. One behavior was smoking tobacco products. The story of how smoking came to be recognized as responsible for higher rates of death from many diseases is a fascinating one, and the slow adoption of measures to control the exposure of nonsmokers to smoking by others was long and arduous in all countries. Currently, individual countries are found at many different places along the continuum of control over the availability and use of tobacco products by the population. The success of many legal challenges to the rights of tobacco companies to promote their products, especially to the young, and the penalties many of these companies have been required to pay as a result of their actions, has led to a marked reduction in the rate of smoking of tobacco products in the United States, Western Europe, and many other countries across the world (Eriksen, Mackay, and Ross 2013). Nevertheless, international sales of tobacco products continue to grow in many countries as marketing science continues to play a strong role in promoting the use of tobacco products throughout the world.

Many well-known causes of ill-health are the subject of controversies over the role of public decisions to control them. Common questions that are still highly debated in developed countries include whether the number of retail outlets that sell “fast food,” liquor and tobacco products, and guns and ammunition should be regulated; whether fines should be increased for driving under the influence of alcohol, or for not wearing a seat belt or motorcycle helmet; whether infants should be required to be restrained in rear seats; and questions concerning countless other interventions known to reduce death and illness. On these and many other similar questions, people disagree on the role of the state in regulating personal decision-making. Libertarians are generally viewed as a group of persons who want to protect the rights of individuals to make their own decisions about their patterns of consumption and their rights to offer products to others.

Other circumstances that affect the health of populations relate to philosophies of life held by different population groups. An example would be whether the decisions of women concerning childbirth should be regulated by legislatures or whether they should be left as individual decisions made by the persons affected by them. In another example, research has been conducted on the local circumstances in which people become addicted to drugs. This research led to many policy recommendations that would likely reduce rates of drug abuse in specific populations if adopted (Thomas, Richardson, and Cheung 2008).

Societies differ on whether the geographical accessibility of essential medical services should be regulated by governments. Where many medical personnel are employed directly by governments, control of access is commonly found, but some other countries, such as the United States, generally rely on incentives that will encourage individual medical personnel to choose to practice in areas for which there is a known need for expanded services. Models linked to geographic information systems have been developed to facilitate this purpose.

New areas for public health intervention are environmental health and cancer control.
and prevention. In many countries, the public has reached the conclusion that one source of ill-health that could be controlled are chemicals in the environment that have adverse health effects. Materials that affect the respiratory functions of children and others are common. These chemicals, it is asserted by many of the public, could be reduced or eliminated from the environment. Notable examples are smog and fine particles that originate in the transportation system through the extensive use of oil products. Other industries also produce large quantities of dust and chemicals during the manufacturing process. Many children are exposed to environmental substances that are now known to cause ill-health and even death. Some mining products also contribute to ill-health. Asbestos and lead proved to be very dangerous products used extensively by the public in their everyday lives until, in the interests of public health, their use and people’s exposure to them were drastically limited.

An example of a successful program to eliminate an environmental health threat is the program started in many US cities to reduce exposure to lead. Research showed that lead in the blood of infants and children originated in lead particles in the environment from the time when lead was a common ingredient in paint. A strong correlation was found between the age of a residence and the levels of lead in the blood of infants and children. Children living in pre-1970s residences had higher blood-lead levels than those living in residences built after the mid-1970s, which were not painted with paint containing lead. In the United States, individual cities and towns needed to make the decision to clean up lead droppings from around older residences and enforce the ban on using lead-based paints. Many incidences of developmental disabilities were found to be associated with the levels of lead in the blood of children.

As the number of cases of cancer increases sharply in countries across the world, public health increasingly is involved in activities designed to prevent their occurrence and control the numbers of deaths caused by them. Human dynamics enter this fight in many ways. First is the decision to research the characteristics of cancer. Increasingly, cancers are identified using their molecular components rather than the traditional identification by the organ in the human body in which it is found. Second, an important recognition is the development stage at which the cancer is identified in the body. The earlier the stage, the more likely the cancer can be successfully treated and death avoided. Accordingly, the role of public health often is to map the proportion of the people at risk of having the cancer who are in the late stages at the time of their first diagnosis – the larger the percentage, the higher the death rate from the disease. The goal of public health is to increase the “surveillance” of the cancer in question in the population at risk in order to increase the number of people at risk whose cancer is recognized at an early stage when it can be treated and, often, death avoided.

After reviewing the dynamics of public health activities, the number of disciplines involved in them, and the essential role of the public and the responsibilities of individuals and of society at large, one essential question remaining concerns the development and control of the infrastructure of public health. This infrastructure is none other than the collective actions of individuals, groups, institutions, and countries. The dynamics of this collective action are very large, as well as the effectiveness in the grand task of ensuring the health of the people. The complexity is enormous, the grand challenge, breathtaking in scope, the actors, many, the final healthy state of the world, essential.

Public policy

Kevin Ward
University of Manchester, UK

Public policy is policy named, designed, delivered, monitored, and evaluated for the public good. There are many areas of public policy, including crime, education, environment, housing, and transport. In these, government has decided to establish a course of action, setting aside a budget to finance its intervention based on a particular set of objectives. Rarely are the decisions to label something as “policy” and to allocate a particular budget to its delivery and evaluation neutral, however. Rather, they embody a particular strand of thinking among those in government whose remit it is to make policy. Decisions over public policy involve decisions over prioritizing or targeting some areas over others (e.g., crime over housing), which means prioritizing some groups of people over others and some geographies or places over others. There are always “winners” and “losers” in public policy even if who they are is not immediately apparent. Public policy is the product, then, of a complex set of decisions involving those inside and outside of central, regional, and local government.

It is important to place public policy within its wider geographical context. Each country has its own constructions of “public policy.” In part these reflect the role that government has historically played in the country. In some cases governments have adopted a relatively interventionist strategy, expanding their remit in term of public policy. A good example would be the Japanese government’s approach to industrial policy. While there have been changes over the years, for the most part the government has sought to invest in a number of industries that were identified as those in which Japan might be able to develop a comparative advantage. This approach to industrial policy in Japan was probably at its peak in the 1980s. In other cases, governments have been circumspect. Their remit has been more laissez-faire. An example of this approach is that of the British government to banking policy during the early 1980s. It liberalized the supply of money and reduced the reserves required to be kept by banks. The differences between types of public policy making reflect the particular ways in which cultural, economic, political, and social factors have combined in each country, even among those countries that appear to share some common characteristics. This point applies equally to countries in the North and in the South. There is a variety of public policy types, and thus considerable differences between countries in terms of how they name, design, deliver, monitor, and evaluate public policy, and the overall thinking that underpins these decisions.

It is also possible to identify a number of patterns across countries in constructions of “public policy.” First has been the emergence of the notion of “partnership” at the center of public policy. In a number of countries governments have historically taken the lead on the naming, design, delivery, monitoring, and evaluation of policy. They worked with representatives of business and labor unions nationally in corporate arrangements. While government continues to be the dominant partner, the last three decades have seen the emergence of “government +”
PUBLIC POLICY

arrangements in most areas of policy; that is, the uneven and partial emergence of governance as the dominant mode of public policy making. Whether an area-based policy – such as that focused on downtown or a whole city – or a thematic policy – such as that focusing on the banking or environmental sector – a range of others have been brought more centrally into the public-policy-making framework. While the role of business has been expanded, in many cases labor unions have found themselves less involved. Others, such as community or resident groups and neighborhood associations, have been brought into partnerships with government, not just nationally but also regionally and locally. So, not only has partnership become the new orthodoxy in public policy, but the makeup of the partnerships has changed as their number has grown.

Second has been the growth in the notion of “best practice” in public policy. This term refers to those locations – cities or countries – that are generally understood to have been successful by governments and others involved in public policy. For example, in urban regeneration public policy, Barcelona in Spain is often referenced (Garcia-Ramon and Albet 2000). The city is constructed as an example from which others around the world can learn, in terms of how the regeneration was financed, what partners were involved, and the nature of the outcomes. The establishing of “best practice” takes place in a number of ways. One is through the circulation of policy documents, allowing others involved in urban regeneration policy to read about Barcelona. A second is through exchanges and visits, as those from elsewhere visit Barcelona or those from Barcelona visit other cities. Of course, the making of public policy has always involved an element of comparison between examples; however, in recent years there has been an expansion of the geographical reference points.

The third has been the growing role of consultancies in the various aspects of public policy. In some cases this growth has been at the expense of government. So, in such examples there has been a withdrawal or downsizing of government. In its place consultancies have seen their role expand. In other cases the increased involvement of consultancies has constituted an expansion in the work done around the naming, design, delivery, monitoring, and evaluation of policy. Private sector consultancies, both the large transnationals such as KPMG and the smaller independents, have seen their involvement expand in the public policy process. This growing market for consultancies has occurred as local, regional, and national governments in a number of countries around the world have purchased their expertise, experience, and reputation.

Fourth has been the proliferation of ways of monitoring and evaluating public policy. While its different aspects have always been subject to scrutiny and review, the nature and means of this monitoring and evaluating have changed in recent decades. There has been a growth in the data generated on the different aspects of policy. So, every stage is now subject to attention in a way that it has not been in the past. This enumeration of the aspects of public policy has translated into a growth in the way that data are represented. Benchmarks, key performance indicators, and league tables are just three of the most high-profile ways in which the data are brought together and used to compare and assess the effectiveness of policymaking. In the United Kingdom, the emergence of New Public Management (NPM) during the late 1980s involved the restructuring of government and the making of public policy. A central feature of NPM was the production and use of indicators as a means of assessing and evaluating the performance of policymaking.
For some, taken together, these general patterns in the making of public policy are evidence of how neoliberalism has emerged as the dominant institutional context for policy-making, at least in some countries (Peck 2003). Here, neoliberalism is being used to refer to the qualitative restructuring of the state, involving new forms of statecraft, such as the widespread emergence of partnerships across many areas of public policy. This attention to its broader institutional field reflects a renewed interest in human geography in relation to the study of public policy, and includes some reflection on the role of academic geographers in the different aspects of public policy (Ward 2005). For, as the making of public policy has been restructured to involve a wider range of partners, so alongside community groups, consultants, and think tanks, universities and academics have featured more prominently. This has led academic geographers to reflect on their roles in the making and evaluating of public policy, as, despite claims to more open and transparent government, participation by those who are most affected by policy remains rather limited.

Public space

Erin DeMuynck
University of Wisconsin–Fox Valley, USA

Public space is understood as diverse, vibrant, and inclusive of all members of society. It offers opportunities for sociality outside of work and home, which can add pleasure to the everyday. Beyond its capacity to enhance enjoyment of everyday life, public space is identified as an essential element of urban life and a vital site of democracy. It serves as a site for making struggle and dissent visible and audible, where different groups have the opportunity to declare and debate diverse opinions and viewpoints and to express their needs and wants. More casual planned and unplanned meetings with others also take place here, allowing for exposure to ideas and ways of life that might not otherwise be encountered or considered, and which can enhance understanding, tolerance, the free flow of ideas, and the potential for greater inclusion and participation in the making of urban spaces and urban life.

This notion of public space, in which it exists as a truly open, democratic, and peaceful place, is an idealization – a goal to strive toward rather than something that presently exists or has ever existed in a pure form. Even the ancient Athenian agora, for example, often considered a quintessential public space, was accessible only to men. True publicness has remained elusive in contemporary cities. One reason for this is that a degree of conflict is inherent in public space. The rights or comfort levels of certain individuals or groups may be encroached on when individuals or groups with conflicting values, or with differing ideas about the appropriate use of a certain space, come into contact. Exclusion from an ostensibly public space may be explicit, enacted through rules and regulations or even violence, or it may be very subtle, achieved through a feeling of uneasiness or through real or perceived incompatibility with the dominant values associated with a space or its dominant uses.

Whether exclusion from public space is implicit or explicit, it is constantly being challenged. Through these challenges, whether subtle or overt, public space is continually being made and remade. Moreover, it is through these challenges and continuous remaking that public space does its democratic work. Many examples throughout history can be used to illustrate how public space plays important roles in the redefinition of who is included in “the public” and in the advancement of human rights for a number of groups. Through claiming and acting in public space, groups that were at the margins or excluded from many aspects of society have challenged their exclusion. The rights of women, people of color, people with disabilities, and the LGBTQ community, among others, have been fought for in and through public space.

The women’s suffrage movement in the United States in the early 1900s made extensive use of public space. Women occupied streets, plazas, and urban parks to raise the profile of the issue of women’s suffrage rights to national consideration. Entering spaces that were considered public, but in practice were male-dominated, helped women redefine what “public” meant, broadening the dominant conceptualization of “the public” to include women. African
PUBLIC SPACE

American civil rights activists made use of public space during the 1950s and 1960s as a way of claiming rights as members of the public. Activists carried out marches and sit-ins, claiming rights to white-only spaces from which they were explicitly excluded. Later in the 1960s, the gay rights movement brought gay identities out of the realm of the private or underground and into public space in order to legitimate gays and lesbians as members of the mainstream public. Much progress has been made toward women’s rights, African Americans’ rights, gay rights, and the rights of many other groups, but work remains to be done. Rights continue to be fought for today, in and through public space, throughout the world.

For people experiencing homelessness who may not have access to private spaces, public space is crucial. Without the right of entry to private space, the alternative for carrying out daily activities and simply living must therefore be public space. Without public space, people experiencing homelessness may have no place to legally exist. Local regulations against activities like panhandling, as well as lying down, sitting, and even body odor have been increasingly implemented as a means of targeting people who are homeless and other groups. These types of regulations, along with the advent of benches designed to restrict lying or sitting comfortably, strategically placed sprinkler systems, and increased surveillance that are identified as unwanted in these locations, make spaces uncomfortable and often difficult or impossible to use.

It should be mentioned here that, even for the most open and accessible of public spaces, as the values and beliefs, uses, or social needs of one group are being declared or claimed, the ability of another group to use the same space in ways that meet their own interests and needs is likely to be diminished to some degree. This limitation disproportionately affects marginalized groups, but may affect anyone. For example, people experiencing homelessness find it increasingly difficult in today’s cities to find spaces where they are not excluded by law and oversecuritization. On the other hand, a public park that is a congregating space for men may be viewed by women as a space that makes them feel uncomfortable or unsafe and one that they avoid. Publicness is always subjective to some degree and the extent of a space’s publicness may vary from moment to moment.

Nevertheless, a general reduction in the inclusiveness of public space has been identified in contemporary society. The possibility of encountering a variety of social groups or of raising alternative and dissenting viewpoints has become rare in cities today. New regulations, design elements, and increased policing have been enacted that restrict the use of public space. This is a consequence of the increasingly instrumental stance taken by cities toward public space. Public space has been reconceptualized in contemporary cities as a component of sanitized city livability primarily for middle- and upper-class consumers, hampering the capacity for public space to fulfill its democratic role. Efforts to commercialize, sanitize, and securitize public space, while they may appeal to some and be beneficial to capital, curb the rights of others who are excluded from these spaces, sometimes punitively.

Geographic research places the changes in the way public space is perceived, used, and experienced within the context of broader urban restructuring processes. To understand current processes impacting public space, we can start by looking at some of the consequences of suburbanization. Suburbanization and white flight, along with deindustrialization and decentralization of employment, led to dramatic urban...
changes starting in the 1950s and 1960s. Population numbers in city centers declined along with the median income of the residents who remained. The relatively well-paying industrial jobs that had allowed for middle-class lifestyles had become scarce. An increased percentage of the urban population was living in poverty at the same time that federal support for urban social programs was greatly reduced. The local state could no longer afford to provide for citizens’ needs or to maintain urban infrastructure. In this context, public spaces deteriorated. Crumbling streets and sidewalks, litter-strewn vacant lots, and unkempt parks with dilapidated playground equipment and broken benches came to symbolize urban crisis. By the 1980s, many urban centers were viewed as no-go zones for the middle and upper classes.

Urban entrepreneurialism was developed as a strategy to solve this urban crisis. The goal was to attract an economically active population back to the city at a time when funds for services and infrastructure had been drastically reduced, unemployment was rising, and social need was high. As a mode of adaptation, any remaining energy and resources were redirected away from social programs and toward pro-growth and pro-business strategies such as corporate tax breaks, privatization of public services, the creation of public–private ventures, and cultural development and image-building projects. The goal was for postindustrial cities to be perceived as cleaned up, safe, and welcoming to business owners, developers, and wealthy tourists and residents. As part of this strategy, formerly neglected public spaces have been selectively redeveloped in certain parts of the city. This process continues today.

Through the lens of urban entrepreneurialism, which continues to dominate urban policy today, public space is seen as a redevelopment and city imaging tool that can be put into the service of attracting investment to the city. Public space is often given a central role in urban planning and redevelopment as a way to beautify the city, demonstrate quality of life, and gesture toward sustainability, a value that is thought to be held in esteem by the population regarded as being the key to cities’ success; however, because of the drive to create a sanitized, orderly urban image, democratic public space is increasingly under threat. Messiness, disorder, and tension, which are inherent in spaces that are open and accessible to all, are at odds with the goals of contemporary urban governance seeking to attract business investment and middle- and upper-class tourists and residents. As its latent potential for disorder and conflict is increasingly constrained through design, regulations, and increased security and policing, public space loses the capacity to fulfill its democratic potential. People and actions deemed undesirable or incompatible with business interests and land uses are increasingly being formally excluded from public space. Its democratic capacity cannot be carried out when entry is allowed to some while those who neither consume nor add to the aesthetic desired for the city are kept out.

Although exclusion from what is conceptualized as public space, ostensibly free and open to all, is not a new phenomenon, contemporary forms of exclusion place added constraints on public space. Presently, from the perspective of entrepreneurial governance, public space is considered an urban amenity that enhances quality of life and is promoted as a way to encourage private investment and attract tourists and middle- and upper-class consumers. Although public space has become an important discursive and urban imaging strategy, the projects and developments that are actually produced are for middle- and upper-class consumers only. They
PUBLIC SPACE

are public in name alone. The element of autonomy in public spaces is small in today’s cities and continues to decrease. Few spaces today offer freedom from an obligation to conform to externally imposed sets of rules, from the pressure to spend money, or from surveillance and police presence.

The results of catering to a particular demographic slice in urban redevelopment and public space planning can be visually observed in cities. Upscale outdoor shopping districts and nightlife zones have exploded in cities. Urban parks, riverwalks, downtown plazas, and urban greenspace are increasingly incorporated into urban redevelopment plans as well. While these plans discursively express a renewed commitment to public life, the actual publicness of the spaces produced is questionable. The development of business improvement districts and other forms of public–private partnerships adds to the concern as management of public space is controlled by business interests, which displaces public space even more from democratic processes. Resources are directed toward attracting middle- and upper-class consumers. Increased surveillance, policing measures, and regulations aimed at unwanted populations are introduced to keep revitalized parts of the city free from those deemed undesirable. The result is an intensely uneven landscape in which public space has been reinvented in showcase urban districts as a lifestyle amenity for the middle and upper classes while those who are poor continue to be shunted into increasingly neglected and deprived parts of cities.

Securitization has further eroded public space as a response to the real and perceived threat of terrorism, which escalated after the September 11 attacks on the World Trade Center and the Pentagon. Streets and open space around government buildings, for example, are physically cordoned off and people have fewer places where they can protest or congregate. Urban scholars suggest that limitations on public space that are legitimated in the name of security and the prevention of terror attacks are in reality being secured from its users rather than for them. Public protest, social activism, and political mobilization are being repressed as access to public space is taken from all but those with security clearance to enter. In effect, formerly public spaces are further privatized. The implementation of free speech zones is an overt reduction of free speech rights associated with public space in the name of security. When an event surrounding a controversial issue is planned, protesting may be outlawed in nearby public spaces and confined to a zone that is removed from the event itself. While business owners, employees, and shoppers continue to be granted access, protesters and activists are kept away. This control is exercised in the name of safety and security, but the result is that the targets of the protest have no way to see or hear the message of the protesters unless it is reported in the media or on the Internet.

The Internet, for its part, has been suggested as a contemporary form of, or alternative to, public space. Some public space functions can be fulfilled through participation in the virtual space of the Internet. People can connect with others, and disseminate and discuss ideas. Used together, virtual and public space may have allowed the Occupy Wall Street protests and, similarly, the Arab Spring revolutions, to expand their impact beyond what might have been possible without the use of the Internet. The virtual public space of social media was used to coordinate and mobilize protests in physical public space, warn activists of danger, as well as communicate what was happening on the ground in specific public spaces like Tahrir Square in Cairo or Zuccotti
Park in Manhattan with people both nearby and in other parts of the world.

While the role of virtual space was important to these movements, it should be noted that they would not have had the same impact without physical public space. Coming together in physical space remains important in the digital age. Moreover, the ability of the Internet to function as a democratic public space currently faces similar challenges to those faced by physical public space. Both are threatened by uses that privilege profitability. Net neutrality, the notion that all Internet traffic should be treated equally, is regularly challenged. While the US Federal Communications Commission has ruled that Internet service providers are not allowed to prioritize content on the Internet for those who pay more for this service, they continue to work to undermine the open Internet. Without net neutrality, Internet content created by those without wealth would be buried beneath content created and paid for by corporations, making it difficult for alternative messages to be disseminated. Beyond the issue of net neutrality, the digital divide continues to be an important consideration. Access to the Internet is not universal but is contingent on where one lives and on socioeconomic status.

The emphasis on the economic function of public space over its use-value precludes certain conducts, activities, and political practices. Patterns of ownership, design, and management schemes are at times subtly restrictive and/or overtly exclusionary. If making claims, achieving visibility, and influencing public opinion are to occur, public space cannot favor one type of use by one segment of the population and deny other uses and groups. However, although public space has been increasingly privatized, commercialized, and regulated, a great potential remains. In spite of regulation and exclusion, the parks, plazas, streets, sidewalks, and urban squares that fall under the umbrella of what's traditionally considered public space may still offer the best opportunity for social life and social change. Research on public space has focused primarily on the impacts of economic restructuring and urban entrepreneurialism on the decline of public space. Future paths for public space research include interrogating the openings that exist for public space to be claimed in this political-economic context and for demands to be made that challenge the use of public space as a tool of an exclusionary form of urban redevelopment.

PUBLIC SPACE

Public-participation GIS

Rina Ghose
University of Wisconsin–Milwaukee, USA

Spatial data and geographic information systems (GIS) have been essential to resource management, conservation, planning, and policymaking activities since the 1960s, as most decision-making tasks require spatial information. Yet, access to GIS has been uneven due to its cost and complexity. Based on the notion that increased use of spatial knowledge leads to more informed participation in policymaking, public participation GIS (PPGIS) aims to broaden the access of GIS technologies to socially marginalized groups, leading to more informed and empowered communities.

The evolution of PPGIS as a research agenda and a practice is rooted in the tumultuous debates surrounding GIS in the early 1990s. GIS was critiqued for its perceived positivist epistemology, which reduced complex social processes to points, lines, areas and attributes (Pickles 1995). Further, GIS was seen as an elitist technology with uneven access that led to unequal power relations. Critiques considered GIS to be an instrument for production of rational, expert knowledge, implemented in policymaking through a top-down approach. The presence of a GIS digital divide along class and race lines was seen as inherently disempowering to marginalized citizens, for it discouraged their knowledge and their participation in resource allocation and governance.

Led by the National Center for Geographic Information Association (NCGIA), the Friday Harbor conference in 1993 united the critics and the proponents of the GIS to formulate the GIS and society research agenda, in order to address these criticisms. PPGIS arose out of this research agenda as an effort to advance informed participation of marginalized communities through inclusive access to GIS and spatial data. Therefore, the unique nature of grassroots groups and their challenges need to be understood.

Grassroots organizations of marginalized communities tend to be more decentralized and more fragile in financial and staffing support when compared to larger nonprofit organizations and public–private sector agencies. Their resource-poor conditions make it difficult for them to afford the cost of implementing GIS in their organizations. Purchase of data, software, and hardware or provision of ongoing GIS training to their staff members continue to be a challenge for these organizations. Moreover, these organizations are also hampered by frequent staff turnovers that result in higher staff training costs. Finally, grassroots organizations have faced the additional challenge of not gaining easy access to public databases that are often the repository of valuable community-based spatial data at multiple scales.

These difficulties have created a technological divide between the planning agencies that are frequent users of GIS and grassroots groups that face challenges in using GIS. Class inequalities are then further heightened by inequalities concerning the knowledge of and access to such information technologies, for it is clear that such access and understanding create greater opportunities for conferring political, economic, and social power upon the citizens of distressed neighborhoods. The establishment
of “empowerment, marginalization and public participation GIS,” as a critical research agenda by NCGIA and University Consortium for Geographic Information Science (UCGIS) in the late 1990s significantly advanced PPGIS work. A wide range of initiatives emerged across the world, aiming to enhance accessibility of data/GIS to disadvantaged groups and to incorporate multiple voices and local knowledge within a variety of contexts.

An examination of global case studies of PPGIS research and practice reveal certain key goals. PPGIS aims for: (i) equitable access to both spatial data and GIS technologies among socially marginalized citizens; (ii) incorporation of grounded, indigenous, experiential, and local knowledge with public datasets for marginalized citizens to contest or reshape policies; (iii) discouragement of top-down, rational planning approaches in policymaking; (iv) inclusion of both qualitative and quantitative data in GIS; (v) alternate forms of mapping, representation to capture complex social processes and cultures; and (vi) alternate forms of geospatial technology designed to suit the needs of indigenous or socially marginalized groups.

In response to the establishment of PPGIS agenda, various international conferences and workshops have been held that have significantly shaped PPGIS work. Notable among them are the Varenius workshop on “Empowerment, Marginalization and Public Participation GIS” (1998) held in USA, the workshop on Access and Participatory Approaches in Using GIS (2001) held in Italy, PPGIS international conferences held in the USA (2002–2005), and the PPGIS e-seminar (2007). Such workshops and conferences have been sponsored by significant scholarly bodies such as the US National Science Foundation, Urban and Regional Information Systems Association (URISA), European Science Foundation, Institute of British Geographers/Royal Geographic Society, which demonstrate the critical attention that has been given to this topic. A rich body of literature containing both theorization and case study analysis has been published in various journals and books. Notable among these are the special issues in Cartography and GIS (1998), URISA (2003), Cartographica (2004), as well as a seminal book on global PPGIS titled Community Participation and GIS (2002). Literature reviews of PPGIS practices also provide significant assistance in understanding this complex process (Sieber 2006). Other notable volumes, such as the Handbook of GIS and Society Research (Nyerges, Couclelis, and McMaster 2011), have also devoted significant sections on PPGIS. Individuals engaged in PPGIS have thus gained awareness as a distinct community with the creation of new spaces of discourse such as the PPGIS conferences and listserv.

PPGIS initiatives have been carried out by a multitude of social groups, such as activists, universities, government and nongovernmental agencies, community-based organizations, and grassroots communities. University–community partnerships and collaborative planning programs have provided particular opportunities for GIS practitioners and scholars to collaborate with disempowered and marginalized community groups, leading to grounded, bottom-up spatial knowledge production that could be strategically employed in policy activities.

Over the past two decades, the areas of PPGIS applications and theoretical conceptualizations have evolved and mutually informed each other. PPGIS practices have been carried out globally to address a multitude of policymaking, ranging from rural land use, to conservation and natural resource management, to urban planning, to social and environmental activism, and to advocacy (Craig, Harris, and Weiner 2002). PPGIS research has been shaped by an integrated
theoretical framework derived from social and political theory, science and technology studies, human computer interaction, organizational theory, and feminist theory. PPGIS as a process has been critically scrutinized to explicate the notion of public and the nature of participation. Such critical introspection has led to creative tension, with suggestions to rename it to participatory GIS (PGIS). Both terminologies are currently in use; however, PPGIS is also considered by some to be subsumed within the “critical GIS” moniker.

Key issues in critical GIS research span a diverse array of topics – differing national level procedures for spatial data access, effective PPGIS practices from initiatives around the world, and the use and impacts of digital geographic data in spatial decision-making. The nature of participation and the process of empowerment through PPGIS have also been interrogated. Though their areas of inquiry are quite diverse, research indicates that geographic data access and PPGIS projects are place specific, highly contingent, and strongly shaped by the local context in which they are situated. Place thus plays an important role in shaping participatory approaches to spatial decision-making. Further, the nature of these participatory processes is crucial to understanding the differential impacts of PPGIS initiatives for the individuals and communities affected by them.

Examining access to data/technology in PPGIS

PPGIS stresses the importance of enhancing access to existing spatial data/GIS and to participation opportunities in policymaking processes. Within this context, appropriateness and accuracy of data are important considerations, as data and analysis that are found to be appropriate and accurate will lead to greater action. To properly assess this issue, a model has been proposed which asks several questions – Are the data and material produced appropriate to the organization issues? Can the organization use the information in action-oriented ways to support decisions, enhance communication, and inform actions? Is information available to the organization in a timely manner? Is the information pertinent to organization issues? Do the results have a temporal and cross-comparison component, that is, a time perspective? Are the available data sufficiently accurate?

In the case of data/GIS, access is shaped by factors such as existing spatial infrastructure developments, the presence of a supportive network of actors, and supportive local policies. Access to data and technology also lies beyond the simple availability of data, hardware, and software. Issues of appropriateness of data, data accuracy and updates, forms of data representation, and costs of training are important and integral parts of effective PPGIS practices.

Access to public datasets is affected by different legal structures for copyright and licensing, and existing traditions such as the freedom of information access to public data. Data sharing between public agencies and citizen groups also depends upon the degree of government agencies’ openness to accepting grassroots citizen groups as authoritative participants in the planning process. Conversely, budgetary cutbacks and fiscal constraints may compel government agencies to sell their data to the public and/or limit data sharing with selected stakeholders.

Within PPGIS, access to technology leads to questions of GIS implementation in grassroots organizations. The adoption and use of GIS by grassroots organizations has been studied under the moniker of GIS implementation. This body of work is based on the research on GIS
PUBLIC-PARTICIPATION GIS

implementation in local governments, which, in turn, has roots in organizational theory. Here implementation refers to the decisions made by an organization to acquire, install, implement, and use GIS in accordance with organizational needs and tasks.

The presence of supportive actors that assist grassroots groups to gain access to data is another key factor. Because of the resource-poor nature of grassroots organizations, they often rely on external expertise for access to GIS data and technology. External GIS providers in PPGIS tend to contain certain common characteristics. In particular, they tend to be housed in larger institutions, which provide the budget, stability, and credibility to those using its products. However, the institutional homes of the supportive actors are varied, including academia, larger nonprofit organizations, public libraries, and city government offices. In the case of urban PPGIS studies, Leitner et al. (2002) found six major models of PPGIS provision to neighborhood organizations: community-based GIS; university–community partnerships; GIS facilities in universities and public libraries; map rooms through government GIS; Internet map servers; and neighborhood GIS centers. The six GIS provision models are assessed through the following aspects: costs of maintaining GIS (hardware, software and GIS training); ease of data provision and responsiveness to community organizations’ needs; stability and longevity; and ability to support collaborations among stakeholders and among grassroots organizations.

Studies also indicate that access to and participation in the use of geographic information depend on social context such as local culture and institutions. Factors such as a culture’s ability to absorb uncertainty, its level of masculinity, and its ability to accommodate human inequality can significantly shape PPGIS. Other factors include a community’s tolerance of expert solutions, its sense of collective control, and its level of individualism. Prevalent cultural and political norms can limit the type of participants to a specific gender, class, race, or caste. Politically repressive cultures can restrict public access to critical data through legal controls and may control citizen participation to such an extent as to render PPGIS efforts ineffective and irrelevant.

Finally, internal characteristics of a grassroots organization also significantly shape its PPGIS activities, including its data access. In particular, Elwood and Ghose (2001) provide an organizational framework to examine neighborhood organizations’ usage of GIS. The framework includes four major dimensions: organizational knowledge and experience; networks of collaborative relationships; organizational stability; and organizational priorities, strategies, and status. In terms of data access, the organizational ability to form and sustain relationships of support with local government agencies and GIS provider actors is vital. Further, a grassroots group’s awareness of the value of spatial information in policymaking will shape its efforts to access data. Lastly, availability of data in terms of appropriateness, accuracy, access, ownership, and representation are equally pertinent issues.

The context of equitable access to GIS is dependent not only upon mere availability of software and hardware but also upon the GIS skills that reside among the grassroots group. Within the PPGIS agenda, GIS represents a socially constructed technology that can be redesigned to suit the goals of the users, provided they have a fairly high level of technical skills that can be adapted to suit their goals. PPGIS practitioners in the environmental conservation arena often display a high level of technical skill and are adept at using the technology to suit their needs. Therefore, in-house GIS use by such grassroots user groups is common. In the developmental
context, the integrated approaches to participatory development (IAPAD) group developed a process of blending GIS, physical terrain models, and community participation into “participatory 3-D modeling.” This approach exemplifies an interface that is nontechnical. On the other hand, many community mapping projects exist in both rural and urban groups where community members do not engage directly with the GIS but work in collaboration with technical teams to provide their input (such as indigenous, experiential or local knowledge) and evaluate output. Here, it is necessary for community groups to acquire map reading skills, as outputs are in the form of maps. Some projects increase an applicant’s ease of use and lessen the need for GIS skills by enhancing the human–computer interaction (HCI). Other research has produced a bird’s-eye viewer for GIS participants who experienced difficulty in comprehending their community from a 2-D planimetric map.

Human–computer interactions can be characterized from no direct use, to passive use, active use, and proactive use. These are not hierarchical; proactive is not necessarily the optimal level of usage. Nor will stakeholders benefit equally. An effective PPGIS application depends on understanding how much and when technology should be brought into a process. The corollary is how much GIS must be learned by individual stakeholders and what technologies can be supported by available resources.

Advances in Internet technology have significantly enhanced the ease of data access and mapping, and have facilitated data input and communication between different groups. Government agencies have facilitated public access to spatial data and analysis through their Internet GIS sites. However, access to high-speed Internet connection is vital for grassroots groups to effectively access data and perform analysis. Internet GIS is also commonly utilized to elicit the public’s input and opinions in resource management and planning.

Most recent studies have emphasized the development of geospatial technologies in combination with Web 2.0 technologies (Goodchild 2007). Google Maps, Google Streetview, and Google Earth have emerged as popular, user-friendly mapping interfaces, which can also be linked with GIS technologies to create analytical functions. Citizens can locate places and view them at a high resolution through street maps, detailed aerial photographs, and satellite images. Such efforts have significantly increased spatial awareness and mapping among average citizens and have resulted in individuals providing user-generated content through “volunteered geographic information” (VGI) (Goodchild 2007). VGI has provided any citizen with the opportunity to add information to place, upload videos or images, share information, and enrich the understanding of a place. For managing emergencies and disasters, or even for citizen science, such user-generated content and mapping through VGI activities have been very helpful. Both VGI and PPGIS thus provide the opportunity to any Internet–using layperson to contribute geographic information for a broad spectrum of purposes, allowing users to act as both information consumer and information provider. The distinction though is that while VGI is more concerned with individualized information sharing and mapping, PPGIS is oriented towards group decision-making that includes the voice of marginalized citizens and explicitly seeks social change.

Development of free and open source GIS or Open GIS is a significant achievement in eliminating the factor of software cost in PPGIS (Sui 2014). The principles of Open GIS include: the creation of free, open source software; the harnessing of collective intelligence through a bottom-up information flow and user-generated
content; the idea of the web as a platform and the development of web services, cloud computing, and lightweight programming models allowing for application development, such as mash-ups; software that extends beyond a single device to laptops, mobile smartphones, and tablets; and the rich usability of an easy-to-use graphic interface. Moreover, the increasing employment of smartphones with special apps provides great ease in collecting geocoded spatial data and enables new ways of data collection through participatory photomapping. The diverse, mobile, and flexible nature of open GIS provides greater opportunities to collect local knowledge and build spatial narratives in cost-effective ways.

Overall, web-based GIS moves away from one-way information dissemination to two-way interactive communication to three-way public–public communication. Grassroots groups have a better chance to participate in public policy formulation if spatial knowledge and GIS is incorporated into the organization and utilized as management tool, a form of community interaction, and for resource allocation. The ongoing development in web-based geospatial technologies provides community-based organizations a space to represent their knowledge of local places through the maps they create. Web-based GIS mapping programs are a popular way for organizations to incorporate a GIS as part of their internal management and planning strategies and have also made it easier for community-based organizations to share information with one another as well as with the different social actors with whom they are collaborating on participatory projects.

Web-based GIS mapping applications have been cited as effective tools for public participation in collaborative research projects, urban governance, and spatial planning initiatives. Community organizations have used Web 2.0 mapping technologies for a variety of reasons, including, first and foremost, to collect information that can be shared in a way that effectively communicates a message to the organizations members, associated partners, and with whom an organization is attempting to form a relationship. Increasingly, the boundaries between the spatial data user and spatial data creators have blurred.

**Representation and integration of local knowledge**

The nature of spatial knowledge production in PPGIS has been explored through numerous studies. PPGIS research has emphasized the value of indigenous or local knowledge and ways of incorporating local knowledge and indigenous knowledge into GIS databases. Significant efforts have been made to incorporate local knowledge and value-based data into GIS (Cope and Elwood 2009), including community organizations’ active reworking of the meaning of mapping through traditional GIS tools, creative engagement of visualization and multimedia representations, and efforts to rewrite GIS software to embody multiple forms of spatial data.

A number of studies have sought to investigate the existing everyday practices of conventional GIS that integrate local knowledge. Integration of local, experiential knowledge with public datasets creates nuanced spatial knowledge that has proved to be significant for marginalized communities. In the context of urban revitalization processes, studies have shown that community organizations use such spatial knowledge to enhance inter- and intra-organizational communication, to legitimize existing experiential knowledge for obtaining action, to monitor neighborhood conditions for strategic planning, to prepare for organizational tasks and funding recruitment efforts, to enhance service delivery
tasks, and to explore spatial relations to challenge or reshape urban policies. PGIS projects from the Global South also show that there are three major uses facilitated through community mapping: communicating information within communities, communicating information between neighboring communities, and communicating information to outside groups.

Visualization has been acknowledged as an important approach used by community groups in PPGIS to state their position, communicate with stakeholders, and contest official discourse. PGIS projects increasingly incorporate multiple ways to enhance such visualization. Maps are a popular form of visualization used by community organizations. In inner city revitalization, maps help organizations to create spatial strategies to both combat problems and identify opportunities of growth. While mapping of neighborhood problems are important to seek action, community asset maps that showcase the neighborhood’s positive aspects are also frequently used to attract investment opportunities. Such maps can range from simple thematic maps to more complex maps employing kernel density functions. Mapping of neighborhood indicators can be used to compare a neighborhood’s condition with that of other neighborhoods, represented at multiple scales (inner-city scale, municipal scale, metropolitan scale). Such scale jumping can be used as a spatial strategy to highlight the low quality of life in a target neighborhood in order to demand resources and policy changes.

The intersection of critical (or interpretive) epistemologies and qualitative methodologies has led to innovative modes of visualization in PPGIS, as it continues to grapple with underlying questions concerning human identity, lived experience, situated and contingent knowledge, power and positionality, as well as concerns of social oppression and spatial exclusion. Representation is particularly critical where local knowledge is to be integrated. In order to incorporate local knowledge into the building of GIS databases, efforts have been made to include value-based, traditionally intangible information through efforts such as geoethnography. Feminist geographers employing qualitative ethnographic research have created feminist visualization techniques to more effectively understand subjectivities and represent the different experiences and emotions of individuals (Kwan 2002). Such approaches provide multiple ways of integrating indigenous and experiential knowledge in PPGIS. PPGIS studies have thus incorporated pictures, photographs, narratives, videos, sketches, architectural footprints, and so on to construct spatial knowledge. Through the use of a multimedia community integrated GIS project in South Africa, Harris and Weiner (1998) demonstrated how different forms of community knowledge could be integrated to create powerful spatial narratives. Through innovative approaches, PPGIS projects show that multimedia files can be attached as attributes to point layers to represent oral histories, nontraditional weighting schemes for site suitability can be evaluated, and language-specific user interfaces can be created.

PPGIS projects have also demonstrated the use of alternate mapping techniques, such as mental mapping, sketch mapping, and participatory photo mapping, in order to include qualitative data into GIS. Through the act of drawing, a mental map reveals significant dimensions of memory and human perception. Features become emphasized or de-emphasized, revealing individual perceptions and experiential knowledge about places. However, it is important to avoid any normative use of mental maps that assume humans possess perfect locational knowledge.
The aforementioned critical and qualitative turn should not be interpreted as a comprehensive rejection of quantitative research methods. Sketch-maps and participatory photomaps, on the other hand, are spatially referenced and can be considered as examples of methodological pluralism. Narratives and videos can also be georeferenced and used in conjunction with traditional GIS activities. Through these mixed, multi, or hybrid-methodological approaches to human spatiality, qualitative GIS offers innovative opportunities to bridge the intractable qualitative–quantitative divide in the direction of synergism and holism. Applications of such qualitative GIS techniques in PPGIS projects have provided greater opportunities for marginalized individuals and communities of varying age groups, race, and gender to counteract hegemonic narratives of exclusion, to incorporate multiple perceptions of reality, to emphasize local issues of importance and concern, and to draw attention to persistent silences in data.

There have also been notable efforts to rewrite existing GIS software to accommodate the needs of community groups and to challenge hegemonic forms of data representation. In an effort to bridge the qualitative–quantitative methodological divide, qualitative GIS projects have been created to blend GIS software with computer-aided qualitative data analysis software. In order to facilitate the ease of GIS use among marginalized communities, efforts have been also made to create interfaces customized to the unique needs of communities. Nonetheless, while rewriting the code of GIS opens greater opportunities of multiple data representations, given the level of technological expertise required this approach is largely initiated by academia or public agency rather than by the community groups.

Further, while access to spatial data and GIS can enable disadvantaged groups to more effectively participate in planning and policymaking activities, there is also evidence of contradictory outcomes, as such access may empower certain groups within the organization while disempowering others. The ability to use computers and spatial technology varies widely among marginalized groups, leading to exclusion of some members of the community. The contradictory outcomes of PPGIS can be reflected in web-based mapping projects as well. Access to high-speed Internet differs among different social groups and in different regions. The ability to use the Internet for PPGIS is also quite variable, based on race, class, age, and gender divides. It is, therefore, important to inquire into whose knowledge is being represented through PPGIS.

Evaluating outcomes in PPGIS

Scholars have called for critical examinations of the role of GIS usage in a variety of contexts as to whether GIS has empowered marginalized communities or consolidated existing power relations. PPGIS outcomes can differ based on the goals of the project, the local contexts of participation and access, and the internal organizational characteristics.

It is recognized that there are multiple levels of public involved in PPGIS practices within particular contexts. Representing the various perspectives of multiple publics within spatial data structures remain key research challenges. Similarly, participation is a multifaceted process. Many studies have drawn upon Arnstein’s (1969) concept of a participation ladder to illustrate the levels of participation, ranging from tokenism at the bottom to collaboration in the middle and to citizen control at the top.

Another concept that has been widely associated with PPGIS is the notion of empowerment.
PPGIS research shows that it leads to empowerment of marginalized groups. The concept of empowerment has a wide array of definitions. In particular, Elwood (2002) provides an insightful multidimensional analysis of empowerment in the context of GIS usage in community planning. In this framework, empowerment contains three dimensions: distributive change, procedural change, and capacity building. Among these three dimensions, distributive change is the least sustainable and capacity building is the most sustainable. A PPGIS project may result in all of the three dimensions of empowerment and be reflected in multiple forms. Sustainability of PPGIS projects is also a factor in such discussions. Ultimately, empowerment must be seen as a gradual process and not as the end product of PPGIS.

Notions of expanded participation also may presuppose some degree of homogeneity of benefits among those involved in PPGIS. However, various studies have noted that the notion of participation in PPGIS is complex and needs explanation. The notion of individual participation varies according to cultural norms and the notion of participation in indigenous or non-Western cultures is significantly different from that of Western culture. Social structures based on class, race, and gender divides also shape participation. Further, even in the same group, certain individuals may be better able to participate than others. Similarly, all factors being equal, certain organizations are better able to participate than others. In other cases, widespread participation may not be desirable. Similarly, the use of the word participatory may also be problematic, as it implies a need for an intermediary actor or institution.

Evaluating the effectiveness of increased participation through PPGIS has not been easy and is shaped by its contexts. PPGIS activities among indigenous communities show a more activist and confrontational stance. Their goals include gaining recognition of land rights, protecting traditional land, gathering and guarding traditional knowledge, and achieving social justice. In contrast, PPGIS activities in urban governance are undertaken by community organizations in a framework of accommodation and collaboration, which may not lead to any alterations in power.

Political and economic policies that shape governance and policymaking are also deeply influential in shaping the nature of PPGIS. The impacts of neoliberal policies have significantly affected the process of governance and citizen participation across the world, and such impacts have been felt on PPGIS practices as well (Ghose 2007). In particular, the shift to collaborative governance emphasizing public–private partnership and advocating a leaner government has reconfigured the role of the state and led to the rise of new intermediary stakeholders. Simultaneously, citizen participation in governance has been more formalized, in order to shift many of the responsibilities of the state upon the citizen groups. Collaborative governance has led to considerable data sharing between the government agencies and citizen groups, and, consequently, the use of spatial information and mapping among citizen groups in such collaborative governance has become more common. However, cutbacks in state budgetary and funding support for community organizations have reduced the capacity of organizations to participate effectively in collaborative governance. Consequently, community groups still lack sufficient resources to implement in-house GIS, resulting in variable PPGIS productions. The effectiveness of participation and spatial knowledge production is now increasingly dependent upon internal organizational factors (Elwood and Ghose 2001). In particular, the organizational ability to navigate the local politics of turf and building relations among stakeholders plays an
important role in shaping PPGIS outcomes. Relationships among stakeholders in PPGIS range from cooperation, compliance, and collaboration to control. Studies show that grassroots organizations must build dense networks of relationships to build and sustain their PPGIS efforts. Further, dynamic networks of support must be built at different scales (local, regional, national) among community groups and other stakeholders (Ghose 2007). Community organizations in urban governance thus increasingly undertake a cooperative stance rather than a confrontational stance. Within the context of urban governance, marginalized community organizations therefore tend to utilize PPGIS projects for effective navigation into the mechanisms of governance. Their projects have primarily four functions: administrative, organization, tactical, and strategic. These functional categories mirror public and private sector goals, and are similar to increasing efficiency in tasks such as map production, reducing redundancy in databases, and improving effectiveness in decision-making. Certain scholars have identified PPGIS as a mode of “collaborative decision support.” Here, PPGIS has been perceived to add value at several stages of the decision-making process, improving the articulation of stakeholders’ views, increasing individuals’ or groups’ understanding of technology, making complex decisions more transparent and objective, augmenting deliberation and consensus, furthering communication and linkages among internal participants and between internal and external parties, disseminating or sharing information, resolving conflicts, and enabling greater exploration of ideas.

Evaluation of the effectiveness of PPGIS projects has been overall a difficult process. Certain scholars argue that PPGIS projects should be assessed based on (i) appropriateness and match with an organization’s existing activities, (ii) adaptability to local conditions such as local culture, political climate, (iii) fitness to current organizational goals and capacity, and (iv) ability to be integrated into broader societal goals. Others argue that the contingent and place specific nature of PPGIS make it difficult to craft quantifiable assessment measures, and qualitative assessments of satisfaction with PPGIS projects should instead be practiced.

In conclusion, PPGIS practices have been increasingly employed in diverse areas across the world. Major barriers of access to spatial data and technology remain a significant challenge for many disadvantaged groups. At the same time, there have been numerous creative engagements with GIS to incorporate local and multiple forms of spatial knowledge through traditional GIS software, rewriting GIS as well as the recent combination of Web 2.0 technologies with geospatial technologies. Research has shown that PPGIS practices have been highly context-dependable and there are variable outcomes of empowering community organizations. Existing studies have shown the depth and breadth of PPGIS practices. However, there is very little research on the longitudinal investigation of PPGIS practices. This may partly reflect the challenging issue of sustainability of PPGIS projects. Yet, a long-term investigation of PPGIS practices within a particular place will provide important insights into the above three theoretical streams reviewed.

Qualitative data, acquisition

Steve Herbert
University of Washington, USA

Places are made through meaning-laden processes.

This statement seems simple enough, but reckoning with it fully is not. Although a wide range of research questions animate academic conversations in geography, place-making remains a key touchstone to the discipline. Social groups importantly construct themselves through the various means by which they build places. Through the construction of the built environment, through various symbolic acts that convey meaning, through the maintenance of boundaries, societies create an identity and a presumed durability.

Notably, these acts of simultaneous place- and group-construction are ongoing processes. Certainly many enduring structures, such as the capitalist space-economy (Harvey 2007), guide these processes. Yet all such structures are only reproduced through daily action. Their endurance is, thereby, a product of thousands of conscious and unconscious acts. Further, these acts are laden with meaning; they bear a symbolic significance to the group members who perpetuate them (Delyser 1999; Herbert 2000).

Because of the importance of these meaning-laden processes to the construction of places, many questions central to the discipline of geography require recourse to qualitative data. Without in-depth understanding of how and why people build places, and how they render such action meaningful, how social processes and spatial forms are mutually reinforced cannot be fully comprehended. Indeed, there are few research agendas within the discipline of geography that would not profit from qualitative data.

There are, of course, multiple specific goals that might be pursued through gathering qualitative data; for example, the wish to understand the relationships between talk and action. It is one thing for social groups to create any number of discourses through which they articulate a worldview and a set of desired practices. It is another thing entirely for them to actually enact those practices. Indeed, disjunctures between talk and action frequently provide insights into such questions as the importance of ideology in maintaining power (Hall et al. 1978; Willis and Aronowitz 1981). Alternatively, the wish might be to understand how certain cultural schemas are unique to a given group, and how they generate a specific identity that is re-created daily through spatial practices (Herbert 1997; Sewell 1992). If such schemas are contested, either within or across groups, then conflict can emerge. These conflicts may take spatialized form, as when residents of one area resist the incursion of differently-situated others (Coleman 2005; Nevins 2001; Varsanyi 2011). These conflicts can best be dissected through sensitively gathered qualitative data.

These examples hardly exhaust the productive analytic uses to which qualitative data can be put. But they do illustrate how vibrant geographic research profits immensely from attention to the meaning-laden processes through which socio-spatial life is built.
QUALITATIVE DATA, ACQUISITION

Some of the central challenges that a qualitative researcher faces in acquiring useful data are reviewed in this entry. Also reviewed are the two key modes of qualitative data gathering – ethnography and interviews. The key strengths and weaknesses of each of these methods is outlined and when each might be employed most productively considered. As will be clear, gathering high-quality qualitative data is neither quick nor easy, yet such data enable geographic analyses of great depth and insight.

Key challenges in gathering qualitative data

Regardless of which type of qualitative data a researcher seeks to acquire, s/he will face numerous challenges. Though these challenges are rarely overcome easily, they can be approached with sufficient sensitivity to minimize their disruptive potential. Four key challenges are considered here: choice of case, access, trust, and validity.

Choice of case

The intrinsic value of qualitative data lies in its depth. Through extended exposure to a particular group, the qualitative researcher can discern many of the less visible wellsprings of social action. Core group values emerge through exposure to both discourse and behavior. Fissures between group members become more apparent; their significance can be analytically revelatory. Rituals can reveal how meaning is created, and perhaps contested. The meanings of such rituals, or any other form of patterned social action, are often opaque when fieldwork begins. As the qualitative researcher gains greater exposure to the group, what was once mysterious becomes more susceptible to thoughtful analysis.

Such fieldwork takes time. Multiple observations of the same phenomenon are commonly necessary before its significance is clear. Prolonged familiarity with the group’s members is often required to enable the creation of trust, and the more open conversations such trust allows. Because of these extensive investments of time, the qualitative researcher must restrict the number of cases s/he examines. For this reason, qualitative research is often critiqued for its failure to create data that can be generalized across multiple cases.

This is no small concern but it need not cripple the qualitative research enterprise. It does mean that any case needs to be selected carefully. Three common strategies can achieve the goal of finding appropriate cases to study.

One strategy is to find a case that is representative of others. It is often true that a particular social group possesses dynamics that occur in other, similar groups. Because of this, any generalizations that emerge from an in-depth analysis of one group can be extended to others (Stake 1995). A second strategy is to find a case that is somehow unique, one that does not conform to expected patterns. The effort to understand just how and why that group’s uniqueness occurs will likely require the researcher to extend existing theory in productive fashion (Burowayi 1998). A third strategy is to adopt an explicitly comparative approach. Here, the researcher seeks to find two or more groups that are similar in some respects but different in others. The effort to explain these similarities and differences through analysis of in-depth qualitative data should also work to enable the refinement of existing theory (Miller 2000; Ragin 1987).

The investment of time in a single case is the hallmark of good qualitative research. Because this reality places limits on how many cases to open for examination, the selection strategy
must be careful. Yet judicious choices here can yield generalizability.

Access

Careful case selection is the necessary starting point of qualitative inquiry. Yet that does not mean a researcher can gain access to the group most ideal for study. Indeed, the granting of such access is often no small matter for the members of the group in question. Those members must tolerate a newcomer for an extended period. They will likely be asked any number of probing questions; they may have their routines disrupted. They typically will engage the researcher with the full knowledge that they will not control the ultimate results of the work. For groups wary of the attention the researcher may bring to them, it may prove difficult, if not impossible, to grant access to their daily behavior.

Given these realities, the researcher must be thoughtful about how to approach a group to which s/he desires access. A key consideration here is how the researcher wishes to be positioned vis-à-vis the group in question. Classic fieldwork placed the researcher in the role of the seemingly dispassionate scientist. Here, the goal was to remain as “objective” as possible in delineating the kinship structures or other key cultural determinants of social action. From this perspective, the group under study is primarily fodder for academic analysis, and arguably profits little from interactions with members of the research community. While it remains the case that academic researchers are required to publish rigorous and theoretically oriented analyses to advance their careers, it is increasingly likely that any group that grants access will want something more from the encounter. Because of this, the researcher needs to consider just how the group in question might itself benefit from the research. It may be the case that the group welcomes insights from an outside observer. A public agency, for example, might wish to better understand its internal processes. A more politically motivated group might wish to see the researcher conduct work that will assist it in pursuit of particular goals (Routledge 2010). It might even wish to negotiate the contours of the research itself, and remain in active collaboration with the researcher. Such “participatory action research” holds great appeal to researchers who seek to combine scholarship and advocacy (Kindon, Pain and Kesby 2008; Reason and Bradbury 2001).

Yet such collaborations must be approached carefully. However well-meaning a researcher may be, the reality remains that the career advancement of an academic requires a particular type of analysis that is likely distinct from that desired by the group. There will thus always be some degree of self-interested expropriation from the group by the researcher, and it is disingenuous to pretend otherwise. Ethical practice demands that the researcher never lose sight of this reality, and communicate that to the group under study. In addition, the researcher must be careful just which point of contact to approach initially. It may be that certain individuals who can grant access will wish to steer the researcher in particular directions, without revealing their motives for doing so. It may also be that entering the group under the aegis of one individual may lead others to cast suspicion on the researcher. In this author’s experience, the fact of being granted access to the Los Angeles Police Department by a new and reform-minded police chief meant that many feared a “spy” intent on uncovering officer misdeeds. It required significant exposure to the group for that suspicion to erode (Herbert 2001).

The challenge of gaining access to a group is a significant one and needs to be approached thoughtfully. It is necessary to think carefully
about just how a plausible claim to assist the group can be made without losing sight of the fundamental reality that the researcher is doing rigorous social science. And it is necessary to try to discern a route into the group that will allow the development of trusting relations as quickly as possible.

Trust

Of course, trust is not always easily won. Even if a researcher finds a good entry point, much work must still occur to ensure that group members will be forthcoming. Research subjects can commonly be expected to possess concern about how the author will use the data s/he gathers. How will the group be represented? Will the analysis be critical? Will it be accurate? Will individual group members be identifiable? Who is the intended audience? Even if such questions are not explicitly articulated, they often influence a research subject’s initial interactions with the qualitative researcher. It is, therefore, necessary to address these concerns. Several strategies can assist here.

It is imperative that the researcher approach the group in a nonjudgmental fashion. Not only is this stance respectful of the group, but it conforms with sound social scientific practice. The researcher’s task is to understand the world as it is experienced by the group members. This is impossible without bracketing pre-existing conceptions to the greatest degree possible. If the task is to discern the underlying logic of various sociospatial practices, then open-mindedness to group practices is essential. Research subjects will quickly discern how genuinely open a researcher is to their experiences, and this will strongly influence their ability to trust.

A second key component of trust building is the process of informed consent. Human subjects review is now an inescapable component of qualitative data gathering. Such review will invariably require that researchers secure written consent from their subjects to participate in the research. The consent form will include a description of the research and its intended purposes, and a discussion of how participation might provide unwanted consequences for the subject. The researcher is expected to review the form with the subject and to address candidly any questions that emerge. Indeed, this discussion will often be the first substantive conversation between researcher and subject. Trust will develop if the researcher approaches this discussion in an open-minded fashion, and allows the subject ample time to make a considered decision about participation.

A third means to increase trust is to provide explicit protections against publicity to the group. This will commonly include grants of anonymity to individual participants. It may also include disguising the group as much as possible, by providing both a fictional name and locale. Such fictions might be considered an unwelcome component of social science practice, which encourages researchers to make their data gathering replicable. Yet without these protections, group members may well refuse to participate, or they may choose to provide only superficial information. The necessity of trust in the researcher–researched relationship may demand that one disguises enough about the group to prevent a reader from discerning its identity.

The ability to gather substantive qualitative data requires the researcher to assiduously work to earn the trust of the research subjects under study. Such work should be motivated not solely by the researcher’s instrumental goals of advancing his/her career, but by a genuine interest in understanding the world from the subject’s perspective. If such interest exists, and can be communicated both directly and indirectly, trusting relationships between researcher and subject can develop.
Validity

Without trust, the qualitative researcher cannot gather the data necessary for insightful analysis of group processes and meaning structures. The significance of such data cannot be overstated. Without it, the researcher cannot analyze a particular phenomenon with sufficient depth and breadth. The researcher must be able to persuade the reader that s/he understands the group well enough to make generalizations about its patterned practices. Further, the researcher must convince a reader that the data under analysis are reasonably comprehensive, and that they were gathered via ethical and effective practices. In other words, the data must be considered valid if the researcher is to generate high-quality analyses.

The acquisition of valid data requires trust, but it also requires more. The researcher must be ever attentive to the reality that any single group member’s perspective is partial. This is true even if the subject is being completely forthcoming, but is especially the case if a subject is choosing to structure a narrative about the group for some strategic purpose. An informant may, for example, be looking to use the researcher to tell stories that would enhance his/her own status. Because of this, the researcher must endeavor to engage as many subjects as possible as deeply as possible. Further, the researcher will want to observe the group in multiple settings, to be able to discern just how specific contexts shape group processes. Otherwise, the analysis could rest on data that cannot bear the weight of generalization.

The data must thus capture multiple perspectives from within the group. They must also capture those perspectives in sufficient depth. In almost all instances, this will require extensive involvement with the group in question. For that reason, qualitative research is typically time-intensive. Ideally, the researcher can stay involved with the group for long enough to reach a point of saturation. In other words, the researcher gathers data until new information becomes scarce. In many instances, the lack of time or resources may prevent the researcher from reaching this ideal situation. In those cases, the researcher must rely on the data s/he possesses, and explain to the reader the degree to which the data might be limited.

As the foregoing discussion illustrates, the qualitative researcher has some important decisions to take before entering the field, and some important work to do once there. Without considering these decisions carefully, the researcher may end up with insufficient or invalid data. Yet through judicious decisions about which case to study, and assiduous attention to establishing trusting relations with research subjects, the qualitative researcher can capture data that enable insightful analyses.

Another set of important decisions revolve around just which qualitative method to pursue. This is considered in the following section.

Choice of method

It is one thing to thoughtfully choose a case and to establish ethical and productive relations with informants. It is another thing entirely to actually collect data. Just what type of data does the researcher desire and what is the best means by which to acquire the data? Which of the available data collection methods is most sensible in any given situation? These questions do not commonly yield easy answers, but require thoughtful consideration before entering the field, and sometimes even after data collection starts. Each of the principal qualitative methods – ethnography and interviews – possesses certain advantages and disadvantages. Without complete cognizance of what any given method can and cannot provide,
QUALITATIVE DATA, ACQUISITION

the researcher cannot ensure the acquisition of data most essential for the project at hand.

Ethnography

An ethnography consists of a prolonged exposure to a particular social group. In the process, the researcher becomes attuned to the daily rhythms and routines of the group. Indeed, the researcher will be required to become active in the group dynamics, at least to some degree. For that reason, ethnography is sometimes described as “participant observation” (Watson and Till 2010). This term suggests one of the key advantages of ethnography: the researcher, as newcomer, must acquire the necessary cultural competence not only to understand the group but to participate as a member in good standing. All social groups require some specific knowledge to enable competency as a member. The ethnographer acquires this knowledge through daily practice, but does so with sufficient reflexivity to document the process.

The key advantages of ethnography, then, derive from sustained exposure to the group and some degree of participation in its processes. A lengthy fieldwork experience should also enable the steady accumulation of trust and, with it, more forthcoming revelations from group members. Ongoing observations of the group also position the researcher to make assiduous distinctions between talk and action. Group members may say one thing, but their actions may suggest another. For that reason, a qualitative researcher who relies solely on interviews may gain an incomplete understanding of how the group actually functions.

The main disadvantage of ethnography is simultaneously its main advantage: it takes time. This is a resource that few possess in abundance. In addition, ethnography requires sufficient interpersonal skills to develop trusting relations with subjects. Further, the investment of time in a single case places significant pressure on the case selection decision. The researcher must make sure that an analysis of the case under examination can yield broader generalizations of interest to other social scientists (Herbert 2010).

That said, ethnography uniquely enables the acquisition of data of remarkable depth. Provided that the researcher has the necessary time and interpersonal skills, and chooses the right case for examination, s/he can generate social scientific work of considerable significance, as the rich ethnographic literature more than amply illustrates. Of course, not all researchers have the time required to carry out intensive ethnography. Fortunately, high-quality data can result from interviews.

Interviews

Insight into group processes and meaningful structures can emerge from fruitful conversations with group members. Interviews built on thoughtful questions and empathic listening can yield valid data. If done well, interviews can be a very efficient means to achieve a researcher’s goals (Rubin and Rubin 2011; Spradley 1979).

The collection of useful interview data requires several considerations. The first is to isolate a population of interviewees that can provide illuminating data. Success here rests upon the same considerations as for ethnography: identifying well-positioned informants, approaching them respectfully, establishing trusting relations. The second is to structure the interviews properly. Some researchers may wish to ensure a high degree of standardization across the interviews, and hence will employ a well-structured schedule of questions that is repeated identically with all informants. Most interviewers, however, will want to create enough elasticity in the interview to enable the emergence
of unanticipated ideas and themes. For that reason, semi-structured interviews are more common. These ensure that similar terrain is covered in all interviews, but allow the conversation – and potentially the research itself – to expand to include additional and relevant data. Semi-structured interviews also allow the interaction to develop into something approaching a conversation, and thereby help the subject relax. Success here rests upon a third key ingredient in interviewing – establishing trust. Such trust is more likely to result when the researcher is fair, ethical, and honest in all interactions, and when the interviewee feels as if he or she is being listened to empathically.

Unlike ethnography, interviews typically disallow much comparison between talk and action. If unable to observe the research subjects engaging in the social relations under study, the interviewer is left largely to take subjects’ at their word. For that reason, any research project that relies heavily on interviews can benefit from even a minimal amount of participant observation. Even if this is not possible, a well-crafted interview-based project can yield useful data. Targeted conversations with knowledgeable individuals can be enormously efficient means to gain insight into a particular social group.

Most interview-based studies rely on a series of conversations with single individuals. Some, however, bring together multiple interviewees together for a group conversation. Such focus groups can be advantageous (Bosco and Herman 2010). One advantage is that members of the group can challenge accounts from each other. This limits the ability of any one interviewee to expand on an idiosyncratic – and perhaps even erroneous – narrative about key group processes. A second advantage is that group interaction processes can be rendered at least partially visible. In the process, the researcher can learn of intergroup tensions or other dynamics that may be quite relevant for efforts to answer key research questions.

Given the researcher’s desire to cultivate a wide-ranging conversation in the focus group, the schedule of questions is commonly short. This reality places pressure on the researcher to construct the best possible set of questions. It also means that the conversation will necessarily be limited, and hence reduce the researcher’s capacity to uncover unanticipated components of group processes. That said, if focus groups are carefully constructed and skillfully handled, they can unearth insightful data.

Of course, not all qualitative research projects rely exclusively on either ethnography, interviews or focus groups. Indeed, given the inherent strengths and weaknesses of any of these used in isolation, a robust research strategy might employ these in some combination. A project based largely on ethnography may profit from more extensive conversations with particularly well-placed informants to enable a targeted consideration of one particular dynamic. A project based largely on interviews with individuals may profit from focus group discussions to enable some insight into group processes. Not all researchers possess the time or other resources to accomplish a mixed methods approach, but these may provide the best means to ensure the collection of comprehensive and valid data.

Conclusion

The reality that places are made through meaning-laden processes guarantees that the skillful collection and analysis of qualitative data will remain essential to the practice of human geography. While such data are never gathered easily or quickly, they possess the capacity to illuminate and explain a wide range of sociospatial behavior. The challenges of gathering
Qualitative Data, Acquisition

High-quality qualitative data are numerous and substantial, but they can be addressed effectively, and thereby provide unparalleled opportunities to understand and document the complex undercurrents of sociospatial life.

Qualitative data

Iain Hay
Flinders University, Australia

Qualitative data comprises non-numeric information recording and describing the ways in which people regard, experience, understand, and construct the places they inhabit. It is typically drawn from naturalistic settings and reveals what participants understand about how and why specific events or relationships have come to pass. It can also capture the worlds of researchers’ and participants’ senses, conveying ideas like how a place smells, how something tastes or feels, what it looks like, or what memories it evokes. As data, qualitative information comprises records or descriptions, but does not include explicit judgments about content – notwithstanding the subjectivity or positionality of any observer gathering the information. Qualitative data is customarily and contentiously distinguished from quantitative data, which comprises numerical information, such as “how many,” “how much,” “how often,” all capable of various forms of statistical manipulation and interpretation.

Qualitative data: variety and verstehen

Qualitative data emerges from research seeking to understand the qualities of things, rather than their quantity. It is something that can be observed, but not measured. Although qualitative data might include accounts of taste and smell (e.g., describing the reek of an abattoir visited on a fieldtrip), it more typically encompasses text, images or sounds, including the words and actions of participants as read, heard, or observed by a researcher (e.g., a researcher’s observations of teenagers’ behavior in a shopping mall and those teenagers’ own explanations for their behavior). It may also describe or express emotions and sentiments (e.g., how a refugee feels about their former homeland).

Qualitative data also emerges from research that seeks to reveal subjective understandings or the meanings of action from the perspective(s) of participants (e.g., the value Australian suburban homeowners attach to recreational gardening; how people regard their own daily commuting contributions to global warming). Rather than treating research participants as objects of the study, they are held to be subjects, with their own capacities to comprehend and craft their worlds. In this regard, qualitative data materializes from the pursuit of that which German antipositivist sociologist Max Weber termed verstehen (i.e., understanding the meaning of action from the actor’s point of view).

Qualitative data can take many different tangible and intangible forms. In some modes of research, qualitative data has been taken to mean records that have a nominal or categorical scale of measurement drawing, perhaps, from a single-word answer to a question (e.g., “From what country have you most recently traveled?”) or describing, gender, occupations of residents in a neighborhood, or car brands (e.g., “what type”). These categories can then be assigned numerical values, describing, for instance, the number of: men or women; carpenters, medical practitioners, and teachers; or Fords, Toyotas, and Renauls in the neighborhood. While some

QUALITATIVE DATA

Statistical tools may be applied to such qualitative data, they are largely limited to descriptive statistics (e.g., mean, mode, standard deviation).

Numerical representations of data are used in some qualitative contexts, perhaps most notably in content analyses. For instance, in their study of The Australian newspaper’s reporting of Seattle antiglobalization protests, McFarlane and Hay (2003) included simple numerical analyses of the extent and type of reporting associated with different groups involved in the disputes (e.g., protestors, politicians). However, understanding of qualitative data as categorical information that can be enumerated offers a much narrower appreciation than is now most commonly understood.

It is much more usual for qualitative data to be regarded as including photographs, audio recordings, weblogs, policy documents, diary entries, web content, documentaries and movies, personal correspondence, observational and interview notes, or even advertising brochures. And, as these forms imply, qualitative data may be gathered or produced through a broad array of techniques, including interviews, focus groups, observation, and participatory methods (Hay 2016), or is retrieved from public and private archives.

Patton (1990) aligns qualitative data with the three dominant forms of qualitative methods. First, the data from interviews or focus groups comprises direct quotations from informants, outlining matters such as their experiences, feelings, beliefs, and interpretations. Second, data from observations includes the researchers’ thorough descriptions of observable activity. Third, data from textual sources, including quotations and other selections, comes from a diverse array of documents, including letters, diaries, organizational records, official reports, newspaper articles, or government memos and randa. These textual sources might also be expanded to include those other forms described previously, such as photographs, movies, or brochures.

Qualitative data need not be gathered first-hand. It is increasingly being made available through national and other archives, such as ADA (Australian Data Archive) Qualitative (https://www.ada.edu.au/qualitative/home), the Irish Qualitative Data Archive (http://www.iqda.ie/), the United States’ National Opinion Research Center at the University of Chicago (http://www.norc.org/Pages/default.aspx), and the UK Data Archive (http://www.data-archive.ac.uk/). These agencies typically acquire, curate, and provide a central access point for qualitative social science data produced in or about a specific jurisdiction or territory. Their collections offer access to high quality contemporary and historical information that might otherwise be unavailable to researchers for reasons such as cost, time, or physical inaccessibility. Moreover, the collections facilitate a range of work, such as comparative research and re-analysis, as well as offering useful real-world materials for research training. Some researchers are now also making available qualitative data, such as interview recordings or transcripts, through scholarly journal websites (e.g., Geographical Research) as part of those journals’ emerging dataset and code availability policies.

Trustworthiness, quality, and quantity

Whereas qualitative data is associated with a range of epistemological positions (e.g., postmodernism, poststructuralism, interpretivism), most quantitative data gathering is underpinned by positivist philosophical foundations. The hegemony of positivism and that philosophy’s long-term methodological associate, the so-called scientific method, with their conjoint

Source: Adapted from Shenton 2004, 73.

Demands that data be measurable and that data gathering be replicable, have led to common beliefs that qualitative data lies outside the scope of legitimate, “scientific evidence.” Indeed, the very trustworthiness of qualitative data is sometimes questioned by sceptics whose key positivist principles of validity and reliability cannot be tested in true-to-life work in the same ways as may be possible under closely controlled conditions. In response to the ideology of scientism, educational researcher Egon Guba (1981) proposed four guiding principles to help ensure the trustworthiness of qualitative data.
QUALITATIVE DATA

1 Credibility (compared with internal validity) – would the data/findings be recognizable to study participants and comprehensible to those outside the study?
2 Transferability (compared with external validity/generalizability) – do the data fit in other relevant contexts?
3 Dependability (compared with reliability) – have proper research practices been followed?
4 Confirmability (compared with objectivity) – are the data a reflection of the participants’ ideas and experiences rather than those of the researcher?

As the points indicate, Guba’s influential ideas parallel the four quality criteria employed by positivist researchers, but they are not intended to be obligatory mechanisms for evaluating the worth of data.

Building on other scholars’ subsequent work elaborating these four principles, Shenton (2004, 73) very helpfully sets out in summary form a range of steps that might be taken by a qualitative researcher seeking to enhance the trustworthiness of their data (Table 1).

In other related and important work making a point similar to that of Guba, Andrew Sayer (2010) proposes that the qualitative counterpart of replication is corroboration. For example, to test qualitative data a researcher might seek to verify or substantiate the opinions or experiences of one interviewee by observing the context within which they are placed, or by interviewing other people involved, or those with similar experiences. It is useful to conceive of corroboration as resembling a legal trial in which various forms of evidence and testimony are called upon to test the veracity of police, witness, or defendant claims, although the crime itself is not repeated! But while this metaphor has some use, it cannot be stretched too far as it implies a quest for a singular truth, whereas qualitative data may in fact disclose multiple, competing, and valid perspectives on reality – which may indeed be its aim.

Yet another useful and related way of assessing the quality of specific qualitative data is to examine the extent to which it helps to produce an account that would make or does make sense to the actors themselves. In some types of research, such as participatory action research, where data and other outcomes are generated with participants, this form of corroboration should be more-or-less inevitable.

As part of the process of demonstrating characteristics of credibility, transferability, dependability, and confirmability, and therefore the trustworthiness of its data, a qualitative study needs to detail its workings, outlining for audiences explanations of how and why particular settings were selected (e.g., Why were the three specific factories chosen for a study?); how and why specific research activities were undertaken (e.g., Why were focus groups employed as the primary data gathering approach?); what actions were taken to ensure the ethical conduct of the research; and how and why different analytic, synthesizing, or causal themes were selected. Moreover, contemporary qualitative research also demands reporting on the researcher’s positionality (i.e., their social or political position relative to the people with whom they are working) and the ways in which researcher(s) and participant(s) regard one another. Rather than presenting themselves as dispassionate observers, qualitative researchers increasingly acknowledge and make explicit the various subjectivities they bring to their work, describing, for example, their politics, their socioeconomic status, and their ethnicity, acknowledging the significance these subjectivities might have for their analyses and for the ways in which their narratives may be written.
This leads to another key difference in the production of qualitative and quantitative data. Most commonly, the relationship between quantitative researcher and participant is mediated by an instrument (e.g., questionnaire survey, experiment), whose fitness-for-purpose can be readily assessed. The instrument itself may also be reused to assess the reliability/validity of the data gathered. By contrast, in qualitative research, the researcher is the data-gathering instrument, conducting interviews, leading focus groups, observing behavior... The value and potency of qualitative data that is produced depends, therefore, on the researcher’s integrity, their methodological skill and critical capabilities, the nature of their relationship(s) with participants, and mutual perceptions of one another. Generating good data from an oral history, for example, calls for much more than having a friendly chat with the informant about some period of their life. Instead, it requires: a strong background in interviewing, knowing when, for example, to prod and when to stay silent; a detailed background knowledge of the informant; and a highly developed appreciation of the context about which the participant is talking.

While most quantitative studies have statistical measures that can be used for determining how many data are required to make general statements about them and the degree of certainty that can be applied to those statements, there are no such numerical indicators of, for example, sample size, that can be applied readily to qualitative data. Instead, the concept of saturation (less commonly termed “redundancy”) is employed. At its core this concept challenges the researcher to whether sufficient informant/participant experiences have been gathered for development of the conceptual framework, theory, or explanation. Are informants’ accounts and interpretations being repeated and are incidents, features, and facts being verified by different sources? If no new or relevant information is emerging and the theory or account being produced appears to be robust, saturation is understood to have been achieved.

Analysis of qualitative data

The texts, sounds, and images that constitute qualitative data may be examined either as objects of analysis themselves (e.g., interpretations of a television travel documentary or regional tourism brochures) or as proxies for experience (e.g., diary notes of pioneer women in the US West). Given that qualitative data is not as rigidly defined in quantity or form as quantitative data, it is unsurprising that its analysis is not characterized by the formal rigor and consistent structures customarily associated with the more standardized approaches of quantitative research (and which arguably yield “rigor mortis,” characterized by banal empiricism, reductionism, and the ecological fallacy). This variation is not to imply, however, that high-quality analysis of qualitative data requires any lesser degree of exactitude or expertise than is required for quantitative analyses. Qualitative data analysis runs the gamut from artistic endeavor, performed by a scholarly virtuoso, to a more structured process, suitable for establishing credibility and providing clear conceptual trails for subsequent evaluation. While the procedures of the former cannot be elaborated, making sense of qualitative data in the second sense is most commonly termed coding – a simple idea often overcomplicated. Coding refers to a range of different programmatic ways of configuring the sometimes messy raw data from interviews, observations, and texts into materials that are more coherent, comprehensible and which might better inform research.
QUALITATIVE DATA

The form(s) of coding that might be chosen depend on data, methods, and research intent. Richards and Morse (2013) usefully identify four successive forms of coding. Descriptive coding typically involves simple categorization of data by some of its key characteristics, so the data can be more easily retrieved in future. For example, a researcher might code interviews by type of informant (e.g., sex, age, occupation), interview location (e.g., workplace, home), or time/date. Topic coding involves reviewing and categorizing data by subject, taking up questions like: “What were they talking about?” “What was this document about?” This form of coding can describe accurately the content of material as well as offering new ways of making sense of the data. Metaphorically speaking, analytic coding takes the researcher above the data, searching to develop ideas, categories, and concepts that seem apparent within it. It is about evolving or germinating categories. And theme coding, which may occur at any stage of data interpretation, concerns identifying pervasive themes, compelling “stories,” or undercurrents that flow through and from the data. Coding is a foundation to analysis: it moves the researcher towards analysis through the process of creating and developing abstractions from the data (Richards and Morse 2013, 151). Coding can be completed manually or using some of the range of computer assisted/aided qualitative data analysis software (CAQDAS) now available (e.g., ATLAS.ti, MAXQDA, NVivo).

Whether performed by a wild-thinking scholarly prodigy or a more pedantic researcher sweating over a keyboard, qualitative data analysis is open-ended and largely inductive (i.e., inferring likely explanations or accounts from particular instances) or abductive (i.e., seeking the likeliest explanation for an incomplete set of observations) and, therefore, its detail cannot be described in the form of a predetermined sequence of analytical stages.

On the powers and liabilities of qualitative data: clearing up misunderstandings

In a very widely cited paper, Danish scholar Bent Flyvberg (2006) points to key misunderstandings associated with case studies, regarded here as being emblematic of much qualitative data. These five troublesome confusions and Flyberg’s correctives are summarized in Table 2. This table is intended to offer a summary indicator of both the ways in which qualitative data is frequently devalued (through the ideology of scientism) and some corrective points about how and why such data can, in fact, contribute to the development of enhanced understanding of social (geographic) worlds.

As several of Flyvberg’s correctives imply, qualitative data offers depth of understanding of sociospatial worlds, providing comprehensive and informative descriptions and explanations of processes occurring in specific contexts. They can allow events to be traced chronologically and spatially and to reveal detailed causal explanations of specific events (e.g., how and why recent government policies of austerity have moved back and forth between particular countries of the global “North” and “South”). More than this, qualitative data can spark new and revised conceptual frameworks or yield unexpected revelations. For example, in his substantial study of medical liability insurance and health-care cost containment in the United States, Hay (1992) found hitherto unnoticed causal connections between malpractice insurance and the global asbestos crises confronting insurers and their offshore reinsurers.
Table 2  Five misunderstandings of case studies and correctives.

</table>

Bazeley (2013, 5) makes clear the conspicuous revelatory and contextual power of qualitative data when discussing the significance of cases, rather than variables, as qualitative data. As clarification he points to the difference between the statements: “With their lack of education, Bill and Stephen struggled to find meaningful work;” and “Low education predicts poor employment options.” Whereas the latter statement simplifies, disembodies, and dislocates relationships between employment and education, the former simultaneously reveals actors and invites further examination of Bill and Stephen’s struggles.

Qualitative data can be used in a variety of ways to make a scholarly argument (Mason 2002). It may be employed evidentially, to help create a very carefully arranged case. It can be used interpretively or narratively, to create a convincing story or to suggest that a specific argument is reasonable. It might also be used to evocatively, illustratively, or aesthetically inform
or add color and substance (e.g., an excerpt from a focus group discussion that clarifies the reactions of a group of high-rise residents to local greenspace development). Clearly, data such as photos, quotations, or video are especially useful for this. It might also be used multivocally, so as to allow a range of perspectives to be presented or voices heard. And, of course, qualitative data can be used in several or indeed all of these ways in a single document such as a scholarly paper, report, or thesis.

Quantitative and qualitative data have, unarguably and problematically (Oakley 1998), been gendered, with the former being represented as masculine, hard, statistical, and objective while the latter has been rendered feminine, soft, nonscientific, and subjective. While this has led some feminist researchers, for example, to discount quantitative methods and their data in favor of those which admit subjective knowledge, the dichotomy and divisions it spawns are generally unhelpful and unproductive. Indeed, the power and versatility of qualitative data have been acknowledged across much of (human) geography. Despite the continuing – yet waning – dominance of positivism within the discipline, the rise and widespread influence of critical theory, poststructuralism, and the cultural turn in geography and other social sciences have all spurred use of qualitative data, which is used either exclusively or in conjunction with quantitative data. Because so much geographical research spans different scales and deals with complex human–physical relationships, multiple data sources have long been required. Indeed, Elwood (2010, 109) acknowledges that so-called “third geographers” (bridging qualitative and quantitative approaches) have been undertaking mixed method and multimethod research for decades, in acknowledgement perhaps that different data sources and data types can enable exploration of different causal relationships and illuminate different explanations of complex processes.

Just as there are significant shortcomings with quantitative data derived from positivist techniques, there are some significant issues associated with qualitative data. Notable amongst these is what has come to be termed the “crisis of representation.” This can be illuminated by a famously perplexing remark from British–Austrian philosopher Ludwig Wittgenstein (2009, 327) who wrote, “If a lion could talk, we could not understand him.” Although the meanings(s) of this inimitable quotation are contested, it can be argued that it questions the capacity (and authority) of a researcher to represent the lives of others. Researchers can never speak completely of others’ lived experiences (or even their own for that matter), nor can they portray social reality in any conclusive or ultimate ways. There cannot be any final, definitive, or conclusive account of lived experiences; instead, we must satisfy ourselves with interpretations, debates, and approximations. Full appreciation of the lives, sentiments, and experiences of others will always be beyond researchers’ grasp. Writing can only ever offer up partial accounts – even when that writing is about the researcher’s own life, as in the case of autoethnography – for every story or representation necessarily has its inclusions and exclusions. And representations of data will always be “political,” reflecting the positionality of its producer. These challenges are certainly not cause to cease the pursuit and production of data revealing experiences, understandings, and sentiments. Instead, the way forward lies in acknowledging and working with these certainties, aspiring to produce insightful accounts of sociospatial worlds that ring true to participants and shed light on hitherto obscured or concealed aspects of social lives.

To conclude, what is currently understood to be the shape and character of qualitative
data are changing and enlarging as the scope of geographical work is transformed. Challenging new work on areas such as affect, performativity, and nonrepresentational theory is emerging. As Elwood (2010, 110) points out, some of this work resists familiar and conventional acts of data collection, analysis, and communication, disrupting for example any clear separation between representation and practice. A good deal of effort will be required in coming years to determine how best to engage with these new developments and give meaning and function to the transforming expressions of qualitative data in geographical research.

Richards, Lynn, and Janice M. Morse. 2013. Qualitative Methods, 3rd edn. Los Angeles: SAGE.

Only about a decade old, the field of qualitative GIS (QGIS, or qualitative geographic information science) has rapidly grown and expanded into many disciplines outside geography. Today, it straddles the intersection of geographic information science (GISci), social science, humanities, computer science, and the geoweb. In the past two decades, methods became less hard wired to epistemologies, and the seemingly profound epistemological disconnect between GISci, on the one hand, and qualitative research, on the other, no longer appears clear and immutable. That qualitative GIS has successfully established itself as a major research direction was reflected, among other ways, in the 2009 publication of *Qualitative GIS: A Mixed Methods Approach* (Cope and Elwood 2009). Qualitative GIS has been vividly discussed in scholarly journals, books, and blogs across geography and geographic information science. Spatial turn in social sciences and humanities made qualitative GIS an actively sought methodology that combines representation of place, qualitative inquiry, and information technology. It has been used in research in sociology, history, and digital humanities, and interdisciplinary research on information technologies and society in the health sciences, environmental perception, and even environmental engineering.

As social sciences and humanities turn their attention to space, place, and mapping, the epistemological debates in geography about GIS can fruitfully inform these disciplines’ engagements with this technology. Unfortunately, these debates to a large degree remain confined to geography. Social scientists and humanities scholars, consequently, appear to be only moderately familiar with the geographic research on qualitative GIS, critical cartography, and critical GIS. They also tend to overlook rich theorizations of space and place developed by human geographers. When pursuing qualitative GIS, they often do not use the term or trace connections to these important literatures. Yet, the exciting spread of qualitative GIS creates opportunities for geographers to engage in mutually enriching conversations with other disciplines.

This entry, therefore, will not only examine the role of qualitative GIS in geography but touch upon research in other fields that the author, as a human geographer and critical GIS scholar, would identify as directly related to qualitative GIS. The entry begins by briefly reviewing the aspects of geospatial technologies that do align closely with qualitative information and qualitative research. It then discusses how geospatial technologies have been used in qualitative research and the ongoing integration of GIS with qualitative research methods. The recent but wide-ranging forays of GIS into the field of digital humanities, spatial social media, and neogeography are examined next. In conclusion, the entry reflects on the future of qualitative GIS.

### Epistemological interventions of feminist and qualitative GIS

Useful sketches of history of qualitative GIS can be found elsewhere (Cope and Elwood 2009),
QUALITATIVE GIS

so highlighted here will be those epistemological interventions that, in the author’s opinion, played a particularly important role in development of qualitative GIS in human geography and related disciplines.

Qualitative GIS stems directly from earlier interventions by feminist geographers and feminist GIS scholars. When the first feminist geographers argued that mainstream geography ignores experiences of women, they also advocated for qualitative research as necessary for addressing the nonquantifiable aspects of gendered experiences and informal social and economic relations. Once the limitations of quantitative methods were exposed, feminist geographers began to reassess their role and concluded that, if practiced reflectively within the feminist epistemology, quantitative analysis and statistics could be indispensable in the geographic research on gender, together with qualitative methods.

A decade later, feminist scholars have played an equally pivotal role in reclaiming GIS for feminist and critical geographic research. The fierce debates in the 1990s between GIS scientists and critical human geographers acknowledged the growing role of this technology in academic practice. But they also highlighted its ties to the interests of the empire, corporations, state surveillance, and militarism as well as to quantitative geography and positivism. Feminist geographers have specifically focused on the masculinist nature of GIS technology and the gender-blind research that it informed (Kwan 2002). They have not, however, rejected GIS altogether. Instead, feminist scholars have simultaneously led the efforts to reconstruct GIS as a mixed method that uses both quantitative and qualitative techniques. Neither the technology itself nor its applications are fixed, they argued; they evolve and depend upon who is using GIS and to what end (Kwan 2002; Cope and Elwood 2009).

To become a tool for feminist and critical geographies, however, GIS had to be reimagined as suitable for qualitative research. The prevailing assumption that GIS is only good for quantitative computation and modeling, therefore, had to be challenged at the epistemological level (Pavlovskaya 2009; Cope and Elwood 2009). Feminist GIS scholars pointed to the fact that we falsely associate computation with quantitative methods because computer technologies in general handle well qualitative information and tasks such as writing, graphic design, and visualization. Visualization of information in map form constitutes arguably the most important function of GIS. Maps, and digital maps in particular, have a powerful effect; they fascinate and convince the viewer regardless of whether the presented information is quantitative or not.

Moreover, the affective impact of maps provides them with ontological power to produce landscapes. Once visible, the mapped places and phenomena become real; they exist and require explanation. Being on the map, therefore, incorporates actors and phenomena into social imaginaries (this applies to both quantitative and qualitative data but social sciences have been suffering from a dearth of qualitative information because this information was not treated as scientific). Omission from the map, either intentionally or by ignorance, in contrast, leads to theoretical as well as socioeconomic and cultural marginalization (Pavlovskaya 2009). Since mainstream GIS mainly works with quantitative data sets, it fails to represent phenomena, processes, and experiences of paramount importance that are not quantified. Informal social practices, alternative economies, unpaid domestic work, barter exchanges, gift economies, emotions such as trust or fear, local and indigenous knowledge, class oppression, gender exploitation, racism, and other social relations remain invisible in our landscapes and conceptually marginalized.
Qualitative research methods offer insights into these processes. Therefore, integrating them with GIS begins to address their conceptual (and, by extension, political) marginalization.

Geospatial technologies and qualitative information

Assuming that GIS works only with quantitative computer-coded information, we have long ignored the fact that qualitative data such as text, images, and sounds are also coded for computation and, therefore, can be part of GIS analysis. Today, the production of digital spatial information is rapidly expanding (the so-called big data phenomenon) and so is its qualitative component. Some of this qualitative content is a result of conversion from nondigital sources. It includes historical and library archives, diaries and literary narratives, photographs, newspapers, and many other sources. The rest is born out of the digital age itself and incorporates webpages and blogs, geotagged social media such as tweets and Facebook posts, global positioning system-tracked movements, and digitally recorded consumer information. Numerous grassroots mapping projects also generate new digital and often qualitative data about their communities. GIS technology is increasingly capable of handling these diverse newly available qualitative data. In addition, GIS keeps converging with other digital media and this process transforms it into a multimedia visualization and analytical tool popular with digital humanities, social computing, geoinformatics, neogeography, volunteered geographic information (VGI), public participation GIS, augmented reality research, humanitarian aid, and many other projects.

In contrast to the 1990s and 2000s, desktop GIS packages no longer dominate the geospatial field. Various open source and free Internet-based mapping applications are widely available today. Many of them provide new methods and algorithms for handling large volumes of information while the producers of digital spatial information adopt formats compatible with these new analytical tools. Initially a source of information for people, the Internet is becoming a geoweb that act at once as an analytical tool and as a source of data for the new tools. GIS scholars and computer programmers focus on the algorithmic handling of these data (DeLyser and Sui 2013) but constructing meaning from these data in conjunction with social theory requires the insights and methods of qualitative GIS.

Doing qualitative research with geospatial technologies

Qualitative GIS researchers first attempted to integrate GIS into their work by mapping data from in-depth interviews. Initially, they analyzed interview data using grounded theory methods and related coding techniques and then mapped the results in a desktop GIS using the conventional cartographic symbols of different color, size, and thickness (Knigge and Cope 2006). It was vital for them to visualize the marginalized social phenomena that lacked quantitative representation (e.g., household economies or community gardens).

Local knowledge mapping projects also play exactly this role. They reveal understandings of the landscape that differ from the dominant representations created by states, experts, or corporations. Often called counter-mapping projects, they translate local spatial knowledge into claims to resources and land. In some cases, this is achieved by contrasting local ecological knowledge of resource users with professional expertise and satellite image classification. Other projects attempt to secure community access to resources...
by mapping informal land-use rights or how different groups of fishermen collectively use fishing grounds (Weiner et al. 1995; St Martin 2001).

The spreading use of GIS and other digital technologies by indigenous communities to represent indigenous knowledge and organize together gave birth to a new term, “indigital” (Palmer 2009). Digital indigenous mapping practices contribute to renegotiations of colonial legacies in many parts of the world, advancing and also posing challenges to postcolonial struggles. Here qualitative GIS can also make a lasting impact. In addition, public participation GIS (PPGIS) scholars worked to map assets of economically marginalized and minority communities in urban areas as a way to involve these communities in planning and economic decision-making. When visualized and shared as maps, their collective local knowledge has a potential to transform planning practices, together with the ways the communities perceive and value their neighborhoods (Elwood 2006; Knigge and Cope 2006). Qualitative GIS can inform such projects in terms of understanding exclusions created in the collective production of knowledge.

Feminist scholars pushed the “bounds of GIS” to map the experiences of women in a number of ways. Mei-Po Kwan’s pioneering work combined the computational power of GIS, feminist economic geography, and a new take on Hägerstrand’s time–space geography. She analyzed gender differences in access to urban opportunities by mapping daily movements of women based on information from their diaries. The resulting three-dimensional (3-D) visualizations showed that women’s daily life paths differed considerably from those of men, while differences between women by class and race also stood out (Kwan 2002). These visualizations revealed how hierarchies of gender, class, and race continue to shape women’s use of urban space.

In another project, Kwan (2008) turned to mapping emotions and feelings, another under-represented form of experience. She created a geography of fear experienced by a Muslim woman during her daily travels around the city before and after 9/11. Segments of her daily path reflect the strength of her emotion with different colors. This powerful visualization shows that the woman felt unsafe for weeks in her car and even at home after the tragic events.

This author’s work on postsocialist Moscow involved qualitative interviews with households with children in Moscow about the economic practices that helped them survive the economic devastation during the transition to capitalism in the 1990s. Each household used a combination of economic practices in which the share of informal, unpaid, and in-kind exchanges and production of goods and services has increased following privatization of urban services (Pavlovskaya 2009). The theory of transition ignored household economies because it focused on macroeconomic scale and structural transformation of the formal economy. Mapping multiple economies of households made it clear that blindness of the national policy to the scales of households and the form in which the transition was experienced by ordinary people made households bear the everyday brunt of the economic transformation.

Matthews et al. (2005) illustrate the effectiveness of using GIS in combination with ethnographic research that seeks to understand the challenges of the urban poor who struggle to maintain both family and employment responsibilities. Their large-scale ethnographic research project produced geo-ethnographies of five US cities that encouraged new policy approaches by changing the ways in which social scientists and social workers understand the experiences of poverty.

Joining ethnographic methods with GIS has proven fruitful in research on artistic
communities and creative industries. Artists are increasingly engaged in the production, and understanding the meaning, of urban space, but artistic creativity is hard to measure using formal indicators. In their research on distribution of artistic activity in the Australian city of Darwin, Brennan-Horley and Gibson (2009) interviewed artists and mapped their creative spaces (spaces in which they produce art) as well as their travel between those spaces. They found that most creative activity takes place outside the formal cultural centers (such as theaters or art galleries) and concentrates outside the formal cultural hubs. When designing policies that support creative production, local governments need to consider these geographies.

**Integrating GIS with qualitative research**

In addition to mapping the results of qualitative analysis, scholars attempt to integrate qualitative analysis with spatial visualization more directly. Knigge and Cope (2006) developed an approach called “grounded visualization” that involved close interaction between methods of grounded theory (e.g., coding) and GIS analysis. Their spatial database of community gardens in Buffalo, New York, included information derived by continued rounds of qualitative grounded theory analysis. Visualizing this information on the map, in turn, provided new ideas for such an analysis.

Further methodological innovations combined the rigor of qualitative and geospatial analysis at the level of software that allowed for conducting both types of analysis jointly. One such innovation is the so-called computer-aided qualitative GIS (CAQ-GIS) that made it possible to query and retrieve interview information and spatial locations related to a particular qualitative code or concept with greater ease (Jung and Elwood 2010). Another innovative integration involves adding select qualitative analysis functionality to a GIS. By programming qualitative analysis functions in ArcGIS software, Kwan and Ding (2008), for example, constructed the so-called geo-narratives that dynamically linked the interviewed respondents’ stories to the places about which they were told. Visualizing these connections demonstrated a high degree of spatialization of the individual narratives. Kwan and Ding’s (2008) research has also inspired others to visualize human mobilities. These developments are important because conventional GIS still offers only a limited functionality to represent movement.

These innovations nevertheless push the development of market-based and open source software to integrate qualitative research with space. Thus, qualitative analysis software now incorporates basic mapping capabilities while computer scientists within and outside the GIS field pay increasing attention to qualitative visualization. Qualitative GIS, however, can uniquely contribute to the task of explaining these visualizations using social theory.

**Humanities GIS, neogeography, and beyond**

The expansion of spatial digital qualitative information has occurred when both proprietary and open source tools for visualization and spatial analysis are becoming widely available. Some of them replicate nondigital forms of analysis while also making it faster and more expansive (for example, applying grounded theory methods to qualitative data using ATLAS.ti or a similar software package). Other digital tools, however, enable distinctly new kinds of analysis, especially for algorithmic processing of big data. They include, for example, visualization of large
qualitative data sets, knowledge mining, rhythm-analysis, dynamic and semantic analysis, and others (see DeLeyser and Sui 2013; Manovich 2016).

The emergence of digital humanities in the past two decades at the crossroads between humanistic inquiry and digital technologies, according to some authors, might represent a radical break with existing scholarly traditions because of the drastic impact of the technological and informational revolutions on knowledge production. The new field of geohumanities, or spatial humanities, focuses on the meaning of place constructed through digital literary geographies, histories, and memories, and local community participation. (The Association of the American Geographers has recently launched a new peer reviewed journal called GeoHumanities.) In contrast, social computing and geoinformatics are primarily concerned with direct visualization of the information from social media and other high-volume and dynamic data generated by contemporary publics (Manovich 2016). Finally, the ongoing decentralization and increased collective production of place-based geographic information known today as neogeography might represent another pivotal shift (Warf and Sui 2010).

The impact of geoinformatics, social computing, digital humanities, and neogeography on how we represent and understand place would be hard to grasp without the theoretical and methodological contributions of qualitative GIS and critical human geography. These remain vital to understanding the new forms of geographical knowledge because of their insights into the role of spatial (quantitative and qualitative) information in the analysis of place and space; the ontological power of mapping that transforms conceptually marginalized processes into objects of theory and practice; and their commitment to rigorous social theoretical analysis when explaining the emerging spatial patterns.

**The use of GIS in literary geography**

Understanding place using literature as a form of geographic data has been a long-standing tradition in humanistic and cultural geography. Invigorated by critical scholarship, literary geographers have brought into sharper focus the relations between social power and literary landscapes. While it has been common to analyze literary texts through narration, digital humanities and qualitative GIS began to map the spatial settings of literary narratives in order to reveal new aspects of their spatial organization and gain additional insights into their meaning.

It is important to note that the efforts to map literary landscapes originate in different theoretical perspectives. Literary geographers are likely to use advanced visualization capabilities of GIS together with social theoretical insights from humanities, geography, and critical GIS. Travis (2014), for example, combines critical literary theory with feminist and qualitative GIS in order to create sophisticated 3-D visualizations of Irish literary texts that incorporate the nonlinear and even nested literary spaces (e.g., a novel within a novel).

In contrast, humanities scholars who discovered mapping as part of their relatively new focus on space and place construct literary landscapes without using geographic theories of space, place, and time or critical cartography and GIS. They also bypass desktop GIS in favor of online mapping tools (e.g., Google or Open Streets Maps) that allow them to quickly add the needed placemarks to the base maps. The literary cartography project “Mapping St Petersburg,” for example, visualizes in this way the geography of Dostoevsky’s novel *Crime and Punishment* (Young and Levin 2013). These fascinating experimental efforts, however, could benefit from the insights of cultural geography and critical cartography and GIS.
Digital historical atlases

Digital historical atlases have become a hallmark of digital humanities projects. Highly interactive, they put online previously inaccessible information from historical archives. The website Digital Harlem (http://digitalharlem.org/), for example, aims to portray the everyday life in this famous neighborhood for the period between 1915 and 1930. The website includes information “drawn from legal records, newspapers and other archival and published sources” and allows users to search it by different events, persons, and other categories. The results are presented as maps overlaid on contemporary and historical maps of Harlem. The amount of information available through the website is astonishing; however, police records predominate because they are the most systematic source. This puts a particular slant on how everyday life in Harlem at that time is depicted. Critical cartography and feminist and qualitative GIS scholarship on the epistemological dangers of silences created by mapped data would be highly relevant here. This would stimulate more balanced data sourcing and the greater inclusion of, for example, memories, diaries, and newspaper descriptions that are harder to incorporate but would prevent the (unintentional) marginalization of the cultural heritage of this iconic neighborhood.

Neogeography and crowdsourcing geographic data

Neogeography, including VGI, public participation GIS, community mapping, and citizen science, provides new sources of highly decentralized, collectively constructed, and often qualitative geographic knowledge. Warf and Sui (2010, 201) characterize neogeography as part of the citizen science that uses the geoweb to produce and analyze geocoded data. Despite being developed only recently, neogeography, many authors agree, has profoundly changed how geographic information and knowledge are created. Neogeography projects flourished not least because the newly available geospatial tools are easy to learn and work well for basic geovisualization. This has made mapping considerably less dependent on expensive GIS software and technical expertise.

The range of neogeography projects varies from crowdsourcing data on car emissions to humanitarian emergency mapping (most famously in the aftermath of the Haiti earthquake) to deep mapping of cities (see next section), mapping noncapitalist economic practices such as the solidarity economy (www.solidarityeconomy.us/), collective urban resources (such as #MapJam by Sharing Cities Network in 60 cities worldwide http://mapjam2014-shareable.nationbuilder.com/), or activist mapping of election violations (www.kartanarusheniy.org) and wells drilled for fracking (Inman 2015), among many others.

Qualitative GIS has much to contribute to neogeography in terms of understanding the collective practices of geographic knowledge production. This research on community participatory mapping and public participation GIS commonly involves academics who mediate the interaction between communities, GIS technologies, and policymakers. Neogeography, in contrast, is often self-organized, and academics play a less prominent role. In this situation, control over spatial data and resulting knowledge is moving away from a relatively tight circle of GIS academic, government, or industry experts into the hands of nonacademic communities. The degree of decentralization is clear when comparing 1 million GIS users with the 400 million neogeographers worldwide (Warf and Sui 2010, 201). The latter form self-selected groups
with access to the Internet that generate spatial information that serves their interests. This stands in contrast to both the conventional GIS research that seeks to discover the objective truth and PPGIS that aims to generate a representative community view. Qualitative GIS scholars could offer methods for analysis of data produced by neogeography as well as insights into the politics of representation, partiality of knowledge, and political economy of neogeography.

**Deep mapping and digital urbanism**

Humanities scholars have been inspired by GIS because it allows for digital “deep mapping” (Bodenhamer, Corrigan, and Harris 2013). Deep mapping creates rich, textured, and multilayered descriptions of places using environmental, social, historical, political, economic, and cultural information from official sources such as natural history, census statistics, newspapers, and historical archives as well as less formal sources such as personal histories and memories, photographs, observation, interviews, and conversations. The goal is to articulate a collective sense of place. GIS provides a way to generate meaning of place by juxtaposing spatial layers with diverse information, and such digital deep maps can, compared to a narrative, represent place more directly. New digital media allow for creating multimedia deep maps that exist in cyberspace and also interact with the inhabitants of the place. Historical maps are layered over contemporary street networks, and census statistics are combined with memoirs of past residents while local communities articulate contemporary sense of place by posting photographs, comments, and other materials. Digital deep mapping projects could thus become collaborative modes of spatial knowledge production that develop at the intersection of artistic, scholarly, and participatory (neogeographic) representation of places.

One such “digital urbanism” project is edmontonpipelines.org at the University of Alberta. It depicts urban space in Edmonton, Canada, and seeks to build inclusive citizenship. The metaphor of pipelines supports the idea of channeling into a single website the past and present life of this oil city. Among other things, the website includes the indigenous people’s memories, although somewhat superficially, which raises questions similar to those that qualitative and PPGIS scholars have asked in their own research. In particular, why these and what other citizens of Edmonton have been underrepresented in this digital urbanism project? Qualitative GIS research has addressed problems of exclusion through mapping in many contexts, making it directly useful in digital urbanism projects.

**Spatial social media**

Social media (such as FaceBook, Twitter, and other platforms) constitute a new source of large volumes of dynamic qualitative data that social computing scholars seek to analyze algorithmically (Manovich 2016). The increasing number of posts are geotagged, which transforms them into geospatial data that can be semantically analyzed and mapped. Such maps are of great interest to the public and can potentially change how people think about the world (see, for example, www.floatingsheep.org). One popular method to analyze tweets is to generate content clouds in which the most frequently used words are plotted, for example, with larger fonts, and mapped across space. This method is attractive because it maps unmediated textual information. However, it pulls words out of context and shows the frequency of the use of a word instead of the meaning of the tweet. Thus, mapping the frequency of tweets that mention a political
candidate during the election campaign, for example, would not indicate whether people tweet in support of or against this candidate (Jung 2015). To address this problem, Jung (2015) uses a qualitative GIS method that combines grounded theory coding techniques with the semantic analysis of the spatial media content. Codes are words or expressions that show the meaning of blocks of text or tweets. Mapping the resulting “code clouds” would not conflate statements in support of or against politicians, preventing claims to popularity based simply upon how often a name is mentioned in tweets. Mapping the codes reflects spatial differentiation in political support as opposed to a mere presence in mass media.

While the processing of spatial social media information is high on the agenda in big data analytics, very often the data are parsed and visualized mechanistically without using rigorous methods for construction of meaning. Qualitative GIS methodologies, therefore, can usefully inform and work in conjunction with textual analysis of the geoweb. In addition, it is sometimes forgotten that spatial social media suffer from the old and new forms of digital divide. Critical and qualitative GIS scholarship, however, points to the fact that cyberspace is highly fragmented along the lines of class, race, and gender as well as Global North and Global South. This research adds an important dimension to analysis of social media.

**Conclusion**

The formerly dominant view of GIS as a primarily quantitative tool was owed to its origins in military applications, quantitative geographic tradition, and the computer industry. Yet, following critical GIS debates, qualitative GIS has emerged as a field that pioneered ways to map new types of data derived from qualitative interviews, historical archives, literary texts, and, more recently, social media, neogeography, and artistic visions of place. It also advanced integration of qualitative research methods with geospatial analysis in order to account for nonquantifiable, uncounted, and conceptually marginalized but important experiences and socioeconomic practices. Qualitative GIS, therefore, constructs new imaginaries of place and space that can contribute to inclusive citizenship. Advancing the fusion of critical human geography with GIS mapping would help to realize better this potential of qualitative GIS.

In less than a decade, qualitative GIS became widely used not only in geography but across social sciences and humanities. Involving GIS in mixed methods and qualitative research would not have been possible without epistemological interventions by feminist and qualitative GIS scholars. These scholars asserted the importance of qualitative data, argued for its compatibility with GIS, countered conceptual marginalization of unmapped subjects and processes, and theorized the ontological role of mapping and the necessity of participatory generation of geographic knowledge. These interventions both legitimized qualitative GIS as a field and reconfigured GIS technology in the light of feminist and critical epistemologies.

The recent but intense diversification of Internet-based and open source geospatial tools has coincided with the rapid growth of digital qualitative information. Historic archives and library collections are being converted into digital form on a massive scale, making it possible to digitally analyze them for the first time. Tweets and consumer data are increasingly geotagged. In addition, public science, neogeography, crowdsourcing, VGI, and similar projects provide self-selected groups with the means to generate new forms of geographic information. New tools for processing and visualizing the volumes of often qualitative big data appear overnight. New fields are flourishing, including...
QUALITATIVE GIS

social computing, geoinformatics, geo-/spatial humanities, digital urbanism, and indigital networks, among others, that utilize these new data and tools to present and use information in spatial form.

While the context in which qualitative information and mapping intersect today has changed, the debates within qualitative GIS about the nature of geographical knowledge and representations of space remain highly relevant and current to these new fields. The latter, however, are not always aware of qualitative GIS interventions and often use the qualitative GIS approach without naming it as such. Yet, learning about contributions of qualitative GIS would prepare scholars in social sciences and humanities for the challenges of big data and the digital age. Thus, they would be equipped to deal with space and geographic knowledge in a profound way and see their work in the context of ongoing urban, economic, cultural, and environmental struggles as well as the politics of geographic knowledge and barriers to participation in its production.

As these lines of research and social practice continue to evolve and expand, the epistemological significance of qualitative GIS stands to grow. It is well positioned to equip scholars practicing qualitative GIS with theories, critiques, and ideas that enable progressive struggles while also allowing them to generate new insights by learning from the new digital spatial contexts.

Qualitative information: representation

Stephen Burgess
Cardiff University, UK

What is qualitative information?

In order to understand qualitative information representation, it is necessary to first understand what is meant by information. While it has a common lay meaning, information is a technical term not commonly used in the qualitative geographical methods literature. However, there are some areas of geography where the term information is regularly used, and that is in the related fields of GIS (geographic information systems) and geovisualization. GIS and geovisualization have long borrowed from visualization techniques and worked alongside visualization practitioners in the sciences and computer sciences (Dykes, MacEachren, and Kraak 2005, 4–5). This relationship has been reciprocal with many of those working in visualization also interested in representing variation in parameters that have been central to much geographical analysis such as location and time. Therefore, to understand common use of the term information in geography, it is necessary to turn to the visualization literature.

Visualization is a set of practices which emerged at the intersection of the natural sciences, computer science, and graphic design and is concerned with producing and conveying meaning by visually representing complex data. Although it initially struggled to gain currency within the scientific community, several shifts from the 1960s onwards, including the increasing efficiency and proliferation of computing technology and its visual interfaces for scientific analysis, saw visualization become more embedded within scientific practice (see Unwin 2008). As data sets continue to become bigger and more complex, the uses of visualization also continue to expand.

In the overlapping literatures and practices of scientific visualization and information visualization, there is an important distinction made between data and information, where information is created by a process or processes which give meaning to data. This specific contrast between data and information made in the information visualization literature often draws on Shroff’s Continuum of Understanding (1999) which differentiates between data, information, knowledge, and wisdom. Shroff suggests that data are the product of research and the raw material of analysis which, by and of itself, lacks meaning and is not suitable for communication to an audience. Information is produced by “organizing [data] into a meaningful form, presenting them in appropriate ways, and communicating the context around them” (Shroff 1999, 272–273). It is only once researchers have begun to produce meaning, or information, that it is appropriate to communicate understandings to audiences through representational practices. Knowledge is created when information is represented to and interpreted by people (individuals, groups, institutions, etc.) based on individual or shared experiences (i.e., that which contributes to creating understandings, preferences, beliefs, etc.). Shroff argues that the design of visual representational practices should focus on...
knowledge production through the representation of information. Beyond knowledge is what Shedroff calls wisdom, where individuals move the information forward and create their own understandings.

While it should be noted that there are alternative models to that of Shedroff, his model is useful in illustrating that the representation of qualitative information is concerned with representing that which constitutes and/or emerges from the various processes which seek to bring meaning to data (i.e., the analysis and communication stages of qualitative research, and not the data acquisition stage). Because of the relationships between visualization, geovisualization, and GIS, the term information representation is more common in these areas of geographical practice. In both geovisualization and GIS there has recently been some interesting development in the representation of qualitative information as these fields have begun to consider the challenges this presents.

The “crisis of representation” and beyond

While information representation may not be a term that occurs commonly in qualitative geography, issues of representation are themselves important and need consideration in a wider context. Representation, or re-presentation, takes many forms; for example, representation is an activity that is claimed by art, literature, cinema, photography, theatrical performance, and music. To these can be added representational activity familiar to the academic, such as the writing up of ethnography or the graphing of a regression model. These are practices which all concern depiction, including the portrayal of thoughts, ideas, and observations. The proliferation of representational practice across society and culture is reflected in debates around issues of representation which occur across many disciplines including art, literature, the social sciences, humanities, and geography, and within popular culture beyond the academy. These debates, in many instances, continue to cross over with one another and representation is consequently a complex and dynamic notion.

Within qualitative geographical methods, various practices and methods are adopted to capture qualitative data, and produce and represent meaning at different stages of research including data acquisition, analysis, and communication of the findings of analysis. Methods and techniques for acquiring data have been, and still are, dominated by a suite of approaches including interviews, observation, ethnography, and analysis of documents such as diaries and policies. The data acquired by these methods are most often represented as text for the process of meaning making: for example, interview recordings are transcribed and notes written up, producing texts which are the representations of conversations that are used to create meaning. The organization of textual data to make meaning often involves the labeling, or coding, of these textual representations to identify patterns and relationships using a variety of analytical approaches including discourse analysis, conversation analysis, thematic analysis, and semiotic analysis. This may be done using one of several specialized computer software packages, sometimes known collectively as computer-assisted qualitative data analysis software or CAQDAS. The meaning that is made through analysis (which the visualization literature would refer to as information) is then also often represented as written text for communication to different audiences. Different textual formats may be used for different audiences such as academic papers for an academic audience, reports for a policy audience, and newspaper articles for a lay audience. Notably, even where non-textual data
are collected, such as photographs, video, audio, and sketch maps, they will often eventually be represented textually for analysis and/or communication of information. The dominance of textual representation of qualitative information within geography is certain, in terms of both making and communicating information.

Importantly, qualitative approaches have struggled with issues surrounding representation. In 1986, anthropologists Marcus and Fischer coined the term “crisis of representation” to describe a change in thinking that was occurring across the social sciences, including within some areas of geography. This broad change in thinking questioned whether it was possible to ever adequately describe, or represent, social reality. This aligned with epistemological positions (e.g., what might now be called interpretivism) embedded within ontological positions (e.g., what might now be called social constructionism) which conceive of a social world that is continually made, interpreted, and remade by social actors and which can only be understood through the actions and interpretations of these social actors, including academic researchers.

The universal claims and general “laws” made by positivist methods had begun to be rejected by some, who saw knowledge as specific to particular contexts such as different individuals, societies, cultures, times, and places. Interest in the complexity and diversity of understanding eventually turned attention to consideration of the positionality of the researcher in the research process and of the power relations embedded within research: researchers were no longer seen as being able to impartially represent an external reality which they observed but instead were understood as contributing to the creation of knowledge both through their co-participation in the research process and through their analysis, interpretation, and communication practices (i.e., their information representation). For example, postcolonial writing has addressed the ongoing interrelationships between issues of positionality, power relations, and representation between colonized and colonizing groups, including consideration of research practices. Often located within the emergence of postmodernism, changes in thinking also began to challenge the way Western academics thought about representational practice itself: rather than being seen as reflecting an external reality, or “truth,” that was present in the social world, representations were understood as interpretations that themselves were a part of the social world and therefore helped create that world. Often drawing on linguistics, these ideas have developed particularly within poststructural discourses. The presence of varying approaches reinforces the complexity of the term representation and how it has been operationalized by human geographers.

In geography, one response to this thinking has been greater consideration by geographers of how they undertake a key area of academic work: that of writing. The act of writing is inescapable as an academic and is geography’s dominant mode of representation for analysis, meaning making, and communication (see DeLyser 2010 for a useful overview). This entry is itself a textual representation of a collection of ideas and is part of an ongoing process of meaning making, including the author’s engagement with previous ideas and various readers’ engagement with this text. Some academics have argued for the need to write clearly and simply in order that the interpretations and understandings of research participants are not obscured by the researcher. At the same time, particularly emerging within feminist geographies, there has been an acknowledgment of the role of the researcher in making meaning by influencing the production of knowledge in many ways, including their research agendas, how they frame
research questions, the methods they implement, their presence in the research setting, their analysis of data to produce information, and the communication of the information produced. Consequently, attention has been paid to the need to write reflexively, identifying how the self might impact on the production and representation of knowledge and meaning. There has also been an increase in representing multiple viewpoints and interpretations in the production and communication of meaning through writing. Examples include the adoption of multiple authorship, collaborative writing with those who take part in research as well as with other academics, and also the exploration of multiple perspectives around an issue. Geographers are not alone in these challenges and responses, which are reflected across the social sciences and the arts, including within literary criticism and practice.

Another response across geography and the social sciences has been to try and create research methods which attempt to break down the power relations embedded within research. Participatory research, for example, has sought to try and redress the imbalances in research toward voices other than the researcher by focusing on the idea of collaboration. Trying to move away from a top-down model of research, researchers work alongside stakeholder groups addressing topics and research questions which those groups have identified as important. In facilitating the influence of local knowledges and perceptions on the research process and the production of knowledge, multiple voices, including those from beyond academia, become represented within the knowledge that is produced and communicated. Where this research is designed in order to bring about appropriate change through this collaborative effort, it is known as participatory action research. However, it should be observed that the implementation of these processes is variable, and there are questions as to exactly how democratic these methods can be and to what extent they represent other voices in order to address power imbalances within the production of knowledge.

The crisis of representation in geography has also led to the development of thinking around nonrepresentational theory, as originally proposed by Nigel Thrift (1996). A diverse body of work has developed from Thrift’s ideas which have focused on what can be thought of as the “doing” of culture and social life. Meaning, society and culture (indeed all of life) are continually made and remade through the “things” that happen every day. The word “things” is deliberately used here, being a vague word, as the happenings that create the world are myriad, including practices, processes, events, moments, movements, encounters, and interactions, including the mundane and the exceptional, including the human and the non-human (leading to more than human, or posthuman geographies), including the articulated and the unarticulated, including the cognitive and, of particular interest, the noncognitive. In this shift, representation was replaced by performance and a body of work around performative geographies emerged. Performance as both metaphor and substantive research area has developed across the social sciences. In focusing on performance, geographies have become embodied, focusing on how what individuals do, experience, and understand help create meaning, society, and culture. This has allowed a recognition of the importance of individuals and included a focus on affect defined as “properties, competencies, modalities, energies, attunements, arrangements and intensities of differing texture, temporality, velocity and spatiality, that act on bodies, are produced through bodies and transmitted by bodies” (Lorimer 2008, 552). This has led to the recognition of the importance of multisensual understandings of the world as well as the role
of emotion and the development of emotional geographies. It is important to note that within nonrepresentational geographies there is space for representational practices which have affect and can be seen as part of the doing of social and cultural life.

Nonrepresentational thinking has led to an interest in the development of methods which address how complex, multifaceted, and embodied meaning relates to the happenings of life. This includes being sensitive to affect and to multisensorial and emotional experiences of these happenings. Development of research practice includes attention to data acquisition and the production and communication of meaning. Some argue that existing, and dominant, research methods cannot adequately produce these understandings therefore new qualitative methods are necessary. Others, notably Davies and Dwyer (2007), suggest that, actually, it is hard to envisage a wholly new set of qualitative practices and that most change has been to the ways in which existing methods are conceived, conducted, and also to the claims made for the understandings and representations they produce. This latter position is the one most evidenced by the methods that can be found adopted in the empirical nonrepresentational literature. Davies and Dwyer argue that this reconceptualization embraces that there is ambiguity in researchers’ understandings of the world and that it is not possible to claim a precise representation of a world that is so textured (e.g., contingent, subjective, embodied, and often unarticulated) that there is no capacity to fully understand it. Empirical research is still worthwhile, but, intertwining with earlier and broader developments outlined above, it necessitates a reflexive approach. This includes awareness that the action of undertaking (or performing) research, from fieldwork to data representation for analysis and communication, itself contributes to creating the social and geographical contexts from which meaning is made. Reflective practices need to include a reconceptualization of the knowledges that are produced from the research process: that there are various alternative ways of knowing than have been engaged with previously (e.g., embodied, multisensory, emotional) and that knowledges are contingent. Examples of research practices include: the adoption of narrative analysis to study how meaning is created through language rather than just what people say; haptic geographies which are attuned to multisensory knowledges such as sonic geographies; and an awareness of embodied practices such as those found in the mobilities literature. Conveying these practices and the meaning that is made through them still necessarily engages with representational practice, most often in the form of written text, but this engagement aims to be reflexive.

Geovisualization and mapping: visual representation of qualitative information

Despite the broader issues of representation within qualitative geography, the notion of information representation is more often encountered within GIS and geovisualization literature than in qualitative geographical research. Geovisualization is concerned with the visual representation of geographical data to facilitate the exploration and analysis of data in order to produce and communicate geographical knowledge or information. Geovisualization is a key element of GIS in which geographic databases (which can also be analyzed statistically) are visually represented to facilitate the exploration of data and the creation of meaning or information. Primarily, the geographical emphasis within these has been on mapping and modeling spatial relationships. For this reason, fundamental to the geographic databases underlying GIS is that
features (e.g., a road) and their attribute data (e.g., speed limit of road, road name) are georeferenced or linked to a location using a co-ordinate system. For the most part, and reinforced by the adoption of practices and literatures shared with visualization as it has emerged in the natural sciences and computer sciences, information representation within geovisualization has been identified as a quantitative practice embedded in positivism. The juxtaposition of information representation with the term qualitative is suggestive of mixed-methods projects that have emerged around GIS and geovisualization since the 1990s.

The developing importance of information visualization within academia has been reflected in popular culture, with a growing interest in the use of visual representations to deliberately convey complex information. Recent years, for example, have witnessed the increasing use of infographics within the news media. A contraction of information and graphic, infographic has become a popularized English-language term for information visualizations with infographics clearly part of the visualization genealogy, drawing on practices familiar to visualization and geovisualization. A more interactive web environment, sometimes referred to as Web 2.0, has helped bring the tools of visualization to a wider audience as an increasing number of websites appear which help create various information visualizations. Tag clouds (or word clouds) are a common text visualization tool, where the most commonly used words in a piece of text are visually represented in juxtaposition to one another, with the frequency of each word being indicated by text size or font color, for example. Figure 1 shows a word cloud for this encyclopedia entry as produced using www.worldclouds.com, a free web-based application.

Visual representation for meaning making is not itself new and has arguably always been important within geography. Mapping is one of the longest-standing examples of visual representation in geography, its own origins often being tied to the origins of geography itself, with those often highlighted in Western histories of the discipline as being early geographers (e.g., Ptolemy, around the first century CE) being involved in map making. Cartography is an important example here as geovisualization is located at the intersection of cartography and scientific visualization (Unwin 2008, xii). Changes in thinking across geography have been paralleled in cartography and also in geovisualization and GIS. Postmodernist approaches and the crisis of representation helped shift the understanding of maps; no longer were they viewed as objective and accurate reflections of an external reality, but as authored interpretations and representations which are also themselves a part of the social world and which help to create the social world. For example, postcolonial discourses helped maps to be interpreted as tools of power, where the drawing and labeling of maps by colonizing powers both reflected and sustained colonial rule. These perceptions of mapping which politicize maps and draw attention to the power saturated

Figure 1 Word cloud showing frequency of words in the current entry. Source: created using www.worldclouds.com.
within cartography emerged during the 1990s and are often referred to as critical cartography. Over the first decade of the twenty-first century, further changes have happened to mapping as visual representative practice. It is argued by some that mapping has become more democratized. As the World Wide Web has become more interactive, then interactive mapping tools have also become increasingly available on the web. Anyone with an internet connection can now be a cartographer. Open-StreetMap is an example of a global mapping project where the mapping is undertaken by a community of users using various techniques. Famously, in the wake of the large earthquake which devastated areas of Haiti in 2010, there was a lack of detailed mapping of the area. Working mostly remotely, the OpenStreetMap community addressed this by creating detailed local mapping which became the main map used by organizations working on the ground in the wake of the disaster. Such collaboratively created maps bring different perspectives to bear on the cartographic process, the creation of maps as visual representations, and the geographical information they produce. Nonrepresentational theory has also influenced cartography with a rise in practice that is interested in mapping embodied, multisensory, and emotional experience. Often sitting on the juncture between art and academia, and sometimes referred to as counter cartography, these practices are further questioning how, why, and what is mapped. Examples of this include Christian Nold’s biomapping/emotion mapping project (Nold 2014), which seeks to map subjective responses to what Nold calls the “external world,” and a book of geographies of the imagination collated by Katharine Harmon (2004). Through these changes, mapping has seen a shift from being heavily embedded within positivist discourses to being seen (i) as a subjective geographical practice of visual representation which is highly influential in the interpretation and creation of meaning within the social world and (ii) as a practice that has engaged with the challenges of representing information on maps that might be called qualitative.

With geovisualization sitting on the intersection of cartography and scientific visualization, the debates in geovisualization and GIS have followed a similar path to those in cartography. In the early 1990s, a series of debates developed around the limitations and usefulness of GIS and geovisualization methods. These debates can be located within broader debates (some of which are outlined above) that were occurring across geography at the time as new approaches and schools of thought challenged the positivism of the quantitative revolution and the focus on spatial analysis that had come to prominence within geography throughout the 1960s and 1970s while those involved in spatial analysis sought to defend it. These debates within GIS and geovisualization are sometimes characterized by those involved either as resulting in an ongoing standoff between those on different sides of the debate or as resulting in collaborative work. Arguably, both of these positions still exist, but it is the collaborative projects that are pertinent to qualitative information representation. Schuurman (2000) argues that throughout the 1990s these debates moved from hostile to conciliatory with the endpoint being that “[c]ritics were drawn into the upper echelons of GIS research, and the present era of increased co-operation between critics and the GIS community was initiated” (2000, 570). One outcome of this has been the emergence of a self-reflective set of approaches that go under the name critical GIS. This has been characterized as a small, but important subset of GIS practice which seeks to transcend ontological and epistemological divisions.
One outcome of critical GIS has been the emergence, particularly in North America, of participatory GIS (PGIS) which has applied participatory methods, as discussed above, to GIS and geovisualization as representational practices. Another response to critical GIS has been termed qualitative GIS and has emerged in the literature since the mid-2000s, a threshold moment being a special edition of *Environment and Planning A* which was dedicated to qualitative GIS. Qualitative GIS is concerned with mapping the “nonmeasurable properties of place, human experience, social hierarchies, power relations, and theoretical relationships that are of concern to critical geography” (Pavlovskaya 2006, 2015). As well as conducting spatial analysis including these properties, they are also represented, through geovisualization, for the purposes of data exploration and analysis in order to make meaning from the data and produce information. This information, which includes qualitative information, is also represented through geovisualization, often in the form of mapping, for the purposes of information communication. In this way, qualitative GIS has been argued to engage with qualitative information representation with many of its practitioners describing it as a mixed-methods project. A good outline of the emergence of the qualitative GIS project is provided in the collection edited by Cope and Elwood in 2009. Since around 2010, the term qualitative GIS has appeared to decline in use. This decrease in use may be linked to an emerging argument that, actually, qualitative GIS may not be very dissimilar to the GIS and geovisualization practices that have preceded it. In digitizing data to make them suitable for a GIS databases, GIS researchers have often drawn on data that may be termed qualitative. However, an active geographical community remains engaged with this work and this is reflected in very similar practices, although sometimes under different nomenclature, in other disciplines such as the digital humanities and archaeology. Finally, it should also be noted that, given the nonrepresentational turn in geography, consideration must be given to the ways in which these practices emphasize the visual over alternative ways of knowing.

### Representing for different audiences

In making and communicating qualitative meaning, researchers often find themselves engaged with representational practice of one kind or another. Across all these practices (e.g., geovisualization, written text, audio reports, films) the format and character of the representation might be influenced by the intended audience. For the most part, academics have communicated and still do communicate their understandings to other academics via journals, seminars, and conference papers. Often, these follow certain academic conventions depending on the form of representation adopted. However, geography, like other disciplines, also seeks to engage other audiences requiring different conventions and practices. Since the mid-1970s, and influenced by the publication of books such as David Harvey’s *Social Justice and the City* (1973), there has been a self-examination within geography as to how it is relevant to and, indeed, how it can contribute to wider society. A debate around public geography continues to be concerned with these questions. These sit alongside a common observation of the absence of geographical discourse from public debate, reflected by a lack of high profile public geographers in popular culture, unlike academics from other disciplines. Understanding how knowledge and those who make geographical meaning from inside the academy can engage with knowledge and those who make (sometimes geographical) meaning in
other contexts (e.g., policymakers, news editors, and publics) has to pay attention to representational practices. The conventions of geographical academic writing are not familiar to public audiences, for example, and alternative writing styles need to be adopted in order to make geographical information clear and available to engage with. As another example, policymakers tend to have their own conventions for writing (e.g., concise points with the inclusion of executive summaries) and engagement with these will further help the chances of geographers to engage policy and policymakers with the broad spectrum of geographical information.

Qualitative spatial and temporal representation and reasoning

Alexander Klippel
Jan Oliver Wallgrün
The Pennsylvania State University, USA

Qualitative spatial and temporal representation and reasoning (QSTR) is the research area concerned with theoretical and experimental approaches to represent spatial, temporal, and spatiotemporal information, and with performing symbolic reasoning through qualitative abstractions of spatial and temporal information. Representation and reasoning apply to both spatial and temporal properties as well as relations between entities. The main distinguishing characteristic is that spatial and temporal information is abstracted into a finite and typically small number of categories, also referred to as equivalence classes. The field has roots going back to work on naive physics and commonsense reasoning in artificial intelligence (AI), on naive geography, and on topological data modeling. This entry provides an overview of the field covering the main motivations, ideas, and concepts as well as discussing current trends and developments.

There are many different approaches that address how data and information about space and time are represented in formal systems such as computers, and how humans, as the users of spatial and temporal data, engage in making sense of this data. Research on the commonsense understanding of spatial and temporal information has spurred the development of symbolic approaches, particularly qualitative formalisms, in which only a small number of distinctions is made with regard to spatial and temporal properties or relations. Qualitative formalisms are ubiquitous in areas where it is important to design interfaces between human and AI such as natural language understanding, geographic information retrieval, or human–robot interaction.

One of the first things that can be observed about commonsense representation and reasoning about space and time is that humans neither think nor represent the different types of spatial and temporal knowledge with high precision. That is, humans do not demonstrate a natural and intuitive capacity for dealing with infinitely precise information about spatial and temporal relations. In most situations, qualitative information about space and time – in the sense of a fairly small number of equivalence classes (categories) – seems to be sufficient for natural cognitive agents. The way these equivalence classes capture continuous information about space and time in a qualitative way has been referred to as qualitative metrics (Montello and Frank 1996). For example, various studies show that although humans may perceive angular information quite precisely, they conceptualize, think about, and remember it with less precision. To illustrate, imagine the directional relation between two point-like entities in geographic space. Whether humans use an absolute reference frame (cardinal direction) or a relative one to describe this relation, they always will use only a small number of equivalence classes to organize and describe this spatial information. The absolute reference frame may be reduced to north, south, east, or west, and the
relative directions may become simply left, right, in-front-of, and behind.

Inspired by this idea of qualitative metrics, AI and the spatial sciences have developed numerous approaches to formalize fundamental aspects of space and time that are considered equally important to cognitive and artificial systems. Examples are (mero-) topology, direction, and distance. The notion of a fundamental concept that reaches across disciplines is, however, generally not well defined, but it can be approached with the concept of invariance. Researchers in many fields from the cognitive to the spatial sciences have addressed the topic of invariance in the context of cognitive information processing, and used invariance to formally distinguish fundamental concepts of space and time. Worboys and Duckham (2004), for example, employed the concept of invariance as a framework for their characterization of fundamental spatial concepts. First proposed by Felix Klein for the Erlangen program (Klein 1872), geometries can be distinguished based on invariant properties under certain transformations. This approach allows for the differentiation of Euclidean geometry from set-based geometry and from topology, which can be seen as “rubber-sheet geometry” concerned with properties that remain invariant under topological transformations such as bending and stretching. Paralleling these formal approaches are perceptual and cognitive invariants, which are also found to be associated with conceptual primitives, and which have long been of interest to the cognitive science community as well as behavioral geography. The human mind, in adapting to its environment, identifies invariant characteristics of information that form the basis for cognitive processes. This idea is prominently featured in the classic work by Gibson (1979), who refers to temporally constant characteristics of environments as structural invariants. Many recent approaches feature the concept of invariance to explain, for example, perception, categorization, and cognition of spatial, temporal, and spatiotemporal information. The importance of identifying invariants of environmental information is prominently noted by Galton (2000), who speaks of our ability to intersubjectively identify invariants of space and time, which then allows a shared understanding of our physical (and social) environments to be constructed. Without the agreement that certain characteristics of spatial environments ground our meaningful understanding of spatial environments, the concept of a shared reality and our ability to communicate about this reality would not be possible. This is true for human–human communication as well as the communication of humans and artificial systems.

Many researchers have pointed to topology as the cognitively most important qualitative formal theory that also allows for a more precise interpretation of invariance. Although there are other theories that identify potentially relevant invariants for humans’ fundamental understanding of space and time, topology is unquestionably important for understanding cognition. In this brief overview a mereotopological approach is used, namely the 9-intersection model (Egenhofer and Franzosa 1991), arguably the most prominent example of a spatial calculus, to illustrate the ideas of QSTR. Other (more extensive) overviews on this area of research are listed in the “Further reading” section.

**Qualitative calculi: the example of the 9-intersection model**

Prominent in QSTR is the notion of a qualitative calculus. A qualitative calculus defines a finite set of basic relations for a particular spatial (or
temporal) aspect, such as topology (e.g., contains, disjoint, overlaps) or direction (e.g., north, south, east, west). The set of basic relations is typically defined such that for any pair of objects exactly one relation holds, meaning the basic relations are jointly exhaustive and pairwise disjoint (JEPD). Here, as an example, the 9-intersection model (9-IM) for topological relations is described (Egenhofer and Franzosa 1991), discriminating eight basic relations for two spatially extended entities: disjoint, meets, overlaps, contains, inside, covers, coveredBy, and equal (Figure 1). The 9-IM approach is largely equivalent to the region connection calculus RCC-8 by Randell, Cui, and Cohn (1992). Reasoning in a qualitative constraint calculus is performed on the power set of the basic relations. Unions of basic relations are typically written as sets. For example, the relation $A \{\text{disjoint, meets} \} B$ describes that region $A$ is either disjoint from or meets region $B$ (meets is defined as only the boundaries of the two entities overlapping). The universal relation (U) consisting of all base relations denotes that nothing is known about the relation of two objects.

Given a qualitative spatial calculus, the spatial arrangement of a set of objects (Figure 2a) can be described in terms of relations from the calculus by specifying the basic relations holding between each pair of objects. Such a qualitative description is often visualized as a directed graph called a qualitative constraint network (QCN).

**Figure 1** Eight basic relations of the 9-IM arranged in a conceptual neighborhood graph indicating how relations can change over time. Source: author.
The nodes represent the involved objects and the edges are labeled with the relations holding between the objects (Figure 2b). In such a case, the constraining relations in the network are labeled with a single base relation from the calculus selected to represent the scene formally (here 9-IM). Such a qualitative representation, that is, a scene for which all relations are known, is referred to as a scenario.

However, in QSTR qualitative descriptions that are incomplete or imprecise are often dealt with. For instance, the information extracted from observations may provide information about which basic relations hold between certain objects but not between others. Or it may only be known that the relation must be one (out of several possible) from the set of basic relations corresponding to a disjunction as introduced above (e.g., A {disjoint, meets} B). Figure 2c shows a constraint network that corresponds to such a situation: the edge between the spatially extended entities D and C is labeled with the disjunction of the four basic relations {disjoint, meets, overlaps, contains} because it is assumed that nothing more precise is known about the relation between these two objects. Similarly, entities A and C do not have a connecting edge, which should be interpreted such that the constraining relation is the universal relation U, meaning nothing is known about the entities’ spatial relationship.

Given a QCN that is not a scenario, that is, not all qualitative relations between entities are known precisely, one may be interested in inferring as much information as possible from the given relations. The composition operation, an important relation-algebraic operation that needs to be defined for a qualitative calculus (typically in form of a table), specifies the relation between entities X and Z as implied by the given relations between X and Y and between Y and Z. For instance, in the example shown in Figure 2c, given the relations {A disjoint B} and {B contains C}, it can be inferred that the relation between A and C must be disjoint. One challenge is that not all compositions yield a single basic relation that can hold between X and Z as the result. More often, the result is a disjunction of several basic relations or even of all basic relations, so the universal relation U. In the example here (Figure 2c), the composition of relations {D overlaps B} and {B
contains C\} implies that D can be in any of the following relations with C: disjoint, meets, overlaps, contains, or covers. This excludes only the equal relation from the disjunction in Figure 2c.

As this simple example shows, applying the composition operation to a triple of nodes in a QCN may allow the inference of new information not part of the originally observed information. The resulting network is a refinement of the original network in which some basic relations have been removed from the disjunctions. The result of applying the composition operation to infer as much as possible from the given information in the QCN from Figure 2c is shown in Figure 2d as a refined network.

Another important problem, the one most closely studied in theoretical QSTR research, is the consistency checking problem, also termed the satisfiability problem. A QCN is consistent/satisfiable if it has at least one solution. A solution is an assignment of concrete objects from the involved spatial domain to each object variable (node) in the QCN, such that all the relations in the QCN are satisfied. One method to check for consistency is the algebraic-closure algorithm based on the previously introduced composition operation. For most calculi, the algebraic-closure algorithm has to be integrated into a backtracking search procedure that considers different refinements of the original QCN. The algebraic-closure operation performs the composition operation as indicated until no further basic relations can be removed from the disjunctions. The result can be (i) an empty constraint, which means that the network is inconsistent and no solution exists; (ii) a scenario, meaning it was possible to derive complete information from the originally incomplete network; or (iii) a network that still contains disjunctions as in Figure 2d. The algebraic-closure algorithm has a time complexity of $O(n^3)$, where $n$ is the number of involved objects.

### Conceptual neighborhood

Qualitative spatial and temporal reasoning is also concerned with how spatial configurations described on a qualitative relational level may change over time. The notion of conceptual neighborhood has been introduced by Freksa (1991) to capture how the relation between two objects can continuously change over time in terms of relations from a given qualitative calculus. Two relations from a qualitative calculus are said to be conceptual neighbors if they can be continuously transformed into each other without resulting in a third relation in between. For instance, for two polygons A and B in the plane which can continuously move through 2-D space, the relation between them can change from \{A disjoint B\} to \{A meets B\} without any other 9-IM relations holding in between. Therefore, disjoint and meets are conceptual neighbors. In contrast, disjoint and overlaps are not conceptual neighbors because the transition has to go through meets to get from \{A disjoint B\} to \{A overlaps B\}. Figure 1 visualizes the conceptual neighbor relation between 9-IM relations by arranging them into a so-called conceptual neighborhood graph: relations connected by an edge are conceptual neighbors, while the others are not. Conceptual neighborhood depends on which transformations (move, change size, or change shape) the involved objects can perform. Conceptual neighborhood and the conceptual neighborhood graph have been generalized to configurations of more than two objects. Reasoning based on conceptual neighborhood allows for simulation, planning, and explanatory analysis with qualitative relations for both space and time.
Cognitive evaluations of qualitative calculi

QSTR formalisms are inspired by an interest in how humans intuitively make sense of their spatial and temporal environments, that is, their commonsense understanding of spatial and temporal relations between and properties of entities in their environments. Two goals are achieved by relating natural cognitive and formal artificial approaches to space and time. First, cognitive processes can be understood in great depth and detail if it is possible to formally ground hypotheses on, for example, how many spatial relations humans naturally distinguish between spatially extended entities. Second, the ubiquity of computational/formal systems has fostered the desire to make information systems intuitive for seamless integration into humans’ personal and professional lives. While experimental work on evaluating qualitative calculi in behavioral studies has started to catch up with the developments in calculus design, there remain many open questions and challenges in understanding human conceptualizations of spatial relations in relation to formal QSTR approaches. The goal of behavioral evaluation is to confirm, reject, or refine qualitative calculi, and improve their performance from a cognitive and computational perspective in different application areas such as interface design for geographic information retrieval. Important questions in this regard are: What are intuitive levels of granularity for different fundamental concepts such as topology, direction, or distance? How do humans assess the similarity of individual spatial and temporal relations or spatial arrangements? How do natural language expressions relate to QSTR formalisms? How are other forms of human communication and reasoning such as sketch maps captured using qualitative formalisms? Some of the main results of cognitively evaluating QSTR can be summarized as follows: the majority of QSTR calculi makes finer distinctions than natural cognitive agents, for example, humans almost always aggregate relations of containment (see the relations contains and covers shown in Figure 1); and while topological relations are fundamental to how humans understand space, the semantic context (the identity of the entities in question), will change which relations are aggregated. In other words, which relations are considered more similar to each other than others is dependent on what a particular relation means in a particular context. For further illustration see Figure 1: the relation meets can have neutral (two buildings are side by side), negative (an oil pest reaches the shore), or positive (a castaway reaches an island) meanings, which will change its salience for a natural cognitive system. Depending on the context, the order of importance of relations and properties can change. While a hurricane making landfall is an important spatial relation, it may be even more important depending on whether the hurricane is severe (e.g., category 5) or not (e.g., category 2).

Recent trends and developments

Although the field of QSTR is more than three decades old, new calculi are still being proposed, and their theoretical properties investigated. A recent trend has been the development of multigranular formalisms whose resolution can be adapted to the task at hand. Examples of such formalisms are the STAR calculus, a calculus for absolute directions, and the OPRA model for relative directions. Another ongoing research effort is the combination of several spatial aspects (e.g., topology and direction, or direction and distance) in a single reasoning approach.
Important novel theoretical results have also been achieved relatively recently, for instance, the finding that reasoning with relative direction information that distinguishes left and right is computationally intractable. Results like this have spurred new research on reasoning procedures that are tractable but only approximate the sound and complete reasoning methods as well as possible.

Researchers have also started to look at reasoning problems beyond the deduction of new information and consistency checking in different domains. Applications in different domains have resulted in an increased interest in reasoning approaches based on conceptual neighborhood in the areas of spatial planning, explanatory analysis, and data integration. Moreover, the problems of deriving the most compact qualitative spatial description equivalent to a given QCN, and of deriving a geometric representation that corresponds to or exemplifies a given QCN, have recently attracted the attention of the QSTR community.

These developments have been accompanied by the emergence of freely available QSTR software tools. Specialized reasoners, such as GQR, and general-purpose toolboxes, such as QAT and SparQ, relieve application developers from having to implement models and reasoning techniques described in the literature, and in doing so promote the dissemination of QSTR methods into future spatial information and assistance systems.

Further reading

Geography, at least from the perspective of quantitative geographers, can be defined as the study of spatial processes – the processes that generate both the human and the physical environments we experience on the surface of the Earth. Geographers observe these environments and try to understand how they have arisen – that is, they try to answer the question: “What are the processes that produce the things we observe in the world?” For instance, we try to find answers to such questions as the following.

1. How do land values decline as distance from the city center increases?
2. What causes sea temperatures to vary spatially and temporally?
3. How and why do systems of cities evolve?
4. Why do the locations of people with multiple sclerosis often exhibit a very strong geographical pattern?
5. What are the factors that lead to various movement patterns such as commuting, migration, or shopping?
6. Why do social inequalities exhibit strong geographical patterns?
7. What are the factors producing the particular spatial distribution of an animal or plant species?

The list of such questions is endless and points to both the importance and the prevalence of quantitative geography. However, all these questions have the same underlying basis for being answered – we want to understand the processes that led to the geographical pattern we observe on the earth’s surface. Quantitative methodologies in geography supply this understanding by attempting to provide a linkage between form and process through either empirical analysis or mathematical theoretical reasoning. This type of approach has been a major component of geographical studies since the 1960s and it encompasses an extremely broad variety of applications covering every substantive part of the discipline. Quantitative methodologies include statistical methods, mathematical models, visualization, and computation and, although they have been a part of mainstream geography for over 50 years, they also form the major component of relatively modern terms such as “geographic information science,” “geocomputation,” and “geoinformatics.”

The different ways form and process can be linked have led to the evolution of different types of quantitative geography, so there is no “one” quantitative methodology within geography, and the variety of approaches taken is touched upon below. However, before this discussion, it is useful to consider the common features of spatial data that link the different forms of quantitative methodologies practiced.

What makes quantitative geography special

Quantitative geography proceeds from a description of the human and physical environments. This description typically generates spatial data which can be analyzed in various ways, with the
QUANTITATIVE METHODOLOGIES

objective being to improve our understanding of how these data arose. Spatial data contain attribute information, such as the presence or absence of a disease, the level of a pollutant, or the rate of household burglary in a neighborhood, and locational information about where this measurement is recorded. The locational information, usually in the form of coordinates, is key to analyzing the data through a distinct set of quantitative geographical methodologies because spatial data contain three properties that make them unique: spatial dependency, spatial heterogeneity, and spatial scale.

The data we observe about the real world are rarely, if ever, randomly distributed over space, and spatial dependency refers to the general observation that data recorded for nearby locations are often more similar than are data recorded for locations farther apart (Tobler’s First Law of Geography). One impact of this is that we need to be careful about any inferential tests we employ that rely on an assumption of randomly distributed data, such as parameter estimates obtained from a regression of spatial data. A wealth of literature has been generated on this topic (inter alia, Anselin 1998; Cliff and Ord 1981).

Another impact of spatial dependency is that we can use the property that nearby data values are likely to be more similar than those from locations farther apart, ceteris paribus, to estimate values of a continuous variable at locations for which no measurements are available. For instance, suppose we have a set of air quality monitors at fixed locations throughout a city and we want to estimate a continuous surface of values from these finite measurements. Because of spatial dependency in the data, we can estimate the values of air quality at any location from the values observed at nearby locations. If we have some means of measuring the degree of spatial dependency in the observations, we can weight the data from nearby locations according to their distance from the location at which an estimated value is required. A large literature of techniques for what is known as “spatial interpolation” exists and although there are many different types of interpolation measures, such as inverse distance weighting and kriging, they all rely on the property of spatial dependence for their applicability (Lam 1983).

Spatial heterogeneity exists when the processes generating our observations of the real world vary over space. Traditionally, it was assumed that these processes were constant over space so that a “one model fits all” mentality prevailed. For instance, suppose we were interested in the determination of house prices across a major city and related the variable “house price” to a set of attributes describing the property and its surroundings in a classic multiple regression framework. This would yield one parameter estimate for each relationship in the model so that it would be implicitly assumed that each of these relationships is constant throughout the urban area. However, it is quite reasonable to think that what determines house prices in one part of the city might not be the same as what determines house prices in other parts of the city. For instance, the presence of a swimming pool or a garage might have a differential effect on the price of a house, ceteris paribus, depending on whether the house were in the city center or the suburbs. Similarly, suppose we were investigating the sales of surfing equipment in different cities across the USA – we would not really expect that increasing the advertising budget by a fixed amount, ceteris paribus, would have the same effect on sales in Honolulu as in Iowa City. These are examples of where the processes generating the data we observe in the real world might vary over space. A substantial literature has arisen in the past decade on what are referred to as “local models” – that is, models which recognize that processes might be spatially
heterogeneous (Fotheringham, Charlton, and Brunsdon 1996; Fotheringham, Brunsdon, and Charlton 2002; Lloyd 2007). Such models produce a whole new geographical world – that of relationships – as a complement to our usual focus on geographical variations in data.

“Spatial scale” is a term used to capture two properties of spatial data. One is that the processes that produce what we perceive as the human and physical environments might operate at different spatial scales. For instance, in the study of soil moisture content, we know that there are some processes, such as rainfall and temperature, that operate at a regional scale (albeit with minor variations) and others, such as shade, slope, and aspect, that operate at a much more local scale. Similarly, there are macro-level processes, such as regional economic performance, that affect house prices as well as micro-level processes, such as how well the property is maintained, whether it is near a major highway, and so on.

The other effect of scale relates to the units for which spatial data are collected and analyzed. One of the challenging issues in quantitative human geography is that, for confidential reasons, data relating to individuals are typically only released in aggregate form for some set of arbitrary administrative units such as census divisions or political units. However, it has been shown repeatedly and in different contexts that the inferences we draw from the analysis of spatial data can be dependent on the spatial scale at which the data are analysed – a problem often referred to as the modifiable areal unit problem and well documented for bivariate relationships (Openshaw and Taylor 1979), multivariate relationships (Fotheringham and Wong 1991), and mathematical models (Fotheringham, Densham, and Curtis 1995). Consequently, we may draw different conclusions about the nature of the relationships being investigated, depending on the set of aggregate spatial units for which the data are reported. An unseen, but equally worrying, problem is that the results of our analysis might vary over space if the spatial data units we are using are not generated in the same way. A classic case of this is the use of county-level data in the United States – the process by which counties are defined varies by state and the physical sizes and the populations of counties vary enormously across the country.

A brief history

Initially, quantitative methodologies were introduced into geography with little if any recognition of the subtleties inherent in spatial data described above. Prior to the 1960s, geographical studies were almost exclusively descriptive, but mathematical and statistical techniques became increasingly employed for the study of spatial patterns in what is often referred to as “the quantitative revolution.” Such techniques were often imported into geography from other less spatial disciplines, such as statistics, physics, and economics, and although this was a necessary and important initial step in the development of quantitative methods within geography, with hindsight the techniques used were sometimes naïve and lacked a real understanding of explicitly spatial processes. Mathematical models were often geometric and normative, and empirical analyses were often devoid of real spatial awareness. Unfortunately, critiques of quantitative geography often still focus on this era and are repeated by individuals who fail to grasp that the discipline has moved on considerably to address specifically spatial properties and processes. An enormous amount of progress has been made and, today, quantitative geography has matured to the stage where it is a net exporter of ideas and techniques to other disciplines in which researchers recognize that a
large number of processes and datasets in their areas of study are spatial.

Although there are literally hundreds and perhaps thousands of techniques that are incorporated under the umbrella of quantitative methodologies in geography, they can be categorized into two broad groups: mathematical models and statistical techniques. The former emphasize statements about how the world works and include spatial interaction models, optimization models, and differential equation-based models of climate change. The latter emphasize either the description of spatial patterns, such as spatial autocorrelation statistics, or the identification of relationships between variables exemplified by regression models and various other types of multivariate models, such as factor analysis, discriminant analysis, and so on. The distinction becomes blurred, though, in situations such as spatial interaction modeling, where the models are developed from mathematical principles but are then calibrated by statistical processes such as regression and maximum-likelihood estimation.

It is probably reasonable to state that quantitative human geographers have been more concerned with statistical approaches than their physical geography colleagues because of the inherent uncertainty in human spatial behavior. It is both a weakness and a strength of human geography that it is extremely difficult, and perhaps impossible, to develop any statements akin to scientific “laws” because of the great difficulty in understanding and predicting human behavior. However, there are certainly regularities in human spatial behavior that are useful to identify and quantify, an obvious one being that our propensity to interact with a location decreases as the distance to that location increases, *ceteris paribus*. This concept, known as “distance-decay,” is extremely powerful in explaining patterns of movement such as migration, retailing, and commuting, and even patterns of communications where the friction of distance is in theory virtually nonexistent, such as telephone calls, texts, and tweets. However, there are many other factors which also can play a role in determining patterns of movements and communications, so that spatial interaction models are never without error and therefore always contain a stochastic component representing the myriad of unknown or unmeasurable processes that affect our decision to interact with a specific location or person.

The presence of uncertainty does not mean, however, that modeling exercises in geography are doomed to failure and should be abandoned, as some would have it. Modeling human spatial behavior generates very convincing and powerful evidence on the major processes affecting the outcomes we observe whilst recognizing that some uncertainty exists. The power of statistical modeling is that we can quantify this uncertainty and thereby have standards to assess the probability that our inferences about the determinants of human spatial behavior are wrong. In this way, we accumulate evidence to make a compelling case for a relationship. This ability to quantitatively assess the quality of our results and inferences is an extremely powerful reason for the use of quantitative approaches in geography. The element of uncertainty has also acted as a catalyst to the development of new techniques in order both to incorporate it and to minimize it, so that the subject matter of human geography is now one of the most fruitful areas of research in academe, as evidenced for example by the number of nongeographers “discovering” geography (inter alia, Noulas *et al.* 2012; Simini *et al.* 2012).

One final comment on the use of quantitative methodologies by both human and physical geographers is that they act as a means of communication between two potentially diverse groups. In an era when geography has become
QUANTITATIVE METHODOLOGIES

increasingly fragmented and broad, encompassing both humanistic and scientific approaches, it is increasingly important that the constituent components of the discipline have a means of communicating with each other – quantitative methodologies provide this bridge between human and physical geography.

Recent trends

From the early days of geography’s “quantitative turn” in the 1960s, the application of mathematical and statistical modeling to the study of spatial processes has seen a blossoming of approaches as our understanding becomes ever more sophisticated. Five trends in particular are worth commenting upon. These are: (i) the role of geographical information systems or science (GIS); (ii) advances in computing power; (iii) the focus on the local; (iv) the arrival of the “big data” era; and (v) the adoption of visualization as a means of conveying information.

Although it began a decade or so after the so-called quantitative revolution in geography, the development of GIS has roughly paralleled that of quantitative geography. The positive effect GIS has had on the external perception of geography cannot be overstated. Although GIS (particularly geographical information science rather than systems) is for some people synonymous with quantitative geography, the two areas were initially quite distinct, and significant differences remain. GIS arose from the cartographic tradition, and initial developments largely involved computer-based mapping software that allowed different types of spatial data to be linked, queried, and displayed. Statistical and mathematical analysis was almost nonexistent. Even today, when most GIS contain a sophisticated array of quantitative techniques, including many commonly used statistical techniques plus specialized routines for interpolation, optimization, and network and surface analysis, there are many GIS professionals who would not claim to be quantitative and many quantitative geographers who would not claim to be GIS experts. However, GIS has had a profound effect on quantitative geography in that the demand for quantitative geographical techniques has soared as GIS has become virtually ubiquitous. GIS exposed people to the power of spatial data through visualization and simple types of analysis, such as buffering, overlay, and point-in-polygon operations, and as users have become more sophisticated, their needs for spatial data analysis have grown. This has created new markets for quantitative geographical techniques that have been bundled into newer versions of GIS software (an example being that of geographical weighted regression (GWR), which first appeared in ArcGIS 10) and also for stand-alone spatial analysis software such as GeoDa and PySAL (Python Spatial Analysis Library) (Anselin and Rey 2014).

A second trend affecting quantitative methods in geography has been the rise in computing power over the past 30 years. This has had two obvious consequences. One is that statistical inference no longer relies on theoretical distributions being available because brute force simulations can be used to generate empirical distributions for any statistic. This has been particularly beneficial to the application of new types of spatial statistics where theoretical distributions are not always available or are extremely cumbersome to work with. The other is that quantitative geomorphers have been able to develop and calibrate increasingly complex models (see below). Forty years ago it was relatively easy to produce spatial models which were essentially inoperable because of a lack of computer power and/or data. Today neither of these constraints is an issue: the only limitation
QUANTITATIVE METHODOLOGIES

to the development of improved spatial models and spatial statistics is our ability to devise them.

Aided by the advances in computational power, a powerful trend in quantitative geography over the past 20 years has been the development of local statistical techniques and models. Previously, an unquestioned, and probably unrealized, assumption of most quantitative research was that the processes being examined were stationary over space. That is, a “one size fits all” mentality predominated in which a single parameter estimate or a single descriptive statistic such as a measure of spatial autocorrelation was assumed to be constant over space and hence representative of every location. Initially, through spatial interaction modeling, with the development of origin- and destination-specific models, it came to be realized that processes might be spatially heterogeneous and hence new model forms were needed which allowed this variation to be captured. Ultimately, this has led to the development of local spatial modeling techniques such as GWR and local descriptive statistics such as local indicators of spatial association (LISA) (Fotheringham, Brunsdon, and Charlton 2002; Anselin 1995). These techniques, pioneered by geographers, are now commonplace in many other disciplines. They provide potentially enormous amounts of information on spatial process and a whole new geography to investigate – that of relationships rather than data.

Allied to developments in local modeling, which can be termed “big models” because of their complexity, have been advances in data collection technologies and data dissemination resulting in what are known as “big data” (Goodchild 2013). Many big datasets contain geocoded data from new technologies such as LiDAR (Light Detection and Ranging), global navigation satellite systems, and satellite imagery or from new forms of social media such as Twitter and from a recent phenomenon whereby individuals want to make their locations known to others, such as FourSquare check-ins and geocoded photograph repositories. Consequently, we are now in an era when data availability is no longer the bottleneck it once was; rather, the new bottleneck is our ability to provide useful information on spatial processes from these big data. Currently, big datasets in geography are of the order of terabytes and petabytes but, with GPS chips becoming virtually ubiquitous, datasets of these magnitudes will seem relatively small within the next 10 years. The need to distinguish the signal from the noise in these large, multivariate datasets will be even greater and the process even more difficult than it is today.

Big data and big models both provide similar challenges in trying to make sense of often very noisy data. In the former, the data are observations of the real world; in the latter they are model outputs, usually in the form of thousands of parameter estimates. The need to provide useful insights into such large arrays of data has led to an increased use of visualization as an aid to understanding. The challenge to present large, multivariate datasets in a visual form that can provide insights in combination with the human brain has spawned the new field of visual analytics (Dill et al. 2012). A large set of techniques has been developed, and continues to be developed, in order to convert dry tables of data into appealing visual displays which the brain can process much more easily. Often these techniques rely on quantitative methods linked to some form of mapping and this has proven to be a fruitful avenue of research for geographers who can think both visually and quantitatively.

The above trends – the rise of GIS, the development of massive computing power, the stressing of the local over the global, the advent of big data, and the increased role of visualization – have all combined to make quantitative geography more visible but also more data-driven.
and less theoretical. The relative ease by which empirical analyses can now be conducted has pushed theory into the background; we need a steady flow of innovative ideas to maintain our leadership in spatial data analysis and modeling.

Challenges

To conclude this brief overview of quantitative methodologies, it is useful to consider what challenges lie ahead. Three generic issues, all interrelated, can be identified: (i) model choice (or variable selection); (ii) inference; and (iii) robustness.

The problem of model choice or variable selection is common to many disciplines, ever more so with the increasing availability of highly multivariate datasets. Faced with large numbers of potential explanatory variables and very little theory to guide us, the question arises as to how we select the appropriate combination of variables to help us understand the spatial distribution of a particular attribute. If we include too many overlapping variables in our model, we incur the problems of multicollinearity – confusion of parameter estimates and inflated standard errors. If we leave out relevant variables, we incur the omitted variable problem – biased parameter estimates. Of course, there are some standard statistical procedures that provide guidance on model selection, such as various stepwise regression procedures, but they are not always helpful, and the question remains how such techniques are to be applied to local models. In the presence of spatial heterogeneity there could be different optimal models for each location, and global diagnostics would therefore not be very helpful.

One answer is to develop better theory, but in many instances, theory is of little use. Suppose, for example, we are interested in understanding why migrants chose certain destinations over others and we have a model that relates destination choice to attributes of the destinations and the individuals making the choice. Suppose we think one variable that might influence destination choice is a measure of house prices at the destination. We could argue theoretically that the expected direction of this relationship is negative: higher house prices make a destination less attractive, ceteris paribus, due to fewer houses being available in one’s price range or one’s disposable income being reduced due to higher housing costs. On the other hand, we could argue theoretically that areas with high house prices tend to have higher rates of return on housing over time and therefore represent a wise financial investment making a destination more attractive, ceteris paribus. It is extremely difficult to separate these effects, and the empirical result globally might be that the variable appears to be unimportant to the decision. Local models might shed some light on this issue – if the pattern of local parameter estimates is positive in some areas and negative in others, this may give us a better indication of the effects of house prices on the migration decision.

Linked to the above is the issue of statistical inference. In an era when complex local models can be calibrated with huge datasets containing hundreds of potential explanatory variables, we now have the ability to estimate unprecedented numbers of parameters. In theory, this ability should lead to ever-greater insights into spatial processes. However, it also brings greater problems of separating “real” positives from “false” ones. Issues such as the multiple hypothesis testing problem (Williams, Jones, and Tukey 1999) become more important as we add more variables to our models and test the same hypothesis with repeated samples. There is a growing need, therefore, to examine statistical inference more carefully to reduce the chances
of being misled by noise in the data. As datasets become larger and as our models become more complex, it becomes more difficult to identify what is really meaningful.

The issue of robustness has long plagued quantitative geography. The empirical results of our models cannot generally be replicated when applied to a different area. There are countless examples of the same, or similar, models being calibrated with different datasets and yielding different results. In some applications a parameter might be significant, while in others it is not; it might be significantly positive in some cases, yet significantly negative in others. We now have a potential explanation for this in terms of spatial heterogeneity. If we accept that processes might vary over space, it follows that parameter estimates, which measure these processes, should also exhibit variation in excess of that we would expect from random sampling. However, we are still left with the problem that few of our models seem to be robust enough to be applied to situations other than that in which they are calibrated, and therefore lack accuracy in terms of prediction.

Final thought

The above issues should be viewed as challenges and not just as problems. They are what make the area an exciting one in which to work. There is no doubt that quantitative methodologies have much to offer because they can provide strong evidence for how various spatial processes shape both the human and the physical environments. Mathematical and statistical models of spatial processes are useful – nobody claims they are perfect. To criticize them for not being perfect is to misunderstand the application of quantitative methodologies. We are at an unprecedented era in terms of the demand for individuals with skills to analyze spatial data. Geographers with quantitative skills are leading the way in this area whether they are labeled quantitative geographers, data scientists, geoinformaticists, geocomputationalists, or GI scientists. Investment in spatial data capture and analysis has never been higher; society is increasingly not just data-driven but spatial-data-driven; countries around the world are developing centers for spatial data analysis; and demand for such skills in the private sector is booming. The future for quantitative methods in geographical enquiry is very bright.

Further reading

Today, “quantitative geomorphology” could be considered redundant, as geomorphology is fundamentally based on quantifications. In fact, quantitative geomorphology refers to a specific way of exploring geomorphological questions and takes its roots in the early debates between qualitative and quantitative approaches. When reviewing the use of the term “quantitative geomorphology” in the scientific literature, it predominantly appears during two periods: the 1950–1960s and the 2000s.

The first period includes pioneer researchers such as Horton, Strahler, Morisawa, or Chorley, who first published contributions entitled “quantitative geomorphology…” or “quantitative analysis…,” and argued the need to think about processes and explain how forms are related to processes.

The pioneer quantitativists defended the need to move from “qualitative” to “quantitative” geomorphology to study the spatial organization of forms (stream ordering, stream network, and basin characters) as related to driving factors (mainly hydraulics), by developing process-based and systemic approaches to understanding landscape complexity; these are the theoretical framework for the discipline today (Church 2013). This period is seen as the “golden age,” wherein emerged the concepts of “dynamic geomorphology” and “functional geomorphology.” These concepts developed fairly independently of historical geomorphology, which, in turn, gave birth to paleoenvironmental studies and geoarcheology.

A second quantitative revolution occurred in the 2000s with the emergence of new geographic data and expanding computer capacities accessible to scientific teams around the world. Nearly five decades after the pioneers of geomorphology, these new contributions consistently refer to “quantitative geomorphology,” such as in a special issue published in Géomorphologie in 2011, entitled “quantitative hydrogeomorphology” that described the emergence of a new scientific era, similarly argued by Marcus and Fonstad (2010) in “Remote Sensing of Rivers, The Emergence of a Subdiscipline in the River Sciences.”

Qualitative information (mainly visual observation) is biased by the perception and acuity of the observer, his/her experiences, memories, beliefs, and/or attachment to a given theory, as discussed in the case of the Davisian theory of cycles of erosion (Rhoads and Thorn 1996). Qualitative information that supports shared truth is limited to observable facts, even though a large set of them is not visible or is difficult to observe. The qualitative approach is also limited to those processes that are notably changing, many of which are not observable without measurements over time. Quantification is necessary to simulate processes in order to understand and generalize cause and effects based on order of magnitude and changes in volume or mass (e.g., sediment budgeting, appropriate timescale estimates). A qualitative approach is often linked to an inductive approach, so that the observer lets the field speak without formulating any preliminary hypothesis (Rhoads and Thorn
1996). Even if a qualitative approach guided by a critical attitude, multiple-hypotheses, and deductive reasoning reached a truth shared by a large set of people, it would still be limited by a lack of precision and set of facts. Convergence of evidence is also a critical issue to give truth to interpretation. In this domain, quantification is useful as it can provide a wider set of solutions and make interpretations more robust.

Quantification is based on data collected by instruments. Quantitative geomorphology supports the idea that objectivity should be reinforced by quantification, reliable and precise data, and shared procedures to avoid any bias. It is a way to gather more precise information that can be shared by observers. Such factual information can then be interpreted to reformulate questions so as to design a new research strategy to gather additional facts. It allows one to distinguish and interpret facts and introduces a strong experimental framework: the so-called deductive approach of hypothesis validation.

If quantification can be done in different ways, two complementary strategies are often observed, with sometimes disciplinary debates to consider which one is the most valuable, one focusing on physical laws and the other exploring the Earth complexity using mainly statistics. Physics, mainly mechanics, aims to understand the elementary laws controlling the evolution of processes and forms, is mainly grain-based, and is supported by in situ and ex situ experiments, numerical models, and simulations. It simplifies the real world to understand step by step how it works. Earth complexity analysis is usually more holistic, approaching Earth organization and functioning by ordering, classifying, and understanding factors by discriminating temporal states and spatial units. For this type of analysis, statistics has become important, similarly to other integrative sciences such as ecology, to explore complex systems.

Geomorphology now fundamentally relies on quantification to answer different questions, to characterize the magnitude and frequency of events and critical geomorphic phenomena (i.e., sediment transport, landslide), and to assess the evolution and organization of forms and their connections. Quantification is founded in physics. It is made possible by technological advances in optics, mechanics, electronics, or geoinformatics, including geocomputing, statistics, mathematical morphology, geometry, modeling, remote sensing techniques, and geographic information systems (GIS). It deals with dating, geopositioning, and imaging the Earth surface and the water column using a set of innovative techniques such as optical stimulated luminescence (OSL), isotopes (U/Th isotopic ratios, $^{14}$C, $^{137}$Cs, $^{210}$Pb, etc.), airborne and terrestrial LiDAR, various satellite and airborne imagery (hyperspectral, hyperspatial, radar, etc.), ground penetrating radar (GPR), and ground sensors such as radio frequency identification (RFID) and cameras (Thorndycraft, Benito, and Gregory 2008; Carbonneau and Piégay 2012). In this field, temporal resolution is also becoming significantly improved, notably with ground sensors that record phenomena almost continuously (e.g., a few images per second for ground video cameras to a few images per year with the Pléiade 1A and 1B satellites with a spatial resolution equivalent to the conventional ortho-rectified photos provided by national agencies (0.7 m versus 0.2–0.5 m)) or UAV technologies. With the development of the Internet, more and more state services offer archived data online, increasing the data availability for research purposes. These sites include online metadata/data catalogs and online geotreatment tools or tool packages to explore geomorphic systems within GIS. The computer revolution not only allows for more complex modeling in terms of hydraulic simulations but also provides new techniques to
explore complex sets of data needing large computer capacities (e.g., multiple-agent systems, segmentations and classifications, analyses of uncertainties based on probabilistic approaches and randomization tests, etc.).

New techniques and new data provide new insights. There is now the ability to more intensively observe fine sedimentary structures, topography under forest cover, and river bathymetry, in order to study processes which were not yet fully examined (e.g., flux of wood, bank erosion during a flood event, landslides or debris flows, etc.). This has allowed us to widen our range of observations and our vision, which was extremely limited in space and time by field-based approaches. Traditionally field based, geomorphology is now reaching the point in its evolution where remotely collected images are providing more data than field observations, opening exciting prospects to explore processes and forms not only at a local scale but at much wider scales by combining observations and simulations. In a certain way, geomorphologists not only base their knowledge production on field observation but also on remote sensing information, a complementary perspective of observing Earth. In widening our space and time framework, these new data should improve our understanding on how local observations can be generalized.

Methods promoted by reductionists developed in the 1950s are now being progressively adapted for applications at larger spatial scales. Reductionist quantitativists must now collaborate with holistic quantitativists to explore phenomena in this big data era recognizing geomorphology as a “system science.” This new big data era more closely connects physicists with statisticians, who explore Earth complexity from two joined perspectives. It is influencing not only functional/dynamic geomorphology but also historical/evolutionary geomorphology as shown by Thorndycraft, Benito, and Gregory (2008) or illustrated by works such as Notebaert et al. (2009) opening new bridges between these two main branches of the discipline.

Since the recognition in the mid-nineteenth century that glaciers had been considerably more extensive than at present, the Quaternary has been synonymous with glaciation of the mid-latitudes. Today evidence from both the land and ocean floor sediment sequences demonstrates that the major continental glaciations occurred repeatedly over what are now temperate regions of the Earth’s surface. Knowledge about the number of glaciations has increased, and also knowledge about the extent of the Pleistocene ice sheets. Progress has been rapid since the 1970s and can be seen in the INQUA Work Group 5 project “Extent and Chronology of Quaternary Glaciations” (Ehlers and Gibbard 2004a, 2004b, 2004c) and the “Extent and Chronology of Quaternary Glaciations, a Closer Look” (Ehlers, Gibbard, and Hughes 2011) (Figure 1). While the maximum extent has undergone comparatively few changes, the Late Weichselian ice sheet of northern Europe and Siberia has changed fundamentally. Today, a single ice sheet is envisioned instead of the previous three major glaciation centers. Major differences include the (i) glaciation of the Bering Sea, (ii) non-glaciation of the North Sea, (iii) non-glaciation of the northern Urals, and (iv) limitation of glaciation in Siberia to the Putorana Massif and the Taimyr coast. Extensive ice-rafting, an indication that glaciers had reached sea level, is found from the earliest cold stage (2.6–2.4 Ma) in both the North Atlantic and North Pacific oceans. The initiation of conditions that resulted in glaciation resulted from the long-term cooling trend in world climates that began early in the previous Tertiary period. Apart from some limited activity in the Eocene, significant glaciation began in the late Oligocene (ca. 35 Ma) in eastern Antarctica. It was followed by mountain glaciation through the Miocene (23–5.3 Ma) in Alaska, Greenland, Iceland, and Patagonia and later in the Pliocene (5.3–2.6 Ma) in the Alps, the Bolivian Andes, and possibly in Tasmania. From the Neogene, glacially derived ice-rafted debris is found in ocean-sediment cores from the North Atlantic region, including the Barents Sea, and areas adjacent to Norway, north and southeast Greenland, Iceland and northern North America, and in the Southern Ocean off Antarctica (De Schepper et al. 2014).

Glaciation during the Quaternary

The climatic variation of that characterizes the Earth’s climate during the late Cenozoic and indeed before, is controlled by variations of the planetary orbit around the sun that therefore controlled the receipt of solar energy at the Earth’s surface. These Milankovitch variations, named after their discoverer, are responsible for the cyclic climate changes that characterize the Quaternary and indeed much of Earth’s history. One of the most critical ways they are expressed is through the development of “ice
ages” or periods when glaciation extended across large areas of the Earth. The Early Pleistocene (2.6–0.8 Ma) was characterized by climatic fluctuations dominated by the 41 Ka precession cycle, during which relatively few cold periods were sufficiently cold and long to allow the development of substantial ice sheets. Only 14 of the 41 cold stages of that period currently show evidence of major glaciation. They include the Plio-Pleistocene boundary events Marine Isotope Stage (MIS) 104, 100, and 98, together with Early Pleistocene MIS 82, 78, 68, 60, 58, 54, 52, 36, 34, ?30, and 26 which reach $\delta^{18}O_{\text{ocean}}$‰ of c. 4.6–5. It is not until the transition in dominant orbital cyclicity to the 100 Ka cycles, that began circa 1.2 Ma and was fully established by about 800 Ka (“Middle Pleistocene transition”), that the cold periods (glacials) were regularly cold and long enough to allow ice-sheet development on a continental scale, outside the polar regions. However, it is during MIS 22 (ca. 870–880 Ka) that the first of the “major” cold events occurred that reached critical values of circa 5.5 or above $\delta^{18}O_{\text{ocean}}$‰ equivalent to substantial ice volumes that typify glaciations of the later Pleistocene (i.e., MIS 16, 12, 10, 6, 4–2). Potentially therefore, it is likely that there were a minimum of 20 periods during which extensive glaciation could have developed during the last 2.6 Ma, with the most extensive (ca. 5–6 periods) being limited to the last 900 Ka (Table 1, Table 2, and Table 3).

Precisely where these glaciations occurred and how far they extended is very difficult to determine, given that the remnants of less extensive early glaciation tends to be obliterated and mostly removed by later, more extensive advances. Although this is so in all terrestrial areas, it is especially difficult in mountain regions where the preservation potential of older sequences rapidly
Table 1  Occurrence of glaciation in Europe through the Cenozoic based on numbers of observations presented in contributions to the INQUA project “Extent and Chronology of Quaternary Glaciations” (Ehlers and Gibbard 2004a). ?, questionable glacial deposits; arrows, glaciomarine deposits; MIS, Marine Isotope Stage. </table>

diminishes with time and subsequent glaciation. However, examination of the frequency of glaciation through the Cenozoic indicates that glaciation in the Southern Hemisphere having been established first, principally in Antarctica and southern South America, occurred continually from the Early Neogene to the present day. By contrast, Northern Hemisphere glaciation, although initially somewhat restricted, increased markedly at the beginning of the Quaternary, increasing again in frequency in the latest Early Pleistocene and reaching very high levels in the Middle–Late Pleistocene. While this pattern is not unexpected, the striking increase in ice sheets through the Quaternary clearly emphasizes that worldwide glaciation is in effect a northern-hemispheric phenomenon.

Examination of the evidence accumulated in the INQUA project (Ehlers and Gibbard 2004a, 2004b, 2004c; Ehlers, Gibbard and Hughes
QUATERNARY GLACIATIONS

2011), supported by other published sources, demonstrates the current state of knowledge. When examining the resulting tables (Table 1, Table 2, Table 3), it is important to bear in mind that the stratigraphical control between regions, beyond the range of radiocarbon-dating, is weaker than might be desired. This is particularly a problem outside Europe where biostratigraphy is less developed and the sheer extent of the unexplored regions makes future discoveries likely. Thus the presentation below can only be a first step toward a comprehensive overview. The correlations applied here are based on the Global Correlation Chart (Gibbard and Cohen 2013).

Plio-Pleistocene glaciation

Evidence of glaciation is widespread from throughout the Quaternary and indeed the Neogene in the Northern Hemisphere. The longest sequences are restricted to Alaska and the adjacent northwest territories of Canada which, together with Greenland and the Rockies, preserve evidence of glaciation from the Neogene to the present. In northern Canada and Alaska, the oldest till and accompanying ice-rafted detritus in marine settings, dates from the early Miocene, with regionally widespread glaciation occurring in the Pliocene and regularly throughout the Pleistocene. In adjacent British Columbia a comparable sequence is found, particularly in the north. Similarly, in Greenland and Iceland glaciation began in the Miocene, occurring regularly through the Pliocene and onwards to the present day in the mountains. Likewise, in Norway, its adjacent offshore and the neighboring Barents Sea, glaciation is recorded from the early Miocene, early Pliocene and Plio-Pleistocene. By the late Miocene, inland ice shields were periodically present in Greenland, especially in the mountainous east, with ice reaching the sea in southeast Greenland, although contiguous ice sheets have occurred since the earliest Pleistocene (ca. 2.3 Ma). In the eastern Rockies of the United States a much shorter glacial sequence occurs. Here Plio–Pleistocene-aged till is known from Montana, North Dakota, and California. On Mount Kilimanjaro in East Africa the first glaciation is recognized at circa 2.0 Ma (ca. MIS 68). In Europe glaciation before the Middle Pleistocene glaciation is represented only by ice-rafted material, outside the mountain regions (e.g., in the Netherlands, lowland Germany, European Russia, and Britain). Substantial glaciation of the Baltic region late in the Early Pleistocene is indicated by erratic materials in the Netherlands (1–1.2 Ma; MIS 34–36). Glaciation is also established in the Alps from the Plio–Pleistocene.

In the Southern Hemisphere, glaciation is much longer established, as noted above. Here the ice already formed in the late Eocene–early Oligocene in East Antarctica and built up in a step-like pattern through the Neogene (De Schepper et al. 2014). The present polar conditions were already established by the Early Pleistocene after 2.5 Ma. A similar history is known from the Piedmont areas of Argentina and Chile where substantial ice caps were established by 14 Ma. Widespread lowland glaciation between 2.05–1.86 Ma (ca. MIS 68–78) followed by the “Great Patagonian Glaciation” took place at 1.15–1.00 Ma (ca. MIS 30–34). Further north, the earliest glaciation recorded in the Bolivian Andes dates from 3.27 Ma with extensive events at 2.2 Ma (ca. MIS 82). In Columbia the record also begins at 2.5 Ma. The earliest records in Australia are found in Tasmania and New Zealand from the Plio–Pleistocene (2.6 Ma: MIS 98–104). Only slightly younger is New Zealand’s oldest known glacial event (the Porika Glaciation).
The “glacial” pleistocene

The “glacial” Pleistocene effectively begins with ice sheets spreading over vast lowland areas, particularly around the North Atlantic region, and the intensification of global cold period (glacial) climates in general. It coincides with the “Middle Pleistocene transition” (1.2–0.8 Ma) when the transition from the dominant 41 to 100 Ka Milankovitch orbital cyclicity resulted in periods sufficiently cold and long to allow the development of continental-scale ice sheets.

The till sheets of the major glaciations of the “glacial Pleistocene” are found throughout large parts of Europe and North America and especially in the lowlands and under the sea. Widespread lowland glaciation began in the early Middle Pleistocene shortly after the Brunhes/Matuyama palaeomagnetic reversal (780 Ka). In Europe, the phases represented include the Weichselian (Valdaian, MIS 4–2), Saalian (Dniepr and Moscovian, MIS 6, 8, and 10), Elsterian (Okan, MIS 12), and the Donian (Narevian, MIS 16). More limited glaciation may also have occurred in the circum-Baltic region during the latest Early Pleistocene (MIS 20 and 22). Curiously, evidence for early Middle Pleistocene glaciation is absent from the North Atlantic and Norway, while it is certainly present in Denmark, the Baltic region, and European Russia. In the Italian Dolomites, glaciation becomes established in MIS 22. Comparable evidence is also found from north of the Alps in Switzerland and southern Germany. Further to the west, in the Pyrenees, the oldest glaciation identified is of late Cromerian age (MIS 16 or 14). Widespread lowland glaciation again is first seen throughout North America in MIS 22. From this point onwards, major ice sheets covered large regions of the continent during the Middle Pleistocene pre-Illinoian events MIS 16, 12, 8, and 6 (Illinoian sensu stricto) and the Late Pleistocene MIS 2–4 (Wisconsinan). In Mexico, the oldest moraines on volcanoes have been dated to 195 Ka and probably relate to a pre-MIS 6 glaciation. Evidence from east Greenland suggests that its quasi-permanent ice sheet may have almost disappeared during the Eemian Stage interglacial (ca. MIS 5e). Glaciation of Tibet and Tianshu is not recorded before the Middle Pleistocene, of which that during MIS 12 was the most extensive. In Tianshu older glaciation (?MIS 16) may have also occurred. This apparently delayed glaciation of the Himalayan chain might reflect a late uplift of high Asia. Subsequent events took place during MIS 8, 6, and 4–2, and continue today in the highest peaks.

As in Europe and North America, glaciation increased in intensity throughout the Andean chain from 800 Ka to the present day, but in the south it was less extensive than during the Early Pleistocene events. In Australasia, following a 1 Ma break, the glacial record continues in MIS 12, followed by MIS 6, 4, and 3. In Tasmania, an early Middle Pleistocene event, possibly during MIS 16, is followed by glaciations during MIS 6 and 3. The glacial record during this time in Africa is restricted to the East African mountains, Mount Kilimanjaro, Mount Kenya, and the High Atlas, where glaciations appear to be broadly equivalent to those elsewhere, that is, during MIS 12, 6, and 2.

Last glaciation

The term Last Glacial Maximum or LGM is widely accepted as referring to the maximum global ice volume during the last glacial cycle corresponding with the trough in the marine isotope record centered on c. 18–14 C Ka BP (Martinson et al. 1987) and the associated global eustatic sea level low also dated to 18–14 C Ka BP (Yokoyama et al. 2000). It has also been assigned
Figure 2  Distribution of glaciers and sea ice in the (a) Southern and (b) Northern Hemispheres during the Last Glacial Maximum.

Chronozone status (23–19 or 24–18 Ka cal BP dependent on the dating applied), the event being centered on the calibrated date at 21 Ka cal BP (i.e., LGM *sensu stricto*). However, since the last maximum glaciation after MIS 5 occurred much earlier in some areas than in others, the term LGM should be used with caution. For the purposes of this entry it is defined as the interval 27.5–23.3 Ka (= Greenland Stadial 3) (see Hughes, Gibbard, and Ehlers 2013; Hughes and Gibbard 2015).

During the LGM, the extent of the glaciation of the Southern Hemisphere differed very little from that of the Pleistocene glacial maximum. Glaciers in Antarctica still reached to the shelf edge and on New Zealand, Tasmania, and in South America the glacier tongues were only slightly smaller than during earlier events. On mainland Australia, local mountain glaciation occurred. It seems that the LGM in the Southern Hemisphere began earlier than in the Northern Hemisphere, probably around 27 Ka. The high mountains of East Africa were glaciated. There is no unequivocal evidence of glaciation in South Africa, although minor glaciers have been postulated by various authors. However, it must be borne in mind that South Africa is located relatively closely to the equator to the north. Were it in the Northern Hemisphere, Cape Town would be situated at the same latitude as Atlanta in Georgia, USA or, if placed relative to the European ice sheet, it would be south of Tunis. Consequently, sea ice cover did not reach the southern end of Africa (Figure 2a).

Likewise, during the LGM, ice in many parts of the Northern Hemisphere reached an extent very similar to the Quaternary glacial maximum. In North America, the differences are very small. Again, most parts of Canada were ice covered, including the shelf areas. It is the same in Greenland. The map of global ice distribution (Figure 2) shows that while sea-ice cover went very far south, most parts of the land areas of Beringia remained ice free.
In Europe, however, the situation was different. New evidence suggests that the North Sea was not fully glaciated during the Weichselian glacial maximum but slightly earlier. An ice sheet covered the Barents Sea and extended well into the Kara Sea but hardly touched the Russian mainland (Svendsen et al. 2004). The ice sheet was markedly smaller than during the Quaternary glacial maximum. It seems that the northwards drainage of the Ob and Yenisei rivers was not impeded. Not only has the glaciation of the Alps been mapped in great detail (Figure 3), but also knowledge of other mountain glaciations has increased considerably. In glaciated mountain areas outside the major ice sheets, such as in Italy and Greece, the maximum Middle Pleistocene glaciations were much bigger than the local last glacial maxima. This is attributed to a change in equilibrium-line altitude (ELA) because it has a much bigger impact on glacier size in areas characterized only by mountain glaciation than in areas where ice covered the lowlands during multiple glaciations.

There were major ice sheets or mountain glacier systems in the Siberian mountains further to the east. Because of the lack of detailed investigations to date, in most cases it is not possible to differentiate between the extent of the LGM and earlier glaciations. Likewise, the age and extent of the glaciers in Iran and the mountain ranges and high plateaus further to the east, and especially the extent of glaciation on
the Tibetan plateau, are still matters of debate. In contrast, the small mountain glaciers of Japan are well mapped and dated and, unlike those of the adjoining Asian mainland, the maximum ice advance of the last glaciation occurred in MIS 4. The same date for the maximum extent is found in New Zealand.

Quaternary science

Xiaoping Yang
Zhejiang University, China

Quaternary science is the multidisciplinary studies focusing on the Quaternary period, which encompasses the last 2.6 million years according to the chronology defined in 2009 by the International Commission on Stratigraphy (ICS). The Quaternary period is further divided into Pleistocene and Holocene (Figure 1). While the Quaternary science focused on describing and interpreting geomorphic features and glacial landforms on the Earth surface earlier, it now largely examines all kinds of proxy evidence to reconstruct the past environments during this period in order to decipher knowledge about the climatic and environmental changes and to assess triggering factors of such changes.

From a geological perspective, Quaternary refers to the youngest and shortest system of the Earth’s history. The term was adopted for the first time by the Italian mining engineer Giovanni Arduino (1714–1795) when he distinguished four orders of strata – Primary, Secondary, Tertiary, and Quaternary. The first two terms were discarded long ago, the last two are still used although Tertiary has been out of the 2004 updated geological timescale by ICS. Quaternary was mistakenly seen as an outmoded relic also while the ICS deleted the Quaternary and the Tertiary out of the ICS timescale altogether in 2004. Then the Quaternary communities around the globe went into open revolt. After open discussions and formal proposals from the Quaternary communities, two rounds of voting took place at the ICS in 2009 and the proposal passed. The Quaternary is redefined and its beginning is placed at 2.6 million years ago, it was defined in 1985 to cover the last 1.8 million years. Different from other periods of geological histories, the Quaternary is the time period in which humans evolved and live today. During this period the bipedal, toolmaking, fire-use hominids emerged from Africa and gradually moved out to occupy Eurasia, Australia, and the Americas, as well as the oceanic islands throughout the planet. Thus, the Quaternary is not only part of the Earth’s history, but also the time during which humans developed and the most active part of the Earth system. Humans now live in the recent epoch (Holocene) of the Quaternary period of the Cenozoic era (meaning “new life”). The famous US geologist Grove Karl Gilbert commented already in 1890 on the importance of the youngest period: “When the work of the geologist is finished and the final comprehensive report is written, the longest and most important chapter will be upon the latest and shortest of the geological periods.”

Quaternary science studies not only all aspects of this geological period but also the connections and interactions between Quaternary and modern as well as future times. It is the field where geography interacts most extensively and intensively with geology. In the United States, Quaternary science is often heavily affiliated in geological departments and geological institutions, but it is based strongly in geographical schools in Western Europe where this subdiscipline was originally initiated. At a time of widespread concern over the negative human impact on our environment, Quaternary science can offer key options and concepts for reconstructing the
history of past environmental changes and for drawing some relevant lessons from research on former human interactions with their natural environments (Eitel et al. 2005). The attempt to predict possible future climate fluctuations, possibly triggered by anthropogenic increase in the atmospheric concentration of carbon dioxide, methane, and other greenhouse-enhancing gases, has considerably invigorated the Quaternary science in the last several decades, since the scientific communities assume that past climatic events could be used as analogs for possible future climatic changes (Williams et al. 1998). Quaternary science, earth system science, and sustainability science are suggested to be the three major interacting and mutually reinforcing subfields of geosciences in the early twenty-first century. Among the three subfields, Quaternary science is considered to be the most firmly established (Matthews et al. 2012).

Part of Quaternary science is about studies of clearly visible landscape changes and their mechanisms. In such areas it has a strong interaction with geomorphology and sedimentology, since the landforms and their constitutions are the main research materials. Glacial theory has been an important development of Quaternary science. The glacial system is controlled by two major climatic parameters: the input of snowfall (accumulation) and the loss of snow and ice (ablation) resulting from evaporation or melting. The boundary line along which summer melting is equal to all of the preceding winter’s snowfall is called snowline. Glacial ice covers about 10% of Earth’s land area at the present time and alpine glaciers can be found in mountainous regions on most continents. The Pleistocene Epoch was the time of recent geologic history that experienced several major advances and retreats of continental ice sheets over large portions of the land (Figure 2). With the improvement of the physical dating methods of glacial sediments, the precise estimate of the events of glacial advance and retreat, as well as changes of snowlines is now potentially possible. The so-called surface exposure dating has been successfully used to date glacial moraines and has helped to establish precisely the timing of glacial advances and retreats. The surface exposure dating is based on the measurement of abundance of accumulated nuclides in certain minerals at the surface through cosmic ray activity. The more recent dating results, partly via the surface exposure method, shows that fluctuations in mountain glaciers are not always synchronous in different regions owing to differing regional patterns of rainfall and temperature response to global-scale climate variability. At present, most of the alpine glaciers on Earth are receding, possibly owing to global warming.

Ice moved into the northern United States after 26 000 $^{14}$C years BP (radiocarbon dating, before present), yet the extent in the sense of the last glacial maximum was also reached at different times in different places in the United States (Mickelson et al. 1983). Lobes in the Great

---

**Figure 1** The updated definition of the Quaternary, as approved by the International Commission on Stratigraphy in 2009.
Lakes and New England regions reached their maximum extension before 21000 $^{14}$C years BP, but lobes to the west of the Great Lakes reached their maximum extent at about 14000 $^{14}$C years BP, out of phase with the rest of the ice sheet margin. Rapid retreat of the ice sheet began after 14500 $^{14}$C years BP, but the re-advance of lobes are found all along the southern Laurentide ice sheet margin at 13000 $^{14}$C years BP, 11800 $^{14}$C years BP, and 9800 $^{14}$C years BP. After 9800 $^{14}$C years BP ice retreated out of the northern United States (Mickelson et al. 1983).

Another important field of Quaternary science is to investigate the Quaternary environmental changes in the world’s arid and semiarid regions, because arid and semiarid regions occupy about one-third of the global land surface, occurring in all continents. While the formation of ice and glaciers is considerably controlled by temperature, the occurrence of deserts is much more dependent on the aridity or the ratio between precipitation and evaporation. Many imprints of climate change in arid zones are large scale and easily visible, in particular the desiccation of lakes and rivers, shifting of sand seas’ boundaries, as well as the stabilization or reworking of sand dunes. Sedimentary sequences occurring in desert dunes reflect changes in desert systems and as such may contain signals useful also for recognizing spatial and temporal changes of deserts and their response to regional or even global climate fluctuations. One of the earliest
recognitions of Quaternary climatic instability was from the geomorphological field studies in arid regions of western China (*China: Ergebnisse eigener Reisen und darauf gegründeter Studien* (China: The Results of My Travels and the Studies Based Thereon) by Ferdinand von Richthofen in 1877). This work even pre-dates the landmark publications on Quaternary glaciations in the Alps of Europe (*Die Alpen im Eiszeitalter* (The Alps in the Ice Age) by Albrecht Penck and Eduard Brückner in 1909). In more recent years, a large amount of new information on the nature, timing, and extent of past climatic changes in arid and semiarid regions has emerged. Optically stimulated luminescence (OSL) dating enables age control for aeolian deposits that were previously hard or impossible to be dated directly. Since the temporal and spatial density of chronological datasets on past environments in deserts has increased, the spatial variations of the patterns of dune activities has become increasingly evident, requiring revisions and reinterpretation of the regional and global correlations of aeolian processes (Lancaster, Yang, and Thomas 2013).

Multiple Quaternary periods of both increase and decrease in the level of aridity have been found in all arid and semiarid regions on Earth. During the Pleistocene glacial period linear dunes of the western Sahara extended onto the continental shelf, accompanied by dramatic shrinkage of lakes in the region, southward shifting of sand dunes, and large-scale contraction of Guinean forest in West Africa. At the same time, the dryness level increased in South Africa and Australia as well as in parts of the Americas due to a decrease in precipitation. The glacial increase in aridity, however, was much less clear and inconsistent in the drylands of Asia. Lacustrine records in western China suggest that an increase in effective moisture at around 20,000 to 18,000 years BP was likely due to an intensification of mid-latitude westerly winds bringing moisture from the Atlantic and an expansion of glaciers in the surrounding mountains. Between 35,000 and 25,000 years BP, the world’s largest sand sea, Rub Al Khali, experienced moister grassland to semi-desert conditions.

Even during the Holocene, at least one distinctly wetter period has occurred in every part of the arid and semiarid regions of the world, although the precise timing of this epoch did not occur synchronously globally nor regionally. In contrast to the earlier assumptions of the extreme longevity of the deserts in northern China, more recent studies of the physical and biochemical indicators in the sediments and their OSL chronology show that most of the current dunes in the mid-latitudes of eastern Asia are of Late Pleistocene or even Holocene age and the dune system has responded sensitively to climate change. During the middle Holocene a large-scale stabilization of the dunes occurred in the eastern part of the desert belt in northern China. In more arid parts of the region, however, the increased rate of annual precipitation was not sufficient to fully stabilize dunes, thus some active dunes persisted even during this long-lasting wetter epoch (Figure 3). In general, Holocene dune stabilization due to paleosol formation varied along the climate gradients across the various sandy lands of northern China and in general it began earlier and lasted longer in the east than in the west (Yang et al. 2013).

Although paleoclimatic records can provide an analog for assessing the impacts of global warming on environment, climatic parameters in the past and potentially for the future need to be carefully compared to make a realistic forecast. Yang *et al.* (2013) estimated that the annual precipitation of the Hunshandake Sandy Land in northern China (Figure 3) during 9600–3000 years BP could be 30–140 mm more
Figure 3  Comparison of the dune fields in northern China during the mid-Holocene (a) and at the present (b), showing the obvious changes of dune landscapes during the Holocene. Individual deserts (sand seas) and sandy lands (dunes partly stabilized by vegetation): Key: 1 Taklamakan; 2 Gurbantunggut; 3 Kumtag; 4 Chaidamu; 5 Badain Jaran; 6 Tengger; 7 Wulanbuhe; 8 Kubuqi; 9 Maowusu; 10 Hunshandake; 11 Horqin; 12 Hulunbeier. Modified from Yang et al. (2013).
than at present. Driven by the higher insolation in the summer, this period was characterized by higher temperatures globally. The warming in this century in the eastern part of the desert belt differs from the globally warmer climate during the early and middle Holocene with respect to magnitude and seasonality of temperature changes, both of which would not be favorable to the vegetation in the entire region in the future and not the same as during the middle Holocene warmer period (Li and Yang 2014).

Quaternary scientists around the world have been reconstructing changes in flora and fauna in terrestrial areas for more than a century. Stratigraphic analysis of macrofossils and pollen of plants in terrestrial, lacustrine, and marine sediments and the sedimentary features of various deposits has enabled the reconstruction of vegetation history and the interpretation of climatic fluctuations and human impacts on environment throughout the world. The studies of ice cores, speleothems, and tree rings have greatly improved the temporal resolutions for Quaternary paleoenvironmental reconstructions. Results of the studies of ice cores from the Greenland and Antarctica ice sheets produced continuous paleoenvironmental records for the last several glacial–interglacial cycles.

Studies of marine and coastal environmental changes are other important areas of Quaternary science. Various international efforts, including the Deep Sea Drilling Project (DSDP), Ocean Drilling Project (ODP), and Integrated Ocean Drilling Project (IODP) have studied the deep sea and continental margin sediment cores that have shed light on ocean basin history, changes of Quaternary climate, and ocean circulation. The interpretation of marine and speleothem records and the numerical simulations of Quaternary climate changes have also helped the Quaternary communities to reconsider the astronomical theory by the Serbian mathematician Milutin Milankovitch who used the potential changes of orbital parameters of Earth (precession, obliquity, and eccentricity) to explain the periodic alteration of glacial and interglacial climates in 1941. There have been also significant glacial–interglacial changes in sea level during the Quaternary, for example, the global sea level has risen by circa 150 m from the last glacial maximum to present. During the last glacial maximum, roughly 5.5% of the water on Earth was locked up in the form of ice (the corresponding number today is 1.7%). When current sea level rise is a great concern for human wellbeing in coastal areas, a complete understanding of natural cycles of sea level change as well as anthropogenic effects is imperative for future development in the coastal areas and beyond (Murray-Wallace and Woodroffe 2014).

While Quaternary science progresses are presented in various geological, geographical, geomorphological, climatological, and anthropological meetings and events, the Quaternary Geology and Geomorphology Division (QG & Q) of the Geological Society of America (GSA) organizes sessions and field trips every year at the GSA Annual Meeting that has become a large annual gathering for Quaternarists all over the globe. In more recent years, the organization PAGES (Past Global Changes, based in Bern in Switzerland) has also become an international coordinator for studying past global changes, one of the key areas of Quaternary science nowadays. The large number of Quaternary publications appearing each year and the continuing high impact factors of specific Quaternary journals (e.g., *Quaternary Science Reviews*, *Quaternary Research*, *Quaternary International*) also confirm the vital status of Quaternary science in a global scientific context.

Further reading

The Quaternary is the most recent period in the Cenozoic era comprising the Pleistocene and Holocene epochs. The Pleistocene epoch extends from the beginning of the Quaternary 2.6 million years ago to the beginning of the Holocene epoch 12000 years ago. The most recent 12000 years make up the Holocene, which includes the present-day interglacial period. One of the most distinctive features of the Quaternary period is the expansion of ice sheets and mountain ice caps in many parts of the world.

During the Quaternary, Earth’s climate has shifted back and forth between glacial and interglacial states. The cyclical nature of the shift between these states is often attributed to the astronomical Milankovitch cycles of eccentricity, obliquity, and precession. Eccentricity refers to the change in Earth’s orbital path around the sun, which has a periodicity of about 100 000 years. Obliquity, or axial tilt, refers to the change in Earth’s axial incline. Over a time period of about 41 000 years, Earth tilts on its axis from 21.5° to 24.5° relative to the equator. Today, Earth’s axial tilt is about 23.5°. Precession, or Earth’s “wobble” on its axis, has a periodicity of about 23 000 years.

The variation in the Milankovitch cycles affects the seasonality and impact of solar radiation on the planet’s climate system. These shifts largely account for the swing between glacial and interglacial periods. While the astronomical cycles play a large role in the behavior of Earth’s climate, they do not exist in a vacuum. Other factors, such as plate tectonics, have an effect on the movement of glacial ice from the poles and also impact Earth’s overall albedo, or solar reflectivity. The chain of relationships continues in the alteration of ocean currents and global atmospheric composition.

While there is strong evidence that the Milankovitch cycles play a role in regulating factors that drive glacial and interglacial cycles, it is unlikely that these cycles alone drive the beginning or end of an ice age, or series of glacial periods resulting from a long-term decrease in Earth’s overall surface temperature. In fact, the ice ages observed through the geological record happen on an irregular basis, which contradicts Milankovitch patterns. This means that additional factors are necessary in exploring the causes of ice ages as well as shifts between glacial and interglacial cycles.

**Landforms**

During glacial periods, the mid to high-latitudes of the Earth are covered by large ice sheets extending from the poles. Interglacial periods, such as the one we have been experiencing since the beginning of the Holocene, witness glacial recession and an overall increase in Earth’s temperature. The Holocene is characterized by the disappearance of the ice sheets that expanded during the Pleistocene. The most recent glaciation is known as the Wisconsin glaciation, which was at its maximum about 20 000 years ago and drove the formation of many landforms observable in the current day. Residual glaciers still exist in Antarctica, Greenland, the high
Canadian Arctic, Iceland, and some high alpine environments.

As glaciers grow and recede from the poles, sea levels pulse, currents shift, and winds change direction. The combination of these responses affects global precipitation patterns and acidity levels, factors that play a large role in weathering and erosion patterns. These factors drove the evolution of topography on a global scale. Landforms, or features that are the result of the surficial processes impacting topography, arose during the Quaternary, which allowed for the expansion of flora and fauna species.

Geomorphology is the study of the processes that shape Earth’s landforms and the combined landforms in an area, or landscapes. Geomorphologists, or scientists who study these processes, investigate changes in Earth’s landscape over time. Thus, Quaternary geomorphology is the study of landscape changes during the recent Pleistocene and Holocene epochs. While geomorphologists typically study landforms with a historical perspective in mind, Quaternary geologists focus on the surficial sedimentary cover as well as deeper layers of sedimentary deposits, which provide a window into the past of Earth’s changing climate.

Paleoclimatology is a field concerned with the study of past climate system activity. Paleoecologists develop a timeline of Earth’s geological past through proxies, which help to tell the story of Earth’s history, including the Quaternary period. Both land and ocean features provide a geological record of the Quaternary period.

The only direct record of Earth’s atmospheric history exists in the form of ice cores. The most recent of ice core investigations covers a history of nearly 1 million years, and serves as a calibration tool for other geological records (see Figure 1).

Quaternary sediments make up the surficial layer of land, marine, and shoreline environments and are particularly useful in reconstructing paleoclimates. The coring of lacustrine (lake), fluvial (river), and marine sediments allows for paleoclimate reconstruction using stable isotope analysis. Other paleoclimate proxies include the study of dendrochronology (tree rings), foraminifera (planktonic organisms), fossils (plant and animal), pollen, and speleothems.

The Quaternary period left behind distinctive landforms in the form of glacial erosion during glacial advance and glacial deposition during glacial retreat. The pulse of ice sheets from the poles during Quaternary glacial periods left evidence of climate shifts through a variety of landforms while also setting the stage for mountain glaciers to build in high alpine environments. Glacial features are the primary characteristic of high alpine environments such as the Rocky Mountains, the Alps, the Cascade Mountains, the Himalayas, the Sierra Nevada Mountains, the Andes, and the Tibetan Plateau.

As a glacier flows, it scours the environment with collected debris through erosion and deposition. This process of abrasion repeatedly shaped the land of the Quaternary. Landforms that
exist in the current day are those carved by the most recent glacial activity. Evidence for the timeline of Earth’s most recent glaciation exists in features such as moraines, drumlins, kettles, kames, outwash plains, V and U-shaped valleys, and arêtes.

The creation of glacial features allows for the study of glacial history. The features that arise from glacial advance and retreat provide a window into the past movement of glacial ice, which plays a large role in paleoclimate reconstruction. The aggregated information from paleoclimate proxies and physical features allows scientists to model past, present, and future glacial activity.

Glacial activity from the Quaternary also left behind evidence of past geological activity through the disruption of the surficial drainage system and the resulting creation of glacial lakes. As glaciers moved across Earth’s surface, they eroded the bedrock below, creating new features that would remain long after glacial retreat. As glaciers began to recede, meltwater discharge filled depressions in the landscape, which produced a notable number of lakes in previously glaciated landscapes (see Figure 2).

Periglacial activity

The oscillation between glacial and interglacial periods during the Quaternary directly conditioned periglacial environments through melting and refreezing processes, often on the margins of glacial areas. These environments are characterized by frost action, which modifies the ground surface with the movement of water through the area and the redistribution of glacial sediments. Today, periglacial processes dominate more than one third of Earth’s land surface.

While the melting and refreezing processes are the signature mark of periglacial environments, these areas are also associated with perennially frozen ground. When the ground is frozen for two or more years in a row, the frozen soil, rock, and sediment is called permafrost. (Other definitions of permafrost include ice that is frozen throughout the year or on an annual basis.) While many periglacial areas contain permafrost, others are dominated by the freezing and melting processes, absent of permafrost.

Location is one of the most important factors affecting the extent of periglacial environments, which are concentrated in high latitudes. The distribution of Earth’s land masses is such that there is more land in the high latitudes of the northern hemisphere than in the high latitudes of the southern hemisphere – this means that a larger portion of the Earth’s periglacial regions exists in the north than in the south.

While periglacial regions are more common in high latitudes, lower latitudes can see the existence of periglacial regions in areas of high elevation, such as in mountainous regions. Finally, location relative to the coast plays a large role in the freeze–thaw processes that dominate periglacial regions. Areas subject to polar surface currents near a coast can support periglacial activity. Additionally, inland areas without a nearby water body to moderate the temperature can experience the seasonal freezing and thawing characteristic of periglacial regions.

The result of climate variation during the Quaternary period was an assortment of ground ice features, some of which were preserved in the fossil record. During the cycle of freeze–thaw, the ground contracts as temperatures drop, causing cracks to form. As temperatures rise, the ground expands and moisture builds in the cracks. When this water freezes, it fills the cracks, creating an ice wedge. When temperatures rise again, soil, rock, and sediment collect and allow for the fossilization of these formations (see Figure 3).

The extent of periglacial environments varies with the Earth’s climate. Changes in the climate
Figure 2 Kettle Lakes of the Turtle Mountains, 2015. About 25 kya, ice sheets expanded southward and covered the Turtle Mountains. As the climate warmed between 15 and 13 kya, the glaciers stopped flowing. Over time, a debris layer formed on top of the stagnated glaciers, which insulated the ice. This process resulted in the present-day landscape of the Turtle Mountains. Photo courtesy of NASA/GSFC/METI/ERSDAC/JAROS and US/JAPAN ASTER Science Team, August 16, 2015.

during the Quaternary period affected periglacial regions by impacting the hydrological cycle, sedimentation, atmospheric composition, and vegetation.

Vegetation

The oscillation between glacial and interglacial periods during the Quaternary affected vegetation distribution worldwide. The paleovegetational record combined with present-day species distribution provides an indirect history of global climate change. While the spread and abundance of plant species track climate shifts, the present-day variety of plant species tells the story of Quaternary vegetation movement.

The shifts between glacial and interglacial cycles during the Quaternary impacted atmospheric and oceanic circulation patterns, which shaped global plant distributions across the planet. The changes in vegetation that occurred during this time played a part in a feedback loop between climate variation and plant life. While
climate influenced vegetation, this feedback loop meant that changes in vegetation also impacted the climate. Plant species across the world influenced the global energy cycle by affecting the planet’s *albedo*.

The changes in Earth’s albedo amplified temperature swings worldwide, creating additional feedback loops that shaped the Quaternary period. As ice spread from the poles during this time, the overall abundance of vegetation at high latitudes decreased, leaving these areas with a higher albedo, which amplified cooling. Evidence of this influence exists in the latitudinal organization of plant species in the modern day. Furthermore, changes in evapotranspiration, hydrological, and carbon cycles drove feedback loops that defined the biosphere of the Quaternary.

**Climate change**

While evidence for glacial activity comes in a variety of forms, subsequent glacializations erase the history of prior ice extent, complicating the interpretation of the geological record. Despite the difficulty of teasing apart the signal and noise within Earth’s climate record, analyses of
the Quaternary time frame show that the shift between glacial and interglacial periods is related to a variety of factors.

Today, atmospheric temperatures are warmer than they have been throughout 90% of the Holocene (Marcott et al. 2013). Although high temperatures are unsettling, the rate of warming that characterizes the twentieth century is particularly concerning – temperatures have risen faster in the most recent century of our history than they have in the last 2000 years. Scientists have learned that the most recent changes in Earth’s climate system, in the time from the 1850s to the current day, are largely attributed to human influences on the global system. In fact, anthropogenic, or human-caused, influences on the climate system are the driving factor of global warming in the present day (see Figure 4).

Queer geographies

Lynda Johnston
University of Waikato, New Zealand

Queer theory and queer geographies are difficult to define. The concept of queer is often associated with identities such as lesbian, gay, bisexual, transgender, and intersex (LGBTI). Yet, queer is also a perspective, or a way of thinking and knowing. It calls attention to taken-for-granted assumptions regarding bodies, genders, sex, and sexualities. One of the main contributions queer theory has made to studies of sexualities is a critique of sexual identity politics. Queer theory sits precariously with constructions of queer identities, places, and spaces. The word “queer” is not fixed, and its meaning is socially produced through language. What it means to be queer, and what can be queered, have multiple meanings and are subject to change over place, space, and time.

Studies of sexualities are heavily influenced by postmodernism, poststructuralism, and anti-essentialism. Social theorists, including geographers, employ different understandings of bodies, places, and spaces in order to question grand claims and single truths of the modernist era. A postmodern approach recognizes that all knowledge is partial, fluid, often queer, and contradictory. There is recognition of difference and multiple truths, realities, voices, and identities. Queer theory – viewed through a poststructural theoretical lens – challenges ideas of preconstituted sexual subjects and allows for the examination of power as productive rather than as merely oppressive. This approach moves beyond humanist understandings of essentialized, gendered, and sexual subjectivities. It has been argued that queer theory is anti-normative – therefore anti-essentialist – and can be employed to critique the normalization of bodies, spaces, and places. Any attempt to reduce, mainstream, or even define and summarize queer theories is potentially anti-queer.

How have critical geographers used queer theory? There has been a tendency to claim queer spaces as existing in opposition to—and in transgression of—heteronormative spaces and places. Heteronormativity, as discussed later in the entry, is the normalization of heterosexual so that it appears natural. Since the mid-1990s geographers have been adopting the concept of queer space to illuminate and create spaces of sexual dissidents (Bell and Valentine 1995). Some geographers have gone beyond a sexual politics of recognition and produced queer geographies that engage with other theoretical frameworks, such as postcolonial, feminist, and critical race theories. Such accounts bring to the fore questions of race, colonialism, migration, globalization, geopolitics, and nationalism. Queer geographies, therefore, have expanded beyond the confines of sexual identity politics.

Queer activism to queer theory

The term “queer” was, in the 1970s and 1980s, slang for “homosexual” and was often associated with homophobic abuse. In the early 1990s the term began to perform different identity work and took on other meanings. Notoriously indefinable, queer became in the 1990s a key word for radical theorists and activists whose
sexual politics began with reclaiming the very word “queer” from its use as homophobic slang to be a positive label used by a variety of sexual and gender minorities. At this time, being queer meant being countercultural. It was associated with the rejection of mainstream, capitalist profit margins, patriotism, patriarchy, and assimilation. Being queer was anti-elitist and about being on the margins.

Queer politics gained traction at a particular historical juncture, when several Western governments failed to respond adequately to the HIV/AIDS crisis. It was a time when numerous pieces of antigay legislation were put forward by, for example, the homophobic Thatcher government in the United Kingdom. Queer activists in North America formed groups such as Queer Nation and ACT UP. They were visible in pride parades like the 1991 Montreal pride parade. Here queer activists rejected the “official” route that ran only through the city’s gay district. A march through Montreal’s gay neighborhoods would have, they argued, been affirming and empowering of Montreal’s sexual dissidents without challenging or confronting the city’s heteronormative culture. A similar queer struggle occurred over the Auckland, New Zealand gay pride parade when it was moved from the main street, downtown, to a “gay” suburb.

Current understanding of queer theory has evolved from its US origins in literary theory and humanities. Adrienne Rich’s (1980) early intervention argued that homosexuality should not be understood as misplaced (as sexologists were advocating at the time) but, rather, the focus should be on heterosexuality. Rich moved attention away from the marginalized “other” to heterosexuality, which she argued is a “compulsory fiction” designed to perpetrate patriarchal ideas that women are biologically and innately sexually oriented only toward men. This fiction, she claimed, was maintained via state policies and practices that valorized heterosexuals while leaving lesbians and gays invisible. These ideas were further refined by other queer theorists who also recognized the inadequacy of existing theoretical frameworks.

Queer politics are closely linked to queer theory, a diverse literature that is often seen as having emerged out of gay and lesbian literary criticism, particularly in the work of Eve Kosofsky Sedgwick – for example, her Epistemology of the Closet (1990) – who decentered normative understandings of sexualities. Sedgwick claimed that “the closet” had shaped gay life, beginning in the twentieth century and continuing. The “epistemology of the closet” is another way of saying that homosexuality exists through regimes of an open secret: that is, something that is known through not knowing. This scholarship is most commonly situated within postmodernist and/or poststructuralist frameworks that decenter normative notions of sexuality. Humanity scholars, therefore, forged new ways of conducting cultural studies with a focus on fragmented subjectivities.

“Queer theory” is a term originally coined by Teresa de Lauretis that first appeared in her introduction to the special issue of differences called “Queer Theory: Lesbian and Gay Sexualities” (de Lauretis 1991). She traces the way the conceptual framework for analyzing sexualities shifted in the twentieth century from an early emphasis on “homosexuality” to a gender-undifferentiated “gay,” and more recently to “lesbian and gay.” Concerned with the maintenance of differences, she remarks that specificity is elided “in the contexts in which the phrase [‘gay and lesbian’] is used, that is to say, differences are implied [in the phrase] but then simply taken for granted and even covered over by the word ‘and’” (de Lauretis 1991, v–vi). The turn to the word “queer”
is meant to mark “difference between and within lesbians, and between and within gay men, in relation to race and its attendant differences of class or ethnic culture, generational, geographical, and socio-political location” (de Lauretis 1991, viii). De Lauretis questioned the normative stance of heterosexuality against which homosexuality is defined as marginal. There has been a productive – and sometimes fraught – relationship between feminist theorizing and queer theorizing.

Queer theorists understand heterosexuality and homosexuality not simply as subjectivities but as categories of knowledge (Jagose 1996). Queer theories challenge the supposed naturalness of sexual and gendered hierarchies and disentangle any established understandings of gender, sex, and sexuality. To reiterate, it is language that frames constructions of bodies, desires, sexualities, and identities. Queer theorists highlight that normative language shapes moral boundaries and political hierarchies. Queer theoretical frameworks are employed to study homosexuality – a sexual minority – but also to study those knowledges and social practices that organize society as a whole by sexualizing – heterosexually or homosexually – bodies, desires, acts, subjectivities, relationships, knowledges, cultures, and institutions. Queer theory provides a framework from which to draw on critical social theories that challenge heteronormative discourses. Put another way, the task of queer theorists is to critique notions of identity to their fullest extent rather than only searching for radical queer subjects. This task focuses attention on advancing a critical approach to the workings of gendered and sexual normativities and non-normativities.

Judith Butler (1990) has also contested the naturalization of sexual and gender categories, to undo and destabilize binaries such as heterosexual/homosexual, gender/sex, male/female, and mind/body. Queer theorists are committed to the recognition of fragmented power across and between these binaries, pushing their scholarship beyond binary categorizations of social construction versus essentialism that conceptualizes bodies, subjectivities, and desires as fixed. Instead, Butler argues that heterosexuality is an ideal that can only be approximated and performed. It is within the heterosexual matrix that the binary opposition of man/woman finds its cultural and social currency. The gendered norm of male or female is solidified in the heterosexual matrix. Butler argues that this matrix is a masculine sexual economy in which bodies become gendered in order to support a gender hierarchy deemed necessary for compulsory heterosexuality. Her theorizing of repeated stylizations of bodies shows how, over time, bodies produce the appearance of that which is deemed natural and normal. The performativity of gender is described as “the stylization of the body, a set of repeated acts within a highly rigid regulatory frame that congeals over time to produce the appearance of substance” (Butler 1990, 33). By repeatedly conforming to gendered norms and established ideas about sex and sexuality – in dress, language, and everyday behaviors – embodied performances solidify hegemonic heterosexual identities so that they appear normal and seemingly natural.

While some theorists contend that heterosexuality came into being after the delimiting and othering of homosexuality, Butler argues homosexuality is indeed the starting point for heterosexuality. Heterosexuality was, and continues to be, constructed through its otherness to homosexuality. Such queering of heterosexuality also challenges the fixity of categories such as male and female. Butler illustrates the fiction of gendered and sexed embodiment by discussing drag queens and drag kings. Drag queens, for example, are doing femininity in, with, and from male bodies, and this mismatch exposes
the sexed body as the base for gender as a fiction (Butler 1990). Butler’s theory of performativity, however, has been critiqued, and she acknowledges that there is a difference between performance – as an occasional drag act – and performativity. Bodies, spaces, and identities are re-created through performativity, which is the process of repeated behavior and acts. Bodies are disciplined and (self) policed through dominant norms and understood codes of behavior.

The political imperative of a queer critique is to understand how norms and categories are deployed. Butler (2004, 15) notes: “If I am always constituted by norms that are not of my making, then I have to understand the ways that constitution takes place.” Butler’s work has been crucial in the development of queer geographies.

Queer geographies

Queer geographies question the relationships between gender, sex, and sexuality and assert that multiple genders and sexualities exist. At the core of this scholarship is the understanding of sexuality as a social process that allows for expressions of desire (in all directions and beyond dichotomizing discourses). Queer geographers have become dissatisfied with essentializing, limiting, neoliberal, and often Westernized sexual categories. They have turned to fluid, unstable, and ambiguous conceptualizations of sexualities. Spaces and places, like sexualities, are also considered fluid and ambiguous.

Scholarship on sexuality, place, and space started to appear in the 1970s. It was not until the 1980s – when humanistic approaches gained prominence over positivist approaches – that more sexuality and space studies emerged. This period of scholarship is perhaps best known for its emphasis on structuralism, such as theories of Marxism. The intersections of class and gay identity dominated studies of, for example, gay men and gentrification in US cities. There is a move away from reified notions, such as “gay gentrification” and “gay neighborhoods” (which also tend to be celebrated) to understanding bodies, places, and spaces as fluid, ambiguous, and often contradictory.

The first lesbian geographical scholarship appeared in the early 1990s and, in retrospect, this research may be considered “queer geography.” While not explicitly labeled as such, the research attempted to understand why lesbian communities had a quasi-underground character, thus recognizing difference, not sameness. A groundbreaking article entitled “All Hyped Up and No Place to Go” (Bell et al. 1994) also queered geography by considering the ways in which sexual identities – lipstick lesbians and gay skinheads – were performative parodies of hyperfemininity and hypermasculinity. In the mid-1990s the influence of poststructural thinking provoked an array of new research in this field, much of which can be found in a collection that mapped desires and sexualized landscapes (Bell and Valentine 1995). Notably, these studies show the desire to draw on feminist, poststructural, and queer theories in order to examine difference at a variety of spatial scales. This work challenges the notion of fixed identities and spaces by focusing on the proliferation of identities, rather than structural inequalities. Bell and Valentine (1995, 4) introduce their edited collection by noting:

The women’s, gay and civil rights movements emerged in North America and Europe in the 1960s and 1970s on a wave of social and political upheaval. But despite a growing awareness amongst geographers in the following decade of the need to study the role of class, gender and ethnicity in shaping social, cultural and economic geographies, sexualities were largely left off the geographical map.

While this collection is known more for its empirically rich case studies and less for
its advancement of sexuality theories, it did, however, open up new avenues for scholars to focus on queer spatial theories of desire.

While geographers have been slow to question taken-for-granted sexualities, some have been able to show the ways in which people unconsciously use heterosexuality to structure their lived everyday spaces, from bodies to homes to nations and beyond. This normalizing of heterosexual geographies is also incorporated into the canon of thought, which means that heteronormativity permeates the ways in which geographers research place and space. While some geographers have charted the ways in which heterosexism pervades the institutional practices of geography, others have focused on examining the creation of heterosexist scholarship. The turn to queer geographies is, in part, a reaction against heterosexist geographies but also an opportunity to form the subfield of sexuality and space alongside feminist geography. Queer geographies, in particular, have benefited from feminist geographers' critical engagement with gender and sexuality. Feminist geographers have been quick to question the authority assigned to science and “objective” claims of universal truth. For example, feminist geographers have used queer theories to upset the naturalness and legitimacy of global capitalism. Capitalism is often scripted as violently irrepressible, and as a discourse it gathers strength from heteronormative language and practice. Some geographers employ queer theories in order to deconstruct, and “de-phallic” globalization, by highlighting various points of excess, where inscriptions can be seen as uncontrollable or indeterminate, or as potentially inscribing noncapitalist identities (Gibson-Graham 1996).

The term “heteronormative” is a concept now widely used by geographers. The usage can be traced back to Judith Butler (1990, 2004). Geographers such as Hubbard (2012) have researched cities – their acts of planning, health reforms, and environmental modifications – to understand the ways in which regulations are heteronormative and, in turn, discipline and control diverse sexualities. Heteronormativity can be found within an array of geographies from the body to the globe. Language and images circulate globally and often represent maternal bodies and nuclear families. Geographers, taking up the notion of heteronormativity, argue that repetitive embodied performances of heterosexuality – that is, conforming to dominant gendered ideas of how to dress, talk, behave, and perform their embodied identity – make most heterosexual identities appear normal, even natural. This powerful, yet often invisible, performance means that bodies and spaces are mistaken as inherently heterosexual.

This is not to say that heterosexuality easily conflates with heteronormativity, and queer with homosexuality. Natalie Oswin (2008) offers a critical reading of the deployment of the notion of “queer space” in geography and highlights an alternative queer approach that is inseparable from feminist, materialist, postcolonial, and critical race theories. She notes that there is an important distinction between heterosexuality and heteronomativity, which frequently goes unnoticed and unacknowledged in queer geographies. When “queer” is understood to stand solely for LGBTI it forecloses possibilities of understanding the hierarchies of heterosexual privilege, and other identities that intersect with sexuality.

There has also been a great deal of discussion about homonormativity. Geographers have adopted this concept to show how certain performances of homosexuality incorporate the logic of heteronormativity. In other words, becoming a normative homosexual usually means gaining the privileges associated with neoliberal politics and practices that are aligned
Queer Geographies

with heterosexuality and class privileges of consumption (Ossein 2008). Such practices produce a new “homonormative” identity that gains popularity at the expense of radical performances of homosexuality. For example, the emergence of so-called acceptable and trendy gay public spheres is typically aligned with processes of neoliberal gentrification.

Globally, a new kind of normativity is emerging as countries around the world debate and reform marriage laws so that all people, regardless of gender or sexual orientation, have the right to marry and the right to adopt as a couple, if they so choose. These public debates focus on the ways in which state and religious institutions regulate normative sexualities (both hetero and homo). Geographers are adopting queer theories to argue against the privileging of married coupledom as the defining relationship by which access to social justice and forms of belonging are measured. Some debate that LGBTI rights are part of an assimilationist agenda in which the materiality of homo sex becomes rendered as less perverse, and less “scary.”

Hetero- and homonormativities are continually reproduced, and hence there is always the possibility that the norm will be reproduced in different ways. Many queer geographers examine the multiple ways in which genders and sexualities “fail” to be performed in the “correct” way. The potential of this “failure” is that new ways of queering the norm are brought into being. These “failures” also make obvious the normative frameworks that discipline gender, sex, and sexual acts.

There are many articles on queer geographies sprinkled throughout a variety of social, cultural, and feminist geography literature. This has led to studies of “the closet” (Brown 2000), which is used both as a metaphor and also as a spatial practice of power-knowledge that takes up the notion of spatial scale. The body, city, nation, and globe are spaces in which “the closet” is not always about disempowerment but can also be understood as a setting for creative and transformative sexual, social, cultural, and political resistances to heteronormativity.

Queer theories are applied to a number of different empirical geographical projects, including the pink economy; gay tourism; pride parades; bisexuality; sexuality in rural areas; sexuality and the cities; sexuality and citizenship; the globalization of sexuality; HIV and AIDS; and sexuality and ethnicity. The notion of deviancy and/or sexual marginalization is often the topic of queer geographies and queer methodologies, as well as gender transgressions (Browne, Lim, and Brown 2007).

This blossoming of queer geographies since the mid-2000s means that it is now an area taught in a number of undergraduate courses in countries such as the United Kingdom, United States, Canada, Australia, and New Zealand, and has succeeded in striking up conversations with a range of other subdisciplinary areas such as cultural and social geography, gender studies, migration studies, and tourism. Hence queer geographies is not a discrete intellectual field but one that has emerged through its relationships with other disciplinary areas.

Geographers are also considering a number of queer intersections. Sexuality and space studies have (and have not) intersected with other identities, such as gender, race, class, age, (dis)ability, and religion. There is a building consensus that if studies of sexualities and space are to be truly queer, then they cannot focus solely on sexuality, but that connections with other social identities must be considered. This kind of critique has been leveled at queer theories and queer activism.

So how has sexuality intersected with other identities to produce differently queered spaces? Most scholarship looks at the importance of place in bringing different identities together,
and less research has been done on the convergence of identities across spaces. One of the most researched intersections is sex, gender, and place (Johnston and Longhurst 2010). A number of geographers group together lesbians and gays as single populations, thus highlighting the importance of intersecting gender and sexual identities. Increasingly this scholarship speaks to the significance of lesbians and gay men at a variety of spatial scales, from bodies and homes to the nation.

After many cries for critical scholarship on heterosexuality and space, there are now publications that attend to the intersection of genders and heterosexual identities. Some have focused on the ways in which particular women may be disciplined and controlled in heteronormative and patriarchal ways, and attention to heterosexual men is a recent trend. Much of this work seeks to highlight the privileges and oppressions at the intersections of genders and sexualities.

Trans identities have added further complexity to the scholarship on gender and sexualities (Halberstam 2005). Recent studies by geographers have shown how transphobia and sexism are experienced by trans people in homonormative gay and lesbian spaces, and some have suggested alternative places where support and security can be found. This scholarship challenges any notions that gender is stable and, at the same time, illustrates the intersection of gender and sexuality, including the persistent “tyranny” of gendered spaces (Doan 2010). What is clear from this scholarship is the political urgency to continue questioning, challenging, and subverting the binary system of gendered and sexed spaces. Trans geographies is one way to do so.

Queer geographical scholarship may highlight the ways homonormative spaces can privilege whiteness and, as a consequence, are deeply racist. Attention too has turned to the prevailing whiteness of queer scholarship. There have been compelling accounts on American homonormativities after 9/11. Other researchers have shown how homophobic discourses are put into operation in order to seek ethnic and national purity by, for example, reproducing narratives of Irishness (and attempting to exclude LGBTI performances) at St Patrick’s Day parades in New York City and in forming national closets.

Class and sexuality is another fruitful intersection that is receiving more attention in queer geographies. This approach can be summarized into three themes: the classing of epistemology and methodology within sexuality studies; the relationship between culture and the economy in framing research on class and sexuality; and the significance of space, place, and intersectionality. Privilege and oppression can be illuminated when considering the intersections of class positions, gender, and sexed identities. Some scholars delve deeply into class divisions of lesbian identity and spaces. The consideration of classed identities fractures the notion of collective lesbian identities, both emotionally and materially. Others have highlighted the class privileges that align with homonormative gay men and lesbian spaces and identities. The confluence of poor, working-class, and heterosexual has also been considered in Vancouver (Boyd 2010); Butte, Montana (Dando 2009); and Nepal (Richardson, Poudel, and Laurie 2009).

Work on sexuality, space, and age is another intersection of identities that is beginning to gain prominence. There are accounts of the way in which heterosexual patriarchal discourses in Vietnam work to control young women (Rydstrom 2006). Bringing together race, sexuality, age, and education, one study, for example, considers the space of a high school campus for Latina, Armenian, Filipina, African American, and Anglo girls. This research shows that, while the girls use the “everyone just wants to get along” discourse, they also perform racism and
QUEER GEOGRAPHIES

uphold spatial segregation (Thomas 2011). Gay, lesbian, and bisexual youth are the focus of an Australian family home study (Gorman-Murray 2008).

There are important connections between disabilities and queer sexualities. Geographers have studied the way in which non-normative sexualities have been categorized as illness or disease, and some studies highlight the challenges that disabled bodies pose to hetero- and homonormativities. Consequently researchers have started to investigate the association of physical ableism with hegemonic notions of beauty and sexuality. Underpinning this research is a critique of embodied normativities, yet much more work is needed in this area.

Queer trouble

While queer geography has troubled normative understandings of genders and sexualities, it must be remembered that queer theory has its origins in US university humanities programs. This point is important because the set of (Americanized) ideas comes out of a place with a particular history within a so-called developed Western nation. Hence, queer theory not only causes trouble, but needs to be troubled itself. Geographers are well placed to consider the spatiality of queer epistemology. In other words, adopting the word “queer” may be appropriate in some spaces and places but inappropriate in others. Similarly, the use of the term “queer” as synonymous for gay, lesbian, or other identities is troubling because it collapses cultural nuances and eliminates the diversity of sexualities beyond “developed” Western countries.

Another trouble with queer is the way in which identity categories are brought into question. Political organizing and activism often rests on identity categories – such as LGBTI – in order to gain rights and be “equal” with individuals and groups that have societal privileges (e.g., men and heterosexuals). Queer theory calls into questions all categories and normative identities, which in turn undermines the basis of identity politics. The deconstruction of identities such as “lesbian,” “gay,” “woman,” and so on means an erosion of the platform from which to argue for social justice. Queer theorists have been accused of throwing the baby out with the bathwater; when identity categories cannot form the basis of political action, the power of collective action is lost. Queer, for some, may be too fragmenting when basic human rights are on the agenda.

A number of feminists have argued that queer erases gendered differences when considering sex and sexuality. Furthermore, the term “queer” – for lesbian feminists – may mean that women become invisible as it collapses differences between gay men, lesbians, bisexual women, bisexual men, and so on. Others assert that using the broad term “queer,” rather than the gender-specific term “lesbian,” is similar to the use of “man” to refer to humans. In other words, women once again disappear under a universalizing signifier. When “queer” encompasses too much, it is rendered of little use.

There is also concern that the deconstruction of categories such as “woman” means that any empowerment associated with that category is undermined. Feminist scholars argue that categories of women are necessary for collective action and collaboration due to the persistent nature of patriarchy and gendered inequalities. Similarly, queer approaches to lesbian and gay identities may weaken the political power of already disenfranchised groups. Many of these scholars recognize that identity categories are not homogeneous, yet need to be enacted to affect legislative, social, or cultural change. This type of strategic essentialism sits awkwardly beside queer theory, yet many scholars work back and forth between the two theoretical positions.
Some geographers ask if queer theory – with its beginnings in the humanities – has any relevance to “real” places and people. For feminist, lesbian, gay, and trans geographers concerned with power relations and challenging inequalities, queer theory may seem too removed from people’s day-to-day struggles. When politicized identities are deconstructed, fragmented, and fractured, it becomes difficult to critique gendered and sexualized harassment, abuse, and violence. Yet, living struggles accelerate changes in language, and language evolves and reforms into new expressions.

The final trouble with queer theory is that it is often considered elitist and exclusionary because of its focus on language, concepts, and ideas. Many of the concepts are not translated into accessible language. Further, queer theory tends to be employed to critique embodied normalizations, with very little focus on empowerment of those who are marginalized by normalizations. The advancement, however, of concepts, ideas, and constructions of identities, and the dismantling of normalizations are powerful ways in which to critique geography’s hegemonies.

Conclusion

Contestation surrounds queer theory and queer geographies. “Queer” is a highly contestable term which, used too frequently, normalizes identities. “Queer” can be used as a term which collapses a range of sexual and gendered identities; it also contests the formation of identity categories. Feminists and sexuality scholars have used queer theory to contest the naturalization of binaries such as heterosexual/homosexual, male/female. At its core, queer theory is anti-normative and thereby contests all assumptions that gendered and sexual identities are fixed, coherent, or stable. Queer theory is a powerful tool used to question hegemonies and hierarchies within and between sexual subjects. The strength of queer theory is its reach into all normalizing practices, including within LGBTI communities.

Geographers have adopted queer theory in order to challenge the aspatiality of identity categories as well as to question the globalization of rights from the West and their application across different nations. Geographers are well placed to consider the performativity of both place and bodies. Queer theory allows geographers to understand not only how place is normatively gendered and sexualized, but also how place sexualizes and genders bodies. Queering geography further has, for some, meant understanding bodies and places at the intersection of multiple identities.

For geographers who are committed to engagement with disenfranchised and marginalized groups, adopting queer theories may be a controversial choice. When identity categories are called into question, so too are civil rights and the ability to organize collectively to fight against patriarchy, homophobia, and transphobia. This is contested, as many queer geographers work from feminist, postcolonial, and antiracist positions. Queer theory has had a major impact on geographers as they work through analyses of social, cultural, and institutional practices and discourses that are productive of gendered and sexual knowledges, subjects, spaces, and places.

QUEER GEOGRAPHIES

Race and racism

Audrey Kobayashi
Queen’s University, Canada

The concept of race as a means of sorting and segregating human beings is ancient, but its modern manifestation, as a means of sorting bodies according to their putative abilities based on phenotypical or genotypical differences, dates to the time of European ocean exploration, starting in the fifteenth century, when the quest to classify bodies based on skin color was folded into the colonial/imperial project, with ramifications for global economic power, the transfer of resources to Europe, and the contest for global geopolitical power. Notwithstanding interaction between Europe and Africa since at least the twelfth century, the contest to control the globe from the so-called age of exploration until the so-called Enlightenment of the eighteenth century involved not only mapping and documenting the globe, but also the active formulation of racial difference in both scientific and popular ideas. Immanuel Kant, who began teaching “physical geography” at the University of Königsberg during the 1750s, lectured on the classification of the human species, a topic that was of immense controversy among scientists at that time. His novel but fundamentally racist theories were based on an attempt to understand the differences between so-called races. He postulated a relationship between skin color and distance from the equator, and believed that those born in Africa are originally white, but become black as the sun interacts with capillaries under the skin, affecting not only their color but also their capacity for intelligence (Kant 1997/1775).

Race is a product of racism, and it is deployed through a process of racialization. Over the next 200 years, both popular and scientific understanding of racial difference advanced to create an overwhelming Eurocentric assumption of the supremacy of the white “race.” The global division of labor was heavily racialized as well as classed, structured to include plantations dependent on slavery from Africa and indentured labor from Asia, as well as labor in situ, for example to work the mines, clear the forests, and build the railways in colonized areas of the world. The forced movement of millions of people around the world resulted in new population geographies, while scientists continued their work of classification, with climate playing a major role in explaining racial differences. By the time Darwin presented his work on human evolution during the mid-nineteenth century, many scholars were prepared to adopt a historical explanation of differential rates of human evolution, while others clung to a polygenetic view of races as independent from one another. Both monogenetic and polygenetic views, however, saw race as a fundamental differentiator of human qualities, including intelligence and capacity for civilization, in what David Livingstone (1991) has termed a “moral discourse” that tangled geography, anthropology, and esteemed groups such as the London Geographical Society.

By the early twentieth century, environmentalism was the dominant paradigm in geography. Geographers produced global maps of racial categories, often associated with putative climatic influences. Such ideas were widely diffused in school textbooks throughout the world.
Ellsworth Huntington (1876–1947), perhaps the most adamant adherent of environmental determinism, wrote many articles and books linking climate and civilization (e.g., Huntington 1924), in which people of the tropics, especially, are depicted as lazy, dishonest, or immoral. Ellen Churchill Semple (1863–1932), influenced by the ideas of Friedrich Ratzel (1844–1904) while she was a student in Leipzig, Germany, is generally depicted in the literature as an environmentalist. Her efforts were directed to understanding how human beings have adapted to and modified the physical environment, however, and not to race itself as an explanatory factor. To the extent that she used the term, it was in reference to groups of people identified with a particular region, and she did not address questions of variations within regions. Indeed, Semple acted as an adviser to President Woodrow Wilson, himself no defender of racial equality, during the post-World War I peace talks. She advocated that the ethnic qualities of national populations be taken into consideration when redrawing European boundaries (Silver 1984).

As debates over environmentalism developed, various countertheories were forwarded, including the belief that, while climate is not the determinant of racial variation, human beings fall into naturally different categories, with naturally different characteristics, in different regions of the Earth. The challenges to environmentalism were many, however, and increased throughout the twentieth century, although in the discipline of geography such challenges were not directly linked to understanding, or opposing, the concept of race. The American geographer Carl Sauer (1889–1975) was perhaps the most vocal – or at least the most cited and listened to – advocate of rejecting environmentalism. Sauer rejected Huntington’s work, as well as that of German scholars such as Ratzel who had informed Huntington. Sauer was deeply influenced, however, by other German scholars such as Franz Boas, whose understanding of cultural processes informed a generation of anthropologists. Sauer did not, however, challenge the assumption of racial differences; rather, he advocated that it was culture rather than race itself that explained variations in human practices in different places. Urged by Sauer and an increasing number of other voices, geographers by and large abolished environmentalism from their analytical lexicon. It has been speculated that so strong was the push to distance the discipline from environmentalist influences that post-World War II geographers seem to have had little taste for any speculation about race. Geographical scholarship was therefore not a part of scholarly discussions that emerged in other disciplines, especially anthropology, challenging the idea of race. Geographers did not take the opportunity, at least in the pages of their scholarly journals, to make clear links between environmentalism and racism.

In Germany, there is no doubt that the determinist ideas of geographers such as Friedrich Ratzel, linking putative racial qualities and the power of the state, had an influence on Nazi ideology. If the same connections had been made with the work of avowedly racist determinists such as Huntington in America, or even of Halford Mackinder in the United Kingdom, the Nazi ideology would have found even more support. On the other hand, Walter Christaller (1893–1969), another German geographer who had published a treatise on the distribution of urban centers according to what he called “central place theory,” in which race did not play even the smallest role, was hired by the Nazi administration during World War II to develop his rational ideas as a basis for planning the repopulation of areas purged of Jews, Roma, and others of a non-Aryan background. His work was later taken up by geographers everywhere as one of the most
important contributions to modern urban geography. In hindsight, the widely different ways in which Christaller’s work was taken up illustrates that scholarly ideas are invoked within particular contexts. It is perilous to make simplistic connections between racist ideas and geopolitical acts. A much more complex understanding is needed of the ways in which ideas are understood, lived, used, challenged, modified, and deployed.

Ashley Montagu (1905–1999), an American anthropologist, published just such a complex analysis in *Man’s Most Dangerous Myth: The Fallacy of Race* (1997/1945). He then became part of a United Nations commission that in 1950 brought together a group of scientists to study the “race question,” who arrived at the definitive opinion that there is no scientific basis for differentiating human beings on the basis of race, a finding that was published by UNESCO in a series of papers during the 1950s. Montagu’s influential text was republished in several editions, the last in 1997. But he was a person before his time; he was denied tenure at Rutgers in 1955 at a time when his ideas were still controversial, notwithstanding the findings of the United Nations in the aftermath of World War II.

A history of the concept of race is more than simply a description of how ideas emerged. It is also an accounting of how the past and the present are interconnected (how past ideas condition and are challenged by present ideas) and also how past silences and omissions are imbricated in present understanding (how silence emerges as the contrapuntal interval of the spoken). Scholarship is in many ways a dialectic of the spoken and the unspoken. By the 1940s, the attention of the entire world was focused on questions of racism. It would take some time before the shock of what had been done in the name of anti-Semitism would resonate in the Civil Rights Movement, but a decade after the war, in 1955, the Montgomery bus boycott in Alabama provided an opening event that would lead over the next decade to a surge in public support for the concept of racial equality. One of the main organizers of the boycott was Thelma Glass (1916–2012), a geographer at the University of Alabama. Notwithstanding her efforts, and doubtless the efforts of many more geographers who may have been involved in the events of the time, the geographical literature remained curiously silent about race and racism.

Also notwithstanding these developments, the uncritical and biologically determinist assumption of racial difference continued to inform the discipline, especially in urban geography. This subdiscipline owed much to work by members of the Chicago School of the 1920s and 1930s, and especially to sociologist Robert Park (1864–1944) and his colleagues, who mapped the spatial patterns of the city according to race and ethnicity. Based on concepts of both urban ecology and an urban moral order, Park believed that, much like plants, groups of people complete for space across the city and engage in activities akin to ecological invasion and succession, thus traveling through the city’s residential areas from the center to the periphery as their circumstances improve and their housing options increase. Park believed that urban residential location depended on a racialized science of space from which African Americans were excepted because their moral order prevented them from engaging in this process (Kobayashi 2014). When urban geographers took up Park’s ideas decades later, they ignored his writings on moral order and concentrated only on his theories of space. But they nonetheless mapped and analyzed a racial spatial order, with no indication that they challenged the fundamental assumption that races exist as given.

It is indicative of the academic politics of the time that geographers and other social scientists were drawn to Robert Park and the prestigious
Chicago School rather than to the African American scholars of the time. Park had, in fact, worked with Booker T. Washington, of the Tuskegee Institute, who was well known for believing that the circumstances of African Americans could be understood only as a result of their own cultural capacity, a view that Park shared. At the same time, Park clashed publicly with the African American scholar W.E.B. Du Bois (1868–1963), a graduate of Harvard, who had a very different view. Among his many books and articles addressing what he called the “double consciousness of blackness,” which he depicted as the struggle to remove the color line that separated black and white in America, Du Bois (1967/1899) created maps of ghettoized poverty in Philadelphia based on an 1899 study that reached beyond its times in every respect. Du Bois was very clear that race is a concept invented in order to create the color line, and he was uncannily prescient about the ideas that would develop among geographers more than a century later.

During the 1960s, however, many urban geographers were bent on elevating the science of space as the mainstay of the discipline. They paid little attention to Park’s ideas of race or moral difference, but they leaned heavily on his idea of spatial science to create a new version of urban ecology based on spatial models (e.g., Berry and Kasarda). With the power of new methods of computing, extensive datasets, and sophisticated survey methods, geographers mapped residential segregation to show that, in particular, blacks lived in residentially segregated areas of the city, and that those areas by and large coincided with segregated poverty. Such quantitative analyses paved the way for a small number of geographers who by the 1970s had made a link between spatial patterns and racism (Morrill 1965; Rose 1970). While using the same techniques of mapping, these geographers focused on racism as a form of human behavior, and as such were among the first to question deterministic racial understanding.

Also during the 1960s, a small number of radical geographers Radical geography pushed the discipline to become more socially relevant. Their work was informed by the Civil Rights Movement, as well as by the antiwar movement and (later) second-wave feminism, but their major focus was on class and on the link between capitalism and space. The journal Antipode featured a spirited discussion of race and residential segregation during the late 1960s – probably the most attention the topic had ever received in the discipline – but such discussion was soon eclipsed by other issues. One exception was James Blaut (1927–2000), for whom racism was a product of imperialism. He wrote: “Imperialism … is white exploitation of the non-white world, a plague that began some 500 years ago on the West African coast and spread across the globe” (Blaut 1970, 65). Another exception was William Bunge, who undertook controversial “expeditions” into North American inner cities, working directly with African Americans and others to map poverty (Bunge 1971). But these are the rare examples of white male geographers who have made a difference in bringing the issue of racism to the attention of the discipline.

Racialized geographers at the time were few in number, but they were actively involved in the Civil Rights Movement, albeit under the radar of most of the discipline. Thelma Glass, mentioned earlier, took her work off campus as a member of the Women’s Political Council, the group that organized the Montgomery bus boycott in 1955 and supported Rosa Parks a year later in the Supreme Court case that led to the abolition of legal segregation (George and Monk 2004), but she received no recognition in the discipline until decades later. Others noticed the structural racism of geography itself, and advocated
for social justice within the discipline. At the behest of Saul Cohen, then executive director of the AAG, Donald Deskins became the first organizer of the Commission on Geography and Afro-America (COMGA), an effort to increase the number of “minority” students in graduate programs in US Geography departments (AAG Diversity Task Force 2006). Deskins also compiled a bibliography of geographical scholarship on race, comprising a list of overwhelmingly white, male scholars who wrote primarily about either migration or residential spatial patterns (Deskins 1969).

Notwithstanding these attempts to address and overcome racism, it was not until the 1990s that geographers began a theoretical challenge to the concept of race itself. That challenge was inspired by and had its roots in the Pan-African movement that began after World War I, and by poststructuralist ideas that emerged from it, particularly in France, after World War II. After World War I, it was none other than W.E.B. Du Bois who emerged as a leader of the Pan-African movement, after he attended the Paris Peace Conference of 1919. The movement then consisted of a loose-knit group of black activist intellectuals who met at various places. Post-World War II Paris was a place where a new generation of Pan-Africanists congregated: individuals such as Léopold Sédar Senghor, future Senegalese president; the poet Aimé Césaire; the Congolese independence leader Patrice Lumumba; the Ghanian Léon Damas; and Frantz Fanon, a medical student born in Martinique – as well as a small number of European scholars, most notably Jean-Paul Sartre, in whose apartment the group convened. This movement provided much of the intellectual (and in some cases actual, on-the-ground) support especially for French decolonialism over the next several decades. Their work also profoundly influenced the development of postcolonial studies (see Gilroy 1992; Kobayashi and Boyle 2014).

In geography, the genealogy of antiracist scholarship has two clear lineages. First, James Blaut’s (1993) work on the destabilizing role of colonialist racism in developing countries drew explicitly on the Pan-African movement, and profoundly influenced a generation of geographers to address the international context of racialization. Second, geographers trained in the tradition of ethnic residential segregation, particularly those who studied under Oxford geographer Ceri Peach – such as David Ley, Susan Smith, and Peter Jackson – shifted their focus from studying race to studying racism. Peter Jackson’s (1987) edited collection on Race and Racism was the first expression, especially in social geography, of race as a socially constructed category, and of the recursive relationship between race and racism. Jackson’s work was strongly influenced by that of British sociologist Robert Miles, whose work is a direct translation of that of Colette Guillaumin, a French antiracist, feminist theorist who had also been a member of the UNESCO panel convened by Ashley Montagu. Although these two strands of antiracist thought in geography did not intertwine much at the time, they were both tied firmly to poststructuralism. Geographers have been strongly engaged with that tradition ever since, influenced by the work of postcolonial scholars such as Frantz Fanon, Stuart Hall, and Paul Gilroy, to name a few.

The influence of poststructuralist thinking on geographical approaches to race and racism has been profound. In simple terms, it acknowledges that race is a human invention, albeit one with a long and complex history and geography; perhaps the most powerful concept ever used to sort human beings, positioning them in specific ways, and with specific worth, in the flow of Colonialism, decolonization, and neocolonialism, globalization, urbanization, and geopolitics.
Poststructuralism is based on the principle of anti-essentialism – that human bodies become racialized, through powerful discursive processes of racialization – laying to rest any notions of race as a predetermined, primordial, or precognitive category. This is not to say, as has often been said, that race is not real; the reality is the powerful production of race and the lived conditions of racism that result. Race may be a pernicious concept, but it is not an abstract one.

The importance of anti-essentialist definitions of race (like that of gender) cannot be understated. It is often remarked that race is only socially constructed or only a concept, as though Montagu’s most dangerous myth could be made to disappear by exposing its roots in the human imagination. But anti-essentialism needs to be understood dialectically as the discursive relationship between people and their environment (including other people), mediated by the production of concepts that are not, in themselves, free-floating signifiers. In other words, reality is socially constructed. Reality is the discursive relationship from which ideas cannot be extracted or abstracted, not something that is underlain, structured, or created by some other – more material – something. As a relationship, racialization is also recursive: it involves the dialectical construction of the self and other. This point is made by a number of poststructuralist scholars, particularly Frantz Fanon who wrote at length about the ways in which blackness is constituted by whiteness but acts back to constitute both the black and the white. Fanon was inspired by the dialectics of Jean-Paul Sartre, whose work is particularly compelling for geographers because of his insistence on the importance of situation as a recursive relationship, which he called “spatializing–spatialized” but which also might be understood as “racializing–racialized” (Kobayashi and Boyle 2014).

The process of racialization – and its product, race – is therefore a thoroughly material production (it involves, for example, labor markets, housing markets, and so on), and it is this very materiality that affords race its ontological status. Understanding its ontological status has shifted, however, from debates about what race is (recalling Enlightenment period debates about how many races there are, or what physical attributes mark particular races), to how it has been constructed and deployed in the world, in the creation of specific landscapes that are the Habitus, that is both the dwelling and the doing, of human beings. Race is thus, in simple terms, contextual.

If the process of racialization is contextual, it always occurs in place. This point more than any other has energized a new generation of geographers to take up the study of how the modern world is racialized in specific places or by connecting specific places. The production of racialized places is also deeply political, but racist geopolitics too need to be understood as permeating every aspect of humanity (McKittrick and Woods 2007). For if race is not a given, nor simply an expression of some external science of space, then it follows that geographers should study the process of racialization, the effects of racism, according to actual conditions in places and in reference to the ways in which race is embodied in place, which is pretty much what has happened since the 1990s.

Urban geographers still map the consequences of racialization, often in very useful ways and using the power of new spatial technologies, but they are more concerned with how racializations shift and change in context. The world is now more urbanized than it has ever been. Cities are not only larger but often much more multicultural. International migration occurs at a higher rate than ever before, and there are more refugees fleeing a range of circumstances including war,
environmental disasters, poverty, and oppression. The major movements of people occur both intranationally as people move from more rural to more urban areas, and internationally, where the movement still tends to be from the developing to the developed world. Many of the destinations are settler societies (the United States, Canada, Australia) where colonial patterns remain to condition the lives of newcomers. Many destinations are also to traditional colonizer societies (Germany, the United Kingdom), where difference breaks on a hard core of established national identities. The cities that have the highest levels of recent migration (e.g., Los Angeles, Toronto, Miami, Amsterdam, London, Sydney, Dubai) have the greatest potential to shift popular understanding of what constitutes difference, but they also have the potential to create new forms of residential segregation. One of the ironies of shifting population over the decades since decolonization is that the other is no longer at a distance, but in many places now lives in the metropole, in closer proximity not only to the colonizer but also to other groups of the colonized, with the potential to construct new hierarchies of difference.

But, if cities are changing as a result of recent processes of decolonization, globalization, and urbanization, they are also the result of long historical geographies of racialization, especially as a result of slavery and indentured labor. The urban map of the United States, for example, needs to be read through several epochal movements: the creation of plantation societies based on slavery; the post-Civil War Great Migration to the industrializing North; the devastating effects of deindustrialization and more recent financial crises. All of these processes are shot through with racialized violence that continues today in encounters between racialized youth and urban police forces, in the violence of the prison industrial complex (Gilmore 2007), and in racialized poverty, to name some of the most significant.

If race is socially constructed, then so too is whiteness, and an increasing number of geographers have undertaken Whiteness studies to show that black and white represent a dialectical relationship, two sides of a single disc, one constituting the other. Whiteness studies in geography have unveiled racialization as enacted, spatially and temporally, in the most pervasive of moral, ethical, emotional identity formations that create and sustain difference (e.g., Jackson 1998; Bonnett 2000; Saldanha 2007). Recently Bonds and Inwood (2015) have emphasized the extent to which white privilege is embedded not only in personal relations but also in the state projects that constitute colonialism, as important now as ever. The sociospatial dialectic, they note, how land use practices and histories connect to the legacies and permanence of these structures and to the development of new understandings of the ways in which genocide, land appropriation, and labor exploitation are tied to white supremacy and other structures of oppression. (Bonds and Inwood 2015, 15)

The dialectic of racialization also intersects with other identity-forming discourses in a complex world. Intersectionality varies spatially and temporally, even as one moves through one’s day from one place to another, and it may be contradictory. Geographers seek understanding of landscapes of contradiction along lines of gender, ethnicity, age, religion, or class (Dwyer and Bressey 2008). For example, the way that gender identity is constructed changes not only according to the context in which it is enacted or performed, but also in the course of an event. Similarly, racialized sexual identity is a precarious situation subject to cultural change. Nayak (2003) demonstrates that racism and antiracism are both place- and age-specific, and intersect with whiteness.
Recognition of intersectionality has been a particularly powerful mode of thinking on the part of antiracist, feminist geographers such as Ruth Gilmore, Minelle Mahtani, Patricia Noxolo, Linda Peake, and increasing numbers of others, whose work spans international contexts to show the many and specific ways in which feminists cannot afford to ignore the often different conditions in which gender is constructed. This work collectively emphasizes the importance of understanding the human body as racialized and gendered and classed and differently abled, in ways that shift according to place and context.

Geographers also face a major challenge in their continuing dialogue with the biological sciences. The biologist Stephen J. Gould warned decades ago about the problem of the “mis-measure of man [sic],” of assuming that the study of genetic traits could somehow be hived off from human social history. Preconceived notions of genetic traits as somehow bundled into races have influenced scientists to ignore the fact that the very concept of race is socially constructed. The exciting scientific work of the Human Genome Project has led to many advancements in understanding human bodies and their interrelatedness, and provides plenty of evidence that such bundles are a mismeasure. Yet, ironically, as scientists discover more about genetics, social scientists need to work just as hard to deconstruct the racialized concepts that tend to be reinserted into genetic science. As Catherine Nash (2015) shows, notions of sex, nation, and identity are easily remapped onto genetic patterns, reinforcing old ideas in new packaging.

Such remapping can even lead to new forms of environmentalism. Recent emphases, for example, on the “Anthropocene,” as the period in which humans have had the greatest impact on the surface of the Earth, allows for a comprehensive, and potentially dialectical, thinking about geography. But physical scientists studying human impact, which may be read as a reaction to “nature,” are not trained to study human experience (and vice versa for social scientists); there is a risk of the insertion of popular notions of genetic adaptability that reracialize encounters not only with the Earth itself but also between humans. Similarly, recent attention to the “more than human” that has swept human geography, while giving due significance to the fact that the Earth is not only human, also risks reducing the human to just one of the many actors that have agency, or to bundles of putatively natural traits abstracted from their geosocial context. Here, too, geographers need to exercise not only caution over reinforcing deterministic assumptions, but also careful analysis of the ontological status of their subjects, for most of the more-than-human scholarship to date tends to homogenize the human, ignoring the significance of racialization in mediating human actions.

A similar ontological risk occurs with the implementation of Nonrepresentational theory (NRT) in geography, intended to move beyond fixed images and texts to recognize the flowing and often ephemeral qualities of human experience, including the production of affect that cannot be essentialized. A number of geographers have suggested that “more than representational” is a more appropriate term (see Lorimer 2005) in order not to lose sight of the fact that, on the one hand, all bodily performance is representative; it occurs in structured discursive contexts. On the other hand, even the hardest, most fixed of representations, say a marble statue in a public place, is always in flux, drawn dialectically into the flow of representation that never stops, that shifts with the viewer, with the geopolitical context, with the constant process of interpretation. Perhaps, when it comes to racialization, it is better to talk about how different forms of representation, including
their material consequences (of course all forms of representation, even ephemeral gestures, are material), their durability, their structural legibility, and especially their power endowed by their enactment, put in place racialized consequences.

It is ironic that, notwithstanding the vast amount of scientific evidence that shows race to be nonscientific, coupled with the vast and increasing amount of social science evidence of the ways in which the idea of race has been constructed and is used to organize the world in powerful ways, race remains one of the most dominant but least understood ideas in today’s world. W.E.B. Du Bois named the color line as the greatest problem of the twentieth century. Ashley Montagu named race as humanity’s most dangerous myth. Decades of critical race studies, and the evidence that antiracist geographers can see in the landscapes that surround them, have shown both scholars to be remarkably, and unfortunately, prescient. Bodies become themselves over time in complex ways, and the process of racialization represents a – and arguably the – dominant mode of becoming in the contemporary world. Geographical studies of race and racism have always been a reflection of their historico-geographical times, but too often they have been caught up in the dominant discourses of those times. Recent scholarship, however, provides a means of challenging dominant discourses in order to shift these most powerful of human creations in the direction of more just and democratic futures. Geographers have the ability to play a significant role in that project.

Race, work, and employment

Beverley Mullings
Queen’s University, Canada

The nineteenth-century expansion of industrial capitalism is often the starting point of analyses of the relationship between race, work, and employment, but race and racial ideologies played a defining role in the division of labor as early as the fifteenth century, when an integrated capitalist world system began to emerge. The practice of race-making – assigning social meaning to specific physical traits in order to differentiate, separate, and exercise control over particular groups of humans – is as old as the history of humankind itself, but after the fifteenth century it became inextricable from the social, economic, and political forces that converged to support European colonial expansion.

The emergence of plantation modes of production based on slave labor marked a crucial period in the evolution of social relations and institutional practices that constructed racial categories in order to differentially value the work of particular laboring bodies. By dividing groups of humans into races based on beliefs about the traits, abilities, and qualities that each group shared, and conferring unequal privileges on them accordingly, this early form of capitalism established a global division of labor, and ways of thinking about labor rights, freedoms, and responsibilities that remain even today.

While liberal political economy scholars like Adam Smith (1993/1776) and John Stuart Mill (1848) had little to say about the relationship between race, work, and employment, their views on the relationship between unfree labor and capitalist expansion reflected the dominant racial ideologies of their time. Smith and Mill both viewed unfree labor as distinctly incompatible with a fully functioning and efficient capitalist system. They believed that societies that relied on unfree labor were unlikely to embrace technologies that would boost labor productivity and consequently market expansion. Thus plantation economies dependent on enslaved labor ultimately stifled capitalist expansion because slave owners were unlikely to invest in labor-saving technologies for fear of losses they would incur if they were not to maximize use of their human commodities. Implicit in Adam Smith’s theorizing was also the assumption that economies dependent on enslaved labor could not be efficient because the unfree were unlikely to work hard. He reasoned that where labor was unfree, workers derived no benefit from hard work or from the acquisition of skills associated with innovation. He therefore viewed unfree labor as inefficient and antithetical to the success of capitalist systems of accumulation because of the dampening effect that lack of freedom had on labor productivity.

It is only recently that scholars have begun to question Smith’s claims and the role that racial ideologies played in his characterization of slave labor. For example, Smith claimed that all the most important improvements, whether in machinery or in the arrangement and distribution of work that facilitate labor, were the discoveries of freedmen. Yet, historian Veront Satchell (2010) documented that many of the patents for innovations in Jamaica’s sugar mills between 1760 and 1830 were the inspiration of artisanal
slaves who worked within them. Examining the relationship between race thinking and the value of labor, Brass (2009) also argues that, although Smith never explicitly included slaves in the category of unproductive labor, his views on the relationship between unfreedom and idleness were already racially coded. In this respect, Smith’s inferences reflected views that were popularly held by scholars during the Enlightenment period, even before scientific forms of racism became fully embedded in social practice. Like Immanuel Kant, who viewed African and other racialized peoples as naturally inferior to whites, or David Hume, who reportedly declared there to be no free Negroes who had distinguished themselves with any particular skill, assumptions about the inefficiency of unfree labor were reflections of dominant racial ideologies that constructed the enslaved as predisposed to idleness in order to justify the forms of violence and superexploitation that they experienced.

The belief that racialized labor was synonymous with inferior labor can be traced to the influence of the philosopher Immanuel Kant, who believed that climate triggered permanent, irreversible, and heritable deviations that gave rise to the biological differences and traits that produced races. Thus Kant claimed: “A race, when once it has taken root and extinguished the other seeds, resists all further transformation because the character of race at one point became dominant in the generative power” (Kant, quoted in Larrimore 2009, 15). Bernasconi (2011) alludes to the extent to which the circulating ideas about race, of which Kant was a key progenitor, traveled through time and space. While Kant argued that the enslaved Africans in the Americas could not innovate and that progress through work was a permanent and inherited condition, he tended to support his views with deliberately sourced writings that cast black peoples in a negative light. Drawing on the writings of pro-slavery writers like James Tobin, who is believed to have claimed that, even when freed blacks were encountered in Britain or America, there was no instance where anyone pursued an occupation that could really be called work, Kant’s formulations on race set in motion a way of thinking about racialized bodies in relation to work that continues to be influential even today (see Bernasconi 2002).

Today the idea that unfree workers are inefficient because they lacked an incentive to work hard is recognized as an ideological fiction which, combined with emerging scientific constructions of race in the eighteenth century, served to justify the oppressions of European imperial expansion. But the link between race and human capacities, dispositions, and entitlements to work continues to haunt the discourses and practices that produce inequalities in work and employment.

**Geographical knowledge, race science, and labor market discrimination**

The geographical imagination played an important role in legitimating imperialism and the forms of knowledge about race and work that it produced. As a discipline, geography was widely regarded as the science of empire because of the rigorous way in which it produced detailed generalized accounts of the Earth and its peoples that were indispensable to imperial efforts to conquer and govern others. Geography offered a knowledge of the world that made it possible for the knower to pragmatically engage it. For example, geography’s development of mapping techniques to spatially delineate human environmental interactions within and between specific places functioned as a technology that provided colonizing powers with detailed knowledge of the overseas territories that they had acquired. Particularly with regard to its production of knowledge about the relationship between
climate, environment, and race, geography provided the theoretical frameworks needed to
dignify, as Said (1978) once observed, Europe’s
desire to appropriate geographic space. The ide-
oologies of white supremacy and imperial control
that geographers helped construct created what
Blaut (1993) described as the “colonizer’s model
of the world,” a model that supported a diffu-
sionist view of history that placed Europe and
Europeans at the center of all that represented
progress and modernity.

In the late 1800s, reflecting to the rapid
expansion of European colonialism, geographers
revived and extended many of the ideas about
race and human character that Kant had explored
over 100 years earlier. Geographers like Semple
(1911) and Huntington (1943) saw the biophys-
ical environment as playing an instrumental role
in shaping the psychological mindset of indi-
viduals, their behavior, and the attributes of the
societies they formed. Those in tropical climates
were given to laziness, relaxed attitudes, and
promiscuity, while groups in environments with
greater climatic variability were more deter-
mined and were driven by a strong work ethic.

By the early twentieth century, the popularity
of environmental determinist theories in geog-
raphy helped to establish the natural superiority
of those racialized as white to colonized others,
and consequently their “obligation” and special
capacity to govern them. Thus, even in the
1940s in the United States, when the Southern
states could no longer command the levels of
agricultural capital that they once had because of
crop disease and emigration, scholars continued
to draw on discourses of black incompetence and
lack of commitment to explain the crises within
these labor landscapes. Thus, as geographer J.S.
Gibson (1941) lamented, part of the reason for
the decline of Alabama’s agricultural belt, could
be attributed to the inability of its remaining
black population to facilitate change. For, as
he observed, lacking good judgment, a sense
of thrift, and a feeling of responsibility, black
farmers rarely attempted cattle raising on any
appreciable scale and, when working for others,
required close supervision.

While the ideas underpinning environment-
tal determinism were heavily critiqued and
eventually discredited, the belief in biological
races with sociopsychological characteristics that
reflected the environments within which they
held ancestral affiliations, remained an enduring
rationale for the systems of labor management
that emerged under colonial rule and persisted
until the 1960s. Roediger and Esch (2012)
document the way that labor management in
the United States at the turn of the twentieth
century drew on racial ideologies in order to play
one racialized group of workers against another.
They argue that the “racial” knowledge that
many slave masters and overseers claimed to have
quickly transformed into a set of discourses and
practices that linked whiteness to management.
They contend that it relied on divisions and
competition between racial groups, as well as
the duty to uplift racial others, as its primary
governing technologies. Similar racial ideologies
also existed across the British empire, providing
a justification for the forms of labor market
discrimination that became a part of standard
employment practice up until the 1960s. The
idea that racialized workers should never be
treated equally within labor markets, however,
masked the material nature of labor oppression
that ultimately drove down the overall value of
all workers by keeping wage floors low.

By the end of the nineteenth century, the idea
that the world could be divided into regions,
each populated by homogeneous racial groups
with particular temperaments and capacities to
work, no longer characterized the everyday labor
landscapes in which people worked. Migration,
war, and, importantly, the abolition of slavery
and indentureship brought ethnic groups into contact with each other in ways that had not been experienced before. In the United States, for example, the construction of the Transcontinental Railroad in the late 1800s provides a strong example of the way the strategy of racial competition was used to generate a workforce to undertake the grueling task of railroad construction at the lowest possible cost. Early efforts to generate a white labor force to build the railroads proved to be unsuccessful at the rates of pay, levels of productivity, and exposure to danger that companies like the Central Pacific Railway demanded. Immigrant Chinese workers, however, not only proved more efficient and productive, but were also, at least initially, considered more docile. They eventually displaced the white and mostly Irish workers who resisted the labor conditions associated with railroad construction.

Although Chinese workers emerged as a preferred labor force to whites, their labor was simultaneously devalued by their employers. Chinese workers were systematically paid less than their white counterparts, a practice that was, in large measure, made possible by the power of the circulating racial discourses that constructed them as a despicable group, a contempt that ultimately culminated in the restrictions placed on the immigration of Chinese labor by the US government in 1882 under the Chinese Exclusion Act. Though preferred for their reliability and skill, racialized Chinese workers were considered an expendable workforce whose abilities and rights did not merit recognition.

By the twentieth century, the abolition of slavery and large-scale mass migration opened up labor markets, particularly in the Global North, to broad and ethnically diverse populations, drawn from all over the space of empire. But widespread discriminatory employment practices ensured that the racial hierarchies that had been established over 300 years before could be maintained through the wage process. Racialized wage discrimination remained a largely uncontested practice up until the 1960s. It was an almost universal assumption that groups considered to be “racially inferior” and distasteful should be “taxed” for the privilege of working alongside racialized superiors. Lower rates of pay and the denial of benefits became the primary method of exacting this form of “tax.” Much of the logic behind racial wage discrimination was closely tied to deep-seated concerns about the levels of disaffection among working classes that would emerge if white workers were to work alongside workers considered to be their racial inferiors. But of equal concern was the fear that alliances between racialized and ethnic groups would ultimately destabilize labor control. The East St Louis race violence of 1917, which left 100–200 African Americans dead and an additional 6000 burned out of their homes, points to the deep threat that racialized workers posed to the racial division of labor. Despite that fact that there were labor shortages in the United States because of large numbers of potential workers engaged in active service during World War I, there was still violent outrage at the prospect of black workers from the South filling these vacancies. This was reflected in Marcus Garvey’s speech delivered after the event, in which he proclaimed that, despite the fact that for 300 years “the Negroes of America have given their life blood to make the Republic the first among the nations of the world,” they continued to be oppressed, lynched, burned, and butchered.

In Canada, discrimination against immigrant Chinese people not only took the form of wage discrimination, with workers building the Canadian Pacific Railway routinely earning half that of their white counterparts; once the railways were completed, it became manifest in
Canada’s immigration policies. Devised in 1885, the Chinese Immigration Act, also known as the Chinese Head Tax, imposed a $50 fee on each Chinese immigrant entering Canada. By 1903 this tax had risen to a maximum of $500 in an effort to deter further expansion of the Chinese labor force, and by 1923 it was replaced with an outright immigration ban on most Chinese migrants. By the end of the 1920s the power of the imperial racial imaginary to shape local and global spatial divisions of labor became acutely clear. Not only did race knowledge influence how employers determined the value placed on the labor of specific raced bodies, but even when the work performed was of superior quality it allowed states to maintain racial divisions of labor internationally through the regulation of the international migration of people altogether.

Throughout the 1900s geographers continued to lend legitimacy to these unequal practices through their efforts to establish the naturalness of discrimination. A case in point was the geographer Hereford Brooke George (1905), a fellow of New College, Oxford, and author of the influential textbook, *A Historical Geography of the British Empire*. In this book George’s casual reproduction of much of the circulating race knowledge about Chinese people in Australia supported the racial discrimination that ultimately led to the exclusion of Chinese immigrants from the United States, Australia, and later Canada. Though constructed as a careful observation of the character of different ethnic groups, his likening of Chinese immigration to a flood, and his belief that even those supporting socialist values would agree that “in a country inhabited by white European Christians the fewer Chinese the better,” served to reinforce established patterns of racial discrimination and exclusion (George 1905, 189).

Decolonization, the demise of race science, and the challenge of racism

By the 1960s the idea that the world was composed of biological races with distinct, inherited, and permanent physical and cultural characteristics had been thoroughly discredited. In 1950, at the end of World War II, the United Nations Educational, Scientific and Cultural Organization (UNESCO) produced the first of four statements on race that aimed to communicate what was scientifically known about the relationship between race and biology. The statements, signed by a number of leading researchers from the social and biological sciences were produced in the wake of the Nazi genocide of Jewish and Roma people (UNESCO 1967). They constituted a major step toward discrediting the social and political significance of race science, and contributed to a growing recognition of racism as a shameful sentiment to be disavowed. While the debunking of the scientific concept of race, and the moral condemnation of racism implicit in the UNESCO statements (and subsequent revisions), did not put an end to the production of racial inequalities among individuals or within institutions, the statements galvanized a whole generation of scholars across geography to devote their attention to the exploration of the role that race and racism played in shaping human relationships with environments.

Even though environmental determinism had lost its centrality within geography by the 1920s, it was not until the 1960s and 1970s that geographers began to study in earnest the relationship between race, work, and employment. Motivated by growing pressure to demonstrate its relevance as a distinct discipline with something to offer to an increasingly decolonized world economy, geography reinvented itself after World War II as a science concerned with producing facts and models to facilitate spatial
decision-making in the period. The quantitative turn, with its reliance on abstract theory building and determinist model building, had a profound effect on the study of race and work and employment because it provided geographers with a set of formal statistical techniques from which to draw scientific inferences about the spatial effects of racism – a shift that helped to reorient geographical scholarship away from its unsavory supporting role in the production of race science.

In the United States, the African American Civil Rights Movement was a catalyst in the number of studies that examined the effects of residential segregation on the quality of life of African Americans during that period. Geographers like Deskins (1972) and Morrill and Donaldson (1972) acknowledged the role that racism in labor markets played in the residential opportunities open to African Americans. While their work tended to focus more on the spatial and residential implications of racial discrimination for African Americans, and less explicitly on labor market discrimination, their writings represented a significant shift in the way that geographers engaged questions of race and racism in the discipline.

In Britain geographers were slower in their exploration of relationships between race, work, and employment. Ceri Peach (1966) represents one of the earliest of geographers to write about the relationship between race and racism in Britain, in the context of the postwar mass migration of West Indians and later South Asians to Britain. Like that of his American counterparts, his work in the 1970s focused on the relationship between race and spatial segregation and the spatial patterns of inequality that racism produced, an approach that offered an understanding of racism that focused primarily on its geography rather than its etiology. Thus, despite their clear break with the past, the pioneering studies examining the relationships between race and space between the 1960s and 1970s were limited to documenting patterns of racism rather than examining the economic, social, and political complexities of race as a social and institutional construction that shaped access to work and employment.

Marxist theory and the institutionalization of racism within work

The work of Bridget Leach stands out as a significant departure from the theoretical and methodological approaches to race and racism that were popular among geographers in the 1960s and 1970s. Reflecting the growing influence of Marxist approaches within the discipline, Leach’s short article published in 1974, entitled “Race, Problems and Geography,” was one of the earliest studies to examine race and racism in the context of capitalism and for that reason one of the first to challenge geographers to examine the particular geographies that racism produced in order to serve the needs of capital. Leach criticized geographers for being too narrowly focused on describing spatial patterns rather than the exploring the underlying structures that gave rise to these patterns. Reflecting the growing influence of Marxist theory within the discipline, Leach argued that geography was in danger of serving state and elite interests rather than the interests of racialized groups and working-class communities because scholars tended to problematize the spatial manifestations of class relationships in society rather than class relations themselves. She concluded therefore that the policies advocated by geographers would likely support only cosmetic rather than transformative change.

Leach’s views reflected a broad and growing dissatisfaction with the epistemological direction that geography had taken in the years after
World War II, a dissatisfaction that David Harvey eruditely described in an article received by the Transactions of the Institute of British Geographers, two months after Leach’s, entitled “What Kind of Geography for What Kind of Public Policy?” Harvey observed that geography had undergone an epistemological shift that reflected a desire to change its image from a nonacademic practical activity oriented toward the “technics and mechanics of the management of Empire” to a distinctive intellectual discipline oriented toward the “the technics and mechanics of urban, regional and environmental management” (1974, 20).

As geographers embraced radical approaches inspired by Marxism, their focus increasingly turned to the ways that capital actively produced space and the conflicts arising from the very different conceptions of economic fairness held by labor and capital. Throughout the 1970s and 1980s scholars documented the ways that capitalist systems incorporated labor and the forms of exploitation and inequality that emanated from this relationship. Geographers studied the unique ways that particular racialized groups were incorporated into capitalist markets and the particular forms of inequality that emanated within workplaces and labor markets and across the international division of labor. Influenced by a rapidly changing international division of labor, the feminization of factory production, and large-scale immigration in cities in North America and Europe, geographers examined how particular ethnic and racialized groups fared in a rapidly restructuring world economy.

Among economic geographers, for example, much attention was paid to the large differences in employment rates that existed between black and white populations in the United States, with many arguing that these differentials were the product of the growing mismatch between the spatial location of jobs and the spatial entrapment of African Americans in segregated inner-city neighborhoods long abandoned by industry. A number of feminist geographers also contributed to these spatial mismatch theories in the 1990s by demonstrating how gender and racial differences combined to doubly disadvantage particular racialized and gendered groups.

While spatial mismatch theories examined questions of racial discrimination, segregation, and the formation of an underclass, the methods of analysis were largely quantitative, with little interrogation of the strategies or motivations employed by racialized workers themselves to change their situation. While race was never totally excluded from studies of economic restructuring in the 1990s, it never occupied a central role in framing how the relationship between capital and labor was understood.

From labor geographies to embodied workers: new critical approaches to work and employment

Reflecting on the primary focus of scholarship during the 1980s and 1990s, Herod (1997) and Coe (2012) have both argued that, although much primacy was given to documenting the economic geographies at work in the restructuring of capital-labor relations, levels of analyses tended to examine labor as a largely abstract, aggregate, and disembodied class, with little agency or capacity to effect change. The geographies of labor produced during this period therefore left little space for examining the multidimensionality of labor – that is, as embodied workers engaged in paid and unpaid work who exercised agency even in the face of discriminatory and exploitative systems of work. This shift in focus – from labor as a factor of production understood from the perspective of capital, to workers as embodied
subjects understood from the perspective of workers – began to emerge in the late 1980s as scholars, many using feminist frameworks, began to explore the experiences of women in the context of economic restructuring.

One of the earliest examples of this shift in focus from a geography of labor, toward a “labor geography” (a phrase coined by Andrew Herod in the 1990s), could be seen in studies examining the incorporation of women into transnational factory production. Research by Lawson in the early 1990s, for example, explored the changing relationship between gender and work in Ecuador in the context of the export-oriented industrialization strategies adopted by neoliberalizing Latin American states (Lawson 1995). Feminist geographers, charting the shift from welfare to workfare, also studied emerging forms of regulation within geographically specific local labor markets and their impacts on women’s everyday lives. Pratt and Hanson’s book Gender, Work and Space (1995) was characteristic of the way feminist geographers took account of the embodied nature of work and the way sex-based occupational segregation affected differently how men and women workers ordered their daily lives. McDowell’s (1997) study of the work experiences of women in the UK banking sector is similarly notable for their attentiveness to embodiment and the ways that constructions of gender shaped the nature of work relationships. But, despite the incorporation of gender into geographical studies of work and employment, very few studies incorporated detailed analyses of race (for an early exception see Johnston-Anumonwo 2000). It would, in fact, be almost a decade before labor geography turned its attention to the relationship between social constructions of race and their embodied effects on spaces of work (Wright 2006; McDowell, Batnisky, and Dyer 2007).

The growing incorporation of critical race theory into geographical inquiry has opened up new terrains of inquiry into the relationship between race, work, and employment. Omi and Winant (1994) view race as a fluid, shifting, and yet pervasive social concept that is integral to the maintenance of a given social order. Shaped by ideologies that ascribe social and cultural meaning to specific physical differences between individuals and ethnic groups, racial categorization and exclusion continue to be sustained by a complex array of social, economic, and political structures that operate and interact among individuals and institutions at a range of scales. Thus, contrary to popular views of racism as the actions of unenlightened or troubled individuals, critical race theorists see racism as an ordinary and normal feature of contemporary society, and an integral aspect of all social practices and institutions, including those that govern work.

Critical race theorists like Omi and Winant apply useful frameworks to contemporary issues of work and employment to understanding how racial categories structure interactions in daily life. Much geographic scholarship documenting the relationship between race and employment in the 1960s viewed racism as having deep and intransigent roots in the very institutional structures of society. But studies that rely solely on institutionalized racism as an explanatory frame have not easily attended to the changing nature of racial regimes since that time. In particular, accounts embedded solely within the framework of institutionalized racism have not been able to adequately respond to the fact that, since the 1990s, particular racialized groups have experienced upward mobility, a fact, that has led some to assert that we now live in a “postracial” world. The growing “racial” diversity of populations, the reduction of “race” to “culture,” and the rise of “postracial” neoliberal discourses that view individualism and competition as the
main determinants of success, have all challenged scholars who study the relationship between race, work, and employment to develop new ways of understanding the spaces of work that changing racial regimes produce. Also important has been the challenge to understand how changing racial regimes are being contested by individuals and social groups and how, ultimately, the dynamic and fluid nature of the individual and collective social relations that constitute a given racial regime change across space and across scales.

A number of critical race scholars have begun to examine how racial regimes are negotiated and contested within spaces of work. Many geographers have used social theorist Judith Butler’s work on the social construction of sexuality and gender, and in particular her concepts of performance and performativity, to understand access to and mobility within work. Arguing that performativity must be understood not as a singular or deliberate “act,” but, rather as the reiterative and citational practice by which discourse produces the effects that it names, Butler (1993; 1997) offered geographers new opportunities to study the role of performativity in the production of workplaces. How performances of deference, docility, aggression, or care influence how individual bodies accommodate and resist the social constructions and relations of power that govern places of work and employment opened up new avenues in the study of work and employment. Yet few of these early studies explicitly foregrounded how race functioned as a performance that influenced access and mobility within workplaces.

Arguing that the workplace is an important site of racial construction, Carbado and Gulati (2003) argue that race is a micro and interpersonal dynamic which in workplaces is produced by the images of race that people of color project and how they are interpreted. For these scholars, race is a social construction that people of color perform in their daily negotiation of workspaces in order to shape how (especially white) people interpret their nonwhite identities. They argue that in modern workspaces, where racial discrimination is outlawed and where racial diversity confers institutional legitimacy, employers are likely to develop management techniques aimed at maximizing perceived efficiency gains of a homogeneous workplace culture. They also argue that a similar set of incentives exist for nonwhite employees who, in order to counter racial stereotypes, must demonstrate a willingness and capacity to assimilate. Carbado and Gulati argue that employers respond to homogeneity incentives by picking outsiders whose performance of a racial identity suggests that they will fit comfortably within workplaces that are overwhelming racially homogeneous. They therefore conclude that, without an understanding of the implicit racial norms that structure workplace interactions, and their relationship to workplace efficiency objectives and employer hiring practices, it will be impossible to understand why racially based distinctions continue to structure geographies of work and employment. Studies by McDowell, Batnitsky, and Dyer (2007) make similar observations about the ways that embodied constructions of ethnicity structures workplace access and mobility in the hotel industry in the United Kingdom. Noting associations between Indianness and servility made by hotel employers, coworkers, and guests, they argue that individuals who fail to perform these gender performances adequately experience constrained opportunities for recruitment and advancement.

While the relationship between racial performance and employment is a new and relatively underresearched area, understanding how the racial projects that define particular types of workspaces operate (both discursively and structurally) at specific economic moments offers important insights into the microgeographies at
work in an emerging global racial division of labor.

Back to the global: integrating the local and the global in studies of work and employment

Few scholars have studied in any real detail how social constructions of race shape and order the global division of labor. Indeed, this is a difficult claim to research given the very different meanings assigned to bodies within different racial formations. Most studies draw on largely economic factors such as labor costs to explain why global capital investors might prefer the labor of particular racial or ethnic groups over others. Yet, as scholars like Werner (2015), Roberts and Mahtani (2010), and Thomas and Clarke (2013) argue, current forms of global capitalism obscure the ways that race is embedded in the political rationalities that structure how individuals and whole populations come to be excluded from or included in global labor markets.

Particularly in neoliberalizing economies, where markets are assumed to be free from bias, how race and ethnicity become a meaningful way of determining the value and worth of workers is especially opaque. For, as Roberts and Mahtani (2010) point out, neoliberalism relies heavily on a moral discourse that locates lack of access or mobility in labor markets to individual failings to work hard or to follow the rules of labor markets. Citing the devaluation of immigrant credentials, they argue that racism is able to thrive within Canadian labor markets because immigrants are constructed as not quite “Canadian” and hence excludable from employment practices that claim to be market-based and meritocratic. A number of scholars argue that, in order to evaluate how race functions as a technology that facilitates the maximization of worker output and efficiency, we must examine the ways that workers accommodate, disrupt, and resist the racial scripts given to them. One case in point is the way that race intersects with gender and class to structure the immigration and temporary migrant worker policies brokered by the Canadian and Philippines government. As a number of scholars observe, even though the language of race never enters these policy domains, they nevertheless shape how Filipina women come to be incorporated into transnational care chains. As Parreñas (2001), Bakan and Stasiulis (1997), and Pratt (2004) have observed, whether constructed as celebrated heroines given the faithfulness of their remittances, or as docile, caring, and religious, Filipina women who migrate to metropolitan centers negotiate institutions at home and abroad that draw on specific elements of Filipina ethnic and national identity to construct them as a particular racial category of worker without recourse to the rights and protections open to other types of workers.

If race influences how spaces of work and employment are structured, and if space structures how embodied individuals come to be valued as workers, is it possible to discern how these co-constitutive practices produce a racial division of labor at a global scale? Thomas and Clarke (2013) suggest that the contours of an emerging racial division of labor can be discerned in the ways that older racial orders are entrenched in the emergence of a global working class that remains segmented along racial, gendered, ethnic, and national lines even though the language of race is not mobilized. Examining how race functions as a technology in the production of a low-waged unprotected workforce can therefore be discerned in seemingly disconnected economic processes such as the bilateral trade agreements struck between governments from the Global North and Global South, and also in the repercussions of arrangements
required by international donor institutions for the recovery of sovereign debt, a point that Werner’s (2015) study of racialization and global factory work in the Dominican Republic and Haiti, so poignantly makes.

Recent contributions inspired by new materialist theories draw our attention to the way that global racial regimes are producing new divisions of labor that rely primarily on female biological reproductive labor in ways that resemble the incorporation of Filipina women into transnational care production. Waldby and Cooper (2006), for example, make connections between the rise of medically assisted reproduction as a new global business and the outsourcing of onerous and risky clinical labor to poor populations in the Global South. Focusing on global markets for women’s oocytes (eggs), they argue that if we explore women’s contributions to the biotechnology industry as labor, we can begin to see the ways that the materiality of the female body has become integral to these highly profitable forms of industrial production that rely on the biological labor of living tissues and reproductive processes to produce new humans. Constructions of race have been integral to the profitability of the fertility industry, as they not only determine the market value of bodies but also the value of their reproductive capacities. In keeping with the observations of new materialist scholars, the racialized, segmented, and hierarchical nature of global fertility labor markets cannot be divorced from the globally circulating discourses of human worth that have become integral to the value attached to the reproductive capacities of the female body. In fact, as scholars like Winddance Twine (2011) and Waldby and Cooper (2006) argue, emerging global social reproductive labor regimes continue to be haunted by the social meanings based on specific physical traits that were used to differentiate, separate, and exercise colonial control over particular groups of humans.

To fully understand how race structures work, and employment globally, we must continue to track the ways in which the economic ordering of space generates new labor flows. We must also continue to examine how these macro-level trends are accommodated and contested within the microgeographies of work. In other words, in order to account for the way that race functions as a technology in the global division of labor, we must make connections between macro-level social relations and their manifestation in the institutional practices of the state and corporate sectors, as well as in the everyday social interactions that reinforce and contest workplace practices that produce raced subjects.

RACE, WORK, AND EMPLOYMENT

The term “radar” is an acronym for “radio detection and ranging.” A radar transmits an electromagnetic wave and then receives the echoes to determine the properties of the targeted object, such as its range, location, speed, and altitude. Radar was first developed during World War II. Since then, various radar systems have been developed for different purposes. A good reference work is the *Radar Handbook* edited by M.I. Skolnik (2008).

**Synthetic aperture radar**

Radar technology was developed for remote sensing of the natural environment and objects within it. Radar echo is the interaction of electromagnetic waves with this environment, and might provide quantitative and qualitative information about it, such as the biomass of a vegetation canopy, soil moisture, rain rate, oceanic surface speed, oil spill on water, snow-pack depth, building height, and much more (Ulaby, Moore, and Fung 1986; Tsang and Kong 2000; Jin 1994).

One of most advanced radar technologies is the airborne and satellite-borne synthetic aperture radar (SAR) (in microwave region $\approx 1–15$ GHz) (Olivers and Quegan 1998; Cuming and Wong 2005; Maitre 2008).

Recently, airborne millimeter wave (e.g., 94 GHz) SAR has also been under study. It can produce two-dimensional images of a terrain surface with high spatial resolution. Resolution refers to the fineness of the detail that can be distinguished in a remotely sensed image, as one of the most important performance parameters of radar image quality. In most imaging radars, high resolution in the range direction is achieved by using the pulse compression technique. In this technique, a sequence of frequency modulated (FM) or “chirp” pulses of long duration is used and the received signals are suitably processed to yield fine range resolution. Today, most imaging radars employ the pulse compression technique. In order to obtain fine azimuth resolution, a technique known as “aperture synthesis” is adopted for modern airborne and spaceborne radars, which are called synthetic aperture radar (SAR).

One dimension in the SAR image is called range (or cross track) and is a measure of the “line-of-sight” distance from the radar to the target. Range measurement and resolution are achieved in SAR in the same manner as most other radars: range is determined by precisely measuring the time from transmission of a pulse to receipt of the echo from a target. Range resolution is determined by the transmitted pulse width, that is, narrow pulses yield fine range resolution.

The other dimension is called azimuth (or along track) and is perpendicular to range. It is the ability of SAR to produce relatively fine azimuth resolution that differentiates it from other radars. To obtain fine azimuth resolution, a physically large antenna is needed to focus the transmitted and received energy into a sharp beam. The sharpness of the beam defines the
azimuth resolution. To achieve high resolution, an antenna physically larger than can be practically carried by the platform is required. Radar can collect data while flying over a distance and then process the data as if it came from a physically long antenna, using the flight path of the platform to simulate a large antenna electronically. The distance the aircraft flies in synthesizing the antenna is known as the synthetic aperture. A narrow synthetic beamwidth results from the relatively long synthetic aperture, which yields finer resolution than is possible from a smaller physical antenna.

Today, digitizers and other data acquisition equipment can store data for offline processing or even process imagery in real time. As the object is moving either toward or away from the transmitter, there is a slight equivalent change in the frequency of the radio waves, caused by the Doppler effect. By utilizing the Doppler effect between the platform of the radar and the target, SAR can obtain high-resolution images with small antennae.

SAR systems take advantage of the long-range propagation characteristics of radar signals and the complex information processing capability of modern digital electronics to provide high-resolution two-dimensional imagery. SAR complements photographic and other optical imaging capabilities because of the minimum constraints on SAR of time of day and atmospheric conditions.

Polarimetric SAR

Electromagnetic (EM) fields are vectors, that is, linearly, circularly, or elliptically polarized. Any polarized EM wave can be expressed by dual linearly polarized (i.e. vertical and horizontal) waves. The SAR system that utilizes the polarized EM wave is called polarimetric SAR (PolSAR). For the incidence of a polarized wave from the PolSAR system, the EM fields, both co- and cross-polarized, received by the SAR system are obtained through a $2 \times 2$ complex scattering matrix. The scattering intensity, called the Stokes vector, is a four-dimensional real intensity, and the transform matrix between incident and scattering is a $4 \times 4$ Mueller matrix. PolSAR via these matrices may provide much more information about the observed objects and environment (Lee and Pottier 2009; Cloude 2010; Jin and Xu 2001).

The first spaceborne PolSAR was the Shuttle Imager Radar SIR-C, in 1994. Today PolSAR systems are a popular emerging technique with a high resolution of meters and decimeters.

Bistatic PolSAR

Conventional monostatic SAR has its transmitter and receiver installed on the same platform and collects the backscattered echoes from targets within the imaged area. During the past decade, bistatic SAR with a separate transmitter and receiver flying on different platforms has become of great interest, because this might significantly reduce vulnerability in military systems, enhance the response due to the large angle between incidence and scattering, present additional information, and so on (Chernyak 1998; Wills 1991).

Interferometric SAR

Interferometric SAR (InSAR) is a technique that compares the amplitude and phase signals received during one pass of the SAR platform over a specific geographic area with the amplitude and phase
signals received during a second pass of the platform over the same area but at a different time. The phase difference for each pixel in the resulting interferogram is a measure of the relative change in distance between the scatterer and the SAR antenna. With the collection of complex SAR data from slightly offset perspectives, the separation between these two observation points is termed the “baseline.” This baseline introduces for each point in the scene a slight range difference that results in a phase shift. From this phase shift, a digital elevation model (DEM) in three dimensions can be derived (Gini and Lombardini 2002; Zebker and Goodstein 1986).

The first InSAR system applied to Earth observation was reported in 1974. Since then, a series of satellite-borne SAR have been launched and provide the stable, well-defined orbits and short baselines necessary for InSAR generation of a consistent global DEM and local surface deformation with an unprecedented accuracy. InSAR has also been applied to the long-term study of earthquakes, volcanoes, and so on.

**Tomography SAR**

In the physical principle, SAR maps the three-dimensional reflectivity distribution from a scene of scatterers to be imaged onto the two-dimensional azimuth-range plane. Using several multipass acquisitions on the same scene, the aperture synthesis in the third elevation direction can be performed. It uses data stacks of several acquisitions from slightly different viewing angles (the elevation aperture) to invert or reconstruct the reflectivity function along the elevation direction by means of spectral analysis for every azimuth-range pixel. Hence, the three-dimensional SAR image can be obtained. This multibaseline interferometry with a number of tracks is called tomography SAR (TomoSAR). With SAR tomography, it is possible to separate the ground backscattering in a forest and to estimate height with only signal contributions. TomoSAR has also been applied to high-dimensional multitemporal information, such as seasonal inflation of buildings and deformation of buildings on the ground (Fornaro et al. 2012; Zhu and Bamler 2010).

**Inverse SAR**

Inverse SAR (ISAR) is analogous to conventional SAR, which generally refers to the case where the radar platform is moving while the target stays stationary. ISAR is used for scenarios when the radar is stationary and the targets are in motion, such as with airplanes, ships, tanks, and so on. Stationary radar collects the scattering data from the target at different look angles by utilizing the target’s movement. While the target is moving, the look angle of the target is assumed to be changing with respect to the radar line of sight (RLOS) axis in order to produce a successful ISAR image. This angular diversity in the ISAR dataset is used to resolve different points along the cross-range axis.

Additionally, the ISAR imaging procedure has some conceptual differences when compared to SAR imagery. Motion compensation is the first step in the ISAR image reconstruction chain. Several algorithms have been studied to accomplish motion compensation. After motion compensation, the received signal is processed to form the ISAR image. ISAR technology has been extensively applied to ATR (automatic target recognition). It is capable of displaying dominant characteristic scattering regions (hot points), that is, scattering centers on complex targets, such as satellites, spacecraft, airplanes, ground vehicles, and so on (Özdemir 2012; Fortuny 1998).
Radar sounding

In geophysical studies, such as studies of the ionosphere, land subsurface, and so on, the radar sounding system has been broadly applied. A radar sounder generates high-frequency (usually polarized, approximately MHz) radio waves to transmit and penetrate the underlying media (through approximately meters and kilometers). The radar echoes from the surface/subsurface inhomogeneity with different time delays may provide the structural characteristics of the media, for example, layer thickness, dielectric constant, inhomogeneity, and so on (Joe 2009).

Usually, the echoes directly from the surface and subsurface can be seen as signals, and the clutters from neighbor surface roughness and media inhomogeneity (scatterers) are seen as noise to disturb the signals. Analyzing the range of images from the radar echoes and clutters and then deriving their functional dependences on the media parameters can present structural information about underlying complex media. These technologies have been applied to planetary explorations, for example, of the lunar and Mars surface/subsurface (MARSIS, Mars Advanced Radar for Subsurface and Ionosphere Sounding; and SHARAD, Shallow Radar), detection of land mines and pipes (i.e., GPR, ground penetration radar), and so on (Mouginot et al. 2010; Picardi et al. 2005).

Radical geography

Jenny Pickerill  
*University of Sheffield, UK*

Radical geography is an approach to geographic research that seeks to understand social and spatial problems, and to advocate solutions. Radical geography is not a coherent or unifying concept or methodology. There is great diversity in the research that would be considered “radical.” Radical geography is an approach developed in the 1970s and a contemporary ethos that is fundamental to many geographers’ work. It should be considered as a multiple, dynamic, and contested approach, for which there is no one definition. Instead there are radical geographies.

Radical geographers are interested in everyday lives: the lived experiences of members of society. They are interested in issues of relevance to everyday social life, such as access to safe and affordable food and housing, fair pay, educational opportunities, and basic health care, to name just a few. This emphasis reflects a desire for geographers to do research that is relevant to, and useful for, society.

There has been a specific focus on understanding spatialities of power, inequality, and oppression, which has required an understanding of the causes of such inequality and has led to research on power, neoliberalism, political structures, and corporate hegemony. It has been necessary to understand how neoliberalism and corporate power operate and to relate the everyday experiences of people to the broader structures that shape their lives.

There is an implicit left-wing progressive political agenda to much radical geography work, which prioritizes the oppressed, powerless, or marginalized in society. Such work often aims to transform the world through an emancipatory politics. The political agenda of this work has often been to advocate for a fairer and more equal society where everyone’s basic needs are met and everyone has an equal opportunity to participate. Consequently, radical geography has largely ignored research on elites, the powerful, or the wealthy, and issues that might be considered frivolous or of concern only to the privileged.

Once the causes of social problems have been identified, radical geographers take a normative approach. This means that they seek to offer solutions, alternatives, and possibilities for how the problem can be solved. A quest for social justice permeates much of radical geography. Radical geographers, who are often active participants in social justice campaigns, are also committed to building, supporting, and intellectualizing alternatives. In other words, radical geography is as much about offering alternatives as it is about understanding causes. Contemporary examples include Jane Wills’s work in supporting the campaign for a living wage in London and beyond, Gibson-Graham’s work on diverse economies, and Marc Purcell’s work on direct democracy.

A brief history and ideological foundations

Radical geography emerged in the early 1970s both in response to a changing social context and as a critique of the positivism of the earlier
RADICAL GEOGRAPHY

quantitative revolution in geography. The social context was a growing unease about social and economic inequality, poverty, racism, crime, sexism, and environmental issues, typified in dissent against the Vietnam War and support for antiracist and anticolonial movements. At the time the quantitative approaches and positivist epistemology of the 1950s and 1960s began to be considered as irrelevant to these social problems and as being inadequate in offering solutions or alternatives. Geographers wanted not only to identify social problems, but also to understand their cause and thus identify different possibilities. It was increasingly understood that merely identifying problems was not enough, and that geographers needed to be proactive in advocating change and to do so on the basis of clear theoretical and political foundations.

The shift to radical geography also represented a greater use of philosophical approaches other than spatial determinism to understand the world. Both Marxism and anarchism were employed as ideological underpinnings for the new radical geography. Crucially, these ideologies provide diverging and contested understandings of society, a debate that is ongoing and not limited to academia, least of all academic geography. The huge philosophical differences between Marxism and anarchism represent just one example of the proliferation of approaches that fall under the remit of radical geography, which, as a result, can differ widely and contradict each other. The study of these ideologies does not constitute radical geography: rather, it was the way in which these philosophies enabled geographers to identify action and alternatives to the current order that shaped radical geographical practices.

Such ideological underpinnings existed long before the 1970s, and these quite different ideological approaches have existed side by side within the discipline since the nineteenth century. Karl Marx and Friedrich Engels, although not formally geographers, provided a framework through which class relations and capitalism could be understood, and this became the basis of Marxist geography. Engels’s *The Condition of the Working Class in England in 1844* (1845) was a treatise on the poor urban conditions experienced by the working class. Geographers later took up this project, notably Karl Wittfogel (in Germany), who linked Marxism with geopolitics and materialism in a 1929 paper. In France, post–World War II geographers such as Pierre George and Jean Tricart developed Marxist spatial analysis.

The Marxist tradition was reignited by the work of David Harvey, whose *Social Justice and the City* (1973) advocated a Marxist approach to understanding the world. For Harvey this involved geographers engaging in both practical and theoretical work, which was reflected in his own engagement with political campaigns for social justice in Baltimore. Around the same time, Richard Peet was using political economy and Marxist geography to explore social justices, and the journal *Antipode: A Radical Journal of Geography* was established. These developments also built on the Detroit Geographical Expedition and Institute (1968) created by William Bunge. Bunge wanted to expand the processes and use of geographic knowledge, so he enrolled minority communities in the whole research process, beginning a radical geography approach that would later be developed into a participatory geography methodology.

This Marxist approach influenced radical geographers by offering an analysis of the world based on modes of production and by advocating normative practices. Marxist geography was interested in the dialectical relationships between humans and the modes of production that shape society: capital, labor, capitalism, the
state, class, and the market. These various modes of production were determined by Marxists to create the superstructure of society. As Derek Gregory (1978) pointed out, these ideas shaped the structure–agency debate; the idea that these structures determined society was challenged by Gregory’s assertion that humans had agency in the creation of structures. Agency varied across place, but led to the possibility that humans could challenge and change societies’ structures, thereby leading to social change.

Marxist geography focused on an analysis of modes of production as an explanation of social and environmental problems. It was interested in the inherent contradictions of capitalism. For example, early radical geographers linked environmentally destructive practices, such as old-growth forest logging, as originating in the structures of capitalism. For Marxist radical geographers, most social problems and injustices emanated from the workings of modes of production. Therefore, if the mechanics of production were changed, alternative outcomes would be possible for society and the environment.

The normative approach offered by Marxism encouraged geographers to be bolder in advocating solutions and alternatives. Normative research aims to produce work that has practical use for society. Normative work identifies actions to be taken and is assertive in its support for particular activities. Radical geographers use their research to justify and make interventions to shape certain futures. This radical approach was also mirrored in other social science disciplines, such as the emergence of radical sociology in the 1970s which also advocated human emancipation as its goal.

While Marxist geography became the dominant radical geography approach, anarchist geography proposed an alternative vision. Anarchist geography was established by Peter Kropotkin and Élisée Reclus, who were both formally trained as geographers but were also anarchist philosophers. Reclus’s 32–volume work, The Earth and Its Inhabitants: The Universal Geography (1876–1894) sought to abolish domination, including that of humans over the environment, by a merger between humanity and the Earth, creating equality between humans and nonhumans. Kropotkin published numerous articles in geography journals, pamphlets on anarchism, Fields, Factories and Workshops and The Conquest of Bread, and the hugely influential Mutual Aid: A Factor in Evolution (1902), in which he argued that cooperation rather than competition was the natural order of things. He advocated a life based on decentralization, localism, and self-provision. In 1855 he wrote “What Geography Ought to Be,” a radical anarchist agenda for the discipline.

Anarchism is a shifting set of beliefs adopted by a variety of groups which, at its core, rejects the need for rulers, domination, hierarchy, and any form of government. It provides a critique of power and hegemony and an alternative vision of liberation and autonomy. It was not until the 1970s, however, that geographers re-engaged with the work of anarchist theorists such as Proudhon, Kropotkin, Bakunin, and Goldman, to name just a few, to explore the potential for anarchism, find examples of anarchist practices in places, and advocate the adoption of anarchist principles. They also sought to understand the limitations of the state and how state and capital operate together as forms of control and containment. In particular, anarchist geographers such as Paul Chatterton have explored how the state seeks to limit autonomy and equality and the possibilities to carve out freedom nonetheless.

While anarchist geographers practice normative approaches to their work, much of their worldview contrasts sharply with that of Marxist geographers. Anarchist geographers have sought to illustrate the power and possibility of grassroots
radical politics and action. Anarchist scholars argue that each individual, rather than being passive in a hegemonic superstructure, has the power to change society, albeit most effectively as part of a mass mobilization. The social change advocated by anarchist geographers is one without leaders, government, or hierarchy and, crucially, is not reliant on a revolution (as in the Marxist lexicon). As a result, research by anarchist geographers has focused on analyzing the potential of many currently small-scale anarchist initiatives such as workers’ cooperatives, eco-villages, anarchist communities, alternative food networks, and online open publishing models. In each case, not all examples are overtly anarchist but many are imbued with anarchist principles.

Among other anarchists, Pierre-Joseph Proudhon offered a critique of property, Mikhail Bakunin critiqued the need for a state, Emma Goldman extended our understanding of domination beyond the state and advocated equal gender relations, and Colin Ward argued against planning restrictions and for more affordable and self-build housing. These anarchist principles include an emphasis on cooperation (mutual aid), direct democracy, prefigurative action, nonhierarchical decision-making, free movement, self-organization, and communalism (sharing). Mutual aid is the practice of helping one another and sharing skills, time, and resources freely. It is the belief that individualism and competitiveness are ultimately destructive in a society and that we could achieve much more if we worked together. Direct democracy and nonhierarchical decision-making mean that everyone should have an equal voice in the decisions made in society and that there are no leaders. Prefigurative action is the embodiment of acting now to make the world as we want it to be, rather than the Marxist approach, which advocates waiting for the revolution before we start to live differently.

In the 1970s geographers such as Richard Peet (1978), Myrna Brietbart, and Bob Galois began to use these ideas to call for a more anarchist radical geography. However, after a special issue of *Antipode*, there was little geographical engagement with anarchism until the 2000s. In the late 1990s interest in anarchist and autonomous anti-capitalist protests led to work by Paul Chatterton, Pierpaolo Mudu, Jill Fenton, and Jon Anderson. Central to all this work was an understanding that social transformation is a spatial project.

There were several challenges to anarchist and Marxist approaches to radical geography. Marxist geography was criticized for its overly deterministic view of the world, where individuals were assigned a passive role within a dominant and hegemonic superstructure. This metatheory was preoccupied with the relations between capital and class, while it ignored other dimensions that shape people’s lives, such as patriarchy.

The absence of attention to gender was countered by the emergence of feminist geography in the 1980s. At first, feminist work in geography identified and explored the absence of women in geographical scholarship and their institutional absence within universities. Such a critique exposed a masculinist tendency within academic geography that devalued women’s role in society and ignored their difference and oppression. At the same time, other scholars were becoming critical of the Marxist approach as a result of the changes in Eastern Europe and the disintegration of the Soviet Union, which for many undermined the possibilities of a Marxist future.

By the turn of the century, radical geography was more diverse and inclusive of a greater range of both philosophical approaches and research topics. It began to focus less on a Marxist critique of capitalism or an anarchist approach, and more on the diverse factors that shaped people’s lives, such as gender, sexuality, disability, and race. Marxism could not accommodate this diversity.
of identity politics. The postmodern critique of metanarratives led to a poststructuralist approach within human geography that persists. In the 1990s the terminology of radical geography fell out of favor and was replaced by scholars self-identifying as “critical human geographers.” The establishment of the Critical Geography email forum and the International Conference of Critical Geographers was motivated in part by a rejection of these metanarratives (particularly Marxism).

Radical geography did not entirely reshape the discipline in the same way that the quantification revolution had: its impact was far more partial and fractured. There is now concern that a lack of a clear framework of analysis, or worldview, and the shift toward poststructuralist geographies and the cultural turn, have limited the ability of radical geography to be normative and to advocate clear alternatives. At the same time, there is an ongoing threat from the neoliberal political project, reducing the possibilities and options for alternatives.

**Inequality, capitalism, and marginalization**

Radical geography is grounded in a basic concern for everyday lives and in identifying and making visible the geographical processes that shape and produce inequality, oppression, and marginalization. There are many radical geographers, but here three examples have been picked out to illustrate some of their intellectual and normative contributions to the founding dimension of the field—research on inequality. This work has tended to highlight the inequity of neoliberalism and its unjust consequences, and thus that capitalism is the structural cause of inequality.

The late Neil Smith’s work is exemplary of (Marxist) radical geographers’ engagement with issues of inequality, particularly in cities. His early work, *Uneven Development: Nature, Capital and the Production of Space* (1984), argued that capitalism produced uneven spatial development. He went on to critically identify gentrification as a process of capitalism that benefited from low urban land prices and capitalist speculation in *The New Urban Frontier: Gentrification and the Revanchist City* (1996). Smith developed the term “rent gap,” a concept used by anti-gentrification activists to help explain and fight against gentrifying processes. Indeed, much of his work was used politically and by activists, and Smith worked with many activists over his lifetime, especially the Harlem Tenants Association. He was always concerned with the importance of class to these processes of inequality. Later in his career he drew inspiration from the antiglobalization protests of the late 1990s and the revolutionary potential of the Occupy movement and the so-called Arab Spring. Smith became increasingly critical of the topical focus of contemporary geography, particularly the middle-class obsessions of anglophone geography, such as the concern with the community gardens in New York, rather than recognition of how social processes produced such a geographically uneven world (Smith 2005).

Doreen Massey (1984), another Marxist geographer, was also interested in uneven development and developed the theory of “spatial divisions of labor.” This approach posited that uneven development was a result of the different ways in which the capitalist economy engaged with space and spatial relationships. The outcomes were social inequalities that varied across space, creating a divide between rich and poor regions and between classes. For Massey, understanding space was crucial to understanding inequality and poverty, and once this was grasped it was then possible to identify solutions.
The final example is the work of Jane Wills, an expert on work and labor politics, who in 2005 worked with the campaign group London Citizens to develop the case for the living wage. Wills argued that, although Britain has a basic minimum wage, many people are in in-work poverty: despite being in full-time employment, they do not have enough money to cover their basic living costs (Wills and Linneker 2014). Using economic geography, Wills worked with community organizers to build a business case for a living wage, starting with the example of cleaners at Queen Mary University of London. Their aim was to reverse the trend for global outsourcing, which saw a reduction in the wages and benefits of staff but increasing profits for companies. This social justice work was expanded to a UK-wide campaign in 2011 through the Living Wage Foundation. Wills’s achievements not only illustrate the possibilities of change as a result of radical work, but also the importance of academics working with community organizers in a collaborative bottom-up process.

Activism and social change

Radical geographers’ links with political activists have extended beyond concerns with class and inequality into diverse geographical research of resistance and social change. Many radical scholars work with those who are campaigning, protesting, and instigating social change across a broad range of interests, including poverty, health, food, migration, environment, land rights, gender equality, queer activism, racism, and other social justice issues.

There are several dimensions and approaches to this work. Some scholars, like Paul Routledge, Kye Askins, Jenna Lloyd, Kelvin Mason, and Paul Chatterton (to name just a few), have sought to bring geographical concepts to the aid of activists, and to directly participate in activist struggles. For example, Paul Routledge (2003) has worked extensively with activist communities in India (among other places) on environmental issues and anticapitalist resistances, developing the concept of “spaces of convergence” to understand the global processes of antiglobalization protest. Jenna Lloyd (2014) has explored health activism and in other work critiqued the criminalization and militarization of migration.

As part of the Autonomous Geographies Collective, Paul Chatterton worked alongside Jenny Pickerill and Stuart Hodkinson to explore autonomous activists’ daily lives. This work involved active participation in British anticapitalist activism to understand and advocate for those spaces where there is a questioning of laws/social norms, and a desire to create non-/alter-capitalist, collective forms of politics, identity and citizenship. The collective’s work was able to identify the value of these contested, fractured, interstitial spaces of autonomy. In many ways this work built on the anarchist foundations of radical geography by exploring practices of mutual aid, solidarity, self-management, decentralized and voluntary organizing, and direct action. Chatterton went on to found and research the first affordable urban ecological cohousing community in Britain.

Others have taken a more discursive approach to researching activism, exploring the ways in which, for example, emotions are employed (Fernando J. Bosco) and solidarity expressed and practiced (Gavin Brown), and the gender politics of protest, violence, and militarization (Melissa W. Wright).

This type of research often involves difficult issues around ethics: protecting research participants, illegal activities, and power relations (between resourced privileged academics and underresourced marginalized activists) (Autonomous Geographies Collective 2010).
There remains a tension in much of geographers’ work between supporting and advocating diverse forms of activism and the intellectual need to critique and interrogate activist practices. There are numerous problems inherent in all forms of activism, most commonly around gender relations, measures of “success” (the global capitalist economy often prevails), the temporality of activism, the ghettoization of activist communities, and the time required for alternatives to be created; however, intellectual critique can be viewed as undermining the intentions of collective action and as politically unhelpful. Many radical geographers negotiate such tension by only offering constructive critique and limiting their intellectualization to academic journal publications.

**Participatory approaches**

In the past decade there has been a resurgence of interest in radical methodologies. Recently, radical geographers have advocated wider use of participatory methods. Participatory research methods start by asking groups outside the academy what research they think is required, how it should be conducted, and what outcomes they would like to see. Academics then work with these participants to help them conduct the research. It is a bottom-up approach to research and is based on the premise that research should benefit all, particularly those who have participated in it. This approach attempts to stretch the normative element of radical geography to thinking about who benefits from geographers’ work.

Participatory geography is concerned with empowering people to change their own lives (with the aid of researchers). This requires being proactively inclusive, with researchers seeking out those who might be excluded and taking a detailed approach, rather than categorizing people into groups. There tends to be a focus on disadvantaged groups and in challenging existing power relations. It is also a very reflective process that requires the researcher to self-critically reflect on their actions, learning, and positionality, and to value the expert knowledge of nonacademics. Key advocates of participatory geographies have included Rachel Pain, Sara Kindon, Mike Kesby, Kye Askins, Duncan Fuller, and Caitlin Cahill. In Britain, radical geographers’ support for participatory methods led to the establishment of a new Royal Geographical Society group, the Participatory Geographies Research Group (known as PyGyRG) in 2005 (though it formally became a research group only in 2009).

Participatory geography is simple in its premise – geographers should work with those they are researching and include them in every aspect of that work – but the approach simultaneously critiques contemporary academic practices and knowledge production. In valuing the contributions of nonacademics, participatory geography challenges the presumption that knowledge is best constructed by the academy, and raises questions about the purpose of university research. In the radical tradition, it also privileges work that is more likely to result in action, political change, and demonstrable improvements in society, rather than the highly theoretical esoteric work which speaks only to other academics.

**Grassroots solutions and alternatives**

Since the early years of radical geography, scholars have sought to suggest solutions and alternatives. These alternatives have tended to counter neoliberal logic with different value systems, based on, for example, environmentally sustainable, ethical, participatory, and/or communal processes. Three examples illustrate the
ways in which radical geographers have engaged with, and advocated for, grassroots solutions.

Gibson-Graham (Katherine Gibson and Julie Graham) (1996) developed the concept of diverse economies, which challenged conventional notions that the economy was made up only of formal commodity markets, waged and salaried labor, and capitalist enterprises focused on creating profit for owners or shareholders. Instead, Gibson-Graham proposed that the economy was made up of market, alternative market, and nonmarket transactions and that many of the most important goods and services are taken or exchanged outside the formal economy. This expansion of the economy celebrated its diversity and valued these different forms of transactions, labor remuneration (such as unpaid work), and forms of enterprise. In this approach, the neoliberal market was problematized as not being the main or dominant form of trade, and the potential of alternatives to support society was more visible.

In a similar way, Nik Heynen’s work on civil disobedience and protest in the United States celebrates the potential of activist practices. Using “Food Not Bombs” as one of his examples, Heynen (2010) not only identifies the contradictions of neoliberalism, but critically explores the alternative survival strategies proposed by collective action. Finally, Peter North (2007) advocates the use of alternative currencies while acknowledging their inherent limitations.

Beyond Anglo-American perspectives and sources of knowledge

Radical geographies have been most noticeable (though rarely dominant) in anglophonic geography. Although it has spread beyond North American and European geography, it has tended to be limited to the settler countries of Australia, New Zealand, and South Africa, in great part due to the dominance of the English language in radical geography (and human geography per se). At the same time there has been a lack of attention to the radical geographies of non-Anglo spaces of knowledge.

Manuel Aalbers (2004) identifies this dominance of English as resulting in the “creative destruction” of many non-English speakers’ work. In essence, the peer review process excludes work from beyond anglophone geography by requiring a certain written style and the referencing of key anglophone texts. This process excludes alternative knowledges.

Radical geographers have recognized the problems of such exclusions and the irony of radical geographers being complicit in these processes, given their apparent interest in alternative sources of radical ideas. Lawrence Berg, who established the open source radical journal ACME: An International E-Journal for Critical Geographies, attended to these problems by encouraging the submission and publication of articles to ACME in English, Spanish, Italian, French, or German, and by having a multilingual website. The journal Antipode has also started a project that will fund the translation of accepted articles.

Practicing what is preached

There remains a disjuncture for many geographers between the radical geographical scholarship they conduct, and their own elite positions within privileged educational institutions. For anarchist geographers who support the concept of taking prefigurative action, this can be particularly problematic.

Academic geographers, particularly those in the United States, the United Kingdom, and Australia, are experiencing the consequences of universities’ adoption of neoliberal approaches
to higher education. This is not a new dilemma; there have long been pressures on universities to commercialize and to serve the needs of industry and the political class rather than those of society. However, there are increasing pressures on academic practice, including national accounting measures of performance (such as Research Excellence Framework (REF) in the United Kingdom and the Excellence in Research for Australia (ERA)); profit-driven journal production; the casualization of staff (Purcell 2007); and reductions in grant funding. Such processes have tended to undervalue radical scholarship and participatory empirical work, and instead to valorize individual theoretical work that can be produced and published more quickly. The quantity of output has been valued over quality, and in struggling to secure a permanent faculty position geographers have made compromises. Yet radical geographers have complied with the research assessment processes, and many have excelled in it.

Many radical scholars have identified such pressures and fought to counter them. Neil Smith sought to challenge the “sausage factory” processes of academia. Katharyne Mitchell (2008) celebrated geographers’ scholar activism. Noel Castree, Don Mitchell, and Marc Purcell wrote about, and attempted to resist, the neoliberal assault on universities. In attempting to subvert profit-driven journal production, open access journals like ACME and Human Geography: A New Radical Journal have been established, and Antipode renegotiated its contractual relationship with publishers Wiley-Blackwell, using the additional income to set up a charitable foundation that funds radical geography research.

Recognition of radical geographers’ conflicted positions within neoliberal institutions has raised questions for academics about their power and compliance with such processes. Academics such as Marc Purcell have argued that we need to better challenge the political and social relations that shape academic practice. In other words, radical geographers have to resist neoliberalism within universities if they are to be taken seriously as researchers and activists when working against neoliberalism in society. Practicing what radical geographers preach is becoming increasingly difficult.

Future directions

It is doubtful whether radical geography has achieved its aims. Many social and environmental problems persist and are actually getting worse. Postpositivist theoretical achievements, unfortunately, pale into insignificance in an era of unconstrained inequality and a neoliberal privilege that remains unchecked despite attempts by democratic governments to impose some measures of control. For example, attempts to restrict the practice of awarding large bonuses to bankers in the City of London have largely failed. These right-wing times make radical scholarship harder. Some future possible directions include more diverse radical geographies, a feminist ethics, participatory methods, radical positivism, and understanding the elite.

Radical geographies are becoming more diverse, but they remain anglophone and steeped in either the Marxist or anarchist tradition. As journals and academics begin to operate in more languages, there are possibilities for further diversifying radical geography. Geographers are also increasingly questioning their understanding of knowledge, how knowledge is shaped, and how they represent the world, which opens up the possibility of other knowledges being accommodated. In terms of identity, it matters less whether scholars self-identify as radical geographers than that the practices – political and normative – continue
to spread and evolve. There is concern from academics such as the late Neil Smith that anglophone geography is becoming too conservative, and thus it is especially important to continue the debate on the role of politics in geography (Orzeck 2012).

Radical geography has, unfortunately, retained a certain masculinist edge, indicative perhaps of its Marxist heritage. Linda McDowell (1992, 56) originally identified this as being both “inside and outside ‘the project.’” Despite decades of feminist geography, Victoria Lawson (2009) argues that radical geography still ignores the feminist care ethics, an ethics that is central to human wellbeing and society. This marginalization of care, and gender and bodies, limits radical geographers in understanding inequalities, society, and the possibilities of alternatives to create new caring relations. Many academics still feel outside “the project,” and continued effort is needed to ensure that radical geographies are plural, dynamic, and open.

Although participatory methods are now being broadly accepted in human geography, there remains a need to stretch what a participatory ethics does. Issues of unequal power relations remain, and geographers need to explore ways of relinquishing ownership of the data and the final outcomes of research, a challenge that could be particularly difficult given the ongoing neoliberalism of universities, but working out ways in which participants retain control would be radical.

Wyly (2011) argues that this failure of radical geography to achieve social change can be countered by a form of radical strategic positivism. While it would be helpful to return to a notion of a universal truth, there is a need for radical geography at times to be able to generalize, to employ methods that others can replicate, and to have the appearance of impartiality and measurement. In part this is necessary because of an increasing lack of trust in the scientific process, as illustrated by climate change deniers, the rise of creationism teaching, and the belief that the free market provides equal opportunity of wealth for all. This new form of radical geography includes Sheppard’s (2001) notion of “insurgent quantitative practices,” using statistics to counter official use where they are all too often used to justify a neoliberal conservative agenda. This approach challenges how statistics are calculated, their levels of accuracy, conflicts of interest, and interpretations. There is also the use of constructive cartography, counter-mapping, and critical mapping, such as Sidaway’s (2010) maps of “black sites” and renditions used by the United States after the terrorist attacks of September 11, 2001, which employ positivist approaches but for radical ends. With these approaches it is possible to use radical methodological positivism to translate radical geographic ideas into progressive political agendas.

The dispossessed and marginalized in society have been researched at the cost of understanding the elite in society. Given the normative underpinnings of much radical geography scholarship, this is understandable; however, research to better understand elites, the privileged, and those with power would strengthen the radical geography project.

Radiometric dating/techniques

Phillip L. Larson
Minnesota State University, USA

Ronald I. Dorn
Arizona State University, USA

Geographers both develop and utilize four general types of techniques to determine ages of Earth’s deposits and features: calendar ages, relative ages, numerical ages, and correlative ages. All of these techniques require the ability to measure changes over time. Biological systems can be measured by such approaches as counting annual tree rings. Chemical systems can be measured, such as changes that might occur in soils through the accumulation or depletion of minerals. Physical systems can also be measured through such constants as the decay of radioactive isotopes.

The most precise and accurate techniques assign calendar ages to events through historical record keeping (Figure 1), the use of annual tree rings (dendrogeomorphology) (Butler, Malanson, and Oelfke 1987), or counting annual layers (varve chronology) in lake sediment. The least precise dating method simply orders events in a relative sequence from oldest to youngest, such as soil development over time or a sequence of superimposed river changes (avulsions) (Figure 1). Although no specific age is assigned, relative ages are often used to detect problems with more precise techniques when results contradict a relative sequence. Numerical ages are assigned most often using radiometric techniques, such as radiocarbon dating, and typically have ± uncertainties based on measurement errors. Correlative ages derive from techniques that match an event that has a prior numerical age, such as tephrochronology that correlates the mineralogy and geochemistry of a particular volcanic eruption deposit to a volcanic ash deposit that already has a numerical age. Table 1 presents just a few of the dating methods used in physical geography.

The selection of the right dating technique for any particular project will usually hinge on a series of questions.

- What chronometric information do I need to answer the question?
- What material is available for dating?
- What method(s) are the most appropriate?
- What does the age represent?
- How do the precision, accuracy, and inherent uncertainties influence the ability of the age result to answer the research question?
- How much will the dating research cost?

Since it is not possible to review the entirety of the dating methods presented in Table 1, this entry instead illustrates two different case studies of landscapes where these key questions are being asked, and where a variety of dating methods have been (and are being) employed. One case study involves how geomorphologists are establishing ages of glacial and alluvial landforms to understand the Quaternary history of the Minnesota River Valley and its genetic relationship to proglacial Lake Agassiz. The other case study involves ongoing efforts to understand the glacial chronology of the Sierra Nevada of California. The idea behind presenting these case studies...
Figure 1  The Mississippi River just north of the Atchafalaya River undergoes avulsions frequently, where the relative sequence of events can be seen in the satellite image. (a) Map, 1944; (b) satellite image, September 2, 1999. The most precise dating technique, of assigning calendar ages, required precise record keeping (http://lmvmapping.erdc.usace.army.mil/index.htm). </thead>
<tbody>
<tr>
<td>Calendar</td>
<td>Dendrogeomorphology employs annual growth rings in trees to place a minimum age on the underlying landform. Its great accuracy facilitates use in analyzing erosion rates and alpine hazards such as avalanches on timescales of $10^0$–$10^3$ years (Butler, Malanson, and Oelke 1987).</td>
</tr>
<tr>
<td>Calendar</td>
<td>Sclerochronology studies changes in the accumulating tissues of such organisms as corals and mollusks. The annual growth rings in corals offer a powerful tool in climatic change and coastal geomorphic research on timescales of $10^5$–$10^4$ years.</td>
</tr>
<tr>
<td>Numerical</td>
<td>Radiocarbon measures the abundance of $^{14}$C in samples such as charcoal, wood, peat, shells, and carbon–containing minerals such as oxalate and calcite. The method assumes that the carbon-containing material stopped exchanging $^{14}$CO$_2$ with the atmosphere upon death or deposition. Radiocarbon has been used in almost every geomorphic setting including fluvial, colluvial, coastal, glacial, and eolian materials deposited during the last 40 000 years. Radiocarbon ages are typically translated into calendar ages through the use of calibrations.</td>
</tr>
<tr>
<td>Numerical</td>
<td>Optically stimulated luminescence (OSL) measures when sediments were last exposed to sunlight (e.g., transported and then buried). A light-sensitive signal that is “trapped” over time in crystal defects is released upon irradiation. This technique has seen an explosion of use, because of its utility in establishing ages on timescales of $10^0$–$10^5$ years for noncarbonate deposits such as eolian, fluvial, coastal, glacial, and colluvial settings.</td>
</tr>
<tr>
<td>Numerical</td>
<td>Cosmogenic surface exposure dating relies on cosmic rays interacting with rocks to create new nuclides over time. These include stable nuclides that just build up ($^3$He, $^{21}$Ne) and radionuclides that both build up and also decay at different half-lives ($^{10}$Be, $^{26}$Al, $^{36}$Cl). Through careful sampling and keeping track of the variables that alter build-up rates (e.g., altitude, latitude, burial history, surrounding topography), outputs include a combination of erosion rates and exposure ages, and combinations of nuclides can date surfaces on the timescale of $10^2$–$10^6$ years.</td>
</tr>
<tr>
<td>Numerical</td>
<td>Cosmogenic burial dating relies on the build-up of cosmogenic nuclides in rocks prior to deposition. After deposition, these nuclides decay at different rates, allowing the calculation a burial age on the timescale of $10^3$–$10^6$ years. This technique can estimate the ages of marine terrace, fluvial terrace, and even cave deposits previously undatable due to a lack of suitable materials (Granger and Musikar 2001).</td>
</tr>
<tr>
<td>Numerical</td>
<td>Uranium-series (U-series) dating typically uses a number of different decay pathways, but typically the $^{238}$U–$^{234}$U–$^{230}$Th–$^{226}$Ra system with half-lives of 245 000, 76 000, and 1600 kyr, respectively. Coral and speleothem deposits can yield very precise ages, but other materials are often not in truly closed systems typically applied to carbonates with timescales of $10^0$–$10^5$ years.</td>
</tr>
<tr>
<td>Numerical</td>
<td>K–Ar dating and the more precise $^{40}$Ar/$^{39}$Ar dating methods measure when liquid magma solidified through the decay of radioactive $^{40}$K into stable $^{40}$Ar. This method can determine the ages of lava flows and tephra on timescales of $10^3$–$10^8$ years.</td>

<tbody>
<tr>
<td>Correlated</td>
<td><em>Lichenometry</em> compares the growth of lichens (often the maximum diameter of particular species) on surfaces of known age (e.g., cemetery stones) to develop a growth curve for an area. This growth curve then allows age estimates for such features as glacial moraines, debris avalanches, and other features of cold dry climates over timescales of $10^1$–$10^5$ years.</td>
</tr>
<tr>
<td>Correlated</td>
<td><em>Amino acid racemization (AAR)</em> uses the protein residues in fossil carbonate that degrade through time-dependent reactions. While alive, organisms form L-configured amino acids (levorotatory) that re-equilibrate via the racemization reaction to the D-configuration (dextrorotatory). Although factors other than time (e.g., temperature, moisture, species) can also influence the D/L ratio, calibration via independent dating techniques and modeling the racemization factors makes it a powerful tool in understanding landforms on timescales of $10^0$–$10^7$ years.</td>
</tr>
<tr>
<td>Correlated</td>
<td><em>Tephrochronology</em> “fingerprints” the unique mineralogical and geochemical signature of volcanic ashes (tephra) – allowing the correlation of events over broad areas impacted by an ancient eruption. Since many ashes have precise radiometric ages, tephra events can be used to assign maximum ages for sediment deposited on tephra and minimum ages for the surface underneath the ash (Lowe 2011).</td>
</tr>
<tr>
<td>Correlated</td>
<td><em>Varnish microlaminations (VML)</em> correlate layers found within rock varnish to paleoclimatic events. Calibrated by radiocarbon, K–Ar, and cosmogenic ages, varnish microlaminations deliver millennial-scale minimum ages for the exposure of the underlying rock (Liu and Broecker 2013). This technique is limited to warm deserts, where rock varnish is biogeochemically stable. It can provide minimum ages for such landforms as alluvial fans, debris flows, and bare rock surfaces and petroglyphs on timescales of $10^2$–$10^5$ years.</td>
</tr>
<tr>
<td>Relative</td>
<td><em>Topographic position</em> provides physical geographers important guidance in understanding a relative sequence of events. Examples include: superimposition of a younger glacial moraine over an older moraine; a younger river course cutting off the meander scar of an older channel; lower/younger river (fluvial) terraces inset inside older terraces; younger marine terraces lower than older marine terraces; or a younger sand sheet burying a lower older dune deposit. Such relative sequences provide great power in checking the outcomes of correlated and numerical methods that can yield far more precise results – but if done incorrectly can generate inaccurate data.</td>
</tr>

is to provide the reader with a feel for the art behind the science of dating geographic features.

## Lake Agassiz Case Study

Episodic meltwater discharges from proglacial Lake Agassiz are a possible trigger for periods of abrupt Quaternary climatic change (Licciardi, Teller, and Clark 1999). Understanding the evolution of this ancient lake, the timing of spillway activation, and the processes associated with each spillway’s discharge event(s) has prompted several decades of research within and bordering the Lake Agassiz basin (Fisher 2003). Dating methods have played a crucial role in developing
our understanding of the timing and location of these episodic events – although uncertainty still exists (Fisher 2003).

The initial outlet of Lake Agassiz was to the south through the Big Stone Moraine (BSM) and Glacial River Warren – ultimately draining into the Mississippi River and Gulf of Mexico (Fisher 2003). The underfit nature and boulder strewn headwaters of the modern Minnesota River Valley (MNRV) reflect the catastrophic nature of the River Warren floods (Fisher 2003). In order to establish when the MNRV spillway was active, Fisher (2003) applied \(^{14}C\) dates from wood and seed fragments in two core locations in Big Stone Lake and the Browns Valley fan in the headwaters of the MNRV (Figure 2). He concluded that there were two major episodes of outflow here – the first ending approximately 10,800 \(^{14}C\) years BP (12,740 calibrated years BP) and the second ending approximately 9,400 \(^{14}C\) years BP. These periods of active flooding were separated by lacustrine deposits in the cores dating from 12,500 to 12,340 calibrated years BP, which reveal an approximate window of abandonment of the MNRV spillway. The initial abandonment of the MNRV spillway coincides with a period when the Agassiz outlet is thought to have shifted to lower elevations and likely emptied eastward into the great lakes via Lake Superior (Licciardi, Teller, and Clark 1999) – although some controversy exists about this hypothesis.

The resulting post-River Warren landscape of the MNRV has been a dynamic tale of erosion and fluvial response to catastrophic flooding that induced approximately 65 m of base level lowering. These floods carved out most of the modern MNRV. Archeological studies conducted through the Minnesota Department of Transportation collected \(^{14}C\) ages from organic materials in MNRV bottom alluvial fans and fluvial sediments beneath the fans. These measurements suggest that much of the MNRV incised close to its present depth by 10,400 \(^{14}C\) years BP (Fisher 2003).

Surprisingly, very little is known about the geomorphic history of the MNRV outside of a few studies. Johnson, Davis, and Pederson (1998) is the only modern study that attempted to analyze the morphology and sedimentology of fluvial terraces within the MNRV in order to reconstruct the valley’s history. They hypothesized a relative chronology where a major incision event linked to the initial catastrophic flood event from Lake Agassiz was followed by 22 m of infilling based on sand and gravel deposits with forest bedding up to 15 m in height (Figure 2). This period of aggradation was then followed by a brief “more stable” braided stream period and then another significant flood pulse resulting in incision. They concluded that terrace correlation would be impossible without “high-resolution dates” and further sedimentologic work on other terrace locations in the MNRV.

Several small tributaries of the Minnesota River are far better understood than the MNRV itself. Gran et al. (2013) used the Le Sueur River (Figure 2) as a case study to address the assertion that geomorphologists know very little about transient response in the fluvial system. The Le Sueur River is a transient system responding to approximately 65 m of base level lowering caused by MNRV incision. In order to address the river’s incision history and to compare with numerical modeling, optically stimulated luminescence (OSL) and \(^{14}C\) dating determined the age of fluvial terraces along the stream reach. Overbank alluvium was sampled for OSL dating while freshwater mollusks and gastropods were collected from terrace fills for \(^{14}C\) dating. The results of the study revealed that the Le Sueur River is a detachment-limited system where downstream bedload coarsening inhibits incision and transposes the knickpoint over a larger distance in the longitudinal profile.
Figure 2  Shaded relief map of southern Minnesota highlighting the Minnesota River Valley and important geographic locations discussed in the case study. U – Upham, N – Norcross, and H – Herman represent the three highest shorelines (from low to high) of Lake Agassiz described by Fisher (2003) and Lepper et al. (2007). BVF – Brown Valley Fan and BSL – Big Stone Lake represent the locations of the two core sites dated by Fisher (2003). LeS represents the approximate location of the Le Sueur River which was the focus of Gran et al.’s (2013) research. Kasota Pit is the location of Johnson Davis, and Pederson’s (1998) sedimentologic analysis of a terrace fill within the Minnesota River Valley.
Sierra Nevada glaciation case study

The Sierra Nevada Mountains in California remain a classic range for the study of glaciations starting with the use of topographic position to establish relative ages. The current state of understanding starts with $^{40}$Ar/$^{39}$Ar ages of basalts atop the range that record a preglacial plateau topography prior to 3.3 million years ago (Phillips, McIntosh, and Dunbar 2011). K–Ar and $^{40}$Ar/$^{39}$Ar dating of the Bishop Tuff (Sharp 1968) provided a minimum age for the most extensive glacial event, the Sherwin glacial till that rests under the 760,000-year-old supervolcano Bishop Tuff deposit.

As for glacial events younger than the Bishop Tuff, for many decades at the end of the last century, only relative dating techniques were available to order a host of different glacial moraines. However, it was not until the development and use of cosmogenic nuclide surface exposure dating that researchers began to get a handle on the true complexity of glacial sequences (Phillips et al. 2009). In spite of decades of grouping together moraines into broad age classes called “Tioga” and “Tahoe,” the precision and accuracy of cosmogenic methods continue to reveal that Sierra Nevada moraines reflect the complexity of millennial-scale climatic changes. Whereas all last glacial maxima moraines were once all grouped as Tioga, they can now be differentiated into multiple age groupings throughout Marine Isotope Stage 2, from 28 to 14 ka.

The timing of Holocene glaciation in the Sierra Nevada has been more difficult to understand. The chitin of insects has been preserved in sufficient quantity for $^{14}$C measurements along Bishop Creek in the central Sierra Nevada to establish at least four distinct glacial events at approximately 2700 calibrated years BP, approximately 1300 calibrated years BP, approximately 600 calibrated years BP, and approximately 150 calibrated years BP (Dorn 1996). Later, sediment cores along the nearby North Fork Big Pine Creek revealed a continuous record of sedimentation dated through $^{14}$C analyses of macrofossils. This research found similar glacial maxima at approximately 2800 calibrated years BP, approximately 700 calibrated years BP, and 250–270 calibrated years BP, in addition to other maxima at 2200 and 1600 calibrated years BP. Thus, ongoing research into understanding the ages of glacial moraines in the Sierra Nevada mirrors and lags behind our understanding of paleoclimatology in general – that millennial-scale high-magnitude changes in climate can imprint themselves throughout the geomorphic record globally, but the detection of these imprints is limited by the accuracy and precision of the techniques used to date landforms.

Table 1 and these two case studies illustrate that a great number of options exist for today’s geomorphologists. In both research contexts, the type of dating technique employed reflects a combination of the type of material available for dating and the expertise of the researchers investigating the problem. What remains true, however, is the ongoing need for chronometric information to advance our understanding of Earth’s landforms.

Rail transport: freight

Claude Comtois
University of Montreal, Canada

The geography of rail freight transport

Rail freight transport has played an important role in shaping the economic geography landscape. Global analysis of railway freight transport suggests a complex system of railway patterns and functions. First, several penetration axes can be found in Africa, Australia, Brazil, and Canada. These isolated railroads frequently run inland from a coastal port for the development of regions with resources. The mining cluster of the Mpumalanga region accounts for over 80% of South Africa’s coal production. Coal trains travel 588 km to the port of Richards Bay to be loaded on vessels bound overseas. Rail connection is used as a conveyor belt to ship products toward consumer markets. Rail freight traffic generated along these trade lanes can serve as a tool in opening up new regions, fostering settlements, and attracting investments, together with the emergence of intermediate centers along the penetration routes with tangential feeder services.

Second, railways can operate as a subsidiary of plants. Freight trains run on lines between factories to deliver supplies. As rail freight is well suited to mass production, plant railways facilitate the process of industrialization by carrying minerals, agricultural products, and building materials or chemicals to manufacturing centers for first-stage processing, fabrication, or assembly. Rail freight transport between a large number of interlocking individual firms has created favorable conditions for the development of large industrial complexes, as exemplified by the Ruhr basin in Germany, the Pampas in Argentina, and the Kanto plain in Japan. As traditional customers for the transport of bulk commodities on the input side, industrial enterprises also favor railways as the preferred transport mode for the carriage of any resulting waste and hazardous goods from their plants.

Third, railway pioneers realized the importance of linking water loading sites and inland dry ports with overland modes of transport. The rail transport of large volumes of different kinds of freight flows between transport terminals reinforces the complementarity between marine and land ports. The integration of terminals, transport corridors, engineering structures, and fleet illustrates the cumulative connections between infrastructure and trans-shipment function in the development of fully fledged logistics in freight services. At the port of Duisburg, Germany, the integration of rail infrastructures with barge transport has increased the service efficiency and activity of the fluvial port, reducing the cost of using the port, increasing the capacity of organizing logistics services, and improving the competitiveness of products exported to international markets. These linkages between capital-intensive transport infrastructures permit economies of scale, improve market access, increase fluidity of commercial exchanges, and strengthen industrial networks.

The fourth type of rail system consists of the linkages between continental landmasses. Railway carriers haul freight by means of owned or leased equipment. They operate partially over
RAIL TRANSPORT: FREIGHT

their owned tracks or negotiate a right of way owned by other freight railways. Continental railway lines can be found between Montreal and Los Angeles in North America, from Dalian to Moscow in Eurasia, across Southern Australia between Perth and Adelaide, and between Buenos Aires and Valparaiso in South America. The reduction of obstacles to international trade, including the establishment of economic blocs, has favored the introduction of rail land bridges. A rail land bridge refers to traffic transiting a continent bound to overseas destinations. This is the case of some Asian traffic bound for Europe. Cargo is shipped across the Pacific Ocean, carried by rail over North America, and transferred onto vessels for ocean sailing across the Atlantic.

The geographical distribution of rail freight transport suggests that rail corridors leading to and from important places of origin and destination are servicing the spatial distribution of production, procurement, and distribution of commodities. In addition, rail arterial links are contributing to the development of integrated intermodal transportation systems.

The capacity of rail freight transport

Further geographical expansion of rail freight transport must address issues of railway track standards, custom-made rolling stock, and applied information technologies. Since railways operate on specially prepared roadbeds, the number of railway tracks laid is a key determinant in rail freight flows, as trains can overtake each other only when moving on separate tracks. In regions where large metropolitan centers are spatially clustered, there is justification for promoting a higher utilization level of existing railway lines with double-tracking as transportation demand is concentrated, with large volumes of freight traffic over certain rail corridors. In sharp contrast, in areas where urban centers are relatively scattered, involving long distance and smaller traffic volume, the dominant consideration is to reduce construction costs with a single-track railway.

Rail freight transport is equally influenced by railway track geometry, which is produced mainly by the effects of heterogeneous landforms. This includes elevation, curvature, alignment, and track gauge. In Europe, different track gauges are restricting rail freight movement. The most important track gauge limitations within the European freight traffic are found between central Europe (1435 mm) and the Commonwealth of Independent States (1524 mm), and between central Europe and the Iberian peninsula (1676 mm). The competing conditions generated by liberalization processes have created a new dimension in railway track geography. In Europe, differences were established between rail infrastructure companies and rail transport companies. This suggests that the geographical expansion of rail freight transport is affected by nondiscriminating conditions for network access in terms of train path prices for the compensation of use. In North America, mergers and acquisitions led to a reduction in the number of Class I rail carriers from 11 in 1990 to 7 in 2013. The largest carriers in Canada are Canadian National and Canadian Pacific. In the United States, five companies qualify to be Class I railroads: BNSF Railway, CSX Transportation, Kansas City Southern Railway, Norfolk Southern Combined Railroad Subsidiaries, and Union Pacific Railroad. The commercial trend to reduce costs and offer better services pushed these rail carriers to concentrate on freight movement and to abandon part of their network. The process led to the emergence of new short-line railways. There are currently 30 regional and over 500 local railways operating in the United States and Canada. The benefits
of transporting different commodities between numerous pairs of origins and destinations prompted the private sector to focus on freight traffic. The North American railway passenger services are essentially public-owned and subsidized. These public companies operate almost entirely over private freight railway tracks.

The quality of railway tracks also affects the functionality of railway freight traffic capacity. There are various quality track standards. These pertain to the properties of steel rails in terms of chemical composition, the weight of rail expressed in kilograms per meter, and rail length as indicator of number of welded joints and dilatation spaces. Arguably, all these components of railway track structure determine the speed of trains, the axle load of wagons, locomotive traction, the density of freight traffic, and resistance to hazardous environmental events. Further, the implementation of longer trains, more cars per train, and heavier cars through high-quality infrastructure are concomitant with increasing yard capacity in permitting additional train blocks and higher network fluidity. Following the growth in traffic at the port of Los Angeles and Long Beach, the rail company Burlington Northern–Santa Fe has built a new intermodal terminal 30 km inland where double-stack trains are assembled with a view to distributing containers across the United States. Rail access between the port and the railway yards was impeded by single railway tracks involving 200 level crossings through dense urban neighborhoods. In 2001 a plan was approved to construct a dedicated 32 km rail corridor between the port and the inland rail terminals. The Alameda corridor is capable of handling 100 trains per day, reducing daily truck traffic by over 20,000 movements. Deficits in the standardization of railway networks require major investments in crossing loops, passing tracks, loading sidings, and marshaling yards to expand rail freight activities.

The volume of freight traffic that can be carried by railways is a function of rolling stock. Freight trains are loaded and unloaded at different lineside locations such as mining facilities, power plants, industrial sites, and grain elevators. The consignment of these commodities over long distances necessitates the availability of different types of freight cars adapted for the movement of a host of goods. The most common railroad cars used for carrying cargo are open wagons for minerals and other bulk cargo, flatcars for large break-bulk loads, ventilated box wagons for carrying livestock, tank cars for the movement of liquid bulk, chemical, and gas. In addition, the integration of railways within the global containerized intermodal system has led to flatcars designed for containers or semitrailers. The provision of suitable freight loading space is leading to purpose-built wagons. Developed to answer the transport needs of certain lines of business and to ensure closer ties between consignor and consignee, these include fully enclosed wagons for perishable, moisture-susceptible, or weather-sensitive goods.

The liberalization of the rail transport market has given rise to a multitude of new rail operators with a growing need for locomotives and freight wagons. The integration of rail freight transport in the modern logistics of merchandise and manufactures requires a flexible response to many customer-specific requirements. High investment costs and the maintenance of regular and adequate fleet utilization associated with a wide spectrum of rolling stock are significant barriers to market access of railway carriers with expansion plans. Accordingly, strategies to develop rail freight movement include service cooperation in terms of rail vehicle pools for both locomotives and freight wagons. This flexibility in the provision of vehicles allows railway operators to design railway fleets to freight
RAIL TRANSPORT: FREIGHT

shipments and secure greater market shares in the contested freight sector.

Information and communication technologies are key factors in increasing the market share of freight railways. Rail freight capacity is determined by the number of train movements along a railway line between numerous stopping points. As rail freight traffic becomes larger in scale with varied destinations, rail lines are affected by competing usage requirements and by unbalanced rail freight transport demand. Computer-assisted systems for sequencing trains are defining the rights of use in the form of available train paths on hinterland routes. Information technologies applied to rail freight transport include the remote control of vehicles and facilities, and commands for the operation of railway infrastructures. Railway technology development also encompasses railway equipment automation for shunting, freight handling, and trans-shipment operations. Adaptations and changes in rail freight transport are realized through integrated consideration of flows of information, fluctuating freight demand of commodities, and actual use of railway infrastructure materials, rolling stock, and rail services. Advantages have been derived from appropriate interfaces for exchanging information between rail freight service providers, shippers, and consignees in support of commercial transactions. The introduction of operational information systems permits the efficient organization of the complex process involved in the delivery of freight supplies. Arguably, direct access to complex databases, online planning, and the possibility of simulation pose enormous challenges for rail freight operators. Computer-aided design and transport softwares are increasingly being used alongside geographical information system in the planning, design, construction, and maintenance of rail freight infrastructure. Geographic information systems are playing a significant role in the continual planning and control of the transport processes on the basis of a corresponding application of network representation, modeling, and multivariate statistical analysis. Examples include shortest transport times and favorable turnaround times for freight wagons, balance in network flow, railway facilities location, and land-use planning.

The future of rail freight transport

The promising development of freight railways in capturing new business markets rests on the combination of rail transport, high-speed freight trains, and city logistics. The globalization of trade networks and resultant modal distribution between regions has led to the growth of container traffic. The overwhelming primacy of containers has become an essential feature of the commercial integration of the world’s regions. A key factor in the evolution of hinterland connections with container trade is the role of combined transport. The framework comprises a road or barge segment to the terminal, cargo handling at the shipping terminal, the rail journey, cargo handling at the receiving terminal, and fluvial or truck delivery to the customer. Each mode takes over the transport service segment that is economically optimal for it. The objective is to expand single-mode transport services beyond the single-mode network to achieve greater geographical coverage and involvement in long-distance freight traffic. Rail terminal facilities adjacent to major rivers and highways are offering high-frequency rail, road, and barge connections to and from deep-sea container terminals. The emergence of trimodal terminals along the Mississippi, the Rhine, the Yangtze, and the Saint Lawrence rivers allows shippers to develop clusters of services in the assembly, collection, shipment, and distribution
of freight with a view to offering door-to-door services over extended geographical market areas. The complexity of the services offered at these terminals means that long-term customer relations are important to the railways as a basis for establishing important linkages in the logistics chain.

The advent of just-in-time deliveries and the trend toward small- consignment and short-delivery deadlines in manufacturing processes have influenced the scope and spatial structure of freight traffic. Cargo potential includes perishable goods, express courier, and pre-fabricated components and parts involving substantial just-in-time manufacturing processes. The introduction of the high-speed train from southeast Paris to Lyon has led to the development of customized high-speed swap bodies to meet the technical performance requirements of very fast trains. SNCF, the French national railway, has built trans-shipment stations at the railway stations parallel to the tracks used for passenger transport. Freight is loaded through sliding doors located in the middle of these specially designed vehicles. High-speed freight train movement avoids burdening the highway networks with further lorry traffic and reduces the burden to airlines from airport gate delays. The development of high-speed rail corridors thus gives railways an opportunity to win market shares from road and air transport in long-distance freight movement. The trend toward miniaturization of shipped batches of forwarded goods can be fulfilled through the flexibility, punctuality, and reliability offered by high-speed trains.

Transportation is at the core of many urban problems and challenges in terms of sustainability. Freight railways can advance city logistics while fostering long-term protection of the environment. Cities encompass firms producing and offering goods. Transportation companies are moving these goods using a transportation system in which goods and passengers compete on the same arterial network. A basic rule for the profitability of rail shipments is that large quantities of goods be hauled on a regular basis between two points. In Dresden, the Volkswagen Group has entered into partnership with the federal state of Saxony and the local transport operator for the movement of parts and materials from a freight handling center to a new factory using the tram lines used to transport passengers. Appropriate facilities in terms of sidings are provided at both ends to prevent scheduled services from being disrupted. The system has a design capacity allowing 40 minutes’ headway between freight trams 21 hours a day and meets all requirements in terms of traffic lights and stopping points. The objective is to use tramways to feed automobile production manufacture near the city center from a logistics platform accessible by rail and motorway. The Dresden CarGoTram is an ecological and cost-effective transport alternative, carrying three times the load of a single lorry while offering savings in both labor and energy costs.

Rail freight transport contributes to the performance of complex logistics systems. As rail freight transport moves into the future, there will be additional pressure on rail operations that may result from security and environmental considerations. It is up to geographers to provide insights to minimize the impacts while maximizing the opportunities as rail freight transport closely mirrors changes in local, regional, and global transport geography.

Further reading

Rail transport is a means of conveying freight and passengers by moving wheeled vehicles on rail tracks. In a broad sense, rail transport also includes some new forms of guided land transport, such as monorail and maglev trains that run on electromagnetic guideways. Passenger rail has two main forms: first, conventional intercity rail and high-speed rail (HSR) that connect major urban areas; second, commuter rail, light rail, metros, and trams that mainly provide services within and near urban areas. Conventional intercity rail generally runs along densely populated corridors between cities and supports long-distance passenger travel; HSR, as a new kind of intercity rail, has more advanced technology, higher speed, and better service than conventional intercity rail; commuter rail, also called regional rail or suburban rail, mainly operates between a city center and its suburban or surrounding areas; light rail and metros, which have high capacity and speed, play important roles in urban transport, especially for passengers’ daily commuter travel; trams, as an old passenger rail form, are facing challenges of modernization. In accordance with the different services of these rail forms, their speed, capacity, frequency, and right of way also show some differences. For example, commuter rail usually has higher speed and lower frequency than light rail or metro, but covers a shorter distance with fewer stops than intercity rail; light rail does not have fully grade-separated right of way as do intercity rail, commuter rail, and metro, and it has lower capacity; metro is an electric urban rapid transit with relatively high frequency of service. Nevertheless, all these forms of passenger rail transport provide different kinds of travel services for passengers.

From a geographical perspective, there is great regional disparity in terms of passenger rail transport. The world’s total passenger-kilometers by rail transport reached 2867 billion in 2012. Table 1 shows the regional shares of Europe, the Russian Federation, Africa, America, and Asia, Oceania, and the Middle East and their growth rates from 2007 to 2012 (UIC 2013). It shows that the passenger rail traffic is highly concentrated in the region of Asia, Oceania, and the Middle East. Europe has the second-largest passenger-kilometer share but its growth rate is much lower than that of Asia. Although the passenger rail traffic share is very low in America, it has had a very high growth rate recently. Both the Russian Federation and Africa have low passenger travel shares and negative growth rates. Moreover, railways in Asia and Oceania are intensively used for passenger travel. Asia, Oceania, and the Middle East accounted for 76% of world passenger travel with only 23% of the world’s total (including both passenger and freight) railway length. Europe accounted for 17% of world passenger travel with 26% of the world’s railway length. America only accounted for 1% of world passenger travel with 36% of the world’s railway length, reflecting the dominance of freight transport in the American railway network (UIC 2013).

The great regional disparity of passenger rail transport could be due to several reasons. First,
for short distances, automobiles are faster and more convenient than rail transport. For long distances, air transport is much faster than most rail transport. So, in areas where automobiles and air transport are available and well developed, such as the United States, passengers tend to choose these other transport modes instead of railways. In much of the developing world, such as China and India, railways are still dominant in passenger travel. Second, the operational costs of railways are high and it is only economically feasible if the passenger number reaches a large volume. Facing the keen competition of automobiles and air transport, railways often experience financial difficulties. Although different kinds of strategies were adopted for lowering railway costs, such as closing unprofitable lines, increasing travel speed, adopting new and more efficient fuels, and providing air conditioning, night berths, and restaurant services (O’Dell and Richards, 1971), the decline of railways in many countries was not reversed. Third, the construction of railways requires relatively level ground because of its engineering characteristics and so highways and airports are more economical in regions without level ground topography (Sharma 2007). Nevertheless, in some regions with high passenger demand or undeveloped areas, rail transport was often the most secure and efficient means of passenger travel.

The technology of rail transport has constantly improved over time. As early as the early nineteenth century, steam trains had been successfully developed in England. Although electric trains, trams, and rapid transit systems had been introduced in the 1880s, it was not until World War II that the motive power of rail transport largely changed from steam to diesel and electricity. In the 1960s, HSR technology was first introduced to passenger travel in Japan. Over time, HSR was built in many other countries, such as France, Germany, Spain, the United Kingdom, Italy, and China. Compared with conventional railways, modern railways can accommodate passengers’ mobility needs with higher speed. Urban rail transit systems now support massive passenger travel in many metropolitan areas around the world.

A central issue related to rail transport in geography is its important role in sustainable transport, which covers the environmental, social, and economic aspects. In terms of the environmental aspect, rail transport has relatively less impact than automobiles and air transport per passenger-kilometer carried. For instance, studies show that the carbon dioxide emissions per passenger-kilometer of railways in cities are generally lower than other transport modes, except buses (Loo and Li 2012). Although the absolute level of emissions of HSR are higher than conventional railways, they can have lower emission intensity by having higher load factor, fewer stops, aerodynamic train design, and lower carbon content in electricity supply. Also, rail transport can offer higher passenger capacity than automobiles with less noise and air pollution,

smaller land uptake, and lower energy consumption. However, there are still many challenges for making railways more environmentally friendly, including shifting the demand from automobiles and air transport to rail without generating new or induced demand, increasing the load factor of rail transport, and implementing operational and technological measures to improve the energy efficiency of rail operation (Givoni, Brand, and Watkiss 2009). In the future, as the technologies of clean energy and trains further develop, rail transport may play an even more important role in promoting the environmental sustainability of passenger transport.

In terms of the social aspect, rail transport performs better in safety, social equity, and traffic congestion alleviation. Rail transport is generally safer than other land transport modes because trains usually operate on exclusive tracks. In Europe, the risk of fatality per billion passenger-kilometers for rail transport from 2004 to 2011 was only 0.15, much lower than that of cars (3.8 fatalities per billion passenger-kilometers) (Allianz pro Schiene 2013). Also, compared with private vehicles, rail transport has the characteristics of public transport, which is more affordable to socially disadvantaged groups. Within cities, rail transport can often improve accessibility to different kinds of social activities for the poor and disabled who cannot afford a private vehicle or who cannot drive. In terms of employment, railways can generate different types of jobs, from senior managers, professionals, and engineers to operations staff, for local people and broaden the range of accessible employment for the socially disadvantaged population. At the regional level, rail transport is often built in the hope of improving accessibility for peripheral regions and providing them with more opportunities, thus promoting regional integration. In addition, rail transport with high speed, capacity, frequency, and reliability could effectively relieve the problems of traffic congestion in large metropolitan cities.

In terms of the economic aspect, the main contribution of railways to development is through indirect impacts on regional economies. On the one hand, the accessibility of the region along the railway may be improved by the connection of railways and employment, industry, and trade. It is a strategy of the World Bank to promote regional development and reduce poverty by lending to support railway projects. On the other hand, the investment of railways may stimulate land development and business activities around railway stations. The transit oriented development (TOD) model, which emphasizes mixed land use around a transit stop, gives potential opportunities to integrate railway development and land use. Accordingly, railway stations are no longer seen only as access nodes to railway systems but also as places with many other activities such as residential, commercial, and industrial services (Reusser et al. 2008).

Although rail transport has been recognized as a sustainable transport mode, rail transport projects are financially risky investments in light of high capital and operating costs. The construction of railway systems requires heavy capital investment, that is, planning and land costs, infrastructure building costs, and superstructure costs; and there is no guarantee of sound financial returns in the short term because of the high maintenance and operating costs, not taking into account external costs. Hence, planning and investment in rail transport (passenger) often receive much attention and are the focus of debate. For instance, it is argued that there should be socioeconomic benchmarks for evaluating cities for building or extending metro systems, such as population size and income level (Loo and Cheng 2010). For other railway systems, careful planning and feasible studies to
RAIL TRANSPORT: PASSENGER

contrast benefits and costs should be undertaken before the construction.

Moreover, project management and effective operational management policies are important. Considering the large investment and operating costs, traditional railway regulations were often based on public ownership and operation. However, government control of railways is increasingly being viewed as inefficient, quasi-monopolistic, and unresponsive to the market. Many countries aim to improve the efficiency and competitiveness of their passenger rail system by reforming railway governance: some have completely separated infrastructure management from rail operations and placed it in a state-owned organization, such as in Sweden and Britain; some have retained infrastructure and train operations within the same holding company but as separate divisions, such as in Germany, Italy, and Greece; some have separated infrastructure management from operations while still maintaining an operating company monopoly that retains control of many functions, such as in France (Nash 2008). With more empirical evidence, the discussion on railway governance will remain a key area in rail research.

Recently, the twenty-first century has witnessed a revival of rail transport for passenger travel. The reasons are manifold. First, the negative environmental, economic, and social impacts of automobiles and air transport, such as local air pollution and traffic congestion, as well as global warming, have raised worldwide concerns as the passenger traffic volume increases (Shaw and Docherty 2009). Second, the technological improvement of rail transport makes it not only environmentally sustainable but also more competitive with automobiles and air transport because of the higher speed and greater comfort. Third, since the possibility of alternative solutions for sustainable transport (such as improvement to telecommunications making transport less necessary and the large-scale use of alternative fuel vehicles) will not be realized in the near future, rail transport has been seen as a promising strategy for achieving sustainable transport.

In the last two decades, there has been large-scale construction and planning of HSR and urban rapid rail transit systems around the world. Both HSR and urban rapid rail transit have high capacity and high frequency. Shorter travel times and an improved level of service of HSR have led to changes in modal share along the HSR route (Givoni 2006). Experiences in Europe show that HSR can substitute short-haul air transport for passenger travel. However, whether the urban rapid rail transit systems can bring passengers from automobiles back to public transit is still under debate and there may be induced travel demand due to new rail transport development. Nevertheless, modern rail transport could have some impact on people’s travel behavior and slow down the rate of motorization in developing countries with currently low reliance on private vehicles.

Moreover, fundamental geographical changes are happening. Shorter travel times and increased accessibility of cities by HSR cause compression of time and space and drive change in economic development and social interaction between cities. Meanwhile, the impact of HSR on regional land development can also be great. However, compared with cities with stations in the HSR network, those that are bypassed would probably lose some opportunities. The impact of urban rail transit may not be as wide as that of HSR, but its impact on restructuring urban form could also be significant. The livability of communities along the metro or light railway may be improved and more employment opportunities and services may concentrate near the stations. However, property rents and living costs may also be increased.
Taking a wider perspective, the integration between rail transport and other transport modes and the integration between rail transport and land use have also received more attention from researchers. The former aims to promote the accessibility of railway stations and improve the connection between the railway and other transport modes. The key concern is to enhance the travel experience of passengers and, hence, enable the railway to fulfill its potential role in supporting sustainable transport. The latter considers the coordination between rail transport supply and travel demand depending on land use. The focus is to minimize unnecessary journeys through creating compact activity nodes and to increase the convenience and positive impacts of rail transport as a passenger transport mode.

There has been some progress towards better integration related to rail transport around the world. This includes the building of highly integrated transport hubs, the integration of land-use planning with rail transport planning, and the establishment of common information and ticket-booking systems for different kinds of transport modes. Yet, there is still a long way to go before we realize the vision of seamless integration and more efforts are needed in both infrastructural construction and institutional support.

In the near future, rail transport will remain important in contributing to sustainable transport. Transport geography, the discipline focusing on the network, movement, context, and impact of transport systems, will continue to contribute to the decision-making, impact analysis, and institutional reform of rail transport and its integration with other transport modes and land use.

Realism, critical

Kevin R. Cox
Ohio State University, USA

Critical realism (CR) originated in significant part as a critique of positivism. The philosopher Roy Bhaskar was central to the project, and its entry into geography would be largely through the work of Andrew Sayer, at the beginning of the 1980s. The positivism that had been at the heart of the spatial-quantitative revolution of the 1960s had already come under attack at the hands of Marxist and humanistic geographers. The contribution of CR to that critique and its contributions to method in human geography, though, would be significantly different.

In contrast to Marxism’s totalizing account of the world and its critique of positivism, CR was more pluralistic. It represented a critique not just of spatial-quantitative work but also of the Marxist geography of the 1970s. For humanistic geography the search for laws ran aground on the inherent indeterminacy of human agency. CR recognized the force of this claim while keen to preserve a crucial role for structure. On both these grounds, therefore, it sat comfortably within an emerging society-and-space interest, anxious about what Thrift would call “jumbo Marxism” and about the question of structure and agency.

That it had a positive impact in human geography is without doubt. It was drawn on extensively by people of more radical persuasion such as Simon Duncan, Michael Storper, and Richard Walker. Doreen Massey’s work on spatial divisions of labor was seen to fall within the critical realist approach even while she never articulated her method as such. Significantly, Duncan, Massey, and Sayer would all be on the editorial board of the new journal Society and Space as it took off in 1983. Voices of disquiet were few and far between but David Harvey was notable among them. At its most ambitious, CR was presented as a method for a radical geography, and, according to some, Marx was a critical realist before his time. This now seems quite inaccurate (Cox 2013) and Harvey’s presentiments justified.

What was at stake was a philosophy of science and, as such, ontological claims were fundamental. For critical realists the world consists of the events we experience, the causal mechanisms responsible for them, and the structures of relations that in turn entail those mechanisms. Similar events can be generated by quite different mechanisms; their conditions of existence in structures of relations therefore vary. Structures of relations entail causal powers or causal susceptibilities – characteristic ways of being affected. The enabling of these causal powers or susceptibilities then results in the world of events.

Given the way in which spatial-quantitative geography and positivism in general hewed to a Humean concept of causation in which constant conjunctions of events were a necessary though not sufficient condition for claims about causation, CR appeared to offer powerful critical leverage. The immediate targets were the empirical regularities at the heart of the spatial-quantitative work. Conjunctions of events had their conditions in structures of relations that could vary significantly from one conjunction to another. Something like the distance-decay relation as it applied to migration provides a case in point. For movements at a given distance...
from a point of origin, the structures of relations necessary for them to have occurred can clearly be very, very different: a corporate transfer within the structure of a firm’s spatial division of labor is not at all the same as the case of someone who in the context of a military posting marries someone local and decides to stay. Distance relations might be part of the explanation—the way firm branching tends to be intra—rather than international—but only in a highly mediated way and as something that had to enter into socio spatial rather than simply spatial relations.

Even where a constant conjunction seemed to have some rationale, where it might seem that correlation was not just necessary but also sufficient to impute cause, again it could have other conditions that had to apply if it was to obtain. For example, the way in which, in the United Kingdom, the differential availability of central government employment subsidies seemed to even out unemployment rates in the 1960s attracted attention (Sayer 1986). Subsidies were made available for so-called development areas, which coincided with areas of relatively high unemployment—erstwhile coalmining or shipbuilding areas in particular. But clearly any success that the policy enjoyed depended on still other conditions. Almost invariably, the new locations were of branch plants, suggesting the significance of new spatial divisions of labor of firms. Labor processes requiring limited industrial skills, as in light assembly work, were also high on the list of activities subject to relocation in this way, but this in turn suggested the importance of processes of deskilling that allowed this process to occur, a process entailed, in turn, by the capitalist accumulation process. There was also the fact of labor shortages in existing industrial centers. This suggested that the location of branch plants in the depressed areas would have occurred regardless of the existence of government subsidies. In short, causal structures seemed much more complicated and diverse than those that had been embraced hitherto. One had to look beyond constant conjunctions of events to the structures of social relations that were their condition.

Structures of relations were the sphere of the necessary: what had to be present in order for an event to occur. But whether or not it did occur was a contingent matter—contingent on the presence of yet other conditions. A firm with a spatial division of labor of the parts-process form might have the ability to relocate low-skill production, but whether it did might depend on labor market conditions: how much its profit lines were being squeezed by the wages of semi- and unskilled workers. In contrast to the sphere of necessity defined by structures of social relations, events had a contingent status.

This argument raises the crucial question as to how structures of relations were to be identified. A useful contrast drawn by Sayer (1984) was between what he called “chaotic conceptions” and “rational abstractions.” Chaotic conceptions brought together conditions, practices, and objects that were related to one another regardless of the contingent or necessary nature of those relations. As such it was impossible to impute causal properties that necessarily inhered in them. Rational abstractions, on the other hand, brought together the necessarily or internally related, as in a division of labor. Each part depends on the others and on some sort of coordination mechanism. The result is that those participating in a division of labor find that they have new causal properties, not least an ability to specialize.

Rational abstractions could be identified on the basis of a variety of evidence. Intensive interviewing can go some way in identifying the necessary conditions that agents are aware of and which help them make sense of their actions. Documentary evidence suggesting causal mechanisms and their conditions could be important.
and even empirical regularities when drawn on critically. In any case, the typical approach was to work back from the world of events to what was conditioning them: a process defined as retroduction and in contrast to the inductive approach of positivism. Retroduced structures then stood to be revised in the wake of new research.

The interest in CR in geography generated a number of notable contributions. Critical work was to the fore and some of it involved new empirical investigations (England 1993). In other cases attention focused on particular structures of social relations such as patriarchy and the division of labor and their geographic implications (Foord and Gregson 1986; Cox and Wood 1997). In retrospect its impact on human geography might seem to have been short lived, eclipsed by the interest in the various posts that occupied the center ground of the field from the late 1980s on. Little is now heard of it in geography. Even so, there were some lasting effects: the language of necessity and contingency crept into geographical analysis, though not always accurately. More significant was the way in which, through its emphasis on preconditions for events and the utter contingency of the latter, it lent impetus to a heightened historical awareness in explanation.

Recreation

Anne-Marie d’Hauteserre
University of Waikato, New Zealand

Even though recreation research was earnestly pursued by geographers as early as the 1930s, “recreation geography has never been valued … because it is believed it is impossible to be serious about individuals and groups having fun” (Butler 2004: 151). The specialty has lacked prestige in academia so, until recently, there was a paucity of material covered and relatively little research was undertaken by geographers compared to those in other disciplines. And yet leisure is considered a human right under the United Nations’ Universal Declaration of Human Rights. While geographers have discussed leisure as a force that allows individuals to consider and reflect on the values and realities that are missing in the activities of daily life, and is thus an essential element of personal development and civilization, little debate has emerged about what constitutes the field for geographers.

Recreation is an activity done for enjoyment when one is not working, and it has been emphasized that “recreation is an activity voluntarily undertaken primarily for pleasure and satisfaction during leisure time” (Patmore 1983: 3). The word comes from late Middle English (in the sense of “mental or spiritual consolation”) via Old French from the Latin recreatio(n-), from recreare, “create again, renew.” These roots help explain why recreation has also been considered to be useful for “recharging the battery” so that workers can be more productive. It is important to remember, though, that leisure time is a social construction and that such definitions apply primarily to Western societies, where work and free time (leisure) have long been distinct for some. Feminist literature has demonstrated, however, that women (and also others) often devote much time to unpaid work during their free time, and that historically leisure has been a male prerogative. Leisure and recreation, moreover, have become popular activities only since the 1900s, after workers gained the right to paid “free time” (holidays and weekends). China, for example, only recently provided three weeks of “leisure” per year, to entice the Chinese to travel and discover their own country. The increase in leisure and recreation has coincided over time with increased longevity and, for many, with decreased hours spent on physical and economic survival.

For geographers, recreation is a dynamic phenomenon that provides meaning through which people can construct their identity, as it creates a sense of belonging, enabling friendship, community building, and empowerment through its performance. Recreational activities can be communal or solitary, active or passive, outdoors or indoors, healthy or harmful, and useful for or detrimental to society. Many recreational activities are organized by public institutions, voluntary group-work agencies, private groups supported by membership fees, and commercial enterprises, and are thus considered as formal because they occur at specific times and sites, whereas informal activities tend to be self-organized and are fluid in relation to times and sites. Geographers have also examined the increasing consumption and commodification of recreation and underlined that a resource base (in quantity, quality, and extent) is a precondition for many recreational activities. These can be
formal (e.g., cultural resources such as libraries, museums, and theaters) or based on nature (e.g., parks, forests, farms), and operate as private, commercial, public, or professional ventures. Some facilities can be capital-intensive (e.g., opera houses, ice rinks) or land-intensive (golf courses), or both (sports stadiums), creating financial barriers to their use.

Geographers have underlined the complex relationship between the desire to partake in recreation and the opportunities (such as the existence of resources – the economic, social, and cultural means – and the physical abilities) to do so (Hall and Page 2014). Although motivation to participate might include the need for excitement through the challenging nature of the activity and the use of high-level or special skills, leading to a peak experience, in other cases only relaxing, undemanding, and low arousal activities are sought. A continuous spectrum lies between the two extremes, with different consequences on the environment or other resources. Geographers have also considered how creative expression figures in recreational practices.

Recently, geographers investigating recreation – a process that involves complex social and individual relations and contestations – have emphasized how space, itself socially determined, constructs opportunities for and access to recreation. Geographers have noted the rapidly changing nature of time and space, as in time–space compression, and how this phenomenon has extended the space of opportunities for recreation away from the home just as the home now provides a greater variety of recreational outlets. Recreationists themselves have also become the subject of studies by geographers in terms of their embodied and socialized practices and their multisensory sensitivities. Such studies have revealed a multiplicity of behaviors as well as emotions, affect, and identity constructions based on ethnicity, age, and other social dimensions. Emotions, for example, have much influence on the performance of a learned skill, a characteristic of many recreational activities.

Even though geographers agree that leisure and recreation are considered a human right, they have pointed to obstacles and constraints that prevent their practice. There is a large range of these: an individual’s habitus often determines the specific activity pursued (e.g., attending opera versus playing informal rugby); income influences mobility and accessibility; seasonality dictates the availability of resources (as in skiing); personal constraints may include conflicts with other family desires, lack of time, and health concerns. Geographers have shown how the use of space for recreation is constrained, for example, for women, who may find it difficult to join formal recreational activities as their leisure time is often divided into small blocks not always at convenient times. Some children find their public recreation spaces reduced because of fear for their personal safety. Use of certain spaces, according to some geographers, has also been curtailed by gender and ethnicity: for example, they may avoid peri-urban woodlands and even urban parks through fear of sexual violence and racial attacks.

The impact of recreational activities on natural resources has been a long-standing area of interest in geography, as has the planning of leisure and recreation. Recreation was also long considered by geographers to be significant only in rural areas, as indicated by numerous studies on forests and parks as sites for recreation. Geographers have demonstrated that recreation that occurs outdoors can impact the environment, although its practitioners can also learn to appreciate nature better. Golf courses require water that is then no longer available for other activities in more arid areas, rendering that activity unsustainable in those locations. Certain geographic spaces such as parks, beaches, or the countryside
are essential venues for many recreational activities where active forms of these are becoming more popular. But then questions of access (on the basis of income, race, religion, gender, etc.) arise, or of conflict when practices (on the same basis) clash or incompatible activities take place in the same space.

Early geographic studies of recreation were descriptive in nature, branching out into simple explanatory quantitative studies. Some used quasi-mathematical approaches such as Christaller’s central place theory, applying economic principles to recreation and its spatial patterns. Those who consider recreation as a basic human need, however, have tended toward classification, categorization, and modeling to explain its societal origins. Today, the methods used are very similar to those employed in other areas of geography as authors embrace the turn to cultural, embodied, and emotional theorization and the nonrepresentational aspects of recreation.

Recreation overlaps with leisure and tourism as many aspects of all three converge in personal experience and occur during free time outside of work commitments. Tourism has become a popular global leisure activity, and many tourists are specifically attracted by recreational offerings and often practice recreational activities while visiting a destination. Natural sites and the recreation opportunities they offer have also become an important element of nature-based tourism, and ecotourism in particular.

Reflexivity

Farhana Sultana

Syracuse University, USA

Reflexivity is practicing critical consciousness of one’s location, actions, and power relations during a research process. It involves locating one’s self and positionality both epistemologically and socially vis-à-vis research participants and research process. Reflecting upon and assessing how one is positioned can enable more conscientious and ethical engagement, be it with people, institutions, or texts. Reflexivity requires researchers to continually reassess how they themselves influence the research process and people’s reactions and responses. Useful insights are gained through this process that can then further enrich and inform the research process. Increasing interest in and application of reflexivity by geographers, particularly feminist geographers, has produced a sizable scholarship on the topic in recent years (Rose 1993; Moss 2002). Reflexivity has become established as an important component of research. Being reflexive can be a transformative process whereby the researcher is not only aware of but accounts for power relations, changing subjectivities, and overall effects over time and space. These issues are increasingly becoming critically important in research methods, especially field methods, in human geography that involves qualitative research. It is also important throughout one’s scholarship, which means being critical of not just the research process, but also about one’s writing and reading.

Since field-based research is often unpredictable, an approach that is flexible and reflects on the process continually is able to respond to complexities and contingencies. While this may be contrary to fixed research objectives and goals, or institutionally regulated research permissions, many scholars find the need to navigate such constraints and challenges regularly. A reflexive research process enables scholars to assess and adjust thereby ensuring that pursuits are fruitful and meaningful. While they are mindful of their own location in the process, scholars are also able to respond to situations and relations as they arise with greater awareness and conscience. This is different from maintaining predetermined goals and detached methods that are common in positivistic research approaches. Reflexivity is often contrasted with modernist research that claims to be “objective” whereby the power relations between researcher and researched are erased. There is also often problematic extractive knowledge production, and concerns over gaze, objectification, and reductionism are not directly addressed. To be self-reflexive of the research process is to be cognizant of the situatedness of all knowledge and to recognize that knowledge is partial and always produced from vantage points that are shifting and involve power relations.

Situated knowledge aims for locally “objective” knowledge that is recognized to be partial and context-driven; it does not speak to any absolute truth and thus opposes detachment and modernistic notions of objectivity. Situated knowledge comes as a critique of both logical positivism and standpoint theory. Standpoint theory argues that voices of the marginalized, especially women, should be prioritized and thereby privileges epistemic positions (Harding 2004). Situated knowledge emerged out of poststructuralist engagements in feminist
methodology and espouses that no position is permanent and that all knowledge is partial (Haraway 1988). Situated knowledge can thus be produced through the practice of reflexivity, whereby one’s location and positionality become part of the knowledge production process and evaluation of research outcomes, as well as being mindful of and accounting for the contingencies and partialities of all knowledge produced. Reflexivity is a research method of situating oneself and analyzing these complexities and challenges as well as the unequal social relations that infuse academic endeavors. Embracing situated knowledge means being critically conscious that power relations can produce “others” in the research process and that researchers are themselves part of the process that produces such differences. Self-reflexivity is thus a mindful way to situate the researcher themselves in this very process, to acknowledge the embodiments and scales involved, and to locate the researcher along a range of issues that can be social, political, economic, cultural, religious, or geopolitical. This acceptance of the location of variously situated subjects and the relational aspects of knowledge production thereby leads to an awakening toward the negation of epistemologies of all-knowing at all times or any absolute truths. Reflexivity thus is a critique of the God-trick (or the view from nowhere) (Haraway 1988) as it grounds the researcher and the research process in bodies, places, spaces, and scales. Embodied subjectivities of the researcher and all those who participate, or not (whether by choice or not), thus become central to the critical analysis of any research process and its outcomes.

There are many interpretations and uses of reflexivity and numerous personal and professional concerns that come with it. Scholars grappling with reflexivity are generally committed to maintaining a critical eye to the pitfalls and challenges while attempting to apply reflexivity in productive and meaningful ways. Impacts of the researcher on the research situation and shifting identities become part of the accounting process in research where reflexivity enables researchers to respond to and analyze different aspects of fieldwork accordingly. Reflexivity requires not only assessing and accounting for the researcher’s multiple locations across a series of intersections (race, class, gender, dis/ability, sexuality, nationality, etc.) in relation to others in the research process, it also raises questions of research ethics. Ethical research places importance on being conscientious, reflexive, and morally tuned. The intrinsic importance of critical thinking and ethical engagement are foundational to reflexivity as well as detailed methodological accounts and careful representation.

Since reflexive researchers attempt to demonstrate that research is about social construction and not purely representational, the process before, during, and after research becomes important. Social construction of experiences and interpretations are thus explicitly accounted for. Trying not to speak “for” others, but enabling collective construction of research data and output is often central in reflexive research. Reflexivity can foster rigorous research and encourage critical engagement with one’s methodological choices and outcomes. As such, thorough and rigorous documentation and evaluation of methods and techniques become necessary as well as multiple forms of capturing experiences, narratives, and voices. How people and places are documented and constructed become critical moments of being reflexive about texts and writing. This sheds light on silences and absences as well as any hyper-visibility or overstating of any particular issue at the expense of other issues in the research. By sharing a reflexive research process, the researcher opens it up for reinterpretation and scrutiny by others. Readers are able to judge
and assess methods, content, findings, and the production of knowledge. This public nature of reflexivity can be empowering as well as can open up further conversations and analyses. Validity of data produced or claims made can be gauged against the process through which knowledge was produced.

Being reflexive can also be a political act. This often means a conviction to making a difference in the lives of those involved in the research process rather than simply producing academic outcomes. Such political overtures of reflexivity can be complex and protracted. While being self-conscious does not necessarily rectify problems of representation and power, and the process may or may not result in meaningful research for the peoples and places involved, it has the potential to be so. What becomes important in undertaking reflexive research is to critically account for the research process historically, socially, and spatially. This enables upfront analyses of issues such as racialization, gendering, post/coloniality, geopolitics, and power relations that are intersectional. Being critically mindful of colonial legacies, imperialism and empire, politics of development, controversies of globalization, and other broader cross-scalar and historical issues enables researchers in “other” places to locate themselves on a broader canvas that then enables more comprehensive understanding of situations and contexts. Reflexivity thus should not just be about interpersonal relations but also about a range of cross-cutting and cross-scalar issues that constitute the researcher’s subjectivity (Sultana 2007).

Despite reflexivity having become a key aspect of qualitative research processes, concerns have been raised along multiple lines. While an unreflexive research process would not be encouraged or espoused by most human geographers, emerging concerns raise important questions about theorizing and practicing reflexivity. One concern is that it can become a superficial apology for being of the dominant group that usually has authority and power. While acknowledging being privileged through gender, race, class, ability, nationality, or any other axes of difference may signal a reflexive consciousness, a simple acknowledgment does not necessarily address issues of power and privilege (e.g., noting the researcher as white, male, able-bodied, American or British academic – the largest demographic within the discipline of geography – does not necessarily change anything). This is particularly troublesome when the voices, opinions, and realities of the less powerful or “others” are subsumed into the dominant narrative. This can end up reifying differences and reinforcing dominance as it reasserts attention to the researcher.

Refocusing on the privilege of the researcher has thus become a concern in overly subjective and insufficiently analytical narratives. If this actively shifts conversations and relations of power then this emplacing of the researcher may be more productive; however, it can also tend to silence and marginalize others while reinforcing the privilege of the researcher, however conscientious and ethical the desire may be. This dilemma has been a topic of debate for quite some time among feminist and postcolonial scholars (England 1994; Wolf 1996; Bondi 2003; Domosh 2003). Thus, reflexivity has the risk of being apolitical. It can also obfuscate analytical purchase of a research process if it is mired in auto-ethnographical minutiae. This may end up reinforcing the position of dominance of the researcher thereby absolving them from meaningful engagement, or end up reproducing an authoritative voice that actually can silence others. Reflexive acts can be misused to justify a research process or writing thereby negating the actual goal of reflexivity.
Another area of concern has arisen out of the growing number of publications by researchers who reflect upon their research experience in a way that can range from navel-gazing to tortured autobiographies. This self-indulgence can deflect attention to the positionality of the researcher without sufficiently accounting for a reflexive research process or contributing to debates around reflexivity. It has become increasingly common for geographers in recent years to produce such publications, some with greater success in moving scholarship forward than others. Merely recounting one’s research experience does not necessarily contribute to debates around reflexivity or demonstrate reflexivity. But the reflexive turn in human geography has resulted in scholars seeking acknowledgment of their research process through production of post facto auto-narratives that often lack self-examination or a transformation of the research process.

Beyond the problematic uptake of reflexivity and concomitant proliferation of publications, what is also of concern is that enforcing reflexive accounts of research may result in surveillance and domination by more powerful scholars, especially senior colleagues over junior colleagues. Unequal power relations outside of the research process can thus impinge on the extent and usefulness of reflexivity for emergent scholars and students as consequences can have deleterious impacts on the trajectory of the scholar. This raises some dilemmas for rising scholars who may be in precarious positions or liminal roles. Thus, reflexivity can be a double-edged methodological and scholarly device in that there is increasing pressure to demonstrate one’s reflexivity while at the same time it can have problematic outcomes for the scholar involved. Beyond academics, reflexive research and writing can also pose risks to research participants if sensitive material is inadvertently disclosed or hinted at. The emotional labor involved in reflexive practices can also be a discouragement to those who wish to employ it. Furthermore, the partiality of reflexivity should be acknowledged in that it may not be possible to be fully reflexive. There are thus many ongoing challenges to practicing reflexivity.

However, reflexivity can be very productive of political acts and collaborations and is generally espoused in order to make a difference not only to the research process but beyond it (Rose 1997; Bondi 2002). The simultaneous nature of being reflexive and living in the moment, and adapting and responding to insights generated, can produce useful information beyond the research project and foster relationships that can be generative. Thus, reflexivity does not have to be a self-indulgent or cathartic act, but rather must move beyond methodological tools to improve one’s research and the outcomes of the research process toward more meaningful impacts in the long run. For instance, it can encourage instances or events to be reinterpreted and rethought and thus generate new insights on hidden aspects of a situation that may be fruitful to explore or challenge. It can also have the potential to be politically and socially relevant when research data and experience are carefully and consciously analyzed and processed. Action research that engages the researched as researchers is increasingly being pursued in order to address concerns of privilege, voice, representation, and power. Reflexivity can be the basis of engaged activist scholarship and not just a corrective measure in the research process. Radical vulnerability and radical empathy can be cultivated out of reflexive praxis and thereby enable scholars to become scholar-activists that foreground politics, context, and situations. Collaborative endeavors can emerge from reflexive research and writing and new avenues of collectivization, solidarity, and empowerment.
can result, for instance, around issues of social justice (e.g., Sangtin Writers and Nagar 2006). Such formations and relationships can only be sustained when all participants engage in reflexivity through the process and thereafter.

Practicing reflexivity can be complex and challenging, and there are limits to the insights gained from it. One of the key challenges involves sustaining reflexive relationships and research processes over time, space, and life cycles. Another is the location of this practice within the academy amid growing pressures to produce large volumes of research output and publications quickly. The pitfalls of the extensive need of continuity of engagement and connection can discourage academics from engaging in such scholarship. Similarly, the commitments of time, energy, and taking risks can also discourage research participants from being involved as they may have other priorities of survival and life. As a result, while reflexivity can generate insights and foster relationships to address inequities not only in the research process but also in the wider world, the logistics of undertaking and sustaining reflexive work that has the potential to be politically and socially relevant may be curtailed by a range of factors. Constraints may be overcome depending on the context and people involved, and offer great potential for transformative politics, but continue to pose challenges that may be difficult to resolve in increasingly neoliberalized academic contexts where rapid publication outputs are often valued over other forms of scholarship and engagement.

Despite such challenges, reflexivity is a critically important aspect of research and an important skill in which students and scholars should be better trained so that they can incorporate such practices in their own work. Reflexive research and praxis needs greater engagement and acknowledgment within academia and beyond.

Refugees are individuals or groups who have been forced to leave their home and have sought refuge across an international boundary. Refugees pose a series of challenges to nation-states in terms of classification, accommodation, and the human rights of those outside the formal state system. In this way, the study of refugees sheds light upon the nature of citizenship in contemporary geopolitics. While refugees form one specific group of forced migrants, their reception, representation, and treatment is often conflated with other migrant groups and with concerns over immigration and border security. A strict legal definition of a refugee is outlined in Article 1 of the 1951 Convention Relating to the Status of Refugees, which states that a refugee is a “person who owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country, or who, not having a nationality and being outside the country of his former habitual residence as a result of such events, is unable or, owing to such fear, is unwilling to return to it.”

The legal status that defines refugees distinguishes them from other categories of migrant. In particular, asylum seekers are those who have applied for refugee status but are awaiting a decision on this claim. The forced nature of displacement for refugees and asylum seekers differentiates them from other forms of international migrant, such as economic migrants who travel in order to work. Many refugees travel alongside other migrants and increasingly geographers have argued that distinctions between refugees who flee persecution and migrants who seek to escape systemic poverty are unhelpful as distinctions between “forced” and “voluntary” migration are increasingly blurred.

Refugee histories

The term refugee was first applied to Protestant Huguenots who fled France in 1685. It was not until the twentieth century, however, that refugee populations became more significant. The events of World War I, the Russian Revolution, and the collapse of the Austro-Hungarian empire produced a displacement of people across Europe on a scale not seen previously. This led to the appointment of the first High Commissioner for Refugees by the League of Nations in 1921. The powers of the commissioner were strictly limited and an initial focus on refugees diminished as states focused on concerns over economic and political stability throughout the 1920s and 1930s.

Following World War II, the 1951 United Nations Convention Relating to the Status of Refugees was established as a means to define international obligations to refugees and to provide a definition of the refugee. The Convention was limited to those persons fleeing events before January 1, 1951 within Europe, thus marking a concern to address European groups displaced as a result of World War II. In 1967 the Convention
was amended though a Protocol that removed these geographical and temporal limits and gave the Convention universal coverage.

The 1951 Convention established two central principles that have shaped governmental approaches to refugees. First, Article 31 of the Convention prohibits states from penalizing refugees for illegal entry into a state when the purpose of their entry is to claim asylum. Asylum seekers and refugees are thus distinguished from “illegal” immigrants as their actions in entering a state are not defined as illegal. Second, the obligation of “non-refoulement” (literally to “push back” or “return”) requires that a state may not return refugees to any territory where their lives would be threatened. This obligation seeks to ensure that states are not able to remove refugees to conflict zones or to the sites of persecution they have fled. In order to manage refugee protection, the 1951 Convention saw the establishment of the Office of the United Nations High Commissioner for Refugees (UNHCR) who acts to coordinate resettlement programs and refugee provision.

The question of who qualifies as a refugee remains a contested issue, however, with nation-states often using the humanitarian associations of refugee status for political gain. For example, during the Cold War refugee status was used for ideological purposes, with capitalist states offering refuge to Soviet dissidents as a means to critique state socialism. While the definition of the refugee has not altered since 1951, it has been critiqued for its Eurocentric nature and its focus upon individual forms of violence and persecution. Asylum seekers must provide evidence of specific instances of persecution in order to gain refugee status and must demonstrate that they would face significant risks if returned to their countries of origin. As such, more systemic or generalized forms of violence and persecution may be disqualified.

For example, refugee groups displaced by civil, ethnic, and communal unrest, such as those fleeing the uprisings of the “Arab Spring,” are often unable to demonstrate the individual level of persecution required to meet refugee assessments on a case-by-case basis. Similarly, the need to cross an international border in order to qualify as a refugee has been criticized, as displacement through persecution may not necessarily lead to cross-border mobility. It is for this reason that after sustained pressure, UNHCR began to recognize the category of “internally displaced persons.” This category refers to those “who have been forced or obliged to flee or to leave their homes or places of habitual residence, in particular as a result of or in order to avoid the effects of armed conflict, situations of generalized violence, violations of human rights or natural or human-made disasters, and who have not crossed an internationally recognized State border.” The definition offered here is broader than that of the refugee, reflecting situations of generalized violence; however, it is important to note that UNHCR can only offer a set of “principles” for the protection of internally displaced persons and cannot compel states to enforce them.

Geographers have been critical of the focus on the national scale within refugee studies and of the inscription of national boundaries in refugee law, arguing that refugee status may serve to uncritically reproduce the authority and exclusions of the state (Mountz et al. 2002). Citing the complexity of migration within globalization, many have argued that other scales and sites may be more appropriate to deal with issues of migration, be that in terms of international flows of variegated mobility, cross-border networks of policy and practice, or the connections and social relations of world cities. Increasingly UNHCR are themselves publicly recognizing that the complexity of global mobility
undermines distinctions between refugees and other forms of migrant. As the reasons for individuals fleeing become ever more difficult to untangle and adjudicate, critical geographers and political scientists are challenging the practical and political value of refugee classification. For example, Nyers (2006) argues that the history of refugee institutions serves to construct refugees as temporary fixtures within global politics, as individuals or groups marked by conditions of crisis, and posing a challenge to the territorial assumptions of the state. Refugees in this sense exist as the binary opposite of the citizen, with the solutions proposed to refugee “crises” being to turn refugees into citizens – either through resettlement, integration, or repatriation. All of these solutions uphold the position of the state as the guarantor of rights and political belonging, and position the citizen as the “normal” and aspirational model of political identity.

Refugee resettlement

One of the highest profile “solutions” to refugee displacement is through international resettlement. Resettlement denotes a process in which preselected groups of refugees are assisted in moving to a new country by charities, NGOs, state agencies, and UNHCR. This process may be led by individual states through international agreements or by UNHCR in partnership with particular states. In recent years, the largest resettlement programs have been run by the United States, Canada, and Australia. In each case, governments coordinate resettlement programs with UNHCR in order to identify annual quotas for refugee resettlement and to negotiate the conditions under which they will accept refugees. Conditions include the prescreening of potential refugee groups to assess their needs, their ability to integrate, their level of vulnerability, and the urgency of their resettlement requirement. UNHCR view resettlement as one of the few “durable solutions” for refugee groups who would otherwise be confined to indefinite periods in refugee camps.

Resettlement involves a high level of scrutiny, from both “host” governments and UNHCR, and on arrival many resettlement schemes provide a high level of support. For example, in the United Kingdom the Gateway Protection Programme resettles an annual quota of refugees across the country. On arrival these groups are provided with housing support, a cultural orientation program, language training, and support to move into education or employment. Resettlement is thus a significant commitment from a receiving country as they are asked to provide both legal and physical protection and to aid refugees in becoming naturalized citizens. This contrasts with asylum seekers and other forms of irregular and regular migrants, who are rarely provided with such extensive support and are often restricted from accessing pathways to citizenship.

Despite offering a “durable solution,” refugee resettlement remains rare. UNHCR suggest that they are only able to put forward for resettlement around 1% of the refugees who fall within their remit, and not all of these are selected by “host” governments. The highly conditional nature of such programs has led geographers to be critical of their implementation and of the messages they convey about the politics of humanitarianism. In many respects, resettlement programs represent idealized forms of state managed response to refugees. Most often connected to a language of state “hospitality,” resettlement programs garner significant media attention, and in many cases public goodwill, not least because governments are keen to portray resettled refugees as safe, secure, and prescreened individuals who arrive in regulated numbers. By contrast, refugees who
arrive through other migratory routes or who are awaiting decisions on asylum claims may be presented as less “worthy” of a “hospitality” that is strictly limited.

Refugee governance

Refugee resettlement represents one means of managing refugee populations, yet this is far from the most common mode of refugee governance. Rather, three forms of spatial and social governance can be seen as conditioning approaches to refugees worldwide.

The first of these is through the construction of refugee camps. Refugee camps are constructed by governments or NGOs as a means to temporarily accommodate refugees, although in many cases such sites become semipermanent and have been argued to take on urban characteristics in their most long-standing forms. From a humanitarian perspective camps may be problematic in terms of the spread of disease, difficulties in securing camps against violence, and their precarious nature as informal and temporary settlements. At the same time, they offer opportunities to manage refugee populations through the coordination of resources, health care, and support. In his ethnographic work in the camps of northeast Kenya, Michel Agier (2010) has argued that it is through these forms of humanitarian provision that camps have become semipermanent structures, with their own systems of power, social hierarchies, and norms of everyday life. It is not only humanitarian action that enables the maintenance of camps, however; the policies of many states that seek to spatially segregate refugees from the wider population enable camps to be maintained as designated spaces for refugee groups. Providing such a space not only allows for the containment of the refugee population, it also works to prevent refugee integration and to reinforce the temporary nature of refugee identity. In discussing such spaces, geographers have been influenced by Giorgio Agamben’s notion of the “camp” as a spatial expression of sovereign abandonment, arguing that within camp spaces we might witness the inclusive exclusions that lie at the heart of contemporary geopolitics.

The significance of refugee camps can be seen in contrasting these spaces with recent discussions of urban refugees in the Global South. Despite refugees having long been attracted to urban environments, in part due to the opportunities for informal employment and anonymity, it was not until 1995 that UNHCR first reported on urban refugees. This report compared urban refugees unfavorably to encamped individuals who were presented as the “model” refugee. Only in 2002 did UNHCR recognize the need to deal with urban refugees in a more nuanced manner, highlighting the specific issues they may face, such as a lack of formal documents, everyday harassment and exploitation, the insecurity of informal housing, and fears of detention. Despite this, the priority of both governments and NGOs has been to place refugees in camps. Urban refugees pose a series of challenges for states as they are less easily distinguished from other marginalized groups and harder to regulate. At the same time, the self-directed, autonomous, and often more mobile nature of urban refugees challenges idealized notions of the displaced as helpless and dependent subjects to be fixed to specific camp locations.

The second form of governance arises through the mechanisms of refugee classification that are associated with asylum procedures across Europe, North America, and Australia. A range of governmental practices have been examined by geographers as means to control asylum seekers within countries while decisions on refugee status are taken. These include
practices of dispersal evident in countries such as Denmark, Germany, Sweden, and the United Kingdom, where asylum seekers are accommodated in specific locations so as to “spread the burden” on services. Significant restrictions and conditions apply to such accommodation, including the need to report to immigration authorities on a regular basis and constraints are placed on the ability of asylum seekers to seek employment.

The refugee determination process also produces distinct legal geographies. For, although the 1951 Convention establishes a single definition of the refugee, the interpretation of the grounds for such status differs markedly between states. For example, in 2011, recognition rates across the European Union (EU) for Afghan asylum seekers varied widely from 33% in Austria to 4% in Greece. Similarly, some countries currently implement a system of “safe country” lists, which identify countries where governments believe persecution does not take place and therefore asylum applications are readily refused from such countries. Furthermore, across the EU, the Dublin II agreement means that those seeking asylum may only do so in one member country, and if it can be shown that asylum seekers have traveled through a “safe country” to reach their destination they are returned to this first “safe country.” This serves to relocate asylum seekers from northern to southern Europe, and increases asylum claims in countries, such as Greece, with lower refugee recognition rates. At the same time, the history of refugee determination also illustrates a series of exceptional events where states have established resettlement schemes that go beyond the 1951 convention. For example, in 1999 a range of European countries resettled those fleeing the conflict in Kosovo, and in 2012 Norway, Denmark, and the Netherlands resettled Bhutanese refugees following landslides and flooding in Nepal.

Alongside moves to relocate asylum claims has been an international growth in practices of deportation through which states forcibly repatriate individuals whose claims for asylum have been rejected. Over the last decade, many states have used geopolitical influence to encourage countries of origin to accept deported migrants and to extend the scope of deportation agreements. Deportations to countries such as Afghanistan and Iraq are controversial given the obligation of non-refoulement, yet many governments in the Global North utilize deportation as both a border enforcement mechanism and as a symbolic measure of deterrence against asylum seeking.

Finally, the governance of refugees is intimately tied to discussions of border security. As refugees and asylum seekers have increasingly been conflated with “illegal” migrants, so have many states sought to extend their border control mechanisms and screening practices to extra-territorial spaces. Governments in Europe, North America, and Australia have all taken steps to enforce border controls at ports of origin for many refugees. At the same time, the growing use of detention centers in remote locations, such as the Pacific islands, the Australian outback, and remote military bases, have been highlighted as means to keep asylum and refugee groups isolated from advocacy movements and public visibility. These practices of offshore processing and detention seek to govern those awaiting refugee status at a remove from the territory of the state and the social life of citizens.

Throughout these different mechanisms of governance, practices of social and spatial isolation are notable in dealing with refugees as unwanted and unwelcome migrants. As a result, it can be argued that what unites strategies of refugee management is a desire to manage refugees in the interests of the nation-state,
rather, necessarily, than in the interests of refugees.

Refugees as political actors

While much work has explored how refugees may be produced by state violence and excluded through state practices, recent studies have emphasized the political agency of refugees. Refugee camps have thus been argued to represent spaces for the formation of community and solidarity, such that political possibilities arise in these environments despite their exclusionary nature. Similarly, recent examinations of anti-deportation campaigning and No Borders activism have highlighted how refugees may make claims upon the state despite lacking citizenship rights, working alongside citizens who view immigration controls as inherently racist forms of division (Nyers 2006). Studies of sanctuary movements in Europe, Canada, and the United States are also notable in advocating for the rights of irregular migrants and in seeking to shift public opinion on refugees (Darling 2010). While at times risking the reproduction of an image of the “needy” humanitarian victim, such movements have shown that issues of refugee support and rights are not wholly situated on the terrain of an exclusionary politics which views refugees as a threat to the stability and integrity of the nation-state.

Refugee experiences

Informing these studies has been a rich vein of work focusing upon the experiential aspects of refugee identity. Here studies have explored how state discourses of humanitarianism and border control are translated into prosaic practices which condition the lives of asylum seekers and refugees across the Global North, and the Global South. Links with studies of transnationalism and social networks have also been forged in order to trace the connections that sustain everyday life for refugees (Koser 1997). For example, Hyndman and McLean (2006) examine the experiences of Acehnese refugees resettled in Vancouver, and highlight the challenges they face in creating livelihoods despite their legal status within Canada. Taken together, this body of work demonstrates how geographers have begun to explore the social and cultural dynamics of refugee identity, the everyday conditions in which refugee governance is enacted and the multiple networks that contribute to the formation of “home” in conditions of exile.

Summary

Geographers’ discussions of refugees have been diverse and wide ranging, encompassing the spatial governance of refugees, the production of the refugee as a legal and political category, and the sociospatial experiences that accompany such a category. Refugees and asylum seekers are fundamental products of the nation-state system and, as such, are likely to remain central actors in debates over migration, citizenship, and mobility. Looking forward, the question of how refugees are defined and what limits are placed on their ability to access rights may be a key arena in which geographers can contribute. For example, a rapidly growing body of work is concerned with “environmental” refugees who are not covered under the terms of the 1951 Convention, but who may be forced to migrate through natural disasters and longer-term environmental degradation (Gill 2010). Exploring the complex
interactions between human and environmental processes that lead to displacement offers one avenue through which geographers may highlight the limits of current definitions of the refugee. It is this critical and spatially informed lens that geographers have brought to the study of refugees, and it is through such work that they have sought to support and advance claims for social and spatial justice.

Regional and interregional trade in producer services

William B. Beyers
University of Washington, USA

This entry begins with a discussion of early concepts regarding trade in producer services. The characteristics of this trade are then reviewed from multiple perspectives, including the role of trade in producer services revealed using various statistical sources and a review of surveys of producer services trade. The entry concludes with selected data from input–output models that document the growing importance of the demand for and trade in producer services.

Greenfield (1966) pioneered a vision for what we now accept as producer services – activities whose primary clients are businesses and governments, as opposed to households. The classic view of services as being perishable, being consumed in the moment of their supply, was challenged in Greenfield’s work, opening up the notion that services could be consumed (traded) other than at the time of their production. Greenfield conceptualized “semidurable” and “durable” services, extending concepts introduced by Kuznets as a part of his pioneering work on national accounts. Since Greenfield’s work the modes by which the outputs of producer services can be traded are very different. Information and communications technologies were much less developed 50 years ago; the advent of networked computers to store information combined with telecommunications technologies now allow interactions in modes not even imagined in 1966. Entire categories of producer service industries that are accepted as routine today – such as provision of cloud computing services or investment services guided by modern portfolio theory – did not exist when Greenfield conducted his research. Text, data, and graphic files were certainly created at that time, but their storage and transmission (over media such as the Internet) has subsequently helped to facilitate the growth and development of producer services trade. We can anticipate future changes in producer services supply and demand in ways that are unpredictable at the time of this writing.

Trade is defined as a sale between a buyer and a seller, and from a geographical perspective we can classify where this trade takes place. The simplest dichotomy is between trade that takes place between clients and suppliers locally or in close geographic proximity, and nonlocal trade that takes place over some greater distance. Such interregional trade, however defined, can be defined in a local–nonlocal dichotomy, or within a multiregional framework with many regions of supply and demand.

Unlike trade in goods, which has been tracked through customs and international trade regulations, and reported in great detail (such as through the World Institute for Strategic Economic Research), trade in services has not been the subject of government statistical programs in most countries. Output or sales of services has been measured through series such as the Economic Census in the United States, but the geography of these sales is undocumented. National programs for the measurement of trade between industries are reported in input–output models, but these are typically one-region as opposed to interregional models, and are rarely explicitly international models. Data on the
geography of trade in services have come from two broad sources: ad hoc surveys and regional input–output models that have an export measure of sales. One of the highest priority topics for the expansion of official statistics from national and international government agencies is the development of robust statistics on trade in services. Given the dominance of services employment and output in the global economy, this is a major oversight in measurement programs that needs to be remedied. The reasons include the need for basic documentation of the structure of regional and national economies and the role or value that this type of data has for economic development programs.

It is useful to look back on how the notion of trade in services was treated in early literature on the regional economic base. The classic economic base model divides economies into two markets: export and local. Before direct measures of regional trade were undertaken, authors classified industries as exogenous or localized, but struggled with this dichotomy recognizing that some industries were “mixed.” A paper by Polzin is an example of how services trade was treated in this early literature: “Trade and service activities constitute the bulk of the mixed industries and the planner/analyst has little to lose by ignoring them in the construction of the exogenous sector” (Polzin 1973, 231). The statistical basis for this statement is not explained and it was not until surveys of the markets of service industries were conducted in the mid-1980s that it became evident that this conclusion was erroneous.

The unfolding of perspectives on producer services trade

In a discussion of types of services, Daniels noted that geographic markets are likely to be very different across them. Discussing markets for a greengrocer versus a consultant providing advice on the purchase of telecommunications facilities he wrote: “It is conceivable … that the specialist consultant has a market which extends throughout a country, either because no other organization is able to provide the service or because there is insufficient demand to justify the existence of more than one such firm” (Daniels 1982, 31). Daniels wrestled with location principles guiding the greengrocer, and the producer services firm, noting that central-place model location principles were less likely to apply to location choices of producer service specialists. Without mentioning the geography of trade explicitly, Daniels implied the potential for trade, especially in the face of the development of information technologies.

In 1985 Daniels extended the argument just made, with some of the first estimates of the magnitude of trade in services:

During the last decade trade in services has become one of the most rapidly growing and changing sections of international trade. It has been estimated that services now account for one third of world trade amounting to a massive $550 000 million in 1980. About 20 per cent of the world total is accounted for by the USA, with France and Britain in second and third place respectively (9.4% and 9.2% of world trade in invisibles). Until recently most of the services crossing international boundaries were ancillary to, or in support of, the trade of goods (such as the financial services which permit trade in goods, transportation or consulting services). Now services are traded in their own right: advertising, market research and management consulting, telecommunications services, computer services, specialized financial services in banking and insurance and business services. The spread of multinational enterprises has encouraged the growth of international trade in services, even though some of the transactions will be between the constituent parts of the same enterprise. Unfortunately there is a shortage of reliable statistics on international trade.
in services; it remains difficult to measure and analyse trade volumes, patterns and composition. (Daniels 1985, 35–36)

Ochel and Wegner focused on trade in services in Europe and explored the transformation of markets in the context of the “new economy”:

The internationalization of markets is facilitated by the growing tradability of services. Advances in communications technology and in information storage and processing have made it possible to produce services in one place and to consume them somewhere else and to produce services at one point in time and to consume them at a later date. Any service product that can be reduced to electronically coded pieces of information can theoretically be delivered to any point in the world with great reliability, at relatively little cost, and with no time-lag. Of course, there are many difficulties in implementing such an information system. (Ochel and Wegner 1987, 62)

Their argument seems to ignore types of services where face-to-face communications is important in delivering the service.

Improvements in technology were also important such that:

Trade in producer services is also growing because the cost of “transporting” services is falling over time. The long-term rise of trade in goods is in part due to innovations in transportation technology: navigation, shipbuilding, railways, trucking, and so forth. Improvements in communications technology (telephone, fax, television, courier services, etc.) have had a similar impact on trade in services. To this must be added improvements in the transportation of persons, lowering travel costs for “labor embodied” services. From this follows increasing interregional specialization with respect to services, bringing into play questions of comparative advantage, where services come to play an increasingly critical role in the definition of the economic base of regions. (Bailly et al. 1992, 25) This was later confirmed in a survey of producer service firms that identified increased use of digital modes of delivering services, but no reduction in the need for face-to-face meetings with clients. Bailly et al. (1992) also examined the channels of interregional trade in services, distinguishing between direct service trade, intrafirm trade in services, intrafirm service trade by primary sector and manufacturing firms, trade in services as a result of trade in goods, links with factor flows, labor-embodied services, and service flows versus factor flows. They argued that intrafirm flows are important and can be tracked using survey methods and that survey data on interfirm trade in services underestimates total trade flows.

Daniels returned to the issue of trade in producer services, observing that: “In order for services to become prominent actors in the world economy they must possess attributes that enable them to be exchanged across geographic space” (Daniels 1993, 25). He noted that some services are not tradable, and presented a taxonomy for service firm internationalization with regard to service multinational enterprises, international trade and foreign direct investment in services, the global system of cities, and the internationalization of services and the restructuring of cities. He also speculated about the desirability of service-dominated economies, the inevitability of the globalization of services, the unfulfilled potential of telecommunications, and whether IT advances will impact interaction:

Innovations in the applications of information and telecommunications technology are therefore set to continue. They are worth noting because their ultimate effect, threatened for years but yet to be manifested, may be to replace a global service economy dependent upon intensive transactional flows (people, information, electronic messages, etc.) between a small number of large, highly centralized control-points with a more dispersed
telecommunications-dependent network of transactions. Flows of human capital will be far less significant though still necessary for the conduct of high-level negotiations and information exchange. (Daniels 1993, 175–176)

He went on to speculate about the role of telework and the possibility of business cycles in advanced services.

Another evaluation of the means of exporting services was offered by Reif and colleagues.

There are different ways of selling services across borders. Direct selling is by no means the primary method for residents of one country to provide services to residents of another. … International Consulting. International consulting, also termed transient service exports, occurs when a US businessperson renders a service to a foreign client on a short-term basis. … Direct Exporting. Because the value of some services is embedded in the tangible products associated with these services, the export of a service sometimes can be shipped much like a manufactured good. Examples of this type of service export include books, pharmaceuticals and software. … Telematic Trading. Telematic trade is another means of exporting a service and one which involves the transfer of knowledge and information abroad via telecommunications. … Royalties and Licensing Agreements. According to the Bureau of Economic Analysis, royalties and licensing fees consist of receipts and payments for the use of patented techniques, processes, formulas, and other intangible property rights used in goods production, as well as copyrights, trademarks, franchises, rights to broadcast live events, and other intangible rights. … Franchising. A franchise is a business arrangement in which an established business gives an independent party (the franchisee) the rights to use its brand names or trademarks, and transfers knowledge which is essential to running the business. … Providing services to foreign visitors. This export can be simply defined as a service performed and completed in the United States and sold directly to a foreigner while in the United States. (Reif et al. 1997, 5)

A recent assessment by the EU of the delivery of business services speaks to some of the issues surrounding the expansion of trade in services, including producer services. Four pathways to internationalization are identified and these could also be interpreted as pathways for inter-regional trade in a huge internal market such as within the United States. These pathways are as shown below.

Mode 1 Cross-border supply, which occurs when suppliers of services in one country supply services to consumers in another country without either supplier or consumer moving into the territory of the other.

Mode 2 Consumption abroad, which refers to the process by which a consumer resident in one country moves to another country to obtain a service.

Mode 3 Commercial presence occurs when enterprises in an economy supply services internationally through the activities of foreign affiliates.

Mode 4 Presence of natural persons describes the process by which an individual moves to the consumer’s country to provide a service, whether on his or her own behalf or on behalf of his or her employer. (European Commission 2014)

There are no data included in this EU report to illustrate the relative importance of these pathways.

Broader arguments regarding trade in services

The emphasis in the preceding section of this entry has been on the growing role of inter-regional trade in services, but it is important
to recognize that local demands for producer services remain important. This can be measured using a two-region model inspired by interregional input–output models of trade in all economic activities with explicit producer service trade modules linked to intraregional and interregional demand (Beyers 1990). Figure 1 illustrates this two-region system; in each region there is a block of local final demand (personal consumption expenditures, investment, and government) and a block of local income which is linked to the local production system (producer services and the transformative, distributive, retail, not-for-profit, and mainly consumer services sectors). Exports and imports are shown for all sectors in this fully enclosed system and it was argued that, on the basis of these connections, if demands rose or fell in one region this would lead to interregional consequences across all elements of the multiregional system.

Using data for the Bureau of Economic Analysis (BEA) economic areas in the United States, Beyers used the system illustrated in Figure 1 to estimate producer services trade using location quotients. Beyers concluded:

The growth of producer services employment in a given region should be seen to be a function of the growth of producer services exports and exports of other key industrial sectors. These changing export demands in turn lead to local direct requirements for producer services and other inputs, and they directly create local income. These direct requirements lead to a chain of indirect effects, which have associated with them additional demands for producer services and other sectors that also create additional income. Expenditure of locally created income leads through the consumption and government expenditure process to additional indirect and induced effects, including local final demands for producer services. … In regions with a strongly expanding export base, this set of linkages appears to have led to strong growth in producer services, and the opposite has been the case in regions with a declining or slow growing export base. … Over time, the importance of these interregional connectivities may be increasing in the producer services as businesses are able to extend market areas through the use of advanced information processing and telecommunications technologies. (Beyers 1991, 167)

Returning to trade in services in 2007, Daniels reminded us of the traditional argument for service production and consumption to be co-located because of the “non-tradable” nature of many services. However, he argued that this restricted view has been modified by the advent of information and communications technologies (ICT), including the associated increases in service sector productivity. These forces have led to services globalization with four dimensions: flows, networks, frameworks, and brands and trademarks. Daniels offers a portrait of trade in these dimensions benchmarked against the year 2000; the system of flows is similar to Figure 1, but reports estimates of inter- and intraregional flow (Daniels 2007). This rich diagram documents strong intraregional and export trade in Europe, the Americas, and Asia and Oceania. Implicitly, imports are captured in the system of trade flows documented in Figure 2. The size of the boxes in this diagram is proportional to total exports across the four regions, divided into intraregional and interregional trade. The high intraregional percentages for Europe reflect the large number of relatively small countries with large European markets. The export shares for each regional block add to 100%.

Daniels mentions a number of indicators of these dimensions, such as the availability of infrastructure and institutions allowing the four modes of supply identified above to operate for trade and foreign direct investment (FDI)
(for example, growth in services share of FDI and structural change within OECD countries in the composition of services FDI, especially the strong growth in the share of business services and transportation and communication services, and decreases in the share of trade, financial intermediation, and other services (subject to strong cyclicality)). Another indicator is a new international division of labor allowing integration of production systems across national boundaries (such as the offshoring of telephone-based support systems to places such as India by United States or European service firms), particularly by multinational corporations (MNCs) that threatens services job creation in the United States or Europe.

Producer services trade: survey research

Beginning in the 1980s there was a burst of survey research on the markets of producer service businesses. It is fair to say that this stream of research was stimulated by the lack of industry detail in official statistics and in regional input–output models that presented data for producer services in a highly aggregate manner. It is worth noting that there has not been a comparable body of research undertaken since the turn of the century, so it is not clear whether and how the conclusions of this earlier research may be altered by current data that show continuing increases in the magnitude of trade in producer services.

Beyers and Alvine reported on a large-scale survey of the markets of 2200 producer service establishments in the Puget Sound region of Washington State that found half of them had sales of at least 10% outside the local area (Beyers and Alvine 1985). Of the establishments that met this criterion the average percentage of external sales was 55%, with the overall level of export markets about 35% when merged with the localized establishments. There was no correlation between firm size and export market percentage although a large cohort of establishments that had experienced growth in their export percentage also expected an expansion of export share in the near future. Major variations in export propensities were reported by industry with accounting having a low export market percentage while other industries, such as research and development, reported a very strong export market percentage.

The channels of trade in producer services, including (i) direct service exports, (ii) intrafirm service exports by producer services firms, and (iii) intrafirm service exports by manufacturing firms were surveyed by Coffey and Polèse. They reported that
With the exception of engineering consultants, it appears that direct sales to other regions or nations are not a major element of total receipts. Direct sales for most sectors appear to be highly sensitive to distance or to other barriers. Language may act as a barrier, but other obstacles to the direct “transport” of producer services may also exist: local purchasing policies, professional licensing requirements, work permits, and so forth. Such constraints are often associated with sovereign states and thus seen as barriers to international trade, but their impact may

![Figure 2](image-url)  

*Figure 2* World and intraregional shares of services exports, 2000 (Daniels 2007, 106). Reproduced with permission from Edward Elgar.
also be considerable in federal states and other decentralized nations. Local purchasing policies and the provincial licensing of professions are traditional practices in Canada. Given such barriers and the high communications costs (for outputs), producer-service firms will be tempted to establish local offices to penetrate outside markets, the second channel by which producer services are exported. (Coffey and Polèse 1987, 600–601)

This last channel has a value of about half that of direct exports. Table 1 reports data on markets of Montreal producer service firms from this survey.

A survey of Vancouver, British Columbia, producer service firms measured their markets by sector served (primarily sales to other service industries) as well as their geographic reach (Ley and Hutton 1987). The study found 51.4% of firms had greater than 75% of their sales in the Vancouver area, 20.4% had at least 25% of sales elsewhere in British Columbia, 20.9% had at least 10% sales elsewhere in Canada, and 13.3% had sales of at least 10% elsewhere in the world (percentages do not add to 100% because of the way in which this survey was phrased). The respondents also thought that Vancouver would be a major source of growth (68%), along with the rest of British Columbia (20%). This contrasts with later research that showed a sample of firms anticipating much more growth in markets outside Vancouver (Davis and Hutton 1991). That paper also explored the idea that producer services were becoming increasingly tradable. This draws from Davis’s work on an input–output model of the Vancouver regional economy from the mid-1980s that showed strong exports of business services from the Vancouver area (44.7% local markets, 44.2% to other British Columbian, 7.2% to other Canadian, 1.5% to the United States, and 2.4% to the rest of the world). A related study in 1990 reported higher levels of exports from the Vancouver region for engineering, management consulting, and computer services businesses, while advertising was estimated to have strong local markets. This survey also asked firms about expected changes in markets, finding that they expected a larger share of exports: exactly what the Beyers and Alvine study reported in 1985.

Further corroboration was provided by surveys of the export markets of producer service firms in Edmonton, Alberta which showed an average of 36% in service exports – very similar to Beyers and Alvine’s documentation of trade in producer services in the Puget Sound region (Michalak and Fairbairn 1988). There were large variations across industries in export propensities; accountants largely served local markets, while engineering firms had the majority of their markets outside Edmonton. In findings similar to Coffey and Polèse, foreign markets were modest compared to nonlocal Canadian markets. Michalak and Fairbairn concluded, first, that a peripheral city such as Edmonton did not have strong producer services links to the Canadian economic core (Toronto/Montreal), implying a weak role for the core–periphery model in explaining markets for producer services. Second, the data suggested that the Alberta region was developing independently of the Canadian economic core. Third, they found that services exports were to places unrelated to their size. Fourth, they found market links with services and government and, finally, that a successful regional economy depended upon an adequate supply of producer services as inputs to the production process in ways that made their clients/users competitive.

A comparative study of producer services in Vancouver, Montreal, and the Puget Sound region generated findings that were remarkably similar with the Puget Sound region and Vancouver (Coffey and McRae 1989). A second important observation from the comparative

Data on market orientation concerns the relative importance of service sector exports when allocated to the three categories of nonlocal sales. The Vancouver and the Seattle-based studies reported a very similar share of sales to customers located in British Columbia or Washington State respectively. However, Seattle area services exported a much higher percentage (p. 225) of the value of their output to buyers in other US states compared to the equivalent figure for Vancouver producers; at 5% this was even less than the 10% share of sales to the rest of Canada outside British Columbia reported by Ley and Hutton (1987). It is interesting to note, however, that Vancouver area service firms relied more heavily on international sales than their Seattle-based counterparts – which had international service revenue of only 3%, while the two Vancouver studies estimated an equivalent figure of 7% and 12% (Coffey and McRae 1989, 107–108). In relation to Montreal, a further dimension was identified by Coffey and McRae (1989) who reported a stronger share of markets within Quebec, implying an important role for language in mediating the geography of producer service markets. Their work also confirmed the reality that small firms are just as able to gain export markets as large firms. This was also a key finding in the Puget Sound region studies, although the Canadian studies reported somewhat weaker results on this score.

While the early research in the Puget Sound region was followed by several studies in and around Canadian cities, the next US study centered on Chicago did not appear until the mid-1990s (Esparza and Krmenec 1994). This study was partly driven by the proposition that major world cities strongly interact with each other and producer services transactions are part of that process. Esparza and Krmenec conducted a telephone survey aimed at documenting this type of connectivity, reporting average percentages of local sales for a sample, and a frequency distribution of percentage local sales as a share of the number of firms (this sample does not appear to be weighted by size of firm or size of sales). The number of linkages of individual establishments to other cities and by type of market was documented and showed that manufacturing was not the dominant market of producer services except for advertising firms. The linkages of the firms were mapped, revealing a two-tier system:

The results indicate that the supply of business services takes place within a two-tiered organization of cities. The first tier, which involves interaction among world-class cities, is insensitive to distance as an impediment to interaction. This confirms other research which argues that ‘gateway cities’ dominate interaction in the contemporary global urban systems. The second tier is organized within the US system of cities and more closely resembles a hierarchical structure. In this instance, distance appears to mitigate interaction over longer distances. (Esparza and Krmenec 1994, 44)

In the late 1990s it was recognized that trade in producer services would likely be influenced by considerations such as the adaptive behavior
of firms (Beyers and Lindahl 1997a). Using survey data focusing on changes in services sold, changes in client types, and changes in export markets, Beyers and Lindahl tested the Ansoff model of adaptive behavior with the results clearly indicating that producer service firms engaged in adaptive behavior had higher growth in sales than those that were not adaptive.

The behavior of producer services located in rural areas, rather than the city regions, was also a potential source of variation in local versus nonlocal transactions. Based on an analysis of a national sample of producer service firms in rural counties in the United States, Beyers and Lindahl (1997b) found that 43% of the firms were strongly engaged in selling their services in nonlocal markets, with most being niche market players. These firms were categorized as Lone Eagles (proprietors) or High Fliers (strongly exporting firms with employees). Quality of life, cost concerns, and proximity to the location of the firm’s headquarters were primary location considerations, along with other personal factors. Those working for export-oriented firms often traveled to meet with their clients and generated higher revenues per worker compared to locally oriented firms.

Finally, the results from eight surveys of producer services markets, some of which are referenced in this entry, were usefully summarized by Illeris. He reported that local markets varied from about 32% to 71% of sales, with an average of 49%. Put another way, the Illeris compilation indicates that just over 50% of producer-service markets were nonlocal or export (Illeris 1990, 146).

**Producer services trade: evidence from input–output models**

Useful insights on the scale and geography of trade in producer services are available from studies and reports that rely on a mix of primary and secondary data. An alternative source of data on the use of and trade in producer services is data from input–output models. In the United States these models are estimated annually for the national economy, and every five years at a more detailed industry level in “benchmark” tables. These models document the value of purchases of producer services by industries as well as households, governments, investors, and on export accounts.

Anne Carter reported on the increasing importance of producer services in a landmark analysis of structural change in the American economy utilizing US input–output models. Advertising was the fastest growing portion of the business service sector in the time periods analyzed (1939–1947 and 1947–1958) and, citing Greenfield’s work, Carter wrestled with the reasons for this growth. While there were “costs of coordinating a growing volume of specialized transactions,” externalization (the shift of provision of services internally in a sector to their external procurement) is also important: “Only part of the growth of the service sectors represents actual increases in the total volume of services performed. The rest is the transfer of service functions from firms and establishments primarily engaged in manufacturing and other product–oriented activities to specialized service sectors” (Carter 1970, 65). The data on this trend were sketchy, but she noted increasing contracting out for research and development services, for banks to increasingly perform record-keeping and information-storage functions that were formerly in the province of bookkeeping departments of customer establishments. Similarly, insurance companies assumed an increasing proportion of risks formerly taken by the insured companies themselves. Some of these services, such as workmen’s compensation, are mandatory. Specialized record-keeping and computer services have been growing rapidly.
Such business services range from very sophisticated data retrieval schemes to assisting small businesses in coping with tax regulations. To a greater and greater extent exploratory and trouble-shooting research on engineering and business problems have been delegated to consulting organizations. Advertising work is more centralized in specialized agencies. Complex equipment, including cars and trucks, is beginning to be rented more frequently than being bought outright. (Carter 1970, 65, 68)

Apart from the national level, input–output models at the regional level can also provide data on the demand for and trade in producer services. In practice such models are rare but a set of eight models stretching from 1963 through 2007 are available for Washington State. When combined with data from the US national input–output models, it is possible to compile a very useful portrait of changing levels of purchases and exports of producer services (Figure 3). FIRE (finance, insurance, and real estate) and business services are reported as a composite in Figure 3. Transportation services appear to have been a fairly constant share of inputs over the history of the Washington State input–output models. In contrast, the share of purchases accounted for by wholesale and retail trade has risen over the 1963 to 2007 time period.

Figure 4 shows a clear upward trend in the economy-wide purchase of producer services as a share of output in the United States. It also shows Washington State purchases as a share of output over time, along with the difference between national purchases and Washington regional purchases (these are interpreted here as the implicit imported share of producer services.
Figure 4  Producer service purchases as a share of output.

Figure 5  Implicit imports of producer services to Washington State businesses.

Figure 4 is derived from the history of the Washington and US input–output models and shows the percentage of total purchases accounted for by producer services from 1963 to 2007. (The author has estimated values for some of these years as detail was not sought in the surveys for these purchases.) The large increase in the 1987 to 1997 time period is undoubtedly related to the shift from the Standard Industrial Classification System (SIC) system to the North American Industry Classification System (NAICS), in which some activities were reclassified from industries such as manufacturing to producer services. One example of this type of reclassification is headquarters activity, which was classified as “administrative and auxiliary” employment in each broad class of industry (such as manufacturing or construction) in the SIC system, but transferred to “management of companies” in the NAICS system. The Washington businesses). These estimates are approximate, since the industry mix in Washington differs from the United States, and patterns of purchase within particular industries may differ between Washington State and the same industry elsewhere in the United States.
Regional and interregional trade in producer services

State regional requirement is the sum of values reported in Figure 3 for FIRE and Business Services.

An increase in the share of production costs accounted for by producer services over time is clearly evident in Figure 3. There is a split in this figure between Washington State production as measured in the Washington input–output models and between imports from the rest of the United States, implied by US input–output models. Estimates of the share of imports suggest that they have diminished somewhat over the time period included in these figures, suggesting that Washington producers have supplied a somewhat larger share of total demand for producer services over time (Figure 5).

The Washington input–output models also allow estimates of exports as a share of total sales over time. These have been calculated from the series of Washington input–output models (Figure 6). Several of the early Washington models did not disaggregate services, such that producer services could be identified, but estimates of exports are possible for the years for which these data are available. Two sets of measures are included: a narrow definition only includes FIRE and business services, while a broader definition also includes transportation services and communications. These export measures are presented at three levels – domestic exports, domestic exports plus sales to the federal government, and domestic and foreign exports, including sales to the federal government. There is a clear overall upward trend in exports of producer services (narrow definition) with important growth in foreign exports. This graph shows very strong growth in estimates of traded producer services between 1967 and 1987, and then relative stability in the export share since that date. Sales to the federal government as a share of output have declined and domestic exports as a share of output (not absolute value) are smaller while the share of foreign exports has risen.

The general lack of interregional trade data for producer services in the United States needs to be emphasized. The growth in exports documented in many surveys undertaken during the 1980s and 1990s is mirrored in the input–output data. This suggests that the inferences made here about imports to Washington businesses of producer services are also probably correct.

Distinguishing between exports of services to Canadian provinces and those abroad, Stabler and Howe also used input–output models for 1974 and 1979. Direct exports of services from Manitoba increased from 24.37% to 42.61%, in Saskatchewan they increased from 7.1% to 27.82%, in Alberta they increased from 22.59% to 23.8%, and in British Columbia they increased from 21.55% to 30.57%. These data showed a strong increase in the share of exports to the rest of the world compared to places within Canada between 1974 and 1979 and the share of total economic activity in the provinces related to all exports also rose. Stabler and Howe concluded that: “At the margin, service exports appear to have accounted for between at least one quarter and perhaps as much as one-half of that portion of real growth which could be attributed to an increase in exports from these economies” (Stabler and Howe 1988, 313)

Input–output data complement surveys of producer services markets. The overall use of producer services as an input in production processes has grown, with expansions of supply within regions, at the same time as exports (and imports) of producer services have grown in magnitude and as a share of overall regional exports and imports.

Regional definition and classification

Lewis Dijkstra
Hugo Poelman
European Commission, Directorate General for Regional and Urban Policy

Regions and areas can be defined for scientific, political, or administrative purposes. At present geographical information can be collected either directly for regions or, especially as a result of recent developments in GIS and remote sensing technologies, for grid cells. In the latter case, data can be aggregated to coincide with scientifically, politically, or administratively defined regions and areas of different types and sizes.

In the European Union (EU), the establishment of a regional policy at the start of the 1970s gave rise to the need for standardized regional classifications for the analysis of regional problems, policy design and implementation, and the compilation of regional statistics. At that stage, Eurostat, in collaboration with other European Commission directorates-general and member states, decided to achieve this objective through the establishment of the Nomenclature des Unités Territoriales pour la Statistique (NUTS) or, in English, Nomenclature of Statistical Territorial Units.

The current NUTS system is a three-level hierarchical classification of regions in which each member state is subdivided into a whole number of NUTS 1 regions, each of which is in turn subdivided into a whole number of NUTS 2 regions and each NUTS 2 region is subdivided into a whole number of NUTS 3 regions. The NUTS EC Regulation (1059/2003) lays down the requirements for these regions and how and when they can be changed.

As EU policy increased its interest in areas not derivable from these three levels, and especially in smaller territories (mountainous areas, less favored agricultural areas, coastal zones, and deprived urban areas), smaller NUTS 4 and NUTS 5 regions were also identified.

At present NUTS 4 and 5 areas are classed as Local Administrative Units level 1 and 2 (hereafter LAU1 and LAU2). Each member state has to supply Eurostat annually with lists of LAUs by NUTS 3 region (Dunford 2010, 2011). The NUTS regulation, however, does not cover the LAUs. As a result, they can be more heterogeneous than the NUTS regions which have to fulfill certain statistical requirements.

A problem with administrative or political boundaries is that they do not necessarily coincide with the features of important geographical distributions. Territorial units should ideally reflect the geographical distribution of the phenomena under investigation. In relation to many of the issues dealt with in EU Cohesion Policy, functional areas and, in particular, travel-to-work areas (TTWAs) would make more scientific and policy sense. Also, the harmonized application of rules for defining functional regions would ensure the international comparability of the regions in individual member states. For this and other reasons the EU has embarked on innovative work to establish new regional classifications.
REGIONAL DEFINITION AND CLASSIFICATION

Here, two local and two regional classifications are described based on definitions which rely on the population grid, which can make local and regional definitions and classifications more accurate. The four classifications are interlinked at both the conceptual and the methodological level. The classifications are presented in pairs as the strongest links are between the local and the regional variant of the classifications.

The first pair consists of two classifications that cover the entire territory and create three categories along the urban-rural continuum: the urban-rural regional typology and the (local) degree of urbanization. Both these classifications are based on the population grid. The definitions of the rural area and the rural region are identical with the first applied at the local (municipal or local administrative unit level 2) level and the second to NUTS 3 regions. The definitions of the other two classes are not identical, but both capture the increasing levels of urbanity.

The second pair consists of two classifications that focus exclusively on functional urban economic areas: the EU-OECD city and commuting zone (local) definition and the metro region. As a result, this pair does not cover the entire territory. The EU-OECD city definition captures all the cities with an urban center of 50,000 inhabitants and their commuting zone. A city and its commuting zone together form a functional urban area (FUA). The metro region definition captures only the FUAs of at least 250,000 inhabitants at the NUTS 3 level. In other words, the metro regions only capture a subset of the cities.

The two local classifications are also linked. The EU-OECD city definition is identical to the highest degree of urbanization. The two regional typologies, however, are not directly linked.

First the grid concepts used in the four classification are explained. Afterwards the classifications are explained.

Why use the population grid?

Traditionally, classifications of territories were primarily determined by population density of a municipality (what is referred to as “local administrative units at level 2” by Eurostat) and sometimes population size. For example, the definition of a rural area in the OECD urban-rural typology is a municipality with a population density below 150 inhabitants per km².

This leads to a number of distortions. For example, some municipalities with a very small area and a very small population are identified as urban (or nonrural). For example, Aldea de Trujillo in Spain has a population of only 439 inhabitants, but its surface is so small that it still exceeds the 150 inhabitants per km² and is thus classified as urban.

Some municipalities which include a big city will have a low density if the area covered by the municipality is large enough. So, for example, the municipalities of Badajoz and Cáceres in Spain and Uppsala in Sweden all have a density below 150 inhabitants per km² and are thus classified as rural. All three are, in fact, cities with a population of more than 150,000 inhabitants (see below).

These distortions arise due to the differences in the area of a municipality. The benefit of the population grid is that each grid cell has the same size. (Because the Earth is a sphere and not flat, the grid cells are not exactly the same size, but the differences are minimal compared to the variation in the sizes of municipalities.) See, for example, Figure 1 which shows the population density of a few municipalities in the Netherlands and the density of the population grid. The two circles show two clusters of high-population-density grid cells. In the map with the density of the municipalities, the second cluster is invisible because it is averaged out by the larger size of the area of that municipality.
What grid concepts are used?

The three grid concepts are created using 1 km² grid cells (and clusters thereof). The concepts are based on three criteria: population density, contiguity (see below), and population size.

The three types of grid cells or clusters in the typology are the following.

1 Urban centers or high-density clusters: clusters of contiguous (excluding diagonals) grid cells of 1 km² with a density of at least 1500 inhabitants per km² and a minimum population of 50,000 after gap filling.
2 Urban clusters: clusters of contiguous (including diagonals) grid cells of 1 km² with a density of at least 300 inhabitants per km² and a minimum population of 5000.
3 Rural grid cells: grid cells outside high-density clusters and urban clusters.

Contiguity and gap filling

To determine population size, the grid cells need to be grouped in clusters. The methods presented here use three different rules for contiguity to create clusters:

1 Contiguous including diagonals (used for urban clusters): if the central square (grid cell) in Figure 2 is above the density threshold, it will be grouped with each of the other surrounding eight grid cells that exceed the density threshold.
2 Contiguous excluding diagonals (used for urban centers): if the central square in Figure 2 is above the density threshold, it will be grouped with each of the four cells directly above, below, or next to the central square that also exceed the density threshold. This means that cells numbered

---

**Figure 1** Population density in municipalities and grid cells.
Figure 2  Grid cells and contiguity rules.

2, 4, 5, and 7 can be included in the same cluster. Cells numbered 1, 3, 6, and 8 cannot as they have a diagonal connection.

3 Gap filling using the majority rule (used for urban centers): the goal for the high-density clusters is to identify urban centers without any gaps. Therefore, enclaves need to be filled. If the central square in Figure 2 is not, in its own right, a part of a high-density cluster, it will be added to a high-density cluster if five or more of the eight surrounding cells (therefore including diagonals) belong to a single high-density cluster. This rule is applied iteratively until no more cells can be added.

Figure 3 shows the results of this method applied to a 2006 population grid for Europe. To show sufficient detail a zoom on most of the Benelux and parts of the United Kingdom, France, and Germany is produced. The same zoom level will be used to demonstrate the two local and regional classifications, which at Europe-wide level would be difficult to identify on a small map.

Urban–rural continuum

From these three grid concepts, two linked and compatible classifications have been created. The first is a local definition (degree of urbanization) and the second a regional one (urban–rural regional typology). Both use the population shares by type of cluster to classify municipalities or regions. Each municipality or region belongs to one and only one class. So both classifications cover the entire territory without overlaps or omissions.

Degree of urbanization

Depending on the share of the population living in the different types of cluster, a municipality is classified into one of the three degrees of urbanization using the rules below.

1 Cities (or densely populated areas): at least 50% of the population lives in one or more high-density clusters.

2 Towns and suburbs (or intermediate density areas): at least 50% of the population lives in one or more urban clusters, but the municipality is not defined as a city. This criterion is sometimes expressed, as less than 50% of the population lives in rural grid cells and less than 50% lives in high-density clusters. The results are identical.

3 Rural areas (or thinly populated areas): more than 50% of the population lives in rural grid cells.

In Figure 4, the main cities can easily be identified. The smaller settlements and fringes of the cities are identified as towns and suburbs. The rural areas cover over half of the area (in km²), but less than half of the population.
The degree of urbanization is used in all European statistical household surveys such as the labor force survey (LFS) and statistics on income and living conditions (SILC).

Urban–rural regional typology

This classification is a variant of the OECD urban–rural regional typology, which relies on data at the municipal level to classify regions. This method uses the share of population living in rural grid cells to classify each region (NUTS level 3) into one of the following three groups.

1. Predominantly urban regions/urban regions: the population living in rural grid cells is less than 20% of the total population.

2. Intermediate regions: the population living in rural grid cells is between 20% and 50% of the total population.

3. Predominantly rural regions/rural regions: the population living in rural grid cells is 50% or more of the total population.

In a last step, the size of the cities (based on the definition below) in the region is considered.

- A region classified as predominantly rural by the criteria above becomes intermediate if it contains a city of more than 200 000 inhabitants representing at least 25% of the regional population.

Figure 3  Types of cluster.
REGIONAL DEFINITION AND CLASSIFICATION

Figure 4  Degree of urbanization.

- A region classified as intermediate by the criteria above becomes predominantly urban if it contains a city of more than 500,000 inhabitants representing at least 25% of the regional population.

This classification captures the rural regions well, but the urban regions cannot always be easily linked to a single dominant city (see Figure 5).

The urban–rural regional typology is mainly used to monitor rural development based on figures from regional accounts, which provide indicators such as gross domestic product, gross value added, and employment per sector.

A functional definition of cities and metropolitan regions

Based on the urban centers and commuting flows, two linked classifications have been set up. The first is applied at the municipal level and the second at the regional level. They have been applied to the entire territory of the EU, Iceland, Norway, and Switzerland at the local and regional level.

As opposed to the degree of urbanization and the urban–rural regional typology which rely on population density and size, the two typologies presented in this entry add a functional
Regional Definition and Classification

Figure 5 Urban–rural regional typology.

dimension, the flows of people commuting to work in a city.

Functional urban area: a city and its commuting zone

Definition of a city

The new city definition works in four basic steps and is based on the presence of an “urban center,” a new spatial concept based on high-density population grid cells.

1 All grid cells with a density of 1500 inhabitants per km² or more are selected (Figure 6a).

2 The contiguous (i) high-density cells are then clustered, gaps (ii) are filled, and only the clusters with at least a population of 50,000 inhabitants (6b) are kept as an “urban center.”

3 All the municipalities (local administrative units level 2 (LAU2)) with at least half their population inside the urban center are selected as candidates to become part of the city (Figure 6c).

4 The city is defined ensuring that (Figure 6d) (i) there is a link to the political level, (ii) at least 50% of the population lives in an urban center, and (iii) at least 75% of the population of the urban center lives in a city.
In most cases, as, for example, in Graz (in Austria), the last step is not necessary as the city normally consists of a single municipality that covers the entire urban center and the vast majority of the city’s residents live in that urban center. For 33 urban centers stretching far beyond the city, a “greater city” level was created to improve international comparability.

To ensure that the above definition identified all urban centers, national statistical authorities were consulted and minor adjustments were made where needed and in a way which is consistent with this overall approach. In other words, urban centers with 50,000 inhabitants which this methodology failed to detect were added. In some countries the population grid was a “disaggregation” grid. This means typically that the population of the municipality was distributed across the grid cells using land-use data. This tends to underestimate the population of urban centers. In other cases, steep slopes or fjords mean that the methodology does not detect urban centers.

Identification of a commuting zone

Once all cities have been defined, a commuting zone can be identified based upon commuting patterns using the following steps:

- if 15% of employed persons living in one city work in another city, these cities are treated as a single city (Figure 7a);
- all municipalities with at least 15% of their employed residents working in a city are identified (Figure 7b);
- municipalities surrounded by a single functional area are included and noncontiguous municipalities are dropped (Figure 7c).

The FUA consists of the city and its commuting zone. This method creates mostly cities with a single commuting zone, but in some cases it also leads to multiple cities to be included in a single commuting zone as in the case of the commuting zones in the Ruhrgebiet (Ruhr region), London, and Paris (see Figure 8).

Figure 6 How to define an urban center and a city: the example of Graz, Austria.
Figure 7  How to define a functional urban area; the example of Genoa, Italy.
REGIONAL DEFINITION AND CLASSIFICATION

Figure 8 EU-OECD functional urban area definition.

A typology of metro(politan) regions

Metro regions are NUTS 3 approximations of the functional urban areas (city and commuting zones) of 250,000 or more inhabitants following the definition described above. Each metro region consists of one or more NUTS 3 regions and is named after the principal functional urban area inside its boundaries (see Figure 9).

The typology distinguishes three types of metro regions:

1. capital metro regions;
2. second-tier metro regions;
3. smaller metro regions.

The capital metro region includes the national capital. Second-tier metro regions are the group of largest cities in a country, excluding the capital. For this purpose, a fixed population threshold could not be used. As a result, a natural break served the purpose of distinguishing the second-tier from the smaller metro regions. The regions which do not belong to a metro region are simply called nonmetro regions. This typology can be simplified even further by grouping all individual metro regions together into metro regions.

The boundaries of a functional urban area do not necessarily coincide with those of NUTS level 3 regions. Therefore, NUTS level 3 regions in which at least 50% of the regional population
lives inside a given functional urban area were selected as the components of the metro region related to that functional urban area. In some cases, the NUTS level 3 approximation of the functional urban area is very good. In other cases, the metro region may be larger or smaller than the functional urban area. Each functional urban area is represented by at least one NUTS level 3 region, even if that NUTS level 3 region has less than 50% of its population inside the functional urban area.

Links between the city definition and the degree of urbanization

The first building block of the city definition described above is the urban center and this is identical to the one used in the degree of urbanization typology. As a result, the city (or densely populated area) as defined in the degree of urbanization is identical to the city definition described here. The two maps show the two local typologies for the Benelux area.
The difference arises in the second building block. The city definition identifies contiguous areas which have strong commuting flows. These are the commuting zones (see Figure 3).

The degree of urbanization identifies towns and suburbs (or intermediate density areas) and rural areas (or thinly populated areas) based on population density. As a result, these two categories partially overlap with the commuting zones. The towns and suburbs category will occur both inside commuting zones (in this case they are more likely to be suburbs) and outside (in this case they are towns). Rural areas fall primarily outside commuting zones, but some rural areas have developed a strong commuting relationship with a nearby city and thus can also be found in some commuting zones.

No link between metro regions and the urban–rural regional typology

The two local level typologies have one type in common, namely cities, whereas the two regional typologies each have different types. The typology of metro regions divides NUTS level 3 regions into metro and nonmetro regions while the urban–rural typology divides NUTS level 3 regions into predominantly urban, intermediate and predominantly rural regions.

Despite the absence of an identical type or class of region, the two regional typologies are quite similar:

- most urban regions are metro regions and vice versa;
- most rural regions are nonmetro and vice versa;
- intermediate regions are split between metro and nonmetro regions.

Figure 4 shows the classification of regions in the Benelux area and contains examples of the most common links between these two regional typologies. The differences arise from three main sources: a different logic, different size thresholds, and a different number of classes.

The different logic behind the two typologies can be described as morphological and functional. The urban–rural typology depends more on the population size and density, which in turn is determined by urban form. So this is a variant of the morphological definition. The typology of metro regions relies on the presence of an urban center and of functional economic ties to this center.

The two typologies use quite different size thresholds. Metro regions are related to cities plus commuting zones of at least 250,000 inhabitants. Urban regions represent urban centers of 50,000 or more inhabitants (which also define cities) and/or urban clusters of 5000 or more inhabitants (which also define towns and suburbs).

The urban–rural typology has three types of region, while the typology of metro regions has only two. Due to these differences, some urban regions will become nonmetro regions because the city and its commuting zone are too small (or there is no city). Some rural regions can become part of a metro region if they have strong commuting links to a city in that or a neighboring region.

Taking advantage of a new tool, the population grid, the two regional and the two local typologies were developed to provide a better insight into the development of different types of regions and areas, which is particularly relevant for both Cohesion Policy and rural development. In addition to using these typologies for statistical and analytical purposes, they can also be used for policy. For example, the degree of urbanization is used to report Cohesion Policy expenditure, to identify areas eligible for innovative urban actions and to identify which fund should be used to finance local roads. These typologies have more
potential policy uses. For example, the functional urban areas could be used to facilitate policy design and implementation using more functional geographies. As these typologies become more widely used and understood, it will be interesting to see how their policy use evolves.

Further reading

Policies for regional development are practiced in many countries and rely on spatial differentiation or some form of spatial preference: they may apply to only a limited subset of a country’s regions, or to all of them but in a differentiated way. They aim to stimulate development in order to reduce socioeconomic disparities and inequalities between regions or parts of regions by deploying public finance in a spatially redistributive fashion, often complemented by fiscal, regulatory, or other measures. They have evolved from simple tools for local area regeneration to become geographically based instruments which seek to stimulate socioeconomic growth. Importantly, they have characteristics that make them especially useful in globalized markets and single currency zones, since they constitute a mechanism for supporting areas that are less able to benefit from economic integration and globalization.

A common form of regional development policy applies to a subset of regions within a given country with the objective of reducing politically unacceptable, often persistent, territorial disparities in socioeconomic development. The disparities may be measured, and the areas defined, by such indicators as levels or rates of growth of income and of employment or unemployment, or by demographic changes like depopulation. Typically, policy aimed at a subset of lagging regions allocates public finance in a preferential way to the targeted area in order to subsidize and attract investment, improve the business environment (e.g., through infrastructure provision), and expand the education and training of workers; the amount and intensity of public finance deployed is graduated according to the area’s socioeconomic ranking, with aid being most intense in the worst-off places. This form of regional policy has been extensively operated in Europe, in what is termed its “problem regions.” The regions concerned were genuinely backward (as in the dual-economy case of postwar Italy), or undergoing profound restructuring (such as the industrial north of the United Kingdom, the Ruhr district of Germany, or northwestern or northeastern France), or suffering rural underdevelopment and out migration (such as the northern margins of Europe).

When regional development policies apply to all regions, the overall objective tends to be to harness their underused or spare capacities in order to increase their growth rates. Such policies aim to prompt regions to better understand and mobilize their endogenous potential and to better integrate their actions and resources with the actions and resources of other levels of government deployed in the region and the private sector. The result of this all-region approach tends to be a mosaic of socioeconomic growth strategies and programs adapted by policymakers to different geographical contexts. Such regional development policies are thus instruments for wider, macro-economic growth delivered through multilevel governance systems. In its most comprehensive form, regional development policy can adopt a dual approach, combining an intensive targeting of resources...
in worst-off regions and areas with an approach that is inclusive of all regions.

This entry uses policy practiced by the European Union – which in 2015 spanned 28 member countries, 272 regions, and 507 million people – as a vehicle to illustrate the history of regional development policy as a policy idea and to identify its basic components. Internal regional development policy in the European Union has evolved into an example of the dual approach which concentrates resources on a subset of the most lagging regions, while also seeking to help all regions to invest more effectively and to better organize themselves for growth. The EU experience illustrates some of the difficulties and inhibiting factors in the design and practice of regional policy. Similar policies are practiced in many other places; for example, the antipoverty policy described in China’s Twelfth Five-Year Plan is, in effect, a regional development policy, and policies are also implemented in Australia, Canada, Japan, Korea, Norway, Mexico, and South Africa, to name only a few. The entry concludes by briefly examining a number of issues regularly highlighted by the practical implementation of regional development policies.

While the essential nature of regional development policy is easy to grasp, an inspection of the policies in practice shows that a precise definition may be cumbersome. For example, regional or area development policies may be operated by levels of administration other than national governments; the territorial expression may not be limited to regions but be fixed on groups of regions, or cities, or districts; concerns about capital absorption may weaken a government’s resolve to concentrate its regional development funding on areas of greatest need. Also, the labels attached to regional development policies may vary. In the European Union, for example, “regional policy,” “cohesion policy,” “urban policy,” “rural development policy,” “neighbourhood policy,” and “development and cooperation policy” are all forms of regional development policy. Indeed, much of the inspiration for a government’s “internal” regional policies comes from the development literature and certain kinds of policy for “external” development aid. The term “regional development policies” is, therefore, best understood as referring to a genus containing several species of geographically based development policies.

This difficulty in precisely defining regional development policies is, in part, a reflection that they are first and foremost policies, invented and designed by politicians and policymakers to meet changing political necessities in a variety of administrative circumstances. As policies, in addition to being open to theoretical and empirical examination, they are ideological constructions and are subject to ideological and administrative criticism. Also, regional development studies itself occupies an academic space that combines the disciplines of geography, regional economics, political economy, politics, planning, and sociology, among others, and produces a rich variety of insights and policy recommendations (something evident in publications of the European Union, the International Monetary Fund, the OECD, the World Bank, and the journals of the Regional Studies Association).

Regional development policy and geography

The evolution of regional development policy has accompanied a growing realization and recognition of the importance of the spatial dimension in economic policymaking. A region derives its socioeconomic personality from its
geographical position and climate, its assets and resources (minerals, landscape, population, businesses, infrastructure endowment, technological capacity, culture), and its interaction with the forces of competition and policy. In the twenty-first century, this interaction is largely determined by the region’s capacity to exploit its assets and resources in a globalized market economy. Theories of growth suggest that regions and major urban agglomerations grow fastest when they provide an environment conducive to business investment, attract and concentrate population, and foster wealth-producing economies of scale (often in the form of business clusters). Key elements in the business environment include natural advantage, availability of well-trained workers and pools of creativity or local knowledge, availability of public goods (efficient and reliable basic services, universities, laboratories), and viable supply chains offering a wider variety of suppliers. This concentration enhances growth, thus causing further concentration and, in some cases, the emergence of growth poles or hub regions, frequently leading to a very uneven settlement pattern with wide socioeconomic disparities across the national territory.

Empirical studies point to the disproportionately large contribution that a small proportion of growth poles or hub regions make to national aggregate growth – 8% of regions (27) in OECD countries contributed about one-third of OECD growth over roughly three business cycles between 1995 and 2007. From this, policymakers have been tempted to draw the conclusion that socioeconomic growth and poverty reduction can be achieved by simply stimulating agglomeration and economic concentration.

However, the OECD’s analysis also shows that the remaining regions in aggregate have a substantial potential to contribute to national growth; for example, in the same period in six OECD countries, nonhub regions with an income level below the national average grew more quickly than the national average and contributed a third to national aggregate growth. The key to balanced development and faster growth, therefore, appears to lie in prompting market forces to achieve twin objectives: to continue to provoke the concentration of resources in growth poles and hub regions and, in addition, to foster growth in places beyond these growth poles and hubs, because this will achieve a better overall aggregate performance and contribute to the reduction of social and spatial inequalities.

OECD and other empirical data caution against treating the spatial unevenness of socioeconomic conditions as inevitable, and suggest a warning against policies, especially development policies, which are spatially blind (e.g., sectoral development policies). This is all the more important since the immediate economic benefits of concentration may be offset by longer-term disadvantages to business (congestion, higher transport costs), to working people (spatial mismatch between job vacancies and people searching for employment, housing shortages), and to society as a whole (health costs, longer commuting times, pollution and adverse impacts on global warming), many of which are not captured quantitatively in national and regional accounting.

Indeed, the theoretical suggestion that the externalities of geographical concentration begin at some point to produce overall disadvantages for the economy, and for society as a whole, is borne out by empirical studies which, by their nature, take space and time into account. They demonstrate that factor markets (capital, labor, state of technology) do not work with equal efficiency in all places or at all times and that they may require long adjustment times, be affected by factor rigidity,
REGIONAL DEVELOPMENT POLICIES

or take inadequate account of externalities like pollution. Differences in population density and physical and political geography (e.g., distance from markets; sparse population of mountains, islands, or border regions; legacy of old and declining industry; insecurity due to political instability or criminality) reinforce market imperfections and can slow the rate of socioeconomic development.

In addition, public policies, such as macroeconomic policy, do not have an even impact throughout a national territory: while the economies of some regions may be overheating and require one set of policy measures, other regions may have surplus resources and be suffering depressed economic activity and require different policy measures. The result is that, even where there are relatively limited institutional barriers to internal migration, regional differentials in income, employment, and unemployment may persist for generations.

Academic work that investigates the interaction between economic growth and efforts to reduce inequality through policies of fiscal redistribution indicates that such policies produce benefits. It shows that policymakers are mistaken if they believe that fiscal redistribution slows growth or that inequality will take care of itself in a growing economy, a belief frequently expressed as “trickle down” or in the idea that “a rising tide lifts all boats.” Not only does inequality produce its own undesirable social effects and political consequences, but it may constitute a “drag” on growth, causing it to be slower, because resources are left underutilized, and less sustainable, because it foments discontent, undermines political consensus, and contributes to economic instability to the detriment of investment.

These conclusions from theoretical work and empirical data chime with experience in the political world, where policymakers see compelling reasons for action. The effects of unevenly distributed urbanization and rural depopulation lead to the abandonment of valuable social capital in areas that become less populated and to higher costs of social provision; private capital “trickles up” to big cities rather than investing in poorer areas and thus alleviating some of the public cost; the economies and labor markets of poorer regions are more vulnerable to the economic cycle, presenting challenges to social protection systems; single-currency zones contain areas with disparate economic conditions, yet policymakers are denied economic levers such as exchange rate or interest rate changes with which to seek a remedy.

Such real-world events demand a political response through policy management and intervention. Practical experience shows that fiscal redistribution systems can go a long way to offset inequalities in service provision: for example, in education and health. But they cannot directly address the challenge of improving a region’s (or a nation’s) socioeconomic personality by prompting its factor markets to work better in order to enhance its competitiveness and to increase its stock of modern, productive, physical, and human capital at a regional level.

A regional development policy that is pursued in an integrated way to raise capital investment and labor quality, and to increase innovative and technological capacity, is also necessary.

Regional development policy permits national policymakers to target interventions on places where they consider them to be necessary, and to vary their intensity, thus supporting the goals of macro-economic policy, saving public finance, and avoiding risks of market disturbance. Regional policy may be especially useful in places where successive privatizations have reduced the quantity of public goods and thus depleted the range of possible public investments, adding
further difficulty for governments wishing to raise effective demand.

The potential for authorities to offset disparities through regional development policy is thus supported by academic work. Actual practice has revealed, however, that this is not a simple task. Intervention can be counterproductive through bad timing or by being plain wrong. Further, national, regional, and local administrations may not have sufficient capacity or the know-how to devise and implement development strategies. One of the challenges of regional development policy, then, is to ensure that all regions (better-off as well as lagging) have the administrative capability to design and manage the realization of the investment programs, projects, and actions that will lift their region’s socioeconomic growth performance. Administrations must develop the capacity to frame investment and social measures to stimulate markets to mobilize regional assets, increase employment, reduce unemployment, and delay the onset of increased costs due to overagglomeration. Their programs must aim to make factor markets function so as to diminish socioeconomic disparities and accelerate the growth rate of regions, which, in turn, will imply a gain in national economic efficiency. The administrative effort also needs to make optimal use of its human and financial resources and, once its goals are achieved, to scale back public expenditure.

The evolution of regional development policy

Approaches to regional development policy can be considered as reflecting different evolutionary stages. At its simplest, the policy may aim at the development of a small local area, as opposed to a region, and use public financial support to attract private investment to the area to be assisted and to subsidize public and private investment there (e.g., the siting of Olympic facilities or other flagship projects in run-down city districts). This large project approach focuses on physical capital and seeks to kick-start market activity through a one-off capital injection or through the attraction of a big propulsive industry, for example through foreign direct investment (FDI). It may be more suited to administrative capacity in some lagging regions because it is easier to implement. It is also simpler to organize politically because it may require only a single decision. Enterprise zones, with specific tax and regulatory requirements, are a particular approach to regional development but are suitable only for some regions.

Empirical research indicates, however, that the simplest forms of the large project approach to regional development are insufficient as instruments for socioeconomic development. Although large-scale infrastructure projects have the effect of boosting effective demand in a locality during construction, and of improving the connectivity of goods and labor markets, research shows that regional development also depends on the interplay between physical capital, human capital, and the business environment (linkages between firms, knowledge spillovers, the rate of innovation), and that improvements in worker education and training are important enabling factors. Likewise, history has shown that the benefits of attracting big enterprise investment to locations away from their traditional supply chains are often ephemeral.

When the ambition of regional development policy is enlarged to target whole regions, it aims to promote growth by improving a region’s competitiveness and giving equal weight to physical investments and support for people entering and progressing in employment. In this form, policies tend toward a longer-term and more integrated or programmed approach; seek a balance between environmental and
development concerns; mix public and private finance; and emphasize the importance of performance-oriented quantification and evidence-based policymaking. These multi-year development programs are closer to development engineering: they start from an analysis of the market breakdowns in the regional economy in question and then seek to correct them over the medium to long term through systematic actions embedded into integrated development strategies or plans. They require administrative efficiency, a broader coalition of partners, and longer-term political support.

Regional policies of this more evolved type have a special relationship with other policies – sometimes requiring their support, sometimes providing it. In order to work effectively, they need to be accompanied by a policy, or code, to prevent subsidy wars between territories; a public finance system with a time reach that goes beyond the annual cycle of national budgets and, if possible, lasts the duration of the electoral cycle; and an independent audit system to monitor the policy’s financial management. Since human capital is an important factor in national economic growth and regional development, more evolved regional development policies also need to be accompanied by geographically targeted social inclusion and labor market policies in support of employment creation. At the same time, regional policies can act as a vehicle to help other policies achieve their objectives. For example, since regional policies aim at development, their role is critically important in support of policies to combat global warming, pollution, and the indiscriminate use of resources. A local stimulus to effective demand in a lagging region can be provided as support for business and, in addition, can be conditional on energy efficiency. Income support for marginal farming areas can be channeled as ecological incentives to farmers. In such ways, regional interventions can be engineered to provide double benefits.

Regional development policy’s interrelationship with other policies imposes coordination requirements on government to ensure that the policy mix works effectively: top-down and bottom-up coordination between different levels of government needs to be accompanied by coordination between administrations on the same level as well as with the private sector. Effective coordination enables regional policy to better achieve its goals and to increase the quality, or added value, of public expenditure, by ensuring that each dollar spent may serve multiple objectives and gain double benefits.

The regional development policy that began in the European Union (then the European Economic Community) in 1973 illustrates a policy operating in a subset of regions and based on investment in large-scale public goods. Its main aim was to support the European Union’s social market economy by awarding subsidies principally for publicly owned infrastructure investments in transport, power production and distribution, telecoms, water and wastewater treatment. Its implementation system was rudimentary. It had one financial instrument to support investments (the European Regional Development Fund). Its financial resources were allocated between EU member countries by political negotiation on the basis of an allocation key, which took only partial account of the population of each country’s lagging (or depressed, or worst-off) areas. Projects for subsidy were first selected by member countries in line with their overall regional development plans, with final selection at EU level. The construction of projects was the responsibility of the member country according to its own timetable; subsidies were paid as a proportion of construction costs and were restricted to increases in infrastructure capacity. The policy was, in effect, a “one size
fits all regions” approach, and the effect of its financial redistribution on regional development was correspondingly weak.

EU policy changed little until 1988 but, during this first period, the European Union became aware that the policy’s shortcomings reduced its potential benefit. In particular, the policy favored national as opposed to regional priorities and needs. National governments used EU finance as a substitute for their own spending, thus denying the intended increase in regional investment. Project selection did not take sufficient account of employment creation, and there were long delays between the selection of projects and the start of work, which denied the policy an impact on the ground. Importantly, it had no mechanism for evaluating the economic impact and outcomes of the projects it subsidized. In search of greater efficiency and in parallel with its large project approach, the European Union began to experiment with a more comprehensive implementation system, focusing directly on regions rather than member countries, on collections of investments rather than single projects, and on developing a policy cycle as opposed to a project cycle.

Instead of basing itself on a loose connection between place and physical investment, the policy cycle began to knit together geographic, economic, and social aspects of regional development and to move toward a coherent whole. The emphasis on public goods and public finance remained, as did the emphasis on increased infrastructure capacity, but the starting point was now a regional development program that integrated different investment projects and operated over longer, multiyear time periods. These experimental actions began to subsidize endogenous or “softer” investments (e.g., advice and consultancy support for small and medium-sized businesses, training for entrepreneurs). They allocated EU finance to the region and promoted decision-making at the regional level as to which projects should be selected for subsidy. They encouraged the creation of program management teams within regional and city administrations. The experiments were given a sharp stimulus by the enlargement of the European Union to include Spain and Portugal and the demand that regional development policy allow them to compete more effectively in the European single market, while also helping to counter the competitive challenge that their entry itself posed to agriculture in the Mediterranean regions of France, Italy, and Greece.

At the same time, changes in the wider economy, the practices of government, and the nature of the European Union itself were making reform essential. The EU economy was undergoing a structural, as opposed to a cyclical, crisis, with the sharp decline of coal, steel, shipbuilding, and textiles causing high and persistent rates of unemployment that differed sharply between regions. The disappearance of the Soviet Union affected the defense sector. Governments were preparing to reduce their role as economic producers by outsourcing to private companies many of the services and production processes for which they had been responsible, making it inefficient for regional development policy to operate only in support of the shrinking public sector. The European Union’s program to reduce internal trade barriers was expected to create competitive challenges for many regional economies and to accelerate changes in economic structures – and the same would later be true for the creation of the single-currency eurozone.

By 1988 EU regional policy was ripe for reform and the previous experiments offered a template. It remained unchanged as a development policy that targeted a subset of regions but was relaunched as a decentralized policy with new objectives, a new implementation system, and a radical change in the categories of projects.
REGIONAL DEVELOPMENT POLICIES

to be subsidized. Thus, it integrated another financial instrument (the European Social Fund) to subsidize the development of a region’s human capital, and insisted on the integration of physical and human capital investments. It opened the possibility of publicly financed subsidies for privately owned projects. It devolved implementation to regional partnerships that brought together representatives of national, regional, and local government, business, and organizations from civil society in a framework that became known as multilevel governance. One of its biggest innovations was the policy cycle which firmly anchored policy to the region to be assisted, so that economic geography became the paramount consideration.

The new approach demanded new capabilities and changed attitudes from policy administrators, and created tensions between layers of government. A good example of the need for policy clarification was the notion of regional partnership, which differed according to whether a country had a federal structure with regional self-governance, whether central government administration was carried out through regional offices of the state, or whether the only regional administration was a grouping of local authorities. In addition, there were different approaches to the inclusion of nongovernment bodies in the partnerships, with some governments including employers but excluding trade unions on ideological grounds. It required several years and further policy adjustments before the reforms of 1988 were fully translated into practice.

EU regional policy has now evolved further to combine its targeting of poorer regions with a socioeconomic growth policy for all regions, thus adopting the dual approach. The policy cycle has developed, seeking, among other things, to ensure that the policy, while fully decentralized in operation, is still coherent with EU and member country development objectives. To achieve this coherence, regions implement the policy within a three-cornered framework: they are allocated a sum of EU finance, with the amounts varying according to the regions’ socioeconomic ranking; they plan and implement their programs within an EU set of development guidelines (thematic objectives) which aim to ensure a measure of concentration throughout the European Union on key investments; and they comply with a national indication of which of these key EU investments has the greatest relevance for the overall development of their member country. Within this framework, the regional partnership analyzes the region’s development potential and the market breakdowns that are impeding its progress, agrees on priorities for socioeconomic action, and designs the region’s medium-term development strategy and development programs, incorporating quantified objectives and milestones. It implements the strategy through the medium term (seven years), selecting projects and actions for subsidy. Evaluation is built in to the policy cycle, creating a loop back to objectives, with care being taken to assign effects to particular causes, and making possible results-oriented management. This cycle (which incorporates the principle of subsidiarity) is an integral part of the European Union’s geographically based instrument for socioeconomic growth. In addition, the policy is increasing efforts to ensure that the necessary administrative and executive capacities exist in the regions (and, if needed, at national level), in order to cope with the requirements of implementing the project cycle.

The components of a geographically based instrument for growth

Whether regional development policies operate in a subset of regions in a given country or as a
geographically based instrument for growth in all of them, whether they base themselves around large, publicly subsidized flagship projects or multiyear development programs, they can be assessed according to four broad components: the policy’s objectives, which are intimately connected to the method of selecting regions and areas for assistance; its system of implementation; its dedicated budget; and its content (the types of actions it subsidizes). A fifth consideration is the regional development policy’s dependence on accompanying policies.

The objective of regional development policy is, briefly stated, to improve the wellbeing of citizens by stimulating regional development by, in part, redistributing public finance between regions. A first requirement in setting the objective is to decide whether it is to be achieved by concentrating on reducing regional disparities (which implies that the policy is for a subset of badly-off regions), or by improving overall socioeconomic growth (which implies that the policy covers all regions), or a combination of both (which implies varying the intensity of aid to favor the more problematic areas, however defined, while supporting all regions). The objective may be expressed in a number of ways and, over time, it has tended to become more elaborate. “Inclusive” or “pro-poor” growth objectives tend to embrace the idea of seeking to raise income (GDP) while achieving a more even income distribution among the population, perhaps in addition to seeking to achieve other social goals. “Smart” growth refers to improvements in the technological and innovation content of the economy and levels of productivity or rate of productivity gain.

Global objectives take on a rather different nature the more they are transformed into real action on the ground through the implementation system. There is a hierarchy and sequencing of objectives: for example, where the overall objective may be to raise employment, the strategy may seek to deliver this through selected subobjectives, or “priorities,” such as a higher rate of employment for women. This, in turn, may make it necessary to set an objective for the creation of increased capacity for child care, which may require the objective of establishing more training places for child carers.

Where policy involves performance-based management, each objective in the hierarchy needs to be expressed in quantitative terms and this relies on the availability of regional datasets. Further precision is gained by specifying a time period in which the objective will be achieved. This allows management to be monitored against milestones during the policy’s implementation period. The quantification of objectives permits the evaluation of impacts, outcomes, and comparisons between regions and countries, making it possible to improve the policy’s efficiency and enabling improvements in the added value of its spending. Subregional actions are an important feature of regional policies since administrative regions may not be functional regions in the economic sense, or may contain pockets of deep-seated socioeconomic problems that also make them suitable targets for regional policy. However, the availability of subregional socioeconomic statistical data tends to be limited. For regional policies implemented at supranational level, achieving consistency in targeting subregions across countries can be a particular challenge not just because of the limited availability of data but also because of lack of its comparability.

There is, therefore, a close link between the clarity of the policy’s objectives, the availability of quantified baseline data, policy evaluation, and overall efficiency, with the availability of regional and subregional data acting as a governing condition on the policy’s speed of evolution. But, even when data of sufficient quality are available
to policy managers, experience shows that the quantification of objectives, the selection of suitable indicators, and the setting of targets are difficult and uncertain tasks. It is not uncommon, for example, for high targets to be established as political gestures, only to creep toward more modest levels as evaluation deadlines approach.

EU regional policy can be said to have objectives for the long and medium term, one concentrating on a subset of regions and one for all regions. Its long-term objective, set out in the EU Treaty, is “to promote economic, social and territorial cohesion,” where “territorial cohesion” can be taken to mean reducing the backwardness of least favored regions, including rural areas, and the disparities between the levels of development of all regions. The medium-term objective is today expressed as helping the European Union achieve its 2020 goal of “smart, sustainable and inclusive growth.” These objectives are broken down into subsidiary objectives, relying on quantification in the operational phase. Thus, EU regional policy concentrates its redistributive effort and budget on the subset of poorest regions, defined in statistical terms as those having a gross domestic product (GDP) per head below 75% of the EU average. For these regions, it can be said that the implicit objective is one of increasing their GDP per head to 75% of the EU average, if possible within a seven-year period. In principle, it seeks to achieve this by varying the intensity of its financial support per head of population in line with a region’s distance below the 75% threshold; the further below the threshold, the greater the intensity (additionally, the intensity is modulated with the level of national GDP and the level of unemployment). But, for some of the very poorest regions, the results imply an annual transfer of investment funds that is considered as a matter of political judgment to be greater than their national economies can absorb.

The size of the seven-year transfer is therefore capped in terms of a percentage of the country’s GDP, and the redistributive effort in such cases is reduced. The objective of achieving 75% of EU GDP, which implies that EU regional policy can help the incomes of the poorest regions to grow consistently faster than the EU average, is not often achieved in one seven-year period, although the trend has been one of convergence (a trend reversed, albeit slightly, by the post-2008 financial and economic crises). In practice the poorest regions have tended to experience more than one (seven-year) planning period in which they receive maximum support, although its intensity diminishes as they approach the 75% income threshold. Today, the European Union concentrates over 70% of its resources on the poorest regions, which contain some 25% of population, leaving 30% for two other groups of EU regions: those with a GDP per head between 75% and 90% of the EU average, and the remainder above 90%.

A system of implementation, sometimes called the delivery system, is necessary for regional development policy and incorporates the policy cycle. This is true for policies aimed at a subset of regions in a given country as well as for those operating in all regions or for those based on individual projects or on multiyear programs. The implementation system itself has its own objectives for helping to maximize the policy’s effectiveness. Thus it may integrate wider considerations (environmental protection, action against climate change) into decision-making; increase the policy’s financial impact by concentrating resources on some types of activity; and ensure a timely impact on the ground by incorporating a discipline for project implementation. In the more evolved and more comprehensive examples of regional development policy, the region’s contribution to the policy cycle consists of an overall strategy for a region’s development,
which analyses the region’s potential and weaknesses; the creation of development programs, or action plans, which establish detailed objectives with budgetary envelopes; and the realization of physical or human capital investments which further the strategy’s objectives. Evaluation is integrated as a feedback loop, first assessing strategy, then monitoring implementation, and finally assessing overall outcomes and impacts.

A distinctive feature of the more evolved forms of regional development policy tends to be their decentralized implementation and decision-making. This brings together the various layers of government in a form of multilevel governance, with each layer taking the decisions most appropriate to its knowledge and responsibilities (the principle of subsidiarity) and integrating policy actions at different territorial levels. Multilevel governance is enriched by the establishment in each region or target area of a partnership that contains nongovernmental socioeconomic actors (civil society) as well as representatives of the national, regional, and local layers of government. The partnerships organize and carry out the region’s contribution to the policy cycle. It is the partnerships that analyze socioeconomic conditions in their regions, develop the programs and action strategies that determine priorities, set detailed and quantified objectives to make comparative assessments of projects and actions which are applying for public subsidy, select those which promise the best added value, and monitor and evaluate the results of their implementation.

Decentralization and partnership strengthen regional development policy’s role in giving spatial awareness to macro-economic policymaking. They bring into the development operation socioeconomic actors with a close understanding of local conditions and geography; interlock and reinforce the coherence of their objectives; enable integration of development strategies; and, importantly, help to build and maintain a strong consensus around the development objectives. Experience has shown, however, that they also bring complications that may challenge the administrative know-how and capacity, as well as the mutual trust, of the partnerships and layers of government. These challenges have to be overcome by, for example, ensuring the compatibility of partners in the face of difficulties; working together; deploying the partnership to best effect; maintaining coherence; and avoiding decisions that are in effect merely the lowest-cost denominator of different possibilities. It is therefore important that the objectives of the region’s development strategy are widely agreed and that decision-making procedures are transparent. Decentralized decisions must remain consistent with centrally determined development objectives, and partnerships must be rigorous in selecting the most suitable investments and actions for public support.

EU regional policy is continually encountering and seeking to solve difficulties in its detailed implementation. It has introduced three important modifications to reinforce its overall coherence. Two of these are intended to strengthen its performance-based management and a third its balance between physical and human capital investments. It has established guidelines (thematic objectives) to aid the prioritization of physical and human capital investments. At first, guidelines were offered on a voluntary basis, but they are now more binding since experience has demonstrated the difficulty of ensuring that they are respected. The present attitude is that aid is conditional in relation to agreed objectives, and it is backed up by a compulsory system of performance assessment, measuring progress against quantified performance milestones and targets established at the strategy stage of the policy cycle. The third modification concerned the particular EU difficulty
that member countries were allocated insufficient EU funding for investments in human resource development, despite evidence that a region’s human capital is critical for its rate of development. This has been addressed by placing a greater obligation on member countries to maintain their EU funding for human capital above a minimum level. Faced with an implementation system that grows in complexity, and recognizing the importance of administrative capacity for effective policy delivery, the European Union allocates part of its regional policy funding for the modernization and reform of civil administrations and for the further education and training of regional policy administrators.

The dedicated budget of regional development policy is the medium of its spatial and social redistributive function, and is the root of the coordination and consensus that are necessary for its implementation. The availability of public finance incentivizes socioeconomic actors in targeted regions and subregions to support the policy’s actions, and encourages them to coordinate actions at different levels of administration and between the public and private sectors and civil society. Small budgets require implementation to be more concentrated, both in space and in practical content, in order to be effective. The budget is deployed through the policy’s financial instruments, and the choice of instruments reflects the degree of integration and targeting that policymakers seek between physical and human capital investments and between the different geographical spaces to be covered by the policy (regions, cities, rural areas, etc.). Where there are several instruments, policymakers must find ways to delineate their responsibilities and to allocate available public finance between them.

EU regional policy has five principal financial instruments: the European Regional Development Fund (ERDF), which concentrates on all types of investment project in all types of places; the European Cohesion Fund (CF), which operates as an additional investment fund in the poorest member countries (as opposed to regions) for transport and environmental infrastructure; the European Social Fund (ESF), which concentrates on investments in human capital, social inclusion, and the functioning of labor market institutions, again throughout the territory of the European Union; the European Agricultural Fund for Rural Development (EAFRD) for the socioeconomic diversification of rural areas; and the European Fund for Fisheries and Maritime Affairs (EMFF), which is mostly deployed in coastal areas. The five funds represent the European Union’s determination to concentrate its redistribution of public finance in low-income areas and to integrate subsidy actions in favor of physical and human capital. But, at the same time, they illustrate the difficulty in mobilizing and integrating policies with different spatial references behind a single unifying vision of regional needs (the funds overlap in scope). The allocation of public finance between the instruments has no single set of criteria and is achieved through a mixture of objective, regulatory, and political factors, with historical allocations having considerable weight.

The budget of regional development policy is usually composed of public and private finance, with public finance being the instrument through which government pursues its redistributive and regional development objectives. Public funding levers private capital and thus increases the financial mass being used for regional development. In its simplest form, public–private leverage is achieved through either using public finance as a loan fund (although loan instruments are less effective in times of economic depression or low growth) or by subsidizing only a proportion of a project’s cost, with private capital (from
business, philanthropic, charitable, or voluntary sources) financing the remainder. This presents governments with the possibility of a spatial incentive: fixing a higher proportion of subsidy for projects or actions that it considers important but that are sited in less attractive areas or that appear to carry greater risk and are, therefore, less likely to be carried out by the private sector within a given time. Governments can go further to leverage private capital by focusing public finance on projects or actions that they think will trigger a wider private sector response. Examples include the creation of business sites to attract inward business investment; the construction of access roads to open up land for private industrial development; and the provision of incubator places to encourage the creation of new businesses. The potential for public–private leverage is greatly magnified in Europe by the process of privatization, the transfer of public goods and services into private ownership.

An important requirement – known in the European Union as the additionality principle – is that national, regional, and local governments do not use private capital attracted to the regional development effort as a means to displace public finance that may have been intended for the target area, since this counteracts the increase in the financial resource available for the target area’s socioeconomic development.

Preferences for the practical content of regional development policy can be captured in the question “What sort of projects and actions should regional development policy encourage in order to enhance the socioeconomic personality of a given region?” The answer is linked to both the policy’s objectives and analysis of how the region’s assets and resources can be made more productive.

For a regional policy restricted to the subsidization of public goods, financial support will be confined to projects undertaken by the public sector. For a policy aiming to attract inward investment (FDI), it will take the form of a range of actions to make the region attractive for target businesses. For a policy that aims to improve the competitiveness and the rate of socioeconomic development of a region by better use of its endogenous potential, the policy will be ready to subsidize a wide range of physical or human investments, whether financed by public or private capital. The overall effect of a region’s projects and actions may be to alter some aspects of its socioeconomic personality.

Discussions on the policy’s practical content have provided important insights into economic development and the timing and range of projects or actions that regions may consider for subsidy. But they rarely provide compelling reasons for one type of investment over another, since factors that are peculiar to the region usually predominate in any regionally designed strategy. The general view is that sustainable regional development is the function of a simultaneous combination of investments that will improve the socioeconomic benefits derived from the region’s resources. It will improve human capital (education, training, social inclusion, equality, reform of labor market institutions, and social provision); the endowment of basic infrastructure (transport, power, environmental, communication); technological capacity (linkages between research and industry and between businesses, promotion of innovation); the socioeconomic environment in which business operates (preparation of business parks and incubators, provision of facilities to support start-up and growing businesses, loan and other schemes for capital availability, and support for inward investment); and organization (multilevel governance). One recurrent idea to assist the economic development of local areas, towns, or cities within regions is the adoption of local exchange trading systems (LETS), or
REGIONAL DEVELOPMENT POLICIES

local currencies, in attempts to build on the experience of the Wörgl, Austria, stamped currency of 1932–1933.

Given the importance of human capital in regional development, even policies with a narrowly defined capital project objective will nonetheless contain measures to promote education, vocational training, and social cohesion, offering subsidies to projects or actions that aim to improve the ability of people to enter the labor market (e.g., actions to promote equality in the labor force; prevocational training; language education; employment mentoring).

The nature of regional policy’s practical content has been the source of theoretical debate summed up by the idea of efficiency versus equality. The efficiency argument points to the economies of scale, or agglomeration, that companies derive from being in cities, and argues that investments in favor of concentration represent a superior value for public support. The equity argument urges the reduction of regional disparities, placing importance on investments in human capital and on pro-poor aspects of growth, as well as physical investments in basic and business infrastructure. The debate echoes the theoretical opposition between the benefits of concentration and its negative externalities, and sets the two notions in opposition to one another. The modern approach that underpins the more evolved forms of regional development policy promotes their complementarity, seeking a balance, determined region by region, between investments in human and physical capital.

EU regional policy subsidizes investments in physical and human capital in both the private and public sectors, including investments in productive capacity, with subsidy rates varying in accordance with project types and a project’s revenue generation. One of the difficulties public administrations encounter with the large project approach to regional development or an approach that seeks to favor a particular sector is to detect, and avoid, those that will not prove viable on a socioeconomic basis (“white elephants”). This difficulty is avoided when policy concentrates its attention on improving the overall climate for investment and leaves business to make its own investment decisions.

Regional development policy does not stand alone, and even a simple project-based policy depends for its success on a number of accompanying policies. When considered as a geographically based instrument for economic growth, regional development policy stands within the framework of macro-economic policies and their pursuit of the objectives of growth, trade balance, and exchange rate and price stability. As a financial instrument that targets spending on precisely defined areas and social groups, it offers the possibility to mitigate some of the unwanted regional effects (e.g., increased disparities) of certain phases of macro-economic policy. Indeed, for political leaders regional policies can be perceived as necessary in order to achieve national consensus in favor of other government actions, for example austerity policies. In the European Union, the macro-economic impact of regional policy is an important consideration for countries that receive large annual investment resource transfers (close to €10 billion a year in the case of Poland for the seven years 2014–2020, which is equal to a large part of the country’s investment budget).

All types of regional development policy require a regulatory framework for the avoidance of subsidy wars and to ensure fairness in the policy’s implementation. In regional development policies that limit themselves to the public sector, the objective must be to avoid subsidy wars between regions or countries. In policies that cover both the public and the private sectors and which grant public finance to private investments, competition requirements between
businesses become important to ensure that public subsidy does not distort market conditions. EU regional policy is implemented within a detailed regulatory framework that monitors subsidy rates to both public and private investors, and that has the power to force the repayment of subsidies that are proved to distort market conditions.

Multi-annuality of the national budget is necessary to underpin the multiyear regional development programs that are an important component of more evolved regional policies. It is the multiyear nature of programming that assures regional policy of its medium-term relevance; distinguishes it as an instrument which helps to manage structural change, as well as contributing to the management of economic cycles; provides a framework in which the partnerships of multilevel governance can plan ahead and create project pipelines; and insulates it against too frequent political and budget changes.

All government policies require efficient and sound financial management and this requires independent audit. For a decentralized regional policy where the management of public finance is devolved to a large number of socioeconomic actors, the importance of independent audit is critical. Without it, management systems atrophy; errors begin to occur; and the possibility of fraud and corruption increases. But a proportionate balance between the requirements of financial management and the amount of public finance involved in projects or programs may be difficult to achieve. Political factors may make this even more difficult.

Issues in regional development policy

Regional policy is a volatile field. It is subject to intense debate about its efficiency, effectiveness, and utility. Within individual countries, its importance within the policy framework waxes and wanes with changes in government ideology. Nevertheless, almost all governments recognize the need for policy instruments to address spatial disparities, either because of a commitment to territorial equity in living standards and employment or because of the concern that all regions should strive to contribute to national economic growth. A number of policy and technical issues arise regularly in the design and implementation of regional development policies, whether this is undertaken by central government alone or through a multilevel governance system involving regional and local actors. Seven are mentioned here.

Regional development policies rely on effective organization, and the quality of governance is an essential factor in their implementation. Their decentralized operation emphasizes governance quality because it brings extra layers of administration into the heart of policy implementation, granting more autonomy and wider responsibility for public expenditure. The belief that the quality of a region’s governance increases with improvements in the region’s socioeconomic development – that greater wealth makes possible better governance – is not born out by experience. Instead, studies suggest that low-quality governance is a barrier to growth and that good governance is a prerequisite since it alone can provide and guarantee the stable social and business environment that encourages development.

Among the factors that affect the quality of regional governance are the legal system, which must entrench the rule of law, equality before the law, and nondiscrimination; government administrations and their personnel, who must be free of corruption; and government systems, which must be capable of technological adaptation (e.g., systems of e-government) and open to organizational innovation. The ability and
capacity of administrators and their procedures is a determinant in the take-up of financial resources and ideas flowing from other policies, civil society, and the private sector; it is critical to the coherence, quality, and delivery of development strategies.

These considerations indicate a tension within regional development policies between the desire to ensure the best results, which frequently leads to elaborate and complicated procedures, and the need for bureaucratic simplicity. There is no lasting tradeoff between the two, and a condition for the success of policy is a constant effort to help administrators improve their know-how and capacity and to encourage bureaucratic innovation.

The essential task of regional development policy is to intervene in the working of regional economies, the need for action being strongest in the poorest regions or areas. This sometimes brings the policy into conflict with free-market ideologies that argue that regional economies function best when intervention is kept to a minimum, or even when there is no intervention. Such arguments rarely take account of the fact that there is a geographical impact and market effect of almost all government spending (e.g., road building; siting of military bases; awarding of research contracts). The proponents of spatially blind policies may ignore that agglomerations are often treated preferentially in the allocation of public spending (e.g., financial support for local transit systems). The counter-argument is that regional development policy is market-oriented and seeks to overcome market failures and to stimulate markets to work more effectively, reducing the scope and scale of intervention as market mechanisms prove capable of improving the socioeconomic performance of targeted regions.

Concerns about market intervention may spill over into arguments about aspects of regional policy’s implementation or delivery system. Calls for “flexibility” in implementation, for example, may disguise attempts to escape from a centrally determined policy focus. Such discussions risk treating the implementation system as bureaucracy or red tape (or, in environmental terms, green tape) and overlooking its role as an essential component of policy and as a determinant of its success.

Beyond such red tape arguments are important issues of balance. For example, experience shows the difficulty of achieving a stable balance between the empowerment of regions and the desire to ensure that they implement policy within an agreed framework; between the stringency of controls against bad financial management and the possibility for regions to introduce bureaucratic innovations in implementation; between objective financial allocations and a region’s capacity to design and execute sufficient projects to absorb funding within preset deadlines; between evaluations that serve a political purpose and those that aim to improve program performance; or, more widely, between economic development and the responsibilities of environmental and climate protection. Balance is difficult to achieve and maintain, and issues frequently resurface. The only remedy appears to be to treat administrative and executive capacity-building as an integral element of regional development policy, putting it on an equal footing with, for example, infrastructure provision or the retraining of workers.

A close inspection of regional development policy as a macro-economic instrument shows that it is not easy to place it in a classification that draws distinctions between structural and countercyclical or between supply-side and demand-side instruments. Its spatial and strategic foundation and its medium-term nature make it an apt instrument for guiding and managing structural change. The immediate availability of
its investment programs, containing a pipeline of mature projects and social and training actions ready to go, gives it the capacity to boost effective demand and to provide an effective local stimulus, especially in poorer regions where the policy's redistributive effect is greatest. Its concern with targeting market breakdowns in particular geographical areas to overcome impediments to the supply of factors of production suggests that regional policy is inherently a supply-side instrument. But its task of injecting resources into regional economies gives it the attributes of a demand management instrument, whose effectiveness is enhanced by its geographical targeting and its regional partnerships' knowledge of local conditions and socio-economic requirements. In fact, its distinguishing feature as a macro-economic instrument is what might be termed its "hands-on" nature: where other macro-economic policies are spatially blind (in that they operate at a distance from socio-economic realities), regional development policy is geographical, space-based, and anchored in actual conditions. If other macro-economic policies shape the overall economic and social environment in which economic activities may take place in a country (or group of countries), regional development policies add spatial and financial precision that improves overall political efficiency.

Whatever the geographical scope of the policy (the subset of regions with the weakest economies or all regions), there remains the question of what constitutes a region. An effective region from the point of view of regional policy tends to be one with a critical mass of economic opportunities, which provides a suitable context for integrated, cross-sectoral economic development within its boundaries and combines a certain level of decentralized responsibility in the field of investment policy. In the European Union, the reference region most commonly used has an average population of 1.7 million people which is sufficiently large in most cases to take account of commuting lines and travel-to-work areas. EU regions differ widely in the extent of their policy roles and their level of responsibility for investment – some are also (small) member countries and so have at their disposal the levers of macro-economic policy.

Cities typically meet the requirements for decentralized policy implementation. They contribute substantially to national development but are generally unable to ensure the development of the region as a whole, while their own needs may not be adequately reflected in a development policy targeted at broader territories. Wrapped up in this issue is the difference between administrative and functional regions. The boundaries of administrative regions may not coincide with those of functional regions (e.g., both national and regional boundaries may cut employment centers from their travel-to-work areas) or they may be drawn so as to include dissimilar geographical areas (e.g., island groups, a coastal region including islands). This may also affect the usefulness of regional datasets. In implementation, there are devices for overcoming this, such as allowing support to be granted to projects outside the administrative boundary of the supported region, provided the benefits accrue entirely or substantially to it (e.g., support for the training of the target region's workers in a training institution located outside the target area).

The decentralization of regional policy is important in resolving economic difficulties caused by administrative boundaries. Decentralization allows regions to tailor investments to take account of their own spatial context and of the relationship between their cities and towns and their hinterlands, as well as their relationship with neighboring regions. But the issue of the ideal geographical framework for regional
development policy, both spatial and political, remains. The only available solutions tend to be pragmatic ones, working with what exists while making adaptations to the implementation system in an effort to ensure that policy objectives are attained.

The data available to regional policy are traditionally some regional measure of income, unemployment, and employment, with income being measured through GDP, which, because it measures economic activity in the market, treats investment and consumption in the same way. With these data the policy can seek to quantify its objectives and measure its progress in both economic and social terms. Policymakers accept that there are limits to convergence – all regions may benefit from regional development policy, but not all regions can reach the same levels of development – and this is leading to more nuanced expressions of the objectives of regional development policies, which express concern for the quality of the growth and are reflected in terms like “inclusive” or “pro-poor” growth. This, in turn, calls for a wider demand for regional datasets (gender, labor market, education and training, health) and the creation of new ones that can capture income distribution and quantify “quality” objectives and progress – which are necessary when regional development policies are concerned with such things as impacts on the environment, biodiversity, and resource depletion and incorporate performance assessment. Academic innovations are responding to this development with the construction of “happiness” or “capabilities” indices to measure wellbeing, regional indices of the disposable incomes of households, and “risk of poverty” indices to capture not only progress toward social inclusion but also its durability. However, data are expensive and the wish list of regional data tends to exceed what the authorities can afford, hence the persistent reference over many decades to the same basic (but still meaningful) sets of income and employment data.

The evaluation of regional development programs and actions, and, ultimately, policy, requires data that are capable of expressing its intended and actual results. Thus the practice of evaluation is intimately connected to the availability of regional datasets and creates new challenges: for example, lags in data compilation reduce their usefulness in steering regional development programs; region-wide data may not be able to capture the area-specific results of the projects and actions carried out as part of regional policy. But the difficulty of matching their requirements with the availability of regional data is only one of the problems that have to be overcome in the evaluation of regional development programs. The list would include such factors as the need to ensure that evaluation and baseline indicators are built into program design; that intended objectives are set with sufficient precision to permit the choice of suitable indicators and targets; that quantifiable proxies exist wherever regional data cannot be the appropriate measure; that data is collected regularly; that other factors in the economy that influence the policy’s results (especially when the desired objectives can only be appreciated over the longer term) can be properly taken into account; and that results can be properly interpreted. Overshadowing these questions, however, is the question of whether evaluation is a political or a technical function. The essential task of evaluation goes beyond monitoring and observing to judge the performance of policy. This indicates that questions relating to evaluation reflect deliberate policy concerns – the deliberate policy choices that are made and the extent to which policy objectives are achieved.

Evidence-based evaluations have provided the information to demonstrate the transferability of development know-how from one
REGIONAL DEVELOPMENT POLICIES

region or subregion to another, avoiding the need to reinvent the ideas behind successful projects and initiatives and speeding up policy implementation and impact on the ground. Thus, it is widely accepted that regions can quickly gain from others the knowledge and ability to improve their administration and the development of projects. This is all the more important given the increasing complexity of successful regional development programs as they move beyond basic investments such as transport infrastructure to other types of projects, such as technology parks to spin out the results of university research; business networks to accelerate the rate of innovation in a region’s businesses; social inclusion activities to help long-term unemployed people regain a footing in the labor market; or localized business loan schemes to offset the reluctance of banks to lend at acceptable rates to start-up businesses in risky areas. Encouraging the transfer of proven ideas is an integral part of the implementation of regional development policy, shortening the time lag between political decisions and their impact on the ground.

Conclusion

Regional development policy provides a simple and immediate way to tackle pockets of regional or urban poverty. In its more evolved form, when applied to all regions in a given country, it combines geography, politics, and economics to become an instrument of macro-economic management that is oriented toward the wider spread of socioeconomic development and contributes to its acceleration. It offers a solution to several policy conundrums. It makes it possible for governments to intervene in their national economies in order to respond to structural economic problems without compromising the operation of markets; its spatial targeting makes it possible to raise effective demand in worst-off regions without disproportionate increases in national debt; its investment focus helps to resolve the efficiency versus equity dilemma; its technical nature allows policymakers to sidestep ideological issues and contributes to a consensus in policymaking. Its implementation may be complex, owing to its multiple objectives, but it creates the possibility for evidence-based, spatially targeted economic management in the context of globalization and within single-currency areas, whether nation-states or multistate zones, and can be especially useful in cases where governments wish to boost effective demand but where the range of potential public investments has been reduced by privatization.

REGIONAL DEVELOPMENT POLICIES

The word region derives from the Latin word region, which referred to a realm or kingdom. In contemporary geography the word is used to refer to a delimited part of the surface of the Earth. In geography, three types of region are identified: areas that share certain common characteristics (homogenous regions); areas that are functionally interdependent (functional regions); and areas that are subject to economic, political or administrative dominion or authority (jurisdictional or administrative regions). Although the word is often considered to refer to a part of a nation, it can also denote national and supranational territorial entities. The word model refers either to a stylized representation of a particular historical or geographical pattern of development or to a simplified (abstract) conceptual representation of the characteristics and determinants of real world situations. In the former case, the aim is to identify the variety of forms that development can assume. In the latter case, the aim is to replicate or explain real world situations and to identify underlying causal mechanisms. The word development usually refers to the act of mobilizing and creating resources to make an area and its inhabitants more productive of things that are useful (use values), that in market economies they can exchange for other useful things (exchange values), and that can improve their capabilities and the lives of people who visit an area (human development). A distinction is sometimes made between development of an area and development in it (as a result of external intervention). The idea of development is also associated with the idea that places and their inhabitants can pass from lower to higher stages of organization. Development is, therefore, a process in which people are at one and the same time the actors and the beneficiaries.

Development is usually measured by calculating how much additional wealth (gross domestic product (GDP) or gross value added (GVA)) is created in a particular area in a particular year or how much income accrues to an area’s inhabitants (gross national income (GNI)). Models of regional development are concerned either with explaining such increases in output and income or with explaining the actions and improvements that bring them about. From a human development perspective, wealth creation is, however, a means to an end rather than an end in itself (Seers 1969; Sen 1999). Sen, for example, suggests that development involves expanding the real freedoms that people enjoy: development should increase human capabilities, defined as the freedom to achieve valuable beings and doings (themselves called functionings). These functionings include good health, adequate nourishment, access to educational services, happiness, self-respect, and security. An important implication is that models of regional development should address questions relating to the social and territorial distribution of wealth and income as well as of growth. Moreover, methods of measuring development should consider changes in the stock of wealth rather

DOI: 10.1002/9781118786352.wbieg0650
than flows of income and should employ wider definitions of development that embrace not just productive capital but also human, social, institutional, and natural capital.

In a proximate sense, an area’s wealth, productivity, and income depend on the interaction of four sets of factors (Figure 1). The first is its natural (first nature) and created (second nature) resource endowments (natural resources, population, skills, infrastructures, technologies, etc.). An area’s resource endowment is a cause of development, specialization, and the division of labor. The second is (i) the degree of mobilization of an area’s resources and human potential and (ii) the effectiveness, efficiency, and productivity with which they are used. In turn, these drivers depend on the capacities, strategies, and performance of economic actors, the social relations and institutional structures in which action occurs, and the wider national and international context and rules of the game. The third is the extent to which an area’s inhabitants command and control the resources of others, the degree of unequal exchange, and the extent of transfers of wealth. The fourth derives from the fact that resources are created, conserved, and reproduced in and through development and as a result of policy interventions, so that resource endowments are not just a cause but also a consequence of development. Development processes

![Figure 1](image-url)
are, therefore, cumulative, endogenous, and path-dependent, and can involve self-reinforcing virtual and vicious circles.

Models of regional development also deal with the evolution of regional disparities and the mechanisms that shape them. Existing models can be distinguished according to whether regional differences in GDP, GVA or GNI per capita are expected to get smaller (convergence or catch-up) or wider (divergence or falling-behind). In the recent period of hegemony of neoliberal economic ideas and programs, models that predict catch-up have predominated. The expectation was that convergence would result from the alignment of technologies, lifestyles, consumption patterns, and government policies, in part as a consequence of the discipline exercised by global financial markets and dominant economic and political interests (see Dunford and Greco (2006) and Dunford (2009) on which this entry draws).

**Neoclassical convergence models**

Neoclassical growth, regional development, and trade models all rest on the idea that regional development depends on an area’s resource endowments. Ricardian and Heckscher–Ohlin trade models treat resource endowments as exogenous. Solow-type growth models treat population growth and technical progress as exogenous, while capital resources depend on the rate of saving and the investment/accumulation of physical capital, although the impact of additional physical capital on growth is itself assumed to dwindle to zero. Neoclassical regional development models explicitly allow for the mobility of capital and labor and their impact on initial exogenous regional resource endowments, increasing human resources in areas of net in-migration, and capital in areas of net inward investment.

All three groups of models pay no attention to social relations and institutional performance. All assume that market mechanisms will automatically ensure that resources are employed fully and efficiently. These models all rest, however, on (unrealistic) assumptions of: (i) constant returns to scale, implying that costs of production do not change as the volume of output changes; (ii) the related assumption of perfect competition, with its implication that the economy is made up of small enterprises none of which can affect market prices; and (iii) an instantaneous re-employment of resources, implying that no resources remain involuntarily unemployed. Externalities, market failure, information asymmetries, and coordination failures (where an absence of investment by one enterprise makes it profitable for another to invest), which in practice play an important role in shaping regional development trajectories, are assumed not to exist and not to matter.

The Solow growth model and associated growth accounting exercises were developed as an alternative to Keynesian Harrod-Domar (HD) models. HD models attributed national and regional growth to the savings rate (on which capital investment depended) and the productivity of capital. Clearly, savings and investment are necessary, although not sufficient conditions for growth, which will also depend on human capital and institutions. These Keynesian models also suggested that actual growth could fall short of the rate required to ensure full employment, and identified instability as a possible feature of capitalist economies. The Solow model was radically different. The model itself rested on the idea that regional economic performance depends on (i) growth in the volume of capital and labor inputs, of which an area’s resource endowment is made up, and
(ii) increases in productivity, which depend on technical change. It predicts, however, that the growth path of a country or region will converge on a steady state. As long as labor is perfectly mobile (or regional rates of population growth are identical) and technological know-how is public, this steady state growth rate is the same for every country or region, while, in this steady state, per capita variables such as per capita output do not vary. The existence of similar conditions in the economies under consideration would, therefore, result in a convergence in per capita income. The reason why is that economies that are less developed are expected to grow/approach the steady state faster than economies that are more developed, while, in the steady state, per capita variables do not change. Empirically this claim is associated with the $\beta$ convergence hypothesis (Barro and Sala i Martin 1992).

Two factors underpin the expectation that economic growth will be faster in less developed economies. The first is the assumption of diminishing returns to capital and constant returns to scale. At any given level of technological development, these conditions imply that: (i) increases in per capita output decline as the amount of capital per worker increases; (ii) increases in productivity cease once a steady-state/equilibrium amount of capital per worker is reached; (iii) increases in per capita output associated with incremental investments are greatest in areas/enterprises that are the least mechanized; and (iv) countries that differ only in initial levels of per capita GDP will converge on the same level of GDP per capita. The second factor is the view that technology is a public good, available at no cost to everyone, and that the diffusion of technology and knowledge from advanced to less developed enterprises and areas will close technology and productivity gaps. Technology can only diffuse, of course, if there is no shortage of capital to invest.

Neoclassical models of regional economic development suggest that the flow of capital to low-income areas and of labor to high-income areas will result in an equalization of income per head. The movement of labor from low- to high-wage areas will raise wages in the former and reduce them in the latter. Capital, conversely, will move in the opposite direction, as the rate of profit is expected to be higher in less developed areas where wages are lower (Figure 2a), as will knowledge (Figure 2d). Movement will continue, it is argued, until there are no further differences in rates of return in different areas. Capital in-migration will be the greater the smaller the out-movement of workers and the smaller the rise in local wages. A number of recent cases indicating an interdependence between exporting skilled workers and importing capital in the industries in which they develop capabilities and acquire technological know-how place a question mark over this conclusion, while the assumption of constant returns to scale is crucial, as in its absence the net flow of capital may favor more developed areas (Figure 2b).

Neoclassical Heckscher–Ohlin factor proportions explanations of specialization and trade predict an equalization of factor prices independently of factor mobility. These models suggest that areas specialize in activities that make intensive use of resources that are relatively abundant. Areas with abundant supplies of skilled workers specialize, for example, in skill-intensive activities. Areas with abundant land resources per capita will specialize in land-intensive activities. Increases in the demand for relatively abundant resources and reduced demand for relatively scarce resources will raise the incomes of the former and reduce the incomes of the latter (Dunford et al. 2014), ultimately leading to factor price equalization.
Circular and cumulative causation

Models of circular and cumulative causation (CCC) differ significantly from the neoclassical tradition. These models identify positive/negative feedback mechanisms and emphasize the endogeneity of factors, such as resource endowments, considered exogenous in neoclassical models. CCC models suggest that comparative development depends on the relative weight of unequalizing, centripetal forces of attraction and suction and equalizing, centrifugal forces of diffusion.

Myrdal called the former backwash effects. An example is the way in which net flows of capital and labor are directed towards more rather than less developed areas (Figure 2b). As his aim was to explain increasing economic inequality between developed and underdeveloped areas, these centripetal forces received particular attention. Myrdal recognized, however, that there were spread (trickle-down) effects that worked to equalize development. Myrdal also
REGIONAL DEVELOPMENT MODELS

paid considerable attention to institutional factors and argued for active policy intervention to promote greater equality which, he thought, would contribute to greater economic growth. Net flows of public expenditure from developed to less developed areas designed to counteract the unequalizing effects of market mechanisms are an important example (Figure 2c).

Another strand of CCC models is associated with Kaldor, who drew on Young’s exposition of the possibilities of exploiting economies of scale in manufacturing and Verdoon’s assertions concerning the role of manufacturing as a driver of growth. The core idea was that economies of scale (assumed not to exist in the neoclassical tradition at that time) are a fundamental characteristic of economic life. Kaldor argued that national and regional growth was export-led. Export growth depends on the efficiency wage (the ratio of real wages and productivity). Increased exports of manufactured goods imply increased output. As a result of economies of scale, external economies/spillover effects, and complementarities, greater output implies increased productivity. Greater productivity improves competitiveness, contributing to a virtuous spiral. In the United Kingdom this model led to the introduction of wage subsidies in less developed areas in the shape of the regional employment premium (1967–1978).

The emphasis on export demand is indicative of a second major difference. Neoclassical growth models are supply-led, concentrate on the expansion of potential output on the supply side of the economy, and assume that aggregate demand will equal potential output. Kaldorian models are Keynesian models of demand-led growth. In these models, aggregate supply is adjusted to accommodate demand-led changes in actual output. Adjustment occurs through changes in capacity utilization and/or induced changes in accumulation, migration, and technical change.

Theories of modernization, dependency, and unequal exchange

Modernization theories have informed analyses of regional development. These theories examine the emergence of the modes of economic and social organization and life that first appeared in Europe and were subsequently extended to other parts of the world. An early example was Rostow’s model of stages of (neo-American) economic growth, in which all areas are considered to occupy different positions on the same universal development path (traditional society; the preconditions for take-off; take-off; the drive to maturity; and the age of high mass-consumption). Contemporary examples include neoliberal models of globalization and development that suggest that less developed areas simply find themselves at an earlier stage along a single development path already charted by the most developed capitalist economies in the world. Evident problems with these models are numerous and include, on the one hand, the way in which the emergence of economically advanced areas changes the conditions in which latecomers develop, and, on the other hand, the environmental unsustainability of the ways of life associated with existing concepts of modernity.

An influential East Asian variant of modernization theory was the flying geese paradigm. This model suggests that East Asian catch-up involved the emergence of a dominant growth center (Japan) that subsequently acted as the leader of a hierarchical group of followers that included a second tier comprising the Asian Tiger Economies, a third tier comprising Malaysia, Thailand, Indonesia, and most other members...
of the Association of Southeast Asian Nations (ASEAN), and a fourth group made up of China and Vietnam. Drawing on dynamic versions of trade theory, the idea was that the emerging economies in East Asia pursued, one after another: (i) a product cycle sequence involving successively the import of modern manufactured items, domestic production, export, and, finally, re-imports once production was moved offshore; (ii) an industrial sequence involving a movement from lower to higher value added activities that saw these economies specialize in a succession of supposedly increasingly sophisticated industries (textiles, chemicals, iron and steel, motor vehicles, and electronic products); and (iii) a transfer of products and industries from countries that were more advanced to countries occupying lower positions in the hierarchy.

Theories of dualism deal with structural asymmetries that perpetuate inequality. Developed especially in studies of economically under-developed areas, these theories are a variant of modernization theory that emphasized the existence of sharp differences in the organization, technological sophistication, degree of development, and goals of actors in the modern and traditional sectors of underdeveloped areas and envisaged a progressive expansion of the former at the expense of the latter. A classic example is the Lewis model, which posited the existence of disguised unemployment in the traditional agricultural sector/rural areas so that the transfer of surplus labor from the agricultural sector/areas to the modern sector/more developed areas would leave agricultural output unchanged yet increase the output of the modern sector.

In practice, rural–urban migration was far from smooth and varied widely from one country to another, with cases where: agricultural output declined (implying that the marginal productivity of farmers who left was not equal to zero); urban growth was insufficiently fast for the relatively capital-intensive modern sector to generate sufficient employment, leading to a rapid increase in informality and urban unemployment; profits were not re-invested domestically; and rural incomes were not large enough to provide a market for manufactured goods. To explain these phenomena neo–Marxist accounts of the articulation of modes of production interpreted dualism as a corollary of the rise of a money economy and industrial (as opposed to an earlier commercial) capitalism in less developed countries in which precapitalist subsistence economies or petty commodity production predominated.

Other models of regional development in underdeveloped countries identified vicious circles of underdevelopment. In many areas, for example, there are capital shortages due to insufficient savings, low productivity due to capital shortages, low real incomes due to low productivity, and insufficient savings due to low real incomes. To break out of this and other vicious circles and ensure a progressive expansion of the modern sectors of underdeveloped regional and national economies, a wide range of strategies were designed. Most targeted investment. Models of balanced growth proposed a series of complementary investments capable of providing market demand for each other (Nurkse) perhaps with the added impulse provided by a big push (Rosenstein–Rodan), and active development planning in part to overcome market coordination failures. Models of unbalanced growth (Hirschman) propose a concentration of investment in a few small projects whose backward and forward linkages sequentially create shortages, bottlenecks, and opportunities for further profitable investment. Growth pole models (Perroux) were a variant of an unbalanced growth strategy adapted to
the development plan approach that Hirschman opposed. For Perroux a growth pole is an enterprise or industry that has propulsive effects on related activities through the creation of external and agglomeration economies and forward and backward linkages, while for Boudeville the concept also applied to areas of concentrated development (growth centers and perhaps to industrial districts).

In the 1950s to 1980s, a more critical set of perspectives emerged in the shape of a renewed interest in (internal) colonialism and imperialism on the one hand and the emergence of theories of dependency and world systems on the other. These models contested the idea that all areas were following similar development paths and argued that the causes of relative underdevelopment were to be found not so much in the internal conditions in less developed areas as in the impacts of their dependence on economically more advanced/industrialized areas. Although economically underdeveloped areas did have distinctive characteristics, the characteristics considered were a result of relationships of dependence that created structural deformations, center-periphery relationships, and class divisions between externally-oriented elites and marginalized people within economically underdeveloped areas.

The original thesis derived from the argument of Singer and Prebisch, that the application of the principle of comparative advantage in the global economic system condemned some underdeveloped countries to a specialization in and export of raw materials and agricultural products and the import of manufactured goods from more developed countries. Contrary to the expectation that productivity growth in manufacturing would reduce the relative price of manufactured goods, Singer and Prebisch argued that the prices of rich-area manufactured items increased relative to the prices of the underdeveloped area exports. As a result, this division of labor created a self-perpetuating structure of development and underdevelopment, in which poor countries imported high value added goods and exported low value added goods, so that export earnings were never sufficient to pay for imports. If an increase in the volume of exports from less developed areas was more than offset by deteriorating terms of trade, a further possibility was that of immiserizing growth.

Theories of unequal exchange offered more radical interpretations of the drivers of the terms of trade, arguing that wages are relatively low in economically underdeveloped countries and that rates of profit do not differ (with capital actually flowing to economically-developed areas), so that the merchandise produced in underdeveloped areas is sold at relatively low prices: a worker in a rich area can, therefore, purchase for a few hours of his/her work the product of an entire day’s work of a worker in an underdeveloped area. This proposition was extremely controversial for it suggested that, instead of capitalists exploiting workers, workers in rich areas exploited workers in less developed areas: the former make the latter pay for their high wages through unequal exchange.

The dependency thesis was interpreted more radically with the rise of radical dependency and world systems approaches to explain the underdevelopment of dependent/peripheral/satellite and of semi-peripheral countries by their political and economic subordination to the interests of dominant/center/metropolitan economies and their domestic allies. Underdevelopment was viewed as radically different from nondevelopment or an absence of development on the grounds that the resources of peripheral economies are actively used rather than not used, although in ways that create internal
rural–metropolitan imbalances as underdeveloped economies are organized to satisfy the needs of their export sectors, the enclaves in which they are located, their rich externally-oriented elites, and metropolitan economies.

In the 1980s and 1990s a neoliberal counterrevolution, the Washington consensus and the augmented Washington consensus, saw the emphasis switch to the Solow-type neoclassical models considered earlier. Development, it was argued, should be market-led as markets were considered efficient; collective assets should be privatized; countries and regions should be opened up to global flows of capital and money; and government intervention should be minimized and largely confined to macro-economic stabilization, the protection of private and intellectual property rights and the creation of markets where they are missing (due to externalities for example) or imperfect. And if these measures did not yield economic progress the reason (as this discourse was fundamentally rationalist and deductive) lay not in the empirical invalidity of the neoliberal model but in the absence of good governance and institutions capable of creating the required conditions.

In regional development studies the abysmal growth record of the emerging economies that adopted these measures saw, however, the re-emergence of some earlier themes to deal with low returns to private investment and the cost and availability of finance. Sachs called for greater foreign aid, and a big push involving simultaneous increases in the capital stock (public, human and private) to overcome low returns to capital. The idea was that less developed areas face certain obstacles due to a lack of complements for modern industries, an inability to secure increasing returns to scale since initial capital levels were too small, an absence of higher savings rates channeled into the formal financial and banking system to provide further funds for investment as income increased, or increases in population growth due to higher incomes. The aim was to ensure that returns to capital increase and the economy shifts from low output per unit of capital to high output as the marginal productivity of capital increases, and that the marginal productivity of labor in the urban industrial sector increases relative to marginal productivity in agriculture.

Models of endogenous development I

Theories of dependency led to policies for infant–industry protectionism, import substitution, and autocentric, self-centered and locally-controlled development. In regional development studies two factors underpinned this change of emphasis. The first was the impact of the economic crises of the 1970s on exogenous or externally-controlled investments in many economically underdeveloped areas. The second was the wave of productive decentralization that these crises precipitated, the subsequent identification of industrial districts (especially in southern Europe) as drivers of regional economic development, and the yet later observation of the dynamics of new technology industries.

In many cases, areas of industrial growth were dense concentrations of interdependent small- and medium-sized firms (SMEs) in a single sector and in auxiliary industries and services. These districts were interpreted as the result of two sets of forces. The first comprised economic forces including: (i) scale economies that result from a high degree of specialization and division of labor; (ii) external economies that arise from the existence of shared infrastructures, services, and information; and (iii) the availability of special skills and the pooling of the workforce. The second included the interactions between the economic and social system that generated a
REGIONAL DEVELOPMENT MODELS

social atmosphere and communities of firms and people conducive to industrial development. These considerations opened the door to models dealing with the social, cultural, political, and institutional foundations of the district model, including analyses of social norms and values, political subcultures, associationalism, good governance, institutional density and performance, conventions, trust, social capital, and entrepreneurship.

These theoretical developments were associated with some important shifts in the models that dominated regional development strategy thinking. Self-reliance, autocentric growth and development from below were advocated as an alternative to development from above. New engines of regional economic growth were identified: instead of the consumer and intermediate goods sectors that had dominated growth, attention switched in developed countries to investments in human capital, information and communications technologies (ICT), and the commodification of knowledge to produce informational goods. More generally, emphasis was placed on innovation and learning, investment in research and development, the diffusion of knowledge and their social, cultural, and institutional determinants.

These ideas led, in due course, to approaches to regional development studies whose starting point was a conception not of a world divided into regional economies but of the firm and its environment or, at a meso scale, of global value chains and global production networks spread across the surface of the Earth. Firms were conceived as complex organizations driven by market competition and by a quest to expand and accumulate wealth, and also as a part of an ordered system of firms that makes up an increasingly globalized economy. Competition and the drive by individual firms to accumulate on the one hand and their interactions with other firms and institutions on the other leads to a constant equalization (competition and copying) and differentiation (innovation) of the conditions of production and exchange: the evolution of technologies, processes and products, and the characteristics of places create profit and growth opportunities and are associated with the rise, restructuring, and decline of growth centers and growth poles, constantly reshaping the geography of regional development.

Models of endogenous growth II

These developments in geography were accompanied by the development in economics of new neoclassical models of endogenous growth. Although these models were supply-led, some conclusions were similar to those of demand-led Keynesian cumulative causation models. Associated principally with Rohmer and Lucas, endogenous growth models assume nondiminishing, or, in the limit, nonzero marginal returns to the accumulation of physical capital, human capital, and knowledge. Nondiminishing returns arise because factor accumulation is associated with endogenous technical progress: the development of successive generations of equipment and goods and services are associated with learning, cumulative improvements in human knowledge and technology, and cumulative increases in human skill and know-how. At first these improvements were considered to be spillovers that led to increasing returns to scale at the level of the economy but constant returns at the level of the firm. As a result, economists could continue to assume that firms operated as if they inhabited a world of perfect competition. Subsequently, allowance was also made for economies of scale at the level of the firm and for imperfect competition. This change reflected a final recognition that firms
that carry out organized research and development can recoup the costs incurred by securing a temporary monopoly and restricting temporarily the diffusion of resulting innovations.

Growth can, therefore, stem from societal spillovers associated with the general advance of knowledge, and from the results of partially appropriable research and development. An important feature of this approach is the reconceptualization of the nature of knowledge. First, knowledge itself is a nonrival good that can potentially be used simultaneously by different people, and over and over again by the same people at close to zero marginal cost. Second, knowledge is a partially excludable good protected by patents and intellectual property rights and not a public good as assumed in Solow-type models. Third, investments that increase human knowledge yield increasing returns at the level of the firm for two reasons: (i) enterprises that manage to limit the diffusion of new ideas can spread the fixed costs of developing new products and technologies over a large volume of sales, yielding strong decreases in average costs as output increases; (ii) investments that increase knowledge nonetheless generate strong externalities – since knowledge cannot be perfectly patented or kept secret (and is therefore only a partially excludable good): once it is known that something can be done, other enterprises can seek to replicate it, so that new knowledge has a positive effect on their production possibilities.

Applied to comparative development studies, this movement away from models of constant returns to scale and perfect competition to models of increasing returns and imperfect competition can imply cumulative causation and divergence rather than convergence, as new investments in places and enterprises that are already advanced and associated improvements in knowledge will lead to a continuation of investment and growth and constantly renew development gaps, helping to explain why economically less developed areas fail to catch up.

A striking application of these ideas is found in Quah’s prediction of the emergence of twin peaks (with relatively high frequencies of high and low incomes and a relatively low frequency of middle incomes) in the distribution of regional income/household income. Quah associates this trend with weightless (superstar) economies in which value is embodied in immaterial things. On the supply side of weightless economies, ideas are themselves commodities. The immaterial goods that result are distinct in that they do not have to be transferred from one person to another but are simply replicated or copied at a marginal cost that is close to zero (and where, if equipment is required to use these goods, the upfront costs are small). On the demand side there are two further factors. First, the market for many immaterial goods is extremely large and often global in character (lifting the constraints on the division of labor posed by the extent of the market). Second, consumers often prefer to purchase the products/services of famous people rather than those of people who are less famous but whose talents, skills, and abilities may differ only marginally from the most famous. The combination of a very high level of demand for the goods/services offered by superstars and their very low costs of reproduction creates very high incomes in a world of winners and losers and wide inequalities. These mechanisms clearly have an impact on territorial development as immaterial goods and services are produced somewhere just as the people whose incomes are derived from them must live and work somewhere. Quah suggests that this twin-peak model may be applicable to regional economies.

The concept of endogeneity was important for another reason. Most models of regional development deal with determinate dynamic systems
REGIONAL DEVELOPMENT MODELS

which move towards a final state determined by exogenous data. In economic geography a great deal of recent attention has been paid to evolutionary models that deal with indeterminate dynamic systems in which outcomes are path-dependent. Analyses of indeterminate dynamic systems lead to models of regional development in which the current growth of an area is influenced by its own past record. The models examined earlier do point to generic causal mechanisms. Regional growth is, however, historically-contingent, requiring analysis also in terms of concepts such as cumulative causation, lock in, hysteresis, and evolutionary change.

Economic geography models

Explaining regional development implies explaining the territorial division of labor (who does what, where, and when, what rewards they receive, and in what relationships they stand to other people and economic activities in other places) and the constantly evolving resource endowments on which it depends.

In the past, geographical analyses of the territorial division of labor concentrated on abstract models of economic landscapes (von Thünen, Weber, Hotelling, Christaller, and Lösch). In the 1970s, Hymer, Lipietz and Massey developed conceptually informed classifications of the functional roles of regional economies in wider national and international divisions of labor. In the 1980s and 1990s a diverse array of conceptual models were advanced to characterize geographical systems of production, explain their structure, and account for their relative economic performance. Spatial categories examined included: industrial districts; areas of specialized production, local productive systems, and system areas; localized industrial systems; clusters; new industrial spaces; technopoles and science parks comprising innovative enterprises, research centers, and universities; worlds of production; milieux innovateurs; regional innovation systems; and learning regions. To explain these spatial structures and their reciprocal impact on development, three main groups of causal mechanisms were examined: (i) resource endowments; (ii) industrial organization, industrial strategies, externalities, and transaction costs; and (iii) innovation, systems of innovation, knowledge, individual and collective learning and creativity.

As a result, however, of interpretations of ideas associated with theories of regulation, institutional economics, or evolutionary sociology, these mechanisms were seen as operating in a series of specific historical contexts and of comprising a range of historical development models.

Another important recent development is the new geographical economics, which seeks to explain the emergence of economic landscapes (characterized by spatial agglomeration, regional specialization, and core–periphery structures) and the regional resource endowments that were taken as the starting point for many earlier models of trade and specialization in particular. Models are developed to examine the location of profit maximizing firms often in a world of increasing returns and imperfect competition, drawing on analyses of the increasing returns, forward- and backward-linkages, external economies, endogenous growth, product differentiation, external diseconomies, and so on to generate imaginary economic landscapes (see Figure 3 and Dunford and Greco, 2006).

Conclusions

In this entry most attention has been paid to economic models of regional development. These economic models afford important insights,
Dispersed rural population, yet scale economies lead to relatively few production sites for industrial goods: how few depends on the trade-off between scale economies and transport (iceberg effect) costs.

Differential transportation costs lead to relative growth of increasing returns activities and population in transportation hubs.

Specialization, division of labor and co-location near suppliers and customers. External economies also encourage proximity.

Endogenous growth/accumulation and competition differentially increase/decrease size of economic activities. Dispersion due to diseconomies/reduced transportation/factor costs.

Mobility reinforces agglomeration as does market access: suppliers of differentiated products in dense markets.

leading, in particular, to the identification of two sets of mechanisms. The first is a set of centrifugal forces, of which one of the most important is investment in infrastructure, skills, and economic activities and the transfer of technological and organizational knowledge to less developed areas or less advanced enterprises. Another centrifugal force arises if stagnation and relative decline occur in relatively developed areas. These mechanisms result in a tendency for an equalization of the conditions of production and exchange and of levels of development. The second is a set of centripetal forces. Centripetal forces arise when enterprises and areas that are developed create new sources of competitive advantage through, in particular, further investments in infrastructure, plant, equipment, knowledge, and skills. These mechanisms lead to a constant differentiation of the conditions of production and exchange and of the characteristics of regional economies. The value of these models is that they identify these and other equalizing and unequalizing mechanisms. The relative performance of different regional economies depends on the relative weight of these two sets of forces.

At any moment in time, existing resource endowments matter a great deal. Second nature resource endowments are, however, a consequence of earlier stages in historical processes of development: what happens at each point in time depends in part on what has happened in the past, and while each step can usually be explained in retrospect, it is normally impossible to predict what will happen next, as it depends on choices that cannot be anticipated with any degree of certainty. As a result, regional development is endogenous, cumulative, and path-dependent, with distinct possibilities of the emergence of virtual and vicious circles. The recent growth of interest in evolutionary models of regional development capable of dealing with indeterminate dynamic systems, in which current growth and transformation are influenced by the past record of development and outcomes are path-dependent, is, therefore, a significant step forward.

The relative weight of equalizing and unequalizing forces can change over the course of time. As a result, the evolutions of regional economies are associated with varying degrees of instability. Of the models considered it was Harrod-Domar and Keynesian-type demand-side models that predicted instability. Orthodox neoclassical models consider market systems as self-equilibrating and were ironically given an impetus by the relative stability of managed economies in the postwar Golden Age in Europe, North America, and western outposts.

Marxist and regulation approaches view capitalist development as involving phases of stable growth punctuated by periods of crisis. These crises are often important turning points in historical processes of regional development and in the development of ideas. Stable growth derives from the emergence of a sequence of new development models often centered on fundamental transformations of the preceding economic and social order. These new development models take shape in phases of crisis when older socioeconomic orders fail economically and are rejected politically and socially. As development models succeed one another, so do ways of thinking about regional development. A case in point is the shift from state-led developmentalism in the 1950s and 1960s to market-led approaches in the 1980s and 1990s.

The western financial crisis that erupted in 2007–2008 will mark yet another turning point for two reasons. The first is that it was simply another step in what was a progressive slowdown in the growth of developed regional and national economies. Alongside the relative stagnation of developed economies a number
of emerging economies have sustained high rates of economic growth over relatively long periods of time, radically altering the map of comparative development. The second is that many of these rising powers are associated with distinctive systems of political, social, and economic organization and policy regimes.

In this entry some reference has been made to social relations and to political, institutional, and cultural mechanisms, capacities, and performance as well as to the wider national and international economic and geopolitical context. Generally speaking, political and cultural mechanisms are not considered in modeling approaches designed to identify a small number of economically important factors seen as the main drivers of regional development. Economic mechanisms are, however, always grounded in particular political, institutional, and cultural contexts. Ever since the collapse of the Soviet Union, governments in developed countries have sought politically, diplomatically, and militarily to promote not just markets but also representative democracy. An examination of comparative regional economic performance indicates, however, that many areas that have achieved remarkable progress have on the one hand not embraced this political model and on the other are characterized by strong governance capacity. In the years ahead working out the implications of these trends and examining, in particular, the role of governance capacity and different social models will play an important role in studies of regional development.

Regional economic integration

Gianmarco I.P. Ottaviano
London School of Economics and Political Science, UK

Regional economic integration is the process of creating a unified market for goods, services, and factors of production (capital and labor) across the borders of countries belonging to the same geographical area. In the unified market, goods and services are freely traded, factors of production are freely mobile, and taxation and regulation are harmonized, so that economic activities face the same conditions both between and within countries. It differs, therefore, from national integration which involves the creation of a common framework of law and a common set of duties and obligations applicable to all the citizens of a country.

Real-world agreements differ in the extent to which the countries involved push the goal of economic integration along various economic dimensions. In a preferential trade area (PTA) member countries give one another preferential access to their markets without completely removing custom tariffs. In a free trade area (FTA), member countries agree to abolish custom tariffs among themselves while independently choosing custom tariffs with respect to the rest of the world. In a custom union countries also agree on a common external tariff (CET). The adoption of a common currency creates a monetary union, while the free mobility of factors transforms a PTA into a common market, and the combination of a customs union with a common market gives rise to an economic union. In a fiscal union member countries agree on a common fiscal and budgetary policy. The full harmonization of economic policies and the introduction of supranational institutions lead to a political union.

Examples of economic and monetary unions are the Caribbean Single Market and Economy (CSME) and European Union (EU). La Communauté Économique et Monétaire de l’Afrique Centrale (Economic and Monetary Community of Central Africa, CEMAC) and Union Économique et Monétaire Ouest Afrique (Economic and Monetary Union of West Africa, UEMOA) are customs and monetary unions. The European Economic Area (EEA) and European Free Trade Association (EFTA) in Europe are common markets. Custom unions include Comunidad Andina (Andean Community, CAN) and Mercado Común del Sur (Common Market of the South, MERCOSUR) in South America, the Eurasian Economic Community Customs Union (CUBKR) and European Customs Union (EUCU) in Eurasia, and the East African Community (EAC) and Southern African Customs Union (SACU) in Africa. The Association of Southeast Asian Nations Free Trade Area (AFTA), Gulf Cooperation Council (GCC), and South Asia Free Trade Agreement (SAFTA) in Asia; the Central European Free Trade Agreement (CEFTA) in Europe; the Commonwealth of Independent States Free Trade Area (CISFTA) in Eurasia; the Common Market for Eastern and Southern Africa (COMESA) in Africa; the Greater Arab Free Trade Area (GAFTA) in Africa and Asia; the North American Free Trade Agreement (NAFTA) in North America; the Sistema de la
Integración Centroamericana (Central American Integration System, SICA) in Central America; and the Trans-Pacific Partnership (TPP) in Asia, North and South America, and Oceania are all free trade areas. Even when they span different continents, these examples have a clear regional connotation as they typically involve countries that identify themselves as belonging to specific geographical areas. For instance, even though TPP countries span three different continents, they nonetheless feel attached to a common Asia–Pacific region.

Cutting through the complexity of these agreements, from the point of view of neoclassical economic geography/geographical economics, the most salient distinction between them is whether they seek to promote the cross-border mobility of goods (and services) only or also the cross-border mobility of capital and labor. The reason is that different provisions on what is allowed to move across borders may have different implications in terms of the induced spatial distribution of economic activities.

When goods (but not production factors) are allowed to move across borders and markets are perfectly competitive (i.e., production faces constant returns to scale and neither buyers nor sellers control goods prices because, for each good, there are several buyers and sellers), global economic integration shapes the global economic landscape by fostering the specialization of countries across sectors according to the relative efficiency of their production processes, driven by different technologies (comparative advantage) or different relative availability of factors that different sectors use with different relative intensity (factor proportions). As buyers are allowed to source from the most efficient sellers whatever countries they belong to, the latter expand and the overall efficiency of production increases. This gain is diluted in the case of regional economic integration. Freer goods mobility between member countries still fosters their specialization and trade according to comparative advantage and factor availability (trade creation). It also alters, however, the assessment of these relative characteristics with respect to nonmember countries, leading buyers to source from the most efficient sellers among their regional partners rather than from the world’s most efficient sellers (trade diversion).

When markets are imperfectly competitive (i.e., production faces increasing returns to scale and sellers control the prices because there are only a few of them for each good or they supply differentiated goods), regional economic integration has additional effects on the spatial distribution of economic activities. Lower barriers between member countries create a regional market that attracts producers from nonmember countries. This relocation of sellers (market size effect) is good for buyers in the integrating area but bad for buyers outside it. It also implies trade creation and trade diversion as before: regional integration pushes buyers in the member countries to source disproportionately from sellers based in the integrating area. If comparative advantage and factor proportions are controlled for, accrued efficiency gains are driven by the exploitation of economies of scale in the integrated area. Forgone efficiency gains are, instead, due to the fact that economies of scale would be better exploited in a larger globally integrated market.

The market-size effect is potenitated in the presence of value chains that serve consumers through a sequence of intermediate and final production stages. To see how that happens, one can consider a simple example in which final production uses only intermediate inputs, intermediate production employs only labor, workers are the only source of final demand, and labor is geographically immobile. By lowering the barriers to goods trade between member
countries, regional integration again enlarges the size of the market inside the integrating area. This makes that market more attractive for sellers, engendering self-reinforcing effects on the location of intermediate and final producers. Specifically, if we choose intermediate producers as first movers, for the sake of argument, their inflow into the integrating area increases its labor demand and intermediate supply. As a result of excess demand and supply, respectively, wages rise and intermediate prices fall. This is bad for intermediate producers in the area (market crowding effect) but it is good for final suppliers, which experience falling production costs and higher demand by richer workers. In turn, this makes the market of the integrating area even more attractive for final producers. As they enter its market, the expansion of final production feeds back into stronger intermediate demand so that intermediate suppliers also benefit (market expansion effect). When the market-expansion effect dominates the market-crowding effect, both final and intermediate producers end up being agglomerated inside the integrating area. This mechanism of cumulative causation between upstream and downstream producers’ location decisions can generate persistent asymmetries in the spatial distribution of economic activities, even between insider and outsider countries that are very similar in terms of comparative advantage and factor proportions. An analogous story can be traced using final rather than intermediate producers as first movers.

Cumulative causation is more likely to materialize in the presence of labor mobility and capital accumulation. The reason is that both tend to reinforce the market expansion effect through the additional income they generate. Rising intermediate production in the integrating area increases labor demand and wages in member countries, attracting workers from nonmember countries. As workers move, final demand in the member countries increases, generating an additional cycle of cumulative causation between firms’ and workers’ location decisions. At the same time, the expansion of intermediate and final markets increases profits, fostering investment in capital accumulation.

Regional integration may affect the distribution of economic activities not only between member and nonmember countries, but also within member countries as market crowding and market expansion effects operate inside the integrating area. When market crowding dominates, the economic geography of the integrating area tracks the spatial distribution of comparative advantage and factor proportions. When the market expansion effect dominates, cumulative causation sets in, leading to the possible emergence of a core–periphery pattern of location whereby economic activities concentrate in a small subset of member countries.

When the economic landscape is shaped by the location decisions of people and firms in imperfectly competitive markets, it is generally inefficient. There is, therefore, room for efficiency-enhancing regional policies, for instance, to contrast the emergence of inefficient core–periphery patterns through taxes and subsidies. Even when core–periphery patterns are efficient, regional policy could still be used on equity grounds to redistribute the associated benefits through transfers. It is the need of additional policy levers that calls for deeper regional economic integration.

Another issue of policy relevance is the extent to which regional economic integration paves the way to or stands in the way of global economic integration, which is preferred as it does not cause any trade diversion. Different theoretical mechanisms have been identified through which regional provisions may work as “building blocks” or “stumbling blocks” in the construction of an integrated global economy.

Regional finance

Sheila Dow
University of Stirling, UK
University of Victoria, Canada

“Regional finance” refers to research in the interface between economic geography and economics concerning the relationship between financial variables and real economic development. It has tended to be a small interface since the role of finance has traditionally been regarded as peripheral to economic geography, while spatial concerns have traditionally been regarded as peripheral to economics. Indeed, it is now being argued by some within economic geography that, even if the spatial dimension of finance had been relevant in the past, it is no longer relevant. Nevertheless, the view persists in economic geography that finance continues to be important for regions (Garretsen, Kitson, and Martin 2009 and the following papers).

Within economics, any regional finance analysis needs to be understood in terms of the approach taken to economics more generally (Dow and Rodriguez Fuentes 1997). The mainstream approach is based on the view that money and finance are not fundamental to real economic development. Rather money simply determines the rate of inflation, that is, money is “neutral” (Patinkin 2008) and finance affects growth only insofar as it is more or less efficient. That market inefficiency may nevertheless be widespread opens up the possibility of finance having real effects on regional economies. Such inefficiency is the focus of the New Keynesian stream of mainstream economics (Dixon 2008). This latter approach is to be distinguished from the nonmainstream Post-Keynesian approach, which does not have a neutral-money, full-information benchmark, but rather analyzes substantive and enduring interrelationships between real economic conditions and the financial sector, which have a regional dimension (King 2008; Dow 1987). The concern in the Post-Keynesian literature, rather than being with market efficiency, is that money and finance should be economically functional.

How the regional character of national economies and of the national financial sector is regarded therefore depends on theoretical perspective. One of the main focuses of the literature has been the regional segmentation of the national financial system. This segmentation is understood in mainstream economics as a source of inefficiency, but for Post-Keynesians it is seen potentially as a protection for regional economies. But the nature of the regional segmentation of finance has evolved over the decades as the financial sector has undergone substantial changes. These changes have included the growth of nonbank financial intermediation within national economies, the consequent widening of the range of functions of banks in order to compete, the evolution of international financial arrangements which affect the domestic institutional structure, as in the European Union, and the globalization of finance.

A second major focus has been the spatial impact of national monetary policy, where the nature of such policy has also undergone major changes. Since interest in financial variables, and money in particular, had been fairly limited within regional economics and economic geography, much of the literature draws on the
money-macroeconomic analysis of European Monetary Union (EMU). The mainstream neutral-money view in this literature focuses on the relationship between changes in the official interest rate and inflation within a currency union with free flow of capital. The Post-Keynesian view rather considers differential effects of interest rate changes and central bank signaling on both the cost and availability of regional credit, as well as on expenditure plans and the demand for credit. While the first only allows for a real regional impact of monetary policy as a result of market inefficiency, the second sees a real impact as the norm.

The significance of the theoretical approach extends to the data themselves. Where regional data are unavailable, a common practice is to impute regional monetary aggregates from regional gross domestic product (GDP) shares, building the assumption of money neutrality into the data. In contrast to this mainstream focus on relations between aggregates, the Post-Keynesian approach focuses more on disaggregated financial and economic data and, in their absence, a range of different types of evidence (Rodriguez Fuentes 2006, 58–59). More generally, the field has been able to develop more where regional data are available, such as in the United States, Canada, Spain, and Italy. The best dataset now is probably the Brazilian one developed at the Center for Regional Planning and Development (CEDEPLAR) of the Federal University of Minas Gerais under the leadership of Marco Crocco. (An example of the application of these data to the Post-Keynesian theory of regional finance is set out in Crocco et al. 2012.) The situation is circular. Data are collected where there is more spatial awareness and they can be employed in analysis to inform and test regional finance theory, encouraging further data collection. Where a lack of interest in spatial matters has limited data collection, the limitations this poses for research mean that any lack of interest is reinforced.

A third focus of the literature has been debated as to whether the financial sector generally promotes economic convergence or divergence. The premise of the single European financial market was that it would promote convergence, while the globalization of finance more generally was encouraging the idea that spatial segmentation of finance was ceasing to be a factor in regional economic development. But then the 1997 Southeast Asia crisis raised questions about the continuing, if not increasing, potential for financial liberalization, and particularly free capital flows, to have real economic consequences. The banking crisis that began in 2007 then focused attention more generally on the relationship between the financial sector and the real economy and the consequences of limited availability of bank credit for business.

The analysis of this recent crisis provides a good example of the way in which the three theoretical approaches outlined above address a financial development which clearly has had real effects. The standard mainstream approach sees the crisis as a temporary departure from equilibrium, the result of misguided efforts by the monetary authorities to keep interest rates below their long-run equilibrium level resulting in excessive money creation. The New Keynesian analysis has focused on a range of other distortions of market forces which are more systemic. Many of these sources of market inefficiency were associated with the development of new products (derivatives) and practices (securitization) and come under the category of asymmetric information, although there is also a focus on state protection of failing banks. For both approaches, financial instability and its real consequences can be reduced by increased financial efficiency. In contrast, the Post-Keynesian analysis starts from the view that economies are inherently
unstable and that the financial sector is a major contributor to this instability. Financial fragility and the instability it brings about are exacerbated by financialization, such that financial inefficiency is advocated as a means of reducing the scope for fragility. (Hence the proposal for a financial transactions tax, for example.)

The spatial dimension of the real effects of the crisis is evident in the differing experiences of different economies, whether independent national economies or national economies within a currency union as in the EMU. It has been a persistent outcome of the crisis that there has been divergence in particular between EMU economies along standard center-periphery lines, with a cumulative process of capital outflows from peripheral economies at a time of rising public sector borrowing needs. Relief in the form of European credit was dependent on the introduction of fiscal austerity. From a mainstream perspective, this policy was designed to restore equilibrium through a process of convergence with the aid of private sector capital inflows. From a Post-Keynesian perspective, however, austerity policies have promoted divergence, causing recession, worsening the public sector finances and productivity, and further discouraging private capital inflows. This experience in the EMU demonstrates that there is considerable scope for analyzing the spatial effects of the crisis also at the subnational level. Here, too it is important whether capital flows are equilibrating (promoting convergence) or disequilibrating (promoting divergence).

In what follows, we explore the three topics noted above in turn, starting with the spatial structure of finance and proceeding to discuss the regional impact of monetary policy. The final section focuses on the ultimate question of the real spatial effects of finance. In the process we consider the implications of choice of theoretical approach.

The spatial structure of the financial sector

The histories of different national financial sectors, and in particular of banking, show varying spatial configurations. Awareness of the significance of such configurations for regional economies was perhaps most evident in the United States, where early banking legislation was designed to ensure spatial dispersion of banking; there was a political concern that the rest of the US economy might suffer from the financial strength of New York if the banking system were free to concentrate there. Indeed, the modern literature on regional finance first emerged in the United States in the 1950s, focusing on the relative economic performance of states, given national financial conditions and financial flows between states. But the monetarist premise of much of this literature was that capital flowed freely within and between states at the interest rate set by national monetary policy, such that it was real economic conditions rather than the regional configuration of the banking system that determined regional money flows.

The emergence and persistence of financial centers and their capacity to retain and build on their dominance of financial markets was one focus of the banking history literature. But alongside this enduring phenomenon there have been more complex spatial developments in financial structure. Since the second half of the twentieth century, while banking remains at the core of the financial sector (providing reserves and a payments system for the rest of the sector), other types of institution have increased dramatically in scale and importance. The process of deregulation, which started in the 1970s, allowed retail banks to expand into (spatially centralized) nonbank activities, such as insurance and investment banking. Increasing
competition within the financial sector and the increasing volatility in financial markets in that period threatened the survival of smaller institutions, encouraging a wave of mergers and acquisitions, leading to increased concentration in finance around financial centers. The focus of financial activity was shifting from the traditional economic functionality of providing a means of payment and business and household credit towards activity in speculative financial markets. This process was widely supported on the grounds that it fostered financial market efficiency by increasing the depth of financial markets and reducing spreads, as well as breaking down local monopolies.

These processes were particularly evident in Europe, with the emergence of the single European market in finance and the single European currency. The aim was to remove national barriers to capital flows, increasing allocative and cost efficiency. Financial liberalization also occurred at the global level, again with a view to increased efficiency, encouraging more free flow of capital between national economies. At the same time, information technological advance greatly enhanced the capacity to trade internationally in a range of instruments and markets, accelerating the globalization of finance. The presumption was that there would be general benefit from cheaper and better financial services and the more free distribution of credit according to expected returns. With some qualifications in terms of the fallout of the financial crisis, this is seen by some to indicate the end of geography.

While financial liberalization has led to concentration in the financial sector rather than increased competitiveness, nevertheless some regional segmentation persists. Large businesses tend to conduct their finances within the financial center; in the case of the largest businesses their finances are conducted within their own treasury departments. In any case these businesses have access to capital markets as well as to banks. But small and medium-sized businesses (SMEs) are more dependent on bank credit which remains primarily nationally, if not locally, based. So the issues of the potential for a national banking system to have differential effects on regional development remain.

Where there are nationwide banks, distance (in its various forms) of borrower from lender is shown to influence the availability and cost of credit, to the disadvantage of peripheral regions (Porteous 1995). For SMEs in peripheral regions, the information on which judgements about risk are based is particularly weak for national banks whose credit decisions are made centrally according to uniform conventional criteria. New Keynesians argue therefore that banks will ration credit in peripheral regions. Post-Keynesians agree that local financial institutions benefit from a stronger local knowledge base and thus capacity to assess risk and monitor borrowers is stronger than for national banks. But rather than being concerned with concealment of risk, Post-Keynesians are concerned that uncertainty precludes any notion of objective risk; risk assessment is a matter for judgement, which is socially conditioned. Further, when these judgements are based on weak knowledge, the result may be not just too little credit, but also possibly too much. Weak knowledge may thus explain overenthusiastic supply of credit to peripheral regions at times to finance projects (often natural resource-based) which hold the prospect of unusual profits. By the same token, such capital inflows can be readily reversed when the banks’ confidence in the projects weakens, contributing to increased instability for these economies (Chick and Dow 1988).

Further, Chick and Dow (1988) argue that credit availability and cost in peripheral regions will be influenced by local banks being at an
earlier stage of development than banks in the financial center. They have less easy access to wholesale markets than large national banks and a deposit base vulnerable to swings in local economic conditions. Thus interest rates in local banks will be less advantageous for depositors than those in national banks. Local banks also tend to have simpler portfolios than the universal banks in the financial center, and are thus disadvantaged by the increasingly strict regulatory requirements being introduced in the wake of the crisis, such as higher capital requirements. Local banks therefore are more constrained in their access to funding and competitively weaker than large national banks.

It is therefore of critical importance for peripheral regions how the banking system is structured: the perception of risk attached to lending in peripheral regions varies between national and local banks. But attitude to risk may also vary over time, as expressed by the liquidity preference of national and local banks with respect to peripheral regions. Even with a national branch banking system, it cannot be assumed that there is an elastic supply of credit to all regions (even at a markup over the national rate) if national banks’ liquidity preference means an unwillingness to extend credit in peripheral economies (Dow 1982).

The regional impact of monetary policy

While the literature on the regional impact of monetary policy has also been consistent with differences in theoretical approach (see Rodriguez Fuentes and Dow 2003; Rodriguez Fuentes 2006), the context for analysis of the regional impact of monetary policy has also evolved. In particular, the current discourse on monetary policy in the wake of the crisis has shifted attention from the neutral-money view of monetary policy as a means of inflation control to the view that monetary policy can have real consequences, at least in the short run. The fact that the early supply of liquidity averted a much worse crisis, however, lends support to a more lasting real effect of central bank actions.

The focus of the mainstream regional impact of monetary policy literature has been on the different regional responses to changes in a uniform national interest rate. As in monetarist international macroeconomics, the presumption is that, where money flows freely between economies with fixed (or no) exchange rates, monetary policy has no lasting real impact (regionally or nationally). Nevertheless, some allowance is made for compositional real effects where there are regional differences in interest elasticity of demand for credit, with an emphasis on regional economic structure. Thus, for example, a region whose economy was less diversified would respond differently to a monetary policy shock than a diversified region. Regional differences in financial conditions have also been addressed as a source of a differential regional impact of monetary policy in the mainstream literature. Thus regional differences in levels of wealth and in portfolio composition (based on exogenous preferences) will affect the way in which an interest rate change is transmitted to each region (Miller 1978; Goodhart 1989). For example, a higher level of household mortgage indebtedness in one region makes it more vulnerable to changes in the official interest rate than other regions. More recently, attention has shifted to the institutional environment as a factor in the transmission of monetary policy, for example exploring differences in the relative significance of the bank lending channel and the balance sheet channel between different European economies. While financial market segmentation may affect the regional transmission of monetary policy, this possibility is lessened to
the extent that financial market liberalization has eroded this segmentation.

The Post-Keynesian literature has probed behind the empirical relationship between the official interest rate and regional economies, following up two particular strands of reasoning. First, there may be unsatisfied demand for credit in some regions and excessive volumes of credit in others, while the long experience of financial vulnerability in peripheral regions may even discourage the emergence of credit demand. But if the starting point is not, as in the mainstream approach, an equilibrium position, it is hard to identify statistically the effect of national monetary policy. Second, monetary policy is understood in broader terms than changes in the official rate. Not only may markups on the official rate vary regionally in line with different levels of confidence in different regional economies, but what is regarded as creditworthy demand will vary regionally, affecting credit availability. More generally, liquidity preference and risk assessment, which can vary systematically by region, will be influenced by what is increasingly regarded as a central tool of monetary policy: the communication of central bank analysis.

A central feature of the Post-Keynesian approach is that credit creation is endogenous, that is, it is under the control of the banks, albeit influenced by the central bank. Since the central bank enforces its official interest rate by managing the supply of liquidity to the banks, the banks can create credit confident that the supply of reserves to back new credit is assured. If credit creation in any region is weak, this is more a reflection of the banks’ unwillingness to lend in that region than it is of monetary policy. This puts the spotlight on banks’ credit policies and the strength of the knowledge on which those policies are based. In contrast, according to the mainstream approach, monetary policy establishes a money supply (indirectly through the official interest rate) which the banks then distribute among the regions according to relative creditworthiness. If credit levels are low in peripheral regions, according to this view, it is due to real factors, that is, that regional productivity is low, or to information asymmetry.

The replacement of national monetary policy with a common EMU monetary policy provides a useful case study. One of the rationales for European Monetary Union was not only that it would reduce asymmetric shocks for each member economy, but that it would also remove the balance of payments constraint resulting from any shocks because of the greater freedom of capital flows within a currency union. The interest rate set by the European Central Bank would determine a common rate throughout the EMU. Membership of the EMU would be conditional on convergence in terms of financial variables, which the EMU would then sustain. But the conclusion that the EMU would promote continued convergence is based on mainstream theory which understands market behavior as equilibrating, with labor and capital flowing to maintain common returns across the EMU. The Post-Keynesian approach, however, allows for the possibility that the decline of a region’s sector resulting in labor outflows can if anything discourage capital inflows, driving the economy further from equilibrium; without an independent currency the only option for the region is to contract demand. If an asymmetric shock depresses expectations of returns on capital, then outflows of capital (lower bank lending) in depressed member economies would be encouraged, promoting economic divergence. If changes in interest rates due to monetary policy further disadvantage peripheral regions, then the forces for divergence would be compounded.
Finance and regional development

Regional finance clearly concerns more than just the regional impact of monetary policy, important though that is. There is now a much better understanding, supported by statistical evidence, of the relationship between finance and growth. But again difference of theoretical perspective is crucial. The mainstream literature focuses on the argument that economic growth is served by increased financial efficiency, and that this should be the focus of policy. The more efficient the financial sector, the closer is money to neutrality. The literature on finance and regional development within the Post-Keynesian approach focuses rather on the economic functionality of the financial sector in supporting real economic activity, given that money is not neutral (see Rodriguez Fuentes 2013 and the following papers). The regional character of the relationship between the financial and real sectors arises from the regional composition of the financial sector and from the regional pattern of economic activity, wealth levels, and financial behavior, all of which account for the non-neutrality of money (Chick and Dow 1988).

We have seen that the regional structure of finance is important for the regional pattern of credit creation. But for Post-Keynesians the liquidity preference, not only of banks but also of households and firms within peripheral economies, also plays a part. Whatever the level of expected returns in a region, if confidence in expectations is low, then there will be high liquidity preference in the form of low willingness to lend, borrow, or spend. While these may vary in the short run, the problem for peripheral regions is that there may be a persistently high level of liquidity preference. Unlike the exogenous portfolio preferences of the mainstream approach, Post-Keynesian liquidity preference is endogenous to economic processes. In order to understand financial behavior in peripheral regions, we need to consider the implications of long experience of vulnerability. Peripheral regions are more vulnerable because wealth levels tend to be lower than in the central region and also because there is less assured access to credit. So any economic instability may cause cash flow problems and difficulty servicing debt, further contributing to a normally conservative assessment of default risk. Peripheral regional economies tend to be more unstable than central regions, with dependency on a smaller number of sectors. Where these include raw material sectors, peripheral economies may go through boom periods. The weak knowledge base of the banks can allow large capital inflows which are then subject to sudden reversals.

The reasonable portfolio strategy is then for peripheral regions to have relatively high liquidity preference, not just as a short-run response to cyclical instability, but as a secular response to continuing higher levels of uncertainty and vulnerability to credit constraints. Several studies have found evidence to support this thesis (Porteous 1995; Amado 1997; Rodriguez Fuentes 2006). High liquidity preference takes the form of reluctance to commit to capital investment, reluctance to take on debt, and allocation of wealth to assets issued in the financial center as the most liquid available. Thus, for example, peripheral economies in Europe have been buying foreign (mainly German) sovereign debt, at the same time as limiting availability of credit to local companies. The effect of high liquidity preference is thus weak growth in peripheral regions, weak demand for credit, and higher capital outflows.

It is a common refrain from national banks that their low credit creation in peripheral regions is due to weak levels of demand that is creditworthy. But both may be the outcome of high liquidity preference. Creditworthiness
is a matter of judgement for the banks, where a poor knowledge base is compounded by the consequences of high liquidity preference. The credit decision is performative. By constraining credit availability in peripheral regions, national banks create the conditions that justify their cautious assessment of regional risk. More generally, the centralization of finance leads to the centralization of economic activity.

Concluding reflections

We have seen that the Post-Keynesian literature on regional finance has postulated a range of causal mechanisms which explain the aggregate relationships on which so much else of the literature focuses. These relationships imply that the regional dimension of financial structures and behavior are an important element in generating the regional effects of monetary policy and financial developments more generally. Since structures and their regional dimensions evolve over time and vary from one economy to another, analysis of regional finance in any region is conditional on the relevant economic and financial context. Thus, for example, the way in which financial sectors in different countries have responded to the crisis has differed because of differences in the initial financial structure and in policy, with differing consequences for the regional pattern of economic growth.

Since structure is amenable to policy influence, there is therefore scope for governments to promote a financial structure that is economically functional in general and addressed to the different needs of different regions in particular. Thus support for smaller local banks with more sound knowledge of local conditions would ensure a more robust provision of credit in peripheral regions; such support could take the form of subsidies, or lower capital requirements, for example. Such measures are required to counter the forces for divergence which are encouraged by financial liberalization. These measures would, in particular, increase confidence in and knowledge about peripheral economies and thus increase the willingness to both demand and supply credit to finance real investment.

But such measures would, from a mainstream perspective, damage financial efficiency. The mainstream approach rules out real effects of regional finance except in the form of financial inefficiency so that regional economies are best served by focusing on increasing financial efficiency, which also promotes economic convergence; the assumptions and structure of the theoretical framework and the formulation of evidence all serve to produce this conclusion. The Post-Keynesian approach rather adopts a theoretical framework, and seeks evidence reflecting the priority of economic functionality, with a view to promoting more, and more even, economic development. Choice of theoretical perspective is fundamental to policy direction in the field of regional finance, as in any field.

Further reading

The region is, and always will be, a central concept in geography. So, thinking about regions can tell us a lot about the history of the discipline called geography. Before this though, the perennial question must be addressed: What is a region? In this entry, a region is considered as a “temporary permanence,” not fixed and absolute, but something held stable at different points in time and for different purposes. There is, then, no single reading of a region. Regions are multiple entities and geographical analysis should seek to uncover the process and practices of region-making.

Regions can have administrative territorial shape through the drawing of borders and boundaries and the making of state spaces. Regions can also delimit economic forms relating to particular functions, for example the spaces of exchange and trading such that we can talk of discrete regional economies in global networks. Regions can also act as symbolic shapes – they can become cultural identifiers and sources of belonging, and senses of ownership for political expression and mobilization become interesting objects of analysis thereafter. One helpful way of categorizing these distinctions is to think about the administrative and economic as “regional spaces” and the latter (cultural and political) as “spaces of regionalism” (Jones and MacLeod 2004). Again, these distinctions are never out there waiting to be found; they are forged historically through political and policy struggles involving state and non-state forces. This allows geographers to talk not about “regional geography,” which automatically conjures up fixity and rigidity, but about a “geography of regions” – the process and practices of making and remaking regions through “institutionalization” as Anssi Paasi (1996) puts it. The remaining discussion unpacks this, using four chronological phases, to reveal how geographers have grappled with regional geography. There is a need “to go back” to go “forward,” as Thrift (1994) has put it.

An era of traditional regional geography existed during the long nineteenth century. Here, the region was treated absolute: as an independent backdrop for, first, conducting geographical inquiry and, second, developing thereafter a world of different regional geographical types. Books such as Britain and the British Seas (1902) by Halford Mackinder made assumptions about the interconnected nature of the human and the physical. This regional geography was an ethnographical geography of successive phases and component elements, with (in this case) the physical environment as thus analyzed. The work of Andrew Herbertson (1905) developed “climatic regions” from this, and Hebert J. Fleure offered “human zones” conditioned, rather than entirely governed, by physical circumstances in his Human Geography in Western Europe (1919).

The backlash to this came from the likes of Richard Hartshone, whose The Nature of Geography (1939), contra Herbertson and Fleure, claimed that none of their regional geographies “alone” covered a significant number of features to offer an adequate background to regional study, or to provide a tentative system for organizing all our regional knowledge of
the world. A regional geography of elements (meso-worlds of human–physical interactions) was proposed to produce an elaborate regional geography of “areal differentiation” – the division of the Earth surface by observations that different areas of the world are somehow self-contained and where, extending the work of Paul Vidal de la Blache, relationships between people and land created a distinctive geography. The purpose of this regional geography was to understand what these differences are and how they are related. Books such as *One World Divided* (1964) by Preston James summarized the long results of this thinking through offering different areal differentiations.

Regional science, assisted by the power of computation and the desire to study connected variables as part of modernist social sciences dabbling with theories of physics (such as gravity models), logically followed from this. Walter Isard’s *Methods of Regional Analysis* (1960) suggested that any general theory of the region, whether this be in relation to locational analysis of industry or population, must be supplemented by techniques of regional analysis, which are operational techniques and which yield estimates of basic magnitudes for the space economy for both the proper understanding of social problems and policy formulation. Isard’s work sought to make and model the internal connections between things that flowed through and were seen to actively make regions, albeit in a discrete and bounded way, isolated from external drivers behind the capitalist space economy.

This concern with the structural and strategic forces acting in and on regions could be felt by those critiquing regional science and offering, through regional studies and largely influenced by Marxism, alternatives based around the dynamics and contradictions of capitalism. Books by Doreen Massey such as *The Anatomy of Job Loss* (1982) and the 1984 classic *Spatial Divisions of Labour* presented regions as the medium and outcome of economic and political struggles around the geography of production and class struggle. “Rounds of investment,” phases of capital accumulation dealt out like playing cards, as Derek Gregory (1989) put it, acted as waves on a beach, constantly making and remaking regions in geography as a distinctive economic geography of “localities.”

This emphasis on capital versus the regions, combined with the emphasis on place as a historically contingent process, meant that the mid- to late 1980s was ripe for thinking about a new regional geography. Whereas traditional regional geography talked about fixed and bounded territorial and process entities, new regional geography wanted to study regions as produced and transformed through various forms of agency. Anne Gilbert’s classic (1988) summary of this position drew attention to regions as varying local responses to capitalist processes; regions as the focus of cultural identification (or senses of place); and regions as the medium for social interaction or meeting places for human agency and social structures. The studies of localities in the United Kingdom, funded by the Economic and Social Research Council (ESRC), offered an economic and social window into this, although they often generated more heat than light. Authors such as Nigel Thrift took this further and laid down four challenges for regions in geography: how distinctive meanings are produced and contested; the changing forms of regions in space and time; the relations between people and nature and the deconstruction of landscape; and representing and writing about regions.

Globalization discourses and the politically charged nature of economic development, especially in Europe, overtook these debates, and in the early 1990s geographers and other social scientists were talking about the *new*
regionalism. This regional geography saw regions, not nations per se, as the crucibles for both economic success and democratic legitimacy. A rescaling of economic and social life was being witnessed, according to protagonists, who drew much attention to regional things occurring in Emilia-Romagna (Italy), Baden-Württemberg (Germany), Silicon Valley (United States), the Rhône-Alpes (France), and Tokyo (Japan). Michael Storper’s *The Regional World* (1997) and Michael Keating’s *The New Regionalism in Western Europe* (1998) summarized these trends and speculated variously on their wider applicability.

In short, regional geography was being read through a new economic geography of globalization and regional development and a new political geography of territorial politics and public policy communities. Critics such as Gordon MacLeod (2001) sought to draw attention to three shortcomings of this literature: (i) a “soft institutionalism” (where institutions are seen as the explanation for economic success, as opposed to looking at the historical geography of institutions); (ii) “thin political economy” (the absence of any analysis of the state and the political economy of territory, scale, and region-making); and (iii) “distorted policy” (the inability of some scholars to examine path dependency, the problems of policy transfer and policy borrowing, and how case studies are used to develop both academic and political knowledge.

We are currently witnessing a phase called the new new regional geography. One aspect of this does not and cannot believe in regions in geography. A group of scholars, following Ash Amin and Nigel Thrift (the latter somewhat strangely, as he was a previous advocate of regions in geography) and others advocating a “thinking space-relationally” approach, envisage a world without regions, where rhizomatic flows and networks dominate and help to promote a new politics of place based on “proquinity” (the state of being close to someone or something, achieved through the “folding” of existence, and made possible by globalization and technological empowerment). Three significant points follow from this position (see Amin 2004): regions have no automatic promise of territorial integrity since they are made through the spatiality of relational connectivity; there is a questionable assumption that a regional territory can then be defined and made manageable; and any attempt to fix spatial identities through policy initiatives will be characterized by oversimplification and an inability to capture the ever-changing character of regions. This approach has, in turn, produced a backlash, with scholars seeking to bring regions, territories, and geographical scales back onto the agenda. Their argument is not to completely drop regions but to think about regional geography differently.

Part of the problem is the way the debate is posed, both historically and now, as if the networked worlds of those advocating relational space stand in direct opposition to territories, and, vice versa, those advocating a network position will also find that these are not without regional geography anchors. Geographers are, therefore, seeking a way of reconciling regional geography within a territorial/relational world. In the new new regional geography, where regions remain temporary permanences, the languages of “bundling,” “assemblage,” “method assemblages,” “spatiotemporal fixing,” “com- possibility,” “phase space,” “new localities,” “lengthening of networks,” and so on are all being offered as various ways of examining “region-making.”

A paper by US geographers Alexander Murphy and John O’Loughlin (2009) outlines the framework and mandate needed for an emerging new new regional geography as a tool for understanding rapid and profound changes in
the contemporary world. The authors provide recommendations for, and note the benefits of, a strengthening of regional research and training in geography while, in their case study, mapping out an expanded role for Eurasian geography and economics in disseminating new regional research whose scope extends beyond disciplinary boundaries to embrace current public and political debate. In this sense, then, the important problems that human geographers face today can still be found grounded in the practice of doing regional geography.

Regional inequalities

Michael Dunford
Institute of Geographic Sciences and Natural Resources Research (IGSNRR), Chinese Academy of Sciences

All regions and all places are unique and unrepeatabe, as indeed are all natural and social phenomena. Generalizations can nonetheless be made and theories developed by making abstractions that identify characteristics that regions have in common, such as types of soil, settlement types, or income levels. In scientific approaches to geography these abstractions are the starting point for the making of generalizations and the development of theories, which are themselves the starting point for a process of thought which moves in the opposite direction, from abstract theories to concrete realities, in which all of the details set aside in the process of abstraction are reintegrated such that particular regions emerge as a synthesis of many determinations. In this approach to geography, inequality is used not to refer to an absence of sameness but to differences in a narrower subset of characteristics of different places.

The literature on regional inequalities deals with a large range of indicators representing the wealth, income, employment, life expectancy, health, and education of the inhabitants of different places. Most of this literature focuses on income inequalities, although attempts to explain them involve consideration of possible economic, demographic, political, and cultural differences that may cause income inequalities. In this entry, most attention will be paid to inequalities in output, income, and expenditure, their evolution, and some of the factors that underlie them. Attention will also be paid to the identification of regions and regional classifications and to indicators of inequality.

Territorial units

Essentially, there are three ways in which regions can be defined. Homogeneous regions are regions that are made up of areas that share certain classified characteristics (climate type, soil type, population characteristics, etc.). Analytical or functional regions are regions that are made up of places that are interdependent, such as a travel-to-work area comprising employment centers and the places where the people working in these centers reside. Administrative regions are regions established to manage certain activities and include supranational, national, and subnational administrative entities. Subnational examples include local government districts, health districts, and so on, which are usually defined according to the size of the population considered necessary to carry out these tasks efficiently, perhaps respecting historical legacies or cultural distinctions. Most statistics are collected for administrative areas, though in some cases subnational administrative areas do not make functional sense as they separate areas that are strongly interdependent, as when centers of employment and wealth creation are separated from the places where the people who create that wealth reside.

An example of a regional classification used in regional analysis is the European Union’s (EU) Nomenclature of Units for Territorial...
REGIONAL INEQUALITIES

Statistics (NUTS). The NUTS system is at present a four-level hierarchical classification: each member state (NUTS 0) is divided into a whole number of NUTS 1 regions; each NUTS 1 region is in turn subdivided into a whole number of NUTS 2 regions; and so on. Generally speaking, the first three NUTS levels correspond to the main regional divisions in each member state: Länder and Kreise in Germany; régions and départements in France; Comunidades autónomas and provincias in Spain; and regioni and provincie in Italy. To secure a degree of international comparability and, more specifically, to try to ensure that the areas lie within certain size limits (3–7 million people in NUTS 1 areas, 800 000 to 3 million in NUTS 2 areas, and 150 000–800 000 in NUTS 3 areas) a third administrative level is identified for each member state: NUTS 1 for France, Italy, Greece, and Spain; NUTS 2 for Germany; and NUTS 3 for Belgium. At a more detailed level, there are districts, municipalities, and communes, although these levels are not yet subject to the formal NUTS regulation.

The difficulty is that the national administrative and statistical regional divisions that are the foundation stones of the NUTS classification are not derived from a common set of criteria and in some cases make no functional sense whatever. In spite of the functional interdependence of Inner and Outer London, Inner London is, for example, a NUTS 2 area. Although an attempt is made to identify areas that are comparable in economic size, the size limits are guidelines rather than strict constraints. Consequently, the NUTS classification does not provide a harmonized set of regional units. As a result, the 2011 gross domestic product at purchasing power standards of Level 2 regions varied from 542,049 million euros in Île-de-France to 974 million in Åland in Finland. The population of Åland was just 28,150.

Another eight NUTS 2 areas had fewer than 250,000 inhabitants. At the other end of the scale Île-de-France had 11.8 million inhabitants, Lombardia 9.9 million, and Andalucia 8.2 million.

In spite of these difficulties, the system is used for three important purposes. The first is the collection, development, and harmonization of regional statistics. The second is the analysis of regional economies and societies. The third is the framing of EU regional policies: eligibility for Objective 1 Structural Fund assistance is established at the NUTS 2 level, while eligibility under other priority Objectives is mainly established at the NUTS 3 level.

Indicators

Gross domestic product (GDP) per inhabitant is the indicator most often used to measure national and regional inequalities. A community’s GDP is a measure of aggregate value added. As the new wealth created in production is distributed to those who participate in economic life, GDP is also a measure of primary incomes (profits, interest, rents, and wages) accruing to those who contribute to a region’s economic activities, although the income that results does not necessarily accrue to a region’s inhabitants: where the inhabitants of other regions have property rights in a region, there is an outflow of income, as there is if the human capital of other regions is used locally. GDP estimates do not include the value of those goods and services that people produce for their own use. This omission is significant as self-provisioning, which depends on the resources a region’s inhabitants control and can use, varies significantly from one place to another, especially at a global scale. Conversely, the activities of the informal and hidden economies are included,
at least insofar as government statisticians are able to estimate their magnitude. The primary distribution of income is subsequently modified by state-administered redistribution. The result is the secondary distribution of income. These secondary incomes are saved and/or spent, and thereby permit the establishment of claims over the goods and services produced. Measurement of these expenditures (conventionally divided into consumer and government expenditure, investment/savings, and net exports) offers a third way of measuring GDP. (The existence of inconsistencies between these three estimates helps in the identification of undeclared incomes.)

The use of GDP is, however, problematic. If the aim is to measure wellbeing, wealth (stocks) should be measured as well as income (flows), and the concept of capital should embrace all assets that contribute to long-term welfare increases. Total wealth includes tangible productive capital, intangible capital (human capital, institutional capital, social capital, net overseas financial assets), and natural capital, while the flows include not just the income flows measured in GDP estimates but also, for example, changes in the availability of the environmental services provided by natural capital. In this world, externalities can render individual consumer preferences nonadditive, as increases in private consumption can reduce the quality of the environmental services that enter consumer preferences schedules.

Inequalities in regional GDP per head can be measured in two ways. Measurements in a common international currency indicate the international value of the output of regional economies. The money value of regional output shows (i) what the output of the exposed sector can be sold for and can command on international markets, and (ii) what the output of the protected sector can command directly on regional and indirectly on external markets. If a region’s external trade is in equilibrium, this indicator reflects the “quality” of its goods and services and its competitive strength. Measurements in purchasing power standards (PPS) make allowance for differences in the prices of goods and services in different areas: the quantity of goods and services that a given amount of an international currency will exchange for is greater in a low-cost than in a high-cost region. The PPS measure allows for these differences in purchasing power and is therefore an index of the volume of goods and services that different local economies produce and the volume of output that their economic activities can command or exchange for in their own area. This second measure is an indicator of differences in living standards. A related distinction can be made between qualitative and quantitative growth: increases in the value a region’s goods and services can command on international markets, and quantitative increases in the volume of goods and services commanded domestically.

GDP per head and its growth can be split into productivity and employment rate elements, as indicated by the identities in equations (1) and (2), where $G()$ denotes a growth rate.

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}}
\]

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}} + \frac{\text{employment}}{\text{population}}
\]

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}} + \frac{\text{hours worked}}{\text{population}}
\]

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}} + \frac{\text{hours worked}}{\text{population}}
\]

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}} + \frac{\text{hours worked}}{\text{population}}
\]

\[
\text{GDP per head} = \frac{\text{gdp}}{\text{population}} + \frac{\text{hours worked}}{\text{population}}
\]
This partitioning of GDP per head into elements that reflect the productive performance of regional economies (apparent productivity) and some of the features of their labor markets (hours worked and employment rates) is widely used as an initial step in the identification of the determinants of regional inequalities.

**Measures of inequality**

The simplest measures of inequality are the standard deviation, the mean absolute deviation, the Gini coefficient, and the Theil index. In the case of the first three measures, unweighted and weighted variants are used. An unweighted indicator gives equal weight to the average per capita income of each regional economy. A weighted indicator makes allowance for the fact that the population of regional economies varies. In this case, the average income of each regional economy is weighted by its share of the population. Measures of social, as opposed to regional, inequality deal with the incomes of individual households or individuals, each of which is weighted equally, instead of regional averages.

The definitions of the most important of these indicators are set out in the following equations. If \( p_i \) denotes the population of the \( i \)th region \((i = 1, 2, \ldots, n)\), \( y_i \) denotes its per capita GDP, and \( q_i \) denotes its GDP, the population-weighted standard deviation (WSD) is given by equation (3) and the weighted absolute deviation is given by equation (4).

\[
WSD = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (y_i - \bar{y})^2 \frac{p_i}{\sum_{i=1}^{n} p_i}}
\]  

\[
WAD = \sum_{i=1}^{n} |y_i - \bar{y}| \frac{p_i}{\sum_{i=1}^{n} p_i}
\]  

To facilitate comparisons, the weighted standard deviation and the weighted absolute deviations are expressed as percentages of the mean to give a coefficient of variation (CV).

The Gini coefficient (GC) is given by equation (5).

\[
GC = \frac{1}{2n} \sum_{i=1}^{n} \sum_{j=1}^{n} |y_i - y_j|
\]  

As with the indicators based on the mean, the deviations from which the Gini coefficient is calculated can be weighted by the product of the shares of the total population in each pair of regions.

Finally, the Theil coefficient (TC) is given by equation (6).

\[
TC = \sum_{i=1}^{n} \frac{q_i}{\sum_{j=1}^{n} q_i} \log_e \left( \frac{\sum_{j=1}^{n} q_i}{\sum_{j=1}^{n} p_i} \right)
\]  

Derived from the concept of entropy developed in information theory to measure the amount of information in a random event, the Theil coefficient can be interpreted as “the expected information content of the indirect message which transforms the population shares as prior probabilities into the income shares as posterior probabilities,” and as a measure of the gap between the share of the population that
each individual or group accounts for and the share of income it receives.

Territorial units and the measurement of inequality

In analyzing regional inequality, it is important to recognize that measured inequality increases with the degree of spatial disaggregation. Suppose that a country is divided into 16 areas (A1, A2, …, D4) with similar populations but different levels of GDP per head, and that these areas are grouped first into four and then into two regions (see Figure 1a and Dunford 1993). The standard deviation expressed as a percentage of the mean decreases from 38.5% (16 areas) to 10.6% (4 areas: A1..B2, A3..B4, C1..D2 and C3..D4) and 3.22% (2 areas: A1..B4 and C1..D4). It is important to note, however, that the choice of regional boundaries can affect the result. If in Figure 1a the 16 areas are divided horizontally rather than vertically into two groups (A1..D2 and A3..D4), the indicator falls to 9.67% instead of 3.22%. Alternatively, if four areas are identified in the manner indicated in Figure 1b, the coefficient of variation will equal 24.7%.

Measured regional disparities depend, therefore, not just on the degree of spatial concentration of economic activities, but also on the regional division of the country: the number of areas and the choice of boundaries affect the measure of disparity, just as the delimitation of electoral districts shapes the outcome of elections. Clearly, the ideal solution is to use functional economic areas which combine places of work with corresponding places of residence, though disparities between politically identified areas are significant as determinants of the resources over which different communities can exercise political leverage.

The dynamics of regional inequalities: convergence or divergence

In 1955, Kuznets suggested that there is an inverted U-shaped relationship between inequality and income per head. As an economy starts to develop, and as people move from agricultural to industrial jobs and from rural to urban areas, inequality increases. As income per capita increases further, this relationship is reversed and inequality declines. For Kuznets, the technical reason for the increase in inequality was that the transition to an industrial society was the saving of unskilled labor. In 1965, Williamson extended this argument to regional inequalities, and argued that regional inequalities will at first increase and subsequently decrease as the level of economic development increases. Williamson argued that the evolution of regional inequalities was a result of a set of spillovers associated with different stages of economic development.

REGIONAL INEQUALITIES

development, including migration, capital flows, government policies, and interregional trade. As evidence, Williamson relied on time series data for the first half of the twentieth century, which showed that regional inequalities increased in less developed countries and decreased in more developed countries, and on cross-sectional data, which showed that regional disparities are greater in less developed than in more developed countries. Williamson concluded that regional income inequalities are a natural consequence of economic development and that any attempts to reduce them might inhibit development.

More recent work on the dynamics of regional inequalities has involved investigation of the convergence hypothesis (Figure 2). The initial idea derived from the expectation that economies characterized by similar conditions would converge on a similar steady state rate of growth and similar per capita incomes, with economies that are less developed growing faster than economies that are more developed. Empirically this claim is associated with the $\beta$ convergence hypothesis, which states that the slope parameter, $\left(1-e^{\beta t}\right)/t$, of regressions of per capita GDP growth in $t$ years, $y$, on the logarithm of initial GDP per head, $y_0$, will be negative. It is important to note that this exercise is statistically questionable, as it involves the estimation of an equation in which initial income appears on the two sides, once with a positive sign and once with a negative sign. In these circumstances a negative regression coefficient is at least in part a result of correlating a variable with itself.

Two factors underpin the expectation of faster growth of less developed economies. The first is the existence of diminishing returns to capital and constant returns to scale. At any level of technological development, these two conditions imply that increases in per capita output get smaller as the amount of capital per worker, $K/L$, increases (since areas with low $K/L$ ratios grow faster than areas with high $K/L$ ratios), that increases in productivity cease once a steady-state/equilibrium amount of capital per worker is reached, that increases in per capita output associated with incremental investments are greatest in areas/enterprises that are the least mechanized, and that countries that differ only in initial levels of per capita GDP will converge on the same level of GDP per capita. The second is the view that technology is a public good available at no cost to everyone, and that the diffusion of technology and of knowledge from advanced to less developed enterprises and areas will close technology and productivity gaps.

Empirical convergence hypothesis research showed that there were differences in regional

![Figure 2](image-url)  
**Figure 2** Modeling convergence.
steady state growth rates and permanent differences in income per head. As a result, emphasis was placed on theories of conditional and club convergence that predict cross-sectional heterogeneity as a result of differences in economic conditions. Club convergence theories attribute differences in performance to the fact that economies fall into different groups/clubs because of differing initial conditions. Conditional convergence theories attribute differences to the cross-area heterogeneity of control variables such as rates of accumulation or the quality of modes of governance. In this much more restricted context, the convergence that does occur is very slow: economies converge at only about 2% per year on their own steady state as determined by structural characteristics and starting conditions.

A second strand of empirical research concentrates more on the evolution of the dispersion of regional incomes (sometimes called θ convergence). In this case the unweighted and weighted indicators identified earlier are used.

A third strand of empirical research involves distribution dynamics. This approach involves the application of Markov chain techniques (using either discrete transition probability matrices or continuous stochastic kernels) to examine the evolution of entire income distributions. These methods have indicated complex changes in the dynamics of relative income per head, including divergence, the persistence of inequalities, movements within the distribution, and polarization. Modeling the evolution of the distribution of regional and individual income with these techniques, Quah (1996) found, for example, an empirical tendency for the emergence of twin peak distributions with high frequencies for relatively high and relatively low incomes and relatively small frequencies for incomes in the middle of the distribution.

With the exception of the third, these approaches are associated with the theoretical view that convergence is an expected outcome of market mechanisms. As this entry will show, however, divergence as well as convergence can occur. In the neoclassical tradition it is common to argue that the absence of convergence is due to factors that prevent markets from working. In many respects, this type of claim is extraordinary: if the model’s predictions are not realized, it is the world that is wrong and not the model. There are, however, alternative models of circular and cumulative causation (Myrdal 1957; Kaldor 1972) and new economic geography models (Fujita, Krugman, and Venables 1999) that do not predict convergence. According to these models, comparative development depends on the relative weight of unequalizing centripetal forces of attraction and suction and equalizing centrifugal forces of diffusion. Myrdal, for example, called the former “backwash effects.” An example is the way in which net flows of capital and labor are directed towards more rather than less developed areas. As his aim was to explain increasing economic inequality between developed and underdeveloped areas, these forces received particular attention. Myrdal recognized, however, that there were also spread (trickle-down) effects that worked to equalize development. In addition, he emphasized the importance of institutional factors in shaping development trends and argued for active policy intervention in order to promote greater equality, which he thought would also contribute to greater economic growth. An example of such public action is provided by net flows of public expenditure put in place specifically to counteract the unequalizing effects of market mechanisms.

Another strand of circular and cumulative causation models is rooted in the work of Kaldor, who drew on the earlier work of Young. At the center of this approach was the idea that
Regional Inequalities

Economies of scale were a fundamental characteristic of economic life (yet were assumed not to exist in the neoclassical tradition). Essentially, Kaldor argued that national and regional growth was export-led. The growth of exports depends on the efficiency wage (the ratio of real wages and productivity). Increased exports of manufactured goods imply increased output. The consequent increase in output implies, as a result of economies of scale, external economies, or spillover effects and complementarities, increased productivity. Next, increased productivity improves competitiveness, contributing to a virtuous spiral.

The emphasis on export demand is indicative of a second major difference. Neoclassical growth models are supply-led. These models concentrate on the expansion of potential output on the supply side of the economy, and assume that aggregate demand will equal potential output. Kaldorian models are Keynesian models of demand-led growth in which aggregate supply is adjusted to accommodate demand-led changes in actual output through changes in capacity utilization and/or induced changes in accumulation, migration, and technical change.

Global inequalities

Measured in terms of per capita GDP in 2013 Geary–Khamis (EKS) dollars (converted to 2013 price level with updated 2005 EKS PPS) (Figure 3), the world remained extremely unevenly developed, with high levels of per capita income in North America, Australia, and New Zealand ($51,575), Western Europe ($36,974), Japan ($38,004), and the Asian Tiger economies ($38,655). Next came Russia ($18,596) and the rest of Eastern Europe ($12,579), though there were very wide gaps between the central European Union member

Figure 3  Total population, GDP per capita, and total GDP. The column width of each block represents the population of the country or region. The area of each block represents the total GDP. Modified from The Conference Board (2014).
states and members of the Commonwealth of Independent States. In Africa, per capita GDP stood at just $2747. From being the poorest country in the world in 1949, lying well behind Africa and India, China ($11 106) was an upper middle-income country, had overtaken Brazil ($10 248), and was not far behind the rest of Latin America ($12 810). India ($3 681) still had relatively low levels of income per head. Due to the large size of its population, the Chinese economy was extremely large, as the surface of the areas in Figure 3 shows: in 2013 its total GDP at PPP stood at $15.1 trillion compared with $15.4 trillion for Western Europe and $19.5 trillion for North Americana and Oceania.

These disparities are a result of trends in comparative development mainly in the last 250 years. At the dawn of the Industrial Revolution, the gap in per capita income between Western Europe and India, Africa, or China was probably no more than 30%. With the Industrial Revolution, however, the situation changed radically. In 1870, the per capita income of the wealthiest countries was already 11 times that of the poorest. By 1995, the wealthiest were more than 50 times as rich as the poorest. In the recent past, however, many of the relatively low per capita income parts of Asia have experienced relatively fast economic growth (Figure 4). In most of the continental zones identified in Figure 4, growth rates were faster in the 1960–1973 Golden Age than in subsequent cycles. In the case of Western Europe, growth rates in each subsequent cycle were one-half or less of Golden Age growth rates. The USA, Canada, Australia, and New Zealand saw output grow relatively faster than Western Europe, although their per capita growth rates were at best the same as those of Western Europe, as higher GDP growth rates were accompanied by stronger demographic growth. Communist Eastern Europe also saw strong growth in 1960–1973. Subsequent growth

REGIONAL INEQUALITIES

slowdowns saw the collapse of communism and opened the path to rapid transitions to capitalism. The consequences of these transitions for output were little short of catastrophic. In 1989–1997, output declined at an average of 4.5% per year. In 1997 output still stood at just 68% of its 1989 level. Foregone output over these years was massive. In these transition economies growth subsequently picked up, yet in 2013 output stood at a mere 128% of its 1989 level. More recent growth has depended to a significant extent on net capital inflows which contributed to unsustainable credit-driven growth. This record compares particularly unfavorably with that of China, which chose a fundamentally different development path to the European ex-communist states: instead of shock therapy, which Václav Havel sought to justify with the claim that “you can’t cross a chasm in two small steps,” the Chinese chose a gradual and experimental approach to “reform and opening up” captured in Deng Xiaoping’s aphorism that, to paraphrase, “the way to cross a river is step by step, feeling for the stones as you go.” The remarkable growth of China at an average of 8.7% per year since 1980 is one of the reasons for the growth of Asia at 6.2, 5.1, 5.4, and 6.2% per year in the four cycles from 1960 until 2013, with the growth of Tiger economies slowing down during the 1990s. As for the other parts of the world, high growth rates in 1960–1973 gave way to much slower growth in 1973–1989, especially in the economies of Latin America and Africa. Just as the differences in the performance of European transition economies and China reflect in part different development choices, so do the contrasts between Asia and Latin American and African economies, as the latter implemented the Washington Consensus and the enhanced Washington Consensus (which required that the original goals of stabilization, liberalization, and privatization be accompanied by governance reforms and country ownership), whereas countries such as Japan and the Four Tigers, and later on China, India, and Vietnam, violated virtually all of the rules of neoliberalism.

As a result of the recent rapid growth of very populous countries in Asia, the great divergence set in motion by the Industrial Revolution is starting to give way to a period of global convergence, especially as growth has picked up as a result of recent changes in the political complexion and the economic strategies of Latin American economies and the natural-resource-driven growth of Russia and of Africa. If these trends continue, there will be a significant increase in the relative economic weight of emerging economies, especially in Asia, at the expense of the economically advanced parts of the world.

National and regional inequalities in Western Europe

Figure 5 records per capita GDP at PPS relative to the average in 2011 for the NUTS 2 regions in the EU27 (27 EU member states) and in Norway, Switzerland, Croatia, Turkey, and the former Yugoslav Republic of Macedonia. Even within the EU the gaps are very wide as a result of a geopolitically driven process of enlargement. The addition of countries such as Croatia, the former Yugoslav Republic of Macedonia, and Turkey will make them still wider.

In Figure 5 countries are ordered according to their GDP per head from Luxembourg (264.7%) and Norway (184.9%) to Turkey (35.7%), with national GDP per head represented by red diamonds. The extreme values differ by a factor of more than 15.7. Some of the figures should, however, be treated with caution. In the case of Ireland, GDP far exceeds GNP: the incomes that accrue to people who live in Ireland are some 17% less than the income created in Ireland.
The reason for this discrepancy is that much of the wealth created in Ireland is produced by multinational companies that withdraw profits and that engage in transfer pricing arrangements. Transfer pricing results in an overstatement of the wealth created in Ireland.

For each country, regional GDP per head figures are recorded in the columns as circles. In most countries, and in this group of countries as a whole, there are wide regional disparities. At one extreme lie Inner London (319.0%), Luxembourg (264.7%), Brussels (220.6%), Hamburg (201.2%), Oslo (188.1%), Bratislava (184.9%), Groningen (181.0%), and Île-de-France (181.0%), although some of these figures must be treated with extreme caution as the areas concerned are areas of substantial net inward commuting. At the other end of the spectrum were Severozapaden in Bulgaria (28.6%), Nord-Est in Romania (28.6%), and five regions in Turkey, of which the lowest was Mus, Bitlis, Hakkari (20.2%).

**Trends in European national inequalities**

Empirical evidence derived from research employing the indicators introduced earlier

---

**Figure 5** National and regional inequalities in the EU27 plus Croatia, the former Yugoslav Republic of Macedonia, and Turkey. Data modified from Eurostat (2014).
places a question mark over the Williamson hypothesis; the reason is that in many developed economies regional inequalities, which did indeed diminish in the 1960s and 1970s, started to increase again in the 1980s, 1990s, and 2000s. What is more, in these countries the rates of economic growth were faster in the years of diminishing regional inequality than in the subsequent years of widening regional inequality.

Figure 6 plots the evolution of disparities between West European and East European countries from 1950 until 2013. The chart indicates that there was strong convergence among West European countries from 1950 until the early 1970s. In this period, often referred to as a postwar Golden Age, European economies experienced unprecedentedly fast economic growth: growth was associated with increases in territorial (and social) equality, while the movement in the direction of greater equality made positive contributions to European growth through, for example, its effect on the expansion of markets. After 1971, convergence slowed, and in the early 1980s divergence occurred. After a period of relatively slow convergence, driven by the relatively fast growth of the economically less developed European Union Cohesion Countries, divergence occurred.

A partitioning of West European disparities to identify the roles of productivity and employment rates is particularly informative (Figure 7). As the figure shows, apparent productivity has converged initially quite rapidly and subsequently at progressively slower rates. The main driver of changing trends in inequality is disparities in employment rates, which increased in the late 1970s and early 1990s after the mid-1970s economic crisis of Fordism and again after the
2007 financial crisis and with the subsequent debt and Eurozone crises.

In Central and Eastern Europe, on the other hand, the transition to capitalism saw sharp increases in disparities until the end of the 1990s, after which recovery from the dramatic transitional recession spread to other countries (Figure 7). Figure 7 identifies the trends in GDP growth of some of the Central, East European, and Central Asian transition economies since 1989, and demonstrates the remarkable differential impact of economic transition on GDP (see Dunford 2005). The Visegrad Four (Czech Republic, Hungary, Poland, and Slovakia), Slovenia, and the former German Democratic Republic (GDR) regained their former levels of GDP after sharp slumps and substantial foregone income. Poland was the first to regain its pre-transition GDP in 1996, followed by Slovenia in 1998. Of the rest, Albania regained its former level of GDP in 2000, and two Central Asian republics (Turkmenistan and Uzbekistan) did in 2001. In the case of Russia, the drop in output was about 42%. This fall was far steeper than the one registered by the United States during the Great Depression of the early 1930s. At the root of the collapse was a decline in income and demand, combined with an overvaluation of the rouble. Only after the 1998 financial crisis, devaluation, and the subsequent increase in oil prices did growth pick up, and only in 2007 did Russia reach its 1989 GDP. The Ukraine in 2011 stood at 66.7% of its 1989 level of GDP.

**Italian regional evolutions**

In the case of Italy’s regional economies there was a sharp decline in disparities in 1951–1953 after which territorial inequalities increased in the 1950s. In 1960, the degree of inequality was close to its 1951 level. In 1960–1975 the situation changed dramatically. For 15 years, coinciding in part with Italy’s economic miracle, there was strong catch-up as the less developed parts of Italy closed the gap on the more developed. After 1975 there was a reversal in the trend. Overall there was a clear increase in inequality. A not insignificant part of the relative improvement that had occurred after 1960 was reversed in 1975 and after 1983. Since the mid-1990s, conversely, there has been a renewed phase of convergence (Dunford and Greco 2006).

The recent evolution of Italian regional inequalities is a result of opposite trends in regional productivity and employment rates. As Figure 8 shows, productivity differentials have tended to decline. In 1972–1996 employment rate differentials generally moved in the opposite direction. Clearly, it is not productivity differentials that account for the recent overall increase in Italian regional inequality, as they have tended to diminish, though they remain a significant determinant of differences in the levels of regional development. At the root of the inequality increases up to 1996 were very sharp increases in employment rate variations.

As these two examples show, there are relatively sustained periods in which unequalizing tendencies outweigh equalizing tendencies and vice versa, where these empirical outcomes also reflect, of course, the impact of government policies designed to reduce development differences.

A second important feature of empirical trends in relative development is the persistence of territorial inequalities. Figure 9 records the evolution of Italy’s regional economies relative to the EU15 (15 Members of the EU before the accession of formerly communist East European countries) average. Among other things, it reveals a high degree of inertia at the top and bottom end of the distribution; the top regional economies in 1951 remained for the most part...

at the top end of the distribution in 2013, just as the regional economies at the bottom end tended to remain at the bottom, although it also indicates some striking changes in the relative position of regional economies in the middle of the distribution.

**Chinese regional disparities**

The existence of phases of increasing and diminishing inequalities is also a characteristic of the extraordinary growth of China since the establishment of the new China in 1949, and especially since the start of reform and opening-up after 1978. Figure 10 records trends in disparities in per capita GDP between China’s 22 provinces, four municipalities, and five autonomous regions (excluding therefore the two Special Administrative Regions of Hong Kong and Macau, and Taiwan).

Generally speaking, disparities were relatively high in the planned economy period due mainly to the concentration of industrial growth in Northeast China (Figure 10). Disparities diminished from the mid-1970s and with the first phase of reform and opening-up but then increased strongly from 1990 until about 2004 with the rapid growth of east coast cities and coastal provinces. The end of the 1990s and the start of the new millennium saw, however, the establishment of government programs for the development of Western China, the restructuring of the Northeast, and the uplifting of Central China.

**Figure 10** Evolution of GDP per capita of China’s four main territorial divisions. Modified from National Bureau of Statistics (2014) (http://www.stats.gov.cn/).
China, which with the impact of the downturn in Chinese export markets after the Western financial crisis saw a reversal of trends and a decline in particular in the coastal–inland gap.

China’s regional disparities are, moreover, closely associated with disparities between rural and urban areas: as Figure 11 shows, increases and decreases in regional disparities were accompanied more or less by corresponding trends in the gap between rural and urban areas. These evolutions reflect the close relationship between regional and rural–urban disparities and phases in Chinese economic and political development. The early years of communist rule marked by land reform were, for example, associated with a low and steady degree of rural–urban inequality. In 1957, China embarked on the Great Leap Forward: while investment in heavy industries increased sharply, an agricultural crisis gave way to the Great Famine. In these years inequalities increased, peaking in 1960. From 1960 until 1967 inequalities diminished. 1966 saw the start of the Cultural Revolution which began a phase of increasing inequality, with a peak in 1976. 1978 marked a major turning point. An initial phase of rural reform saw inequalities continue to decline. After 1984, in a period of political decentralization,
increased foreign trade, and foreign direct investment, provincial, urban–rural, and inland–coastal inequalities all increased sharply. Overall inequality was relatively small when the development model was favorable to agriculture and the countryside.

Conclusions

In this entry most attention has been paid to regional variations in wealth creation. The evolving geography of wealth creation is underpinned by the evolving geography of economic activities and the dynamics of labor markets and population distribution. These drivers are themselves shaped not just by economic mechanisms but also by institutional factors and political choices (including, for example, specific policies designed to create a more equal distribution of people and work). Each of these drivers is associated with equalizing and unequalizing tendencies. Whether regional inequalities increase or decrease depends on the relative weight of these two sets of forces and, more generally, on the underlying model of development. Inequalities are, however, not just a result of the geography of wealth creation. Income redistribution and transfers towards economically disadvantaged regions are often substantial so that variations in income and consumption are often smaller than variations in wealth creation. Health, education, and collective services are often entitlements and as such are distributed far more equally than other economic activities.

REGIONAL INEQUALITIES

Further reading

Regional planning in China is a new sphere of activity compared with Western countries. It dates from the 1980s when it focused on “economic cooperation zones,” such as the “planning economic cooperation zone along the Yellow River” (Liu et al. 2011). Since 2000, regional planning in China has been developed rapidly on the basis of learning from Western countries’ successful regional governance experiences.

Regional planning in China refers specifically to an integrative arrangement for development issues in an area (Yang 2010). The core components of regional planning in China include the general strategic development orientation of the region, regional development targets, regional industrial structure, overall arrangement of cities and towns, infrastructure construction arrangements, and so on. Generally speaking, regional planning has served as a method of assisting with the realization of the goals of national development. More specifically, breaking the economic shackles of the administrative division of the country, optimizing the development of regional geographical space, and advancing sustainable regional development are the three goals of regional planning in China (Liu et al. 2011).

According to differences in geographical scale, regional planning in China can be divided into national level, cross-provincial, provincial, and city level. National-level regional planning comprises regional plans that have national significance and are officially approved by the State Council, and include the Northeast Region Revitalization Plan. Regional planning at a cross-provincial level deals with planning regions that cross provincial boundaries of which regional development planning in the Chengdu-Chongqing Economic Zone is an example.

In China, regional plans are compiled and authorized by three different ministries. The National Development and Reform Commission is in charge of the Major Function-Oriented Zone that is incorporated into China’s twelfth Five-Year Plan (Fan et al. 2012) and most cross-provincial regional planning. The Major Function-Oriented Zone strategy, for example, is designed to foster a development model that does not emphasize economic growth at the expense of resources and the environment, by identifying the unique functions that each region should perform in the light of its characteristics, conditions, assets, and requirements. It classifies regions into four categories: development-restricted zones for maintaining food and ecological safety; development-optimized zones for transforming the current model of economic development; development-prioritized zones for accelerating industrialization and urbanization; and development-prohibited zones for protecting the natural and cultural heritage.

The Ministry of Land and Resources is responsible for national- and provincial-level territorial planning that focuses on spatial organization and territorial security (Dunford and Liu 2015). The Ministry of Housing and Urban-Rural Development takes charge of urban system planning, urban agglomeration planning, and
REGIONAL PLANNING: CHINA

metropolitan region planning. In recent years, territorial planning, major function-oriented zoning, and urban agglomeration planning have become major regional planning research foci in China. However, there has not been a uniform regional planning system in China up to now.

Regional planning: the resilience of an imperative

Richard J. Nunes
University of Reading, UK

What is regional planning?

A strength of the idea of regional planning, and why its importance has featured in several seminal texts on planning thought for nearly a century, can be attributed to the fact that this form of planning practice has not been constrained by a single concept of “the region.” Regional planning can address any single issue or interrelated set of supraurban issues that arises, which affected communities may wish to engage. This general understanding of regional planning thus often results in varying or oftentimes overlapping constructs of a region. In other words, regions can be defined in both prescriptive and descriptive terms while addressing a regional problem and aiding other forms and/or levels of planning practice. These distinctions have been and continue to be essential to ongoing debates over the importance of regional planning and the meaning of “the region.” Benton MacKaye is among one of the earliest known writers to ask what regional planning is. MacKaye claims that “regional planning is best defined by splitting the term in two. What is planning? and what is region?” (1940, 350). The region, according to him, is “more than an area, it is an area or seat of movement” (MacKaye 1940, 350; emphasis added). MacKaye’s stress on movement equates the region to a “sphere” or space of flows, from the flow of water in a watershed to the flow of commodities (such as milk or financial services) and population. In other words, if the planner were to concern herself with the flow of a river, the range of that water-flow or its watershed would be the region to be planned – not an area of land restricted to the boundaries of an administrative jurisdiction.

However, MacKaye also knew all too well that both of these notions were “still in the making. They involve not merely what the dictionary states but what it is that planners really mean [by the region, by regional planning]” (MacKaye 1940, 349). Sure enough, notable scholars have periodically revisited this question and reassessed the idea of the region, and altogether this has amounted to a resilience of the “regional imperative”:

By defining regional planning as being most commonly a process arising from tensions and gaps within systems of governance, it [the regional imperative] will always be with us. So much of regional planning arises because of cross-boundary issues and tensions inevitable with any pattern of governance, regardless of whether or not it matches geographical regions. (Wannop 1995, 403)

This resilience of the regional imperative will be explored throughout the following reflection on regional planning. Before elaborating on any definitions, it is best first to situate regional planning within a framework of what planning is. A discussion of the abundant individual definitions of planning is well beyond the scope of this entry. Nevertheless, there are qualities of planning practice that do feature in different types of planning, from identifying a problem, projecting its
future socioeconomic and environmental ramifications, and generating or evaluating a set of alternative courses of action in the form of a policy statement, strategy, or definitive plan. The practice of planning is not, however, restricted to its regulatory fold or its formal processes. There is also “a presumption that planning is being done” in grassroots community-led development activities, as well as in the work of government agencies and of private sector engagement in urban regeneration and subnational economic governance:

Primarily a way of thinking about social and economic problems, planning is oriented predominantly toward the future, is deeply concerned with the relation of goals to collective decisions, and strives for comprehensiveness in policy and program. Wherever these modes of thought are applied, there is a presumption that planning is being done. (Friedmann 1963, 169)

As already mentioned, what constitutes the practice of regional planning, and what it means to plan at the regional level, have been the subject of debate over several decades in academic and policy circles alike. This period has been marked by distinct shifts in regional planning thought and practice, which have sought to balance the principles of regional planning on the one hand, and the intra- and interlevel efficiency demands of supraurban governance on the other. Glasson (1974) outlines four sets of overlapping distinctions of general planning practice against which regional planning and its associated complexities and cross-boundary tensions can be understood, if not defined.

The first draws a distinction between physical and economic planning. Whereas the former has its origins in land use and development vis-à-vis direct regulatory controls, the latter operates through market mechanisms to address concerns with the economic structure of an area. The second distinction is between allocative and innovative planning, which are divided according to function and area of concern respectively. Allocative planning is concerned with ensuring the efficiencies of an existing system, such as housing delivery, in accordance with changing policies. Innovative planning moves beyond efficiency measures toward the betterment of the system as a whole, such as affordable low-carbon housing developments. The third and related distinction concerns single or multi-objective planning. The previous housing example illustrates this distinction whereby the delivery of affordable low-carbon housing can be explicitly evaluated or measured against the multiple objectives of a carbon budget within a local climate-change strategy, and affordable housing targets across a period of projected housing supply need. The final distinction, between indicative and imperative planning, relates to the method of implementation. Indicative planning is advisory in nature, whereas imperative planning works from legally binding directives.

These interwoven distinctions offer a framework for comprehending the complexities of what constitutes regional planning as a form of planning practice. Following this planning typology, Glasson defines regional planning as “both physical and economic planning. Some regional plans may be purely allocative, but the majority includes certain innovative elements … In addition, regional planning is invariably multi-objective, but the method of implementation may vary greatly” (1974, 21; emphasis original). Regional planning is a geopolitical activity, and therefore it cannot be detached from issues of governance and democratic engagement. However, perhaps more importantly, this definition broadly maintains that regional planning practice equates to a presumption that planning is done both within and/or outside the regulatory fold of planning policies, plans, and politics. In other words, regional planning practice is not restricted
to formal regulatory processes over a designated physical area. MacKaye’s early writings underpin this view.

As mentioned earlier, these definitions reflect ongoing academic considerations of the region as a space of flows. MacKaye defines regional planning as a “comprehensive ordering or visualization of the possible or potential movement, activity, or flow (from sources onward) of waters, commodities, or population, within a defined area or sphere, for the purpose of laying therein the physical basis for the ‘good life’ or optimum human living” (1940, 351; emphasis added). Where Glasson’s definition sets out a framework for evaluating regional planning practice and its associated complexities and cross-boundary tensions, MacKaye leaves us with the originating principle behind a presumption of what it means to practice regional planning.

Principal dimensions of regional planning and their interrelations

Regional planning practice consists of the formulation and articulation of local and national objectives into a strategically guided ordering of activities or interventions in a supraurban space. It is this space of interactions that gives rise to regional planning, regardless of whether it constitutes a formalized set of activities. As Wannop (1995, 403) rightly points out, “regional planning arises because of cross-boundary issues and tensions inevitable with any pattern of governance, regardless of whether or not it matches geographical regions.” Regional planning, as a form of planning practice, often has a specific method of procedure attributed to it (procedural planning theory), which is usually initiated by the state. Regional planning will also draw on a specific concept of development (regional planning doctrine) and a variety of theories from the social and environmental sciences (substantive theory in regional planning), notwithstanding competing notions of what constitutes the planned region or territory. Altogether, the planning process, concepts of development, and substantive theories are underpinned by ideological assumptions. These assumptions are set within existing socio-economic, political, and spatial organizations of societies, in turn shaping the contents of regional planning and determining its outcomes. In other words, these ideological assumptions shape why we plan, and to a lesser extent how we go about doing it. In Territory and Function: The Evolution of Regional Planning, Friedmann and Weaver (1979) carefully outlined these points in what largely remains to this day a concise overview of the principal dimensions of regional planning and its interrelations (Figure 1). The next section provides a concise overview of paradigmatic shifts in regional planning doctrine, charting its early advancement through to its subsequent fall and rise, and recent calls for its reconfiguration or transformation.

Epochs in the evolution of regional planning doctrine, 1925 to present

The French geographer Paul Vidal de la Blache provides a useful starting point for a journey into the transformation of regional planning doctrine. Vidal was concerned with everyday life (genres de vie) in a region and its links to socio-economic, ideological, and cognitive dimensions of practices. This Vidalienne tradition of research through regional monographs lies at the roots of what may typically be referred to as the studies of regionalism today.

The narrative of regional planning thought is one of a long and rich history of transformation. It begins at a distinct break in the advancement of regional planning thought and practice in the late...
1970s: “The broad field of development studies of which regional planning is a part, is currently in the throes of a profound transformation of its own which is rendering much of the received planning doctrine obsolete” (Friedmann and Weaver 1979, 2–3). Prior to this “fall” in regional planning was one the most academically rich and experimental periods in the evolution of regional planning doctrine. Fast-forward from this breaking point nearly 40 years, and regional planning is once again the focus of global debate (Hadjimichalis and Hudson 2014; Jones and Paasi 2013). During this period of nearly a century, the presumption of what it means to practice regional planning evolves into a tension between degrees of territorial and functional integration. Table 1 outlines four distinct epochs in this evolution, adapting and expanding on the work of Friedmann and Weaver (1979) to accommodate subsequent developments in regional planning thought and practice.

The overview that follows is structured slightly differently. The first and second sections discuss the early advancement of regional planning thought and practice. The first stresses the territorial integration of natural capital and economic activity within a designated geographical region, followed by later thinking that increasingly concerned itself with the economic globalization of goods and services and its functional integration with regional (economic) development. The third section considers the departure from much of this received regional planning doctrine until the mid-1970s before its resurgence in the 1990s. A final closing reflection addresses recent calls for a repoliticization of this resurgent urban regional doctrine of innovation, competitiveness, and creativity in the face of global crises experienced locally in cities worldwide.

**Territorial integration**

The early thinking, nominally referred to as “territorial integration,” was geared toward physical needs such as the integrated delivery of environmental conservation, housing, jobs, and critical infrastructure, and was thus geographically bounded by them. This resource development doctrine, internationally regarded as “comprehensive river basin development,” was propagated by the work of the Tennessee Valley Authority (TVA) in the United States (Figure 2). As the practical idealism of regional planners confronted the mundane concerns of attracting private sector investment and guiding future economic growth, their thinking increasingly turned to functional urban regions and their integration with the economic globalization of goods and services. Examples of territorial

Integration today are enshrined in watershed- and ecosystems-based approaches, which are increasingly finding functional rural–urban linkages to multiple urban systems, such as the nexus of food, energy, and water.

**Functional integration**

Regional economic development is no longer (since the 1950s) preconceived as bounded to a physical locality. A scientific base that underpinned theories of urbanization, industrial location, and inter-city ties supported this new regional planning doctrine (also known as “regional science”), leaving regional planning practice to follow as a newly established “scientific endeavor.” This transformation in regional planning doctrine was bifurcated. One dimension of these regional policies stressed the spatial organization of urbanization and industrialization through “growth centers” in newly industrializing countries by means of public subsidies to private enterprise and the use of public investment as the main instrument of spatial policy. Peri-urban or hinterland development (including rural development) would be incorporated through the centripetal forces of economic diffusion from core to periphery. The second dimension stressed uneven development in industrially advanced nations,
or “backward” or “less developed” regions. Regional policy with regard to the latter regions remained ambivalent and disproportionately focused on core regions, and the emphasis on the regional increasingly merged with the concept of metropolitan planning. Much of the regional planning of this period was associated with the creation of regions for the coordination of state–local actions. In Europe, this involved European-level strategic frameworks and directives down to national strategic frameworks at the member state level and its delivery through local plans. The French *amenagement du territoire* and German land-use planning traditions embodied these policy developments, later challenging the presumptions of what it meant to *practice* regional planning among the newly acceded member states of Central and Eastern Europe in 2004 and 2007 (Adams, Giancarlo, and Nunes 2011). Local government reform in England in the 1990s similarly reflected the same, including the creation of government offices for the regions (1994), regional chambers (1998–1999), regional development agencies (1998–1999), the Regional Coordination Unit at the Office of the Deputy Prime Minister (ODPM) (2000), and the elected London Assembly and Mayor (2000).

**Fall and rise of regional planning**

Public uneasiness surrounding events such as the student protests of 1968 and the 1973 oil and economic crisis inadvertently spread to the planning profession. “Growth centres did not
grow, backward regions did not flourish, poverty continued to accumulate in cities, inequalities remained engrained as deeply as ever in the landscape” (Friedmann and Weaver 1979, 7). In the years that followed and for nearly two decades, there was a marked disaffection with regional economic development and planning, before a resurgence of interest in regional development policy. This disaffection was part of an ideological shift as planning was seen as interventionist, opposing market-led approaches to development shaped by planning. The resurgence that followed in the 1990s and 2000s included a re-engagement of the functional integration of economic growth and development through a renewed interest in the role of relational assets in global economic restructuring processes and the emergence of transborder regional economies (Krugman 1991; Storper 1997). It was a process that led to the creation of planning regions in Europe, for example, and the institutionalization of European spatial planning (Waterhout 2008).

This period also coincided with growing experimentation in the practice of regional planning and policy, a rethinking of the notion of regions and a re-examination of the idea of territorial development. Principal examples of the application of this thinking include the European Commission’s (1999) European Spatial Development Perspective and the World Bank’s World Development Report 2009: Reshaping Economic Geography (Gill 2009), both of which captured academic attention on a global level. Notwithstanding the critiques of their apolitical stance on development, both reports frame nearly a decade of political and academic thought on the spatial organization of commodities and labor flows within city-regional systems and across polycentric megaregions, and its integration with the restructuring of the global space economy (cf. the “European global-macro region” in Pain, Richard, and Van Hamme 2014; and the “global city-region” in Scott et al. 2001).

Repoliticization of integration

Where the previous period ended and gave rise to the fourth and last of the epochs in the evolution of regional planning is unclear. However, there has been an emergence of the use of information and communication technologies (ICTs), which are ubiquitously integrated into the design and planning of new cities and the ecological retrofit of others. This trend in smart city-regionalism reinforces the idea of the region as a space of flows. It also echoes the aforementioned ideas of regional science at the tail end of the advancement of regional planning thought and practice (1950–1975), while at the same time engaging decentralized processes of data gathering (e.g., citizen science). Smart city-regionalism has accompanied an enthusiastic growth in the suite of microtechnologies, apps, and urban-scale operating systems. These technological advances may well see the emergence of new norms and routines which reframe the presumptions of regional planning practice. The continuing stress on the space of flows of human labor, environmental resources, and financial investment is evident in this regional doctrine. Yet this emergent doctrine, the practice of which has been most evident in its incorporation within spatial planning processes and its contribution to urban management, sits alongside enduring questions of uneven development uneasy.

It is manifest in new high-tech developments and informal settlements within rapidly industrializing “global regions,” and in the retrofit of global city-regions within advanced industrialized economies. Examples include newly built cities such as Songdo (South Korea), and the retrofit of others such as Rio de Janeiro (Brazil). In some respects, this urban response is not far
removed from the systems approach to urban and regional planning (McLoughlin 1969) where planning practice is explicitly more rational, autonomous and, “scientific,” or value-free, ignoring the politics of planning, sources of change, and conflicts between actors. It is closely aligned with global financial investment in new ICT markets or with the commercialization of new ICT products and services, and with the marketization of associated city-regional planning services. Its practice invokes visions of urban utopias and intelligent urban responses to global urban and environmental change, but in what sense are its motivations addressing a “regional problem” (Massey 1979)?

The apparent global race to delivering on smart, or “intelligent,” cities partly reflects the global capital investments in advanced producer services in ICT, the attraction of reduced expenditure on public services, and a desire to re-empower underresourced public authorities. It is an example of resurgent urban regional innovation, competitiveness, and creativity in the face of global crises experienced locally in cities. It echoes the “Third Way thinking” that Hadjimichalis and Hudson (2014) attribute to the schools of thought in new economic geography and new regionalism in the 1990s and early 2000s. Both schools championed the entrepreneurialism, competitiveness, and labor flexibilities of “model regions” in Europe and in other global regions. Under the economic pressures of regional divestment and new global competition that paralleled political economic adjustments to the formation of the eurozone, new theoretical approaches and local and regional development policies were developed around “learning regions,” “regional innovation systems,” social capital, trust, and reciprocity. The ways in which the schools theoretically responded was (at best) de-politicized at a time when what was needed was a frontal attack against neoliberalism. It is unclear as to whether this de-politicization was deliberate or an inadvertent and unintended effect because policy implementation based on these theories is blind to their effects on socio-spatial inequality. (Hadjimichalis and Hudson 2014, 212)

In Territory and Function: The Evolution of Regional Planning, Friedmann and Weaver (1979, 2–3) foreshadow the fall of regional planning with the bold claim that “the broad field of development studies, of which regional planning is a part, is currently in the throes of a profound transformation of its own which is rendering much of the received planning doctrine obsolete.” Nearly 40 years later, in a critical retrospective look at the rise of a regional planning doctrine at the turn of the century, Hadjimichalis and Hudson (2014, 208) point to a time (now) that “is ripe for a paradigm shift in theory and that this should involve a reconsideration of earlier theoretical approaches that fell out of fashion for a variety of intellectual and political reasons, and of current radical social movements.” While both sets of authors suggest a break with regional doctrine, the latter is aimed at a repoliticization of the consensus that has come to characterize regional planning doctrine at the turn of the century and onto which the ethos of smart city–regionalism has been grafted. Hadjimichalis and Hudson (2014, 215) argue for a double paradigm shift: back to earlier political economy paradigms that fell out of political and intellectual fashion, although without repeating the mistakes of the past, particularly those related to clientelism and bureaucratic statism; the other is a step forward integrating lessons from emancipatory grassroots social movements and social struggles across Europe and beyond.

Against these paradigmatic shifts in regional planning doctrine – from its early advancement,
through its subsequent fall and rise, to recent calls for its reconfiguration or transformation, the regional imperative persists: “By defining regional planning as being most commonly a process arising from tensions and gaps within systems of governance, it [the regional imperative] will always be with us” (Wannop 1995, 403). Likewise, “the search for some timeless and universal best planning practice is a quest for the Holy Grail” (McLoughlin 1992, 283).

**Future directions for regional planning research and practice**

Following Hadjimichalis and Hudson (2014), future directions for research and practice could consider urban and regional planning under global crisis. Crisis rhetoric has been couched in the modish take-up of delivering resilience to global risks to infrastructure, economic growth, and health and wellbeing. These challenges or crises are often attributed to population growth, global finance, terrorism, coastal flooding, food, energy and water shortages, affordable housing, and pandemics. Reference to such crises as the “new normal” suggests that cities, regions, and nations alike may be in a constant state of struggle or conflict with processes of global environmental change.

On the one hand, historical-materialist considerations link such crisis scenarios to societal modes of production, or a society’s ability to produce and reproduce the means of its own existence, including the institutionalization of environmental injustices as manifested in class struggle and different ways of thinking which are reflected in contemporary planned economic activity. This context subjects the state apparatus of traditional planning practice to institutional pressures of social movements, civic contestation, and an ever more pronounced “legitimacy crisis” (Habermas 1976). On the other hand, the permanent place of crisis and conflict is variably embraced by businesses, communities, and individuals, yet aimed at accepting and redirecting everyday experiences of crisis positively.

However, whereas an acceptance of crisis as a constant in everyday urban life may prompt positive collective responses from businesses, communities, and individuals to global crisis, the extent to which these “resilience dividends” (Rodin 2014) are able to address the structural challenges of uneven geographical development and sociospatial and environmental justice becomes ever more pressing.

Future regional planning research and practice would help to advance new conceptualizations of the interconnections between insurgencies and radical-subversive planning, cities and global crisis. Potential themes would include but not be limited to (i) the limits of traditional planning practice and/or cultural change and flexibility in planning under global crises; (ii) the legitimacy of urban regional planning; (iii) theories of change and stability in planning thought, positioning planning as critical theory and praxis globally; and (iv) the place(s) for radical-subversive planning beyond the boundaries of professional planning practice and planning laws and regulations.

Nationalization thesis

Modern political science has usually downplayed the importance of territory as a feature of political life. It has tended to a state-based teleology, based on the idea that history is a progress towards national integration in which function, politics, and institutions align on the same territorial basis. Territory is seen as an alternative basis for politics from class, sector or function, so as these last become important, territory must become less so. This applies to party politics and electoral competition. According to the “nationalization thesis,” social structures, value systems, and loyalties are homogenized across national space and political alignments and party systems follow. Lipset and Rokkan (1967) showed how party systems and electoral cleavages in Western Europe configured along national lines as borders were closed and politics turned inward. These cleavages were then “frozen,” in spite of social and economic change. Later, however, Rokkan (1999) noted that national integration was often incomplete, with older cleavages surviving due to the uneven impact of economic and cultural integration. Since then, interest in the politics of territory has increased, with a substantial literature on regions and stateless nations. Yet Caramani (2004) has argued, with detailed evidence, that nationalization continued through the twentieth century. So, is territorial politics becoming more or less important? To answer this, it is necessary to disentangle the strands of the argument, distinguishing convergence of values from convergence of political behavior, and taking into account the role of parties themselves in shaping political space. The assumption that territory must give way to other forms of social and political differentiation must be relaxed. Instead, politics refracts and shapes these other factors in multiple ways.

The first point to note is that voting and party competition may converge even in the absence of social homogenization. Parties seeking power at national level will build state-wide coalitions, which may require compromises to meet particular regional conditions. Indeed, Caramani (2004) shows that homogenization of voting patterns occurred in the nineteenth and early twentieth century (for the left), before social homogenization. Some examples can illustrate this. The Italian Communist Party in the 1950s advanced in the south by gestures to land reform, peasant ownership, and autonomy, which it had previously rejected. In early twentieth century Wales, Labour took over the nonconformist and Welsh-speaking ethos from the Liberals. French Socialists penetrated Brittany in the 1970s by playing down the anticlericalism that marked the left in the south of France. Scottish conservatives forged an alliance of urban protestant populism, the urban middle bourgeoisie, and a deferential rural vote, quite different from English conservatism. Scandinavian agrarian parties enlarged their bases to become centre parties (Caramani 2004). Left-wing parties in Catalonia, the Basque...
REGIONAL POLITICAL MOVEMENTS

Country, Scotland, and the Hapsburg territories synthesized class and nationality politics in different ways.

Second, voting behavior can diverge in the absence of differentiation in values. Just as nationalization does not always indicate a deeper social homogenization, so the re-emergence of territorial politics might not stem from a reversal of homogenizing tendencies at the deeper level of values or social structures. Indeed, as with the nation, the region may be a space for the realization of universal values, whether of liberalism, the market, or welfare.

There is evidence that values converged across European territories from the mid-twentieth century, mainly as a result of secularization (Chauvel 2002). On the other hand, some territorial identities, value systems, and social practices persist over time. They have been detected across Europe (Todd 1990), in France (Le Bras 1995), in Poland (Baldersheim and Swianiewicz 2004), and in Italy. These are not mere legacies of premodern societies but have shaped modernization itself. It is known that nineteenth-century modernization was accompanied by a rediscovery of territory (Keating 1988) and a re-invention of tradition to make sense of it. Similarly, in the late twentieth and early twenty-first century, territorial identities and cultures have been rediscovered and modernized.

Late nineteenth century Europe saw an explosion of regional and nationality movements, with a diverse agenda. Some stressed defense of the church against the secularizing state. Some spoke for local communities against new forms of capitalist production and the peripheralization of former trading regions as the state imposed new boundaries. Others were based on language and others again supported a traditional social order against centralized government. The late twentieth century saw the rise of a new regionalism (Keating 1998), with a different agenda. One issue again concerned language and its social usage. Another driver was economic restructuring and competitive regionalism as states lost control of their spatial economies and “spatial Keynesianism” reached its limits. There were issues of welfare state restructuring and the displacement of older systems of territorial representation by modernizing states. European integration has further undermined state capacity for territorial management and opened up a new level of politics. This has posed a new agenda for territorial politics.

Economic disparities have provoked two types of territorial opposition. There is a “revolt of the poor” in regions that are marginalized in national economies and unsatisfied with the response. More important in recent years is a “revolt of the rich,” in which movements in wealthy regions complain about the burden of national solidarity. These distributional conflicts have become more serious in the context of the opening of national markets, which weakens the capacity of states to manage their territorial economies and puts an emphasis on interregional competition.

So the relationship between party politics and territorial societies is rather complex. Party competition is molded by territory but parties themselves both shape and respond to local demands (Caramani 2004). A territorial dimension has emerged to party systems and elections in the United Kingdom, Italy, Belgium, Germany, and Spain (Swenden and Maddens 2009). State-wide parties in territorially differentiated societies are caught in the middle, alternating between trying to homogenize politics and accommodating local differences. In Belgium, they have fallen apart altogether into territorial-linguistic components while in Italy, Spain, and the United Kingdom they manage the tensions more or less successfully.
Imagining regions

Regions cannot be taken for granted as political spaces but are discursively constructed by political actors themselves. This includes the definition of boundaries, both territorial and social, and the criteria of inclusion. Regions are, however, notoriously loosely defined spaces, without the clear citizenship-based definitions that states can use. At the popular level, conceptions of who belongs to the territory vary and are often based on overlapping categories, including birth, ancestry, assimilation, and will, without a clear hierarchy. Not only do the criteria vary but so does the way they are used. So language may be used as a marker of exclusion or a mechanism for inclusion and integration. Social citizenship may be extended to all residents, or restricted. Integration policies may also be linked to the needs of region or nation-building. So Scottish nationalists are inclusive and pro-immigration for economic and demographic reasons and to legitimize their project. Catalanists accept that integrating incomers is a necessity if the national project is to survive. By contrast, Italy’s Lega Nord has defined Padania against a series of “others,” be they southern Italians, non-European migrants, or muslims. Basque nationalism has moved from the criterion of bloodlines to a more inclusive definition of identity. Some movements in boundary regions seek to distance themselves from neighboring nationalisms by constructing a multi-ethnic or multicultural identity (Stjepanovic 2012).

The construction of the region often involves the attribution of specific values or stereotypical traits. Bavarian regionalists merge tradition and modernity as laptop und lederhosen. Catalanists stress the consensual and pactist traditions of their society, rather than the social conflict that marked early twentieth century Catalonia. Tuscan region-builders exalt the cooperative traditions of the region, the place where the catholic and communist traditions meet together around themes of civil society and subsidiarity. Tuscany and Lombardy vaunt their models of policy-making and service delivery as distinctive. Scots recycle myths of egalitarianism, while in Wales the dominant theme is community. In Brittany, shared identity and cooperation are taken as the markers of local society. In this way, values that are in themselves universal and transferrable can be pressed into the service of a particularist project.

Like nation-builders before them, region-builders need to link past, present and future, pressing history into use and giving themselves a modernist teleology, to combat the older, archaic visions of regional space. They have bought into the new economic regionalism, which presents the region as the space, par excellence, for economic modernization and dynamism. This, too, is projected into the past, as in Flemish region-building from the 1990s and as in Catalonia and the Basque Country (Ibarretxe 2010). The region is credited with the civic virtue that underpins social capital and with an ingrained entrepreneurialism (Keating, Loughlin, and Deschouwer 2003). In another search for legitimacy, regions are vested with democratic and liberal traditions. So in Brandenburg, official region-building has sought to reinterpret the Prussian legacy, rediscovering a liberal tradition. Traditions of popular rule and of pactism in Catalonia and the Basque Country have been opposed to Castilian authoritarianism. Neotraditionalist cultural movements in France and Spain are linked to ecology and opposition to global capitalism.

Territorial definitions of the region are contested. Catalonia and the Basque Country can be defined expansively, based on cultural and linguistic criteria (the Països Catalans and Euskal Herria) or administrative ones, based on their
REGIONAL POLITICAL MOVEMENTS

respective autonomous communities. Modern Flanders is constructed using linguistic criteria and historic materials to unite previously disparate historic units (Kerremans 1997). Bavarian regionalists have added a wider area into the historic community. The Lega Nord has invented Padania, which stretches from the far north of Italy to somewhere around the center. In practice it and its component leagues have opportunistically used many different spaces, tapping into localist and provincial identities often more than regional identities. Progressive political forces have deployed an alternative concept of North East Italy, drawing on European new regionalist ideas but sometimes invoking the Venetian Empire. As the Europe of the Regions idea developed, some regionalists claimed that their territory was quintessentially European. Some regions are imagined as cross-frontier zones. The concept of Middle Europe (Mitteleuropa) is deployed because of its territorial vagueness combined with its positive historical resonance as an alternative to the nationalizing state. Discursive constructions build on pre-state identities, often interpreted anachronistically to suggest precocious forms of statehood.

Regionalisms may challenge the state and merge into counternationalist movements. The difference between regionalism and nationalism is not a descriptive or even analytical one but has a strong normative content. Political movements that describe themselves as nationalist are making a claim for self-determination, possibly as a separate state but sometimes on a federal basis. At the start of the twentieth century, Catalan regionalists transformed into nationalists but not (mostly) separatists. Flemish regionalists sometimes call themselves nationalists and sometimes not. Some movements oscillate between defining their communities as nations or regions, depending on the context, as in Belgium, France, and Italy. These semantic games have a deeper purpose, in shaping the movement to fit with legitimating principles and, in the case of those consistently defining themselves as nationalists, putting themselves on the same normative plane as established nation states. Other regionalisms are deeply loyal to the state but to a particular form of it. So Bavarian regionalism has mostly been about a way of being German; French regionalism opposes the “Jacobin” conception of the state, not the French nation.

Territorial parties

Territorial parties vary both on the left–right and the autonomy axes. Regionalism in Germany and Austria has been associated with the political right, as it was in France until the 1960s when it was taken up by the new left and environmentalists. In Italy, it is historically associated with liberalism, although the left has blown hot and cold on it and Christian Democracy has also had a regionalist wing. Since the 1990s it has found its strongest expression in the rightist populism of the Lega Nord, which itself has to accommodate a poujadist, small business element and a working class vote that expanded rapidly over its years of expansion. Flemish nationalism tends to the right, with a weaker social democratic strand. In the Basque Country, Catalonia, and Galicia, regional nationalism covers the political spectrum except for the extreme right, as that is associated with Spanish nationalism. Nationalism in Scotland historically leans to the center-left but with a center-right tendency always present. Some territorial movements have produced catch-all parties, spanning the range of class and ideological appeals, and positing a common territorial interest.

An essential context for regional political movements since the 1990s has been the changing European and international order, which
may provide new opportunities for territorial autonomy outside the state framework. For separatists, European integration lowers the cost of secession, providing an external support system and dealing with externalities like market access, security, and borders. Others have embraced the Europe of the Regions, a concept that developed during the 1990s, seeking a role as a third level of government within a new political order. Some have been more radical and gone for “post-sovereignty,” arguing that traditional notions of sovereignty are outdated in modern Europe, where authority is shared at multiple levels.

Parties whose own values are closer to those of the European project, rooted in Christian democracy, social democracy or liberalism, have found it easier to use Europe than have extreme right, extreme left, or xenophobic parties. The Lega Nord was initially in favor of Europe, at one point proposing that northern Italy could join the Euro while the south could keep the lira. When it entered government with the post-Fascist Allianza Nazionale, however, it was expelled from the European Free Alliance of regionalist, nationalist, and Green parties. It then turned virulently anti-European. The Vlaams Belang (formerly Vlaams Blok), a xenophobic party of the populist right, was always hostile to the European project.

Adaptation to post-sovereignty ideology is easier in places that possess a historical legacy of mixed sovereignty and interdependence. Catalan nationalism harks back to the kingdom of Aragon, a confederation of Catalonia, Aragon, Valencia, and the Balearic Islands, within the kingdom of Spain, and to Catalonia’s history as a Mediterranean trading nation. Basque nationalists point to the fueros, historic rights of the Basque provinces within the Kingdom of Castile and then Spain, as a rationale for shared sovereignty with Spain as an alternative to the radical separatism of their founder Sabino Arana. In the early 2000s, first minister Juan José Ibarretxe elaborated a plan to make the Basque Country a “freely associated state,” linked with Spain and within a European framework (Keating and Bray 2006). Moderate Flemish nationalists place their project within a European support system, seeing the growth of Europe and of Flemish self-government as complementary.

The Europe of the Regions movement peaked during the 1990s but then stalled and made little progress in the Lisbon Treaty of 2009. This failure produced some disillusionment with Europe as a means to find a middle way and encouraged territorial parties to move towards independence pure and simple (Elias 2008), for example, in Plaid Cymru (Party of Wales) and among Flemish, Basque, and Catalan nationalists. When it comes to specifying their proposals, however, these movements tend to come back to varieties of sovereignty-association and partnership. Even the Scottish National Party, which is in favor of full independence, links this to the maintenance of various unions with the United Kingdom, including a currency union. In a similar way, Quebec nationalists have veered away from versions of sovereignty-association and back again.

Regional parties have been able to exploit the erosion of support for mainstream parties and crises of national party systems. The fall of Italy’s partitocrazia in the early 1990s provided an opportunity for the Lega Nord to revive the territorial dimension of politics. Gradual erosion of Britain’s two-party duopoly allowed for the emergence of the Scottish National Party and Plaid Cymru. Constitutional crises in Belgium led to the successive fragmentation of all the parties on linguistic lines. German unification left a serious territorial cleavage, with the eastern Länder giving disproportionate support to the Links Partei (Left Party), based on the old East
REGIONAL POLITICAL MOVEMENTS

German communists (Hough and Koß 2009). In some regions, such as the Aaland Islands, Greenland, and Northern Ireland, the state-wide party system has never taken root in the first place.

State-wide parties have adapted more or less effectively to the new territorial challenge. Conservative parties can draw on ideological reserves of traditionalism and suspicion of the state. Christian democrats can use the ideas of subsidiarity and autonomy, which are part of their tradition, but must reconcile these with state nationalism, also part of their ideological portfolio. Liberal parties often had local origins, in networks of local notables, and harbor suspicions of the centralized state, but they also have centralist traditions. Neoliberalism might, in principle, seem compatible with regional autonomy but, in practice, neoliberal parties have not been notable regionalists, probably because the region is seen as yet another layer of interventionist government. Social democratic parties have both centralist and decentralist traditions. In the postwar years of the Keynesian welfare state, they favored centralized economic management, top-down regional policies, and spatial redistribution of welfare. The left saw regionalism and nationalism as a distraction from the class struggle. Since the 1970s, social democrats have rediscovered regionalism and localism, and used them in their advance in local government to secure power at the center. Their decentralist zeal has not always survived their return to power at the national level. Trades unions and the left have been drawn into local struggles over plant closures. Social democrats have had to respond to challenges from territorial parties as well as the Green movement, which is instinctively decentralist.

So the territorial challenge has increased stress within state-wide parties. Some have adopted regional structures within their own organization. In others, the regional wing has a federal or confederal relationship with their state counterparts, as with the Catalan socialists and the Bavarian Christian Social Union. The Spanish Partido Popular had for some years to defer to the Unión del Pueblo Navarro as the representative of conservatism in Navarre. The Basque socialists have absorbed an older nationalist party. State-wide parties have given more or less autonomy to their territorial branches, provoking some considerable tensions in Spain and Britain, while in France and Italy the parties remain a centralizing force.

Regional political arenas

The electoral nationalization thesis has been linked to the concept of “second order elections,” in which voters use European or local and regional elections to reward or punishment national governments rather than voting on issues appropriate to that level (Reif and Schmitt 1980; Hough and Jeffery 2006). In Germany, France, Spain, and Italy, national opposition parties usually perform well in regional elections, which are then taken as a mid-term verdict on the national government. On the other hand, in Scotland, Wales, the Basque Country, and Catalonia, local nationalists do better in devolved than in state-wide elections, because they are seen to stand up for the territorial interest (Liñeira 2011). In France and Italy, where the electoral systems favor pre-electoral alliances, slightly different coalitions are put together for regional elections. In Spain outside the historic regions, there has been a proliferation of regional parties competing only in their own autonomous communities, and the regional frame of reference has strengthened over time.

There has been some personalization of party politics at the regional level. National parties have had to live with dissident but successful local
politicians, such as Ken Livingstone in London in 1999 or Francisco Alvarez Casco in Asturias in 2011. In Spain and Germany, party “barons” have carved out a margin of independence and have become brokers in state-level politics and candidates for national office. Local office is an important asset for French national politicians, as city mayor or, since the 1980s, as president of a regional council. Such leaders, lacking automatic sectoral or class support, will usually make a “catch-all” appeal, claiming to embody the interests the region, over and above sectional concerns. Promises of economic growth and competitive regionalism are effective ways to unite the territory, while pitching it against rivals. Such appeals both draw on, and serve to build, a territorial identity, while forcing other parties onto the same agenda.

Multilevel systems give parties the opportunity to play a differentiated political game by forming different alliances or coalitions at each level. The interdependence of the levels in Belgium and the existence of single political class (albeit linguistically divided) induced politicians there to maintain congruent coalitions, although this has begun to break down with the rise of the nationalist New Flemish Alliance. The main German parties experimented with all possible coalition combinations at the two levels (Detterbeck and Jeffery 2009). In Spain, territorial parties have an advantage because the electoral system is based on the provincial lists, favoring territorially concentrated ones. This means that territory and partisanship are always combined in the forming of governments. Non-state-wide parties have given parliamentary support to minority Spanish governments in return for concessions on autonomy and reciprocal support for minority governments in their home territory. At the same time, they try to balance out their alliances by playing off the main Spanish parties, which has often meant different parliamentary coalitions at the two levels. In France and Italy, regional coalitions have been formed with different mixes of parties but they respect the basic right–left division, with no governments bridging these poles. Devolution in Scotland and Wales has allowed for a variety of coalition arrangements centered on the Labour Party, with the Conservatives being the only significant party not to have participated in devolved government.

Rescaling politics

The emergence of regional political movements is part of a wider process in which functional systems, identities, political mobilization, and institutions are migrating to new territorial levels above and below the state (Keating 2013). These trends are sometimes portrayed as an outcome of economic imperatives and functional logic (Alesina and Spoloare 2003). In fact, such trends provide the context but do not yield a definitive outcome. It takes political movements to use these opportunities to create new political spaces and power bases. There are centrifugal trends as regional parties use regions as power bases and these, in turn, generate institutional interests in further autonomy. Yet these are balanced by centripetal forces as regional politics is played back into the national arena. The economic crisis has had contrasting effects. On the one hand, it has accentuated competitive regionalism as systems of fiscal equalization come under strain and movements in wealthier regions emphasize autonomy and the need to keep their own taxes. On the other hand, poorer regions look more to the center. So as Catalonia and Flanders press for more fiscal powers, their poorer compatriots seek to conserve the national framework and, in the case of some Spanish autonomous communities, even want
REGIONAL POLITICAL MOVEMENTS

to hand powers back. Similar territorial strains are observable in Germany, albeit without the element of separatism. Territory now frames debates around the size of the state, austerity, and welfare reform and will remain an integral part both of state and European politics.

University of North Carolina at Charlotte, USA

Defining regional science and the essence of the region

The region has been a core concept of geography, and of many of its branches, since times that even precede its formal establishment as its own field of study. In geography, the region is usually seen as a land area with certain attributes and characteristics that differentiate it from others that are spatially separate. It has long been a unifying concept that used to define the very nature of geography in the minds of some scholars of the discipline, who saw it as the patent expression of the unique relationship between land and the physical environment on the one hand, and people and their agencies on the other. Today, the concept of region remains prominent in geography as it is widely used as an operational means to classify and categorize places based on the shared properties they exhibit. Regional geography itself is the study of places and spaces that constitute regions due to the unique characteristics of their human and natural elements.

Like geography, regional science studies the region. Yet, while regional science and geography share some common intellectual roots and remain closely intertwined fields of study, their modes of inquiry and the specific objects of their studies are different but largely complementary. Regional science is a social science that is concerned with the socioeconomic workings of human societies within the context of a region. The region is a geographic territory, but in the words of the founding father of this field of study, Walter Isard, it “is not merely an arbitrarily demarcated area; rather it is an area that is meaningful because of one or more problems associated with it which we as regional scientists want to examine and help solve” (1975, 1).

As a territorial construct, the meaningfulness of a region is not tied to an arbitrary size, but its size stems from the territorial scope of the problem at hand. For instance, the Washington, DC, metropolitan region defines the proper geographic confines for the understanding of traffic congestion in Washington, DC, in terms of the effects of infrastructure investment strategies, regional governance structures, commuter sheds, and land-use planning strategies. On the other hand, the dearth of trade between Southeast Asian nations is best analyzed for this set of countries as a whole to underscore their deficient fiscal and monetary policies. Finally, a small Midwestern town is the proper regional context in which to assess options for workforce retraining and business strategies after the loss of a major employer. Hence the designation of the region is problem-driven; it is fluid and changing according to the evolution of social, economic, and political conditions, and the study of its longitudinal transformation may itself be of interest as it reflects the evolution of structuring processes of the region. Importantly, the region can reflect and capture multiple scales. When drilling down to the basic agents that are collectively driving the dynamics of the region (such as the citizen, the customer, the patient, the worker, or the firm
or plant), regional science can recognize and analyze the individual locations where the agents are sited. These locations can be regarded as the most elemental regions. Socioeconomic structures exhibited by these regions, as well as their organization into systems, also define the object of regional science.

Each region is supported, and in a sense defined, by a distinctive socioeconomic organization that regulates its workings and its dynamics. Equally important, regions entertain relationships with others to form larger ensembles, or systems, that intersect in different and complex ways, including hierarchically. Sociocultural agencies display these organizational tendencies and private businesses have their own territorial footprint, both on the demand side and on the supply side. A tenet of regional science is that the region and its socioeconomic complexion result from the cumulative interaction between its own human, social, and natural resources and initiatives (local and intraregional processes), how these processes operate across the boundaries of regions (interregional processes), and how they relate with larger regional ensembles or the rest of the world (the global) (hierarchical or multiscalar processes). Some of these systemic processes may be institutionally driven (top down), while others emerge from the bottom up. It has been argued therefore that complexity theory is well suited to frame the dynamics of urban and regional systems (Batty 2005). When an entire regional system is studied as consisting of multiple territorial units, and these units belong to distinct national entities, the policy and political dimensions (including financial matters, national security, and so on) may take precedence over the socioeconomic considerations that are typically at the forefront of regional science research.

Distance is a key feature of socioeconomic structures in a regional context. As such it is also one of the foundational concepts of regional science. Distance is important to regions because it measures the dissipative effect on socioeconomic processes that operate between places and regional territories that are not co-located geographically. While ideas and information are exchanged between individuals and organizations at rates that depend on their own logic, a customary mitigating intervening factor is distance (or some other measure of effectual impedance of the geographic space) (Brown 1981). Social interactions that manage to survive over greater distance are usually looser than those between nearby nodes of a social network, even when this network entirely operates in a virtual space, as social media do. Social and institutional controls are weaker over areas remote from the social core of a region. Similarly, the magnitude of tangible flows of commodities and people (e.g., commuter flows) strongly responds to transportation or shipping costs, which vary in direct relation to distance.

From this brief introduction to the essence of regional science, it may be construed that geography and regional science are in fact one and the same. Their shared intellectual heritage is undeniable and many geography scholars are also scholars of regional science. However, regional science was established to articulate an interdisciplinary perspective on socioeconomic structures within regions and spaces. As such, regional science benefits from contributions from economics, sociology, engineering, planning, and other disciplinary fields. Points of departure between geography and regional science are more than a matter of detail as will become clear through the rest of this entry. Interestingly, geography’s own quantitative revolution occurred in the same years that the essence of regional science was crystallizing in the minds of a few key intellectual leaders (incidentally, some participating in both movements, such
as Edward Ullman, Michael Dacey, William Garrison, William Warntz, and others). In sum, regional science and geography, along with geographic information science, share a common core of concepts, frameworks, and methods, which are collectively subsumed by the umbrella term “spatial sciences.” It should be pointed out that spatial science is the name that was originally envisioned before regional science was settled on.

A brief history of regional science

Regional science was formally born in the United States in the 1950s at a very auspicious time. Coming out of World War II, the United States was positioned to take advantage of incipient economic growth opportunities stemming from new technological innovations, the opening of new markets, financial strength, and more proactive public initiatives in cities, transportation, social welfare, job training, and the energy sector. It became clear to young economist Walter Isard and others that established economic orthodoxy was ill-suited to handle these challenges as it was still wedded to the principle of socioeconomic systems devoid of any spatial extent and spatial context such as transportation and communication costs, and that it failed to recognize that the fortunes and misfortunes of human communities are tied to their internal social and economic logic, to their intrinsic factor endowment, and to the efficiency of interregional networks within national and international contexts. Thus, regional science emerged squarely as a product of its time.

The scientific roots of regional science can in fact be traced much further back in time, namely to the 1826 treatise The Isolated State, written by German economist Johann Heinrich von Thünen. This book provides an analytical argument for the existence of a pattern of crops and land uses according to distance factors, yields, and production costs through the mediation of the land rent. Thünen and his notable followers Wilhelm Launhardt, Alfred Weber, Walter Christaller, and August Lösch established the so-called German school of spatial economics or location theory, which addresses the factors affecting the locational choice of economic activity, including industrial plants, agricultural crops, urban land uses, cities, and so on. Ponsard’s (1958) account of the early history of regional science also recognizes the path-breaking contributions of Swedish economist Tord Palander and American economist Edgar M. Hoover to location theory in these pre-formative years.

The launch of the Regional Science Association (subsequently renamed Regional Science Association International (RSAI) in recognition of its broad international scope) in 1954 was instrumental in the emergence of regional science as a new social science distinct from economics, geography, and sociology. Today, RSAI has an active membership that exceeds 4500 scientists and practitioners distributed over all world regions, and continues to expand its reach in developing countries of Asia, Africa, and Latin America. The scholarship of regional science is primarily published in several core journals, including Papers in Regional Science, Journal of Regional Science, Regional Science Policy & Practice, Regional Science and Urban Economics, and Annals of Regional Science, as well as a number of allied journals such as Geographical Analysis, Growth and Change, Environment and Planning A, and Computers, Environment and Urban Systems. Owing to their extensive research on urban and regional socioeconomic systems, recent Nobel Prize Laureates Paul Krugman (2008) and Daniel McFadden (2000) have left lasting impacts on fundamental theories and methods of regional science.
Regional science in perspective

Regional science resolutely espouses a scientific approach to conceptualize research questions in their regional context and to articulate analytical frameworks that enable researchers to identify and evaluate business, planning, or policy solutions. Like neoclassical economic theory, regional science is based on a strong axiomatic logic that explicitly recognizes the role of various socioeconomic actors, often predicated on the assumption of full and perfect information dissemination, and economic rationality. In this framework, new residents seeking housing are expected to optimize their personal utility which is derived from the characteristics of residential options, once their contributory value to the potential resident has been suitably assessed. A broad set of characteristics (including locational and distance factors) would typically be considered as causal predictors in the individual decision process, and allowance is made for the inability of the analyst to observe or measure every characteristic of the choice situation by resorting to random utility models. Similarly, firms are assumed to be driven by profit maximization imperatives to structure production and distribution, including decisions on what to produce, where to produce, where to source inputs from, and what markets to serve from each facility. This scientific approach has produced an extensive corpus of theories that aim to understand socioeconomic processes at the regional scale and their interactions across regions, ranging from urban real estate markets to emission reduction through public transportation systems, and from innovation-driven economic growth to local taxation systems that establish the equilibrium self-sorting of human communities. Socioeconomic processes at the core of regional analysis often follow a behavioral paradigm that gives rise to the sorts of assumptions noted above.

Since its inception, regional science has been data-centric, aiming to empirically validate the theories and operational models developed analytically. Many primary data sources are available for this purpose, often resulting from governmental data collection initiatives. The decennial Population and Housing Census in the United States and similar initiatives in other countries have supplied critical data at fine levels of geographic granularity (census block, block group, or tract) to test spatial theories of spatial organization of cities such as social area analysis, gentrification and urban filtering theories, theories of real estate markets, transportation theories of urban commuting behavior, regional demographic models, and many others. Economic and labor censuses and annual surveys are staples of economic development models and theories such as the regional economic convergence theory and regional and interregional input-output models, theories on firm creation and innovation, and theories about entrepreneurial environments, human capital (workforce training, education), and metropolitan economic performance. In fact, the considerable demands that spatial data collection, manipulation, and management typically place on regional scientists have made them earlier adopters of geographic information systems (GIS) and technologies necessary to handle such data (Anselin and Getis 1992). Not only did these systems engender greater efficiency in the conduct of regional analysis, but the enhanced capability to do geospatial data processing afforded by GIS enriched the representation of spatial relationships among economic agents (like the substitution of economic and time impedances for simple contiguity-based spatial weight matrices (Gatrell 1984)) and ultimately increased the explanatory and forecasting power of regional models.
As pointed out earlier in this entry, Walter Isard’s drive to stamp a new theoretical paradigm of socioeconomic structures based on the concept of region was prompted by the pressing need to better understand the differential ability of place-based communities to cope with fast unfolding waves of social and economic restructuring in the post-World War II era. Regional science was born as a problem-driven discipline, and has remained so to this day. Early successes at alleviating social and economic hardship on communities at the local or more regional scale, and at formulating path-breaking public policies that leverage local human or natural resources and emerging market opportunities at broader geographic scales, have demonstrated the policy relevance of regional science. The same theories and methods of regional science have also been praised in business practice. In contrast to other perspectives such as regional development or planning, regional science brings to regional policy and practice a “sense of place” (Bolton and Jensen 1995) in conjunction with an understanding of how the place or region maintains socioeconomic relationships with others within a broader economic space through networks or functional flows. Thus, efficacious policies or business decisions account for both local and more global conditions. Edward Ullman (1954), a geographer and earlier advocate of the regional science perspective, relentlessly promoted the radical position that spatial organization and geography are created by processes of socioeconomic interaction between places and regions. Today’s regional practices and technologies have internalized this view.

Core research themes and theories

While the subject matter of regional science consists of socioeconomic realities as they occur in territories that collectively form a space, different research streams have classically focused on different topical areas, often blending different theoretical frameworks and calling for specific methods of analysis. We will briefly touch on five such research traditions in this entry and readers can find a more detailed overview in Fischer and Nijkamp (2014) and Mulligan (2014).

Environmental and resource analysis

The physical environment and natural resources are an integral part of the makeup of a region. As early as the 1960s, the inextricable interdependency between socioeconomic systems and ecological and other natural systems was recognized and explicitly incorporated in models of regional analysis, most notably in input-output models and computable general equilibrium models of regions and systems of regions (find more detail on these models in the “Methodological legacy” section later in this entry). Isard (1975) referred to them as “Combined Economic-Ecologic Systems,” which three decades later would be recast as “Coupled Human and Natural Systems” (CHANS) in other fields of study. The principle is to extend the framework of economic accounting of inputs and outputs of a region, which typically include wages, final consumption by households and government entities, and sales and purchases of intermediate products and services by businesses, to encompass ecologic commodities from and to the environment. A number of such commodities are already included in economic accounts to the extent that they are priced properly at the market. This approach is critically important in case of nonmarket transactions, which are so common in the context of the environment. It is related to a desire to evaluate unpriced effects when the market is patently failing and externalities exist. This would be the
case of pollution of the atmosphere, streams, and soils, resource depletion (i.e., forests and other ground cover, surface and subsurface water reserves, etc.), and others. It should be pointed out that externalities often exhibit a spatial dependency as spillover effects dissipate with distance from the source; environmental externalities manifest themselves within the territorial confines of regions, yet they can also affect interregional relationships. The combined economic-ecologic systems approach is well suited to the study of interdependencies at multiple spatial granularities, such as the localized impacts of global and interregional trade on CO₂ emissions and therefore climate change. It has been central to the articulation of the scientific discourse on resource-based limits to growth and of the principles of sustainable urban development.

In related research, regional science has studied the extent of the validity of a localized relationship between economic development and environmental quality. The environmental Kuznets curve postulates the existence of an inverted U-shaped relationship where environmental degradation tends to worsen as modern economic growth occurs, up to a point where the course of development enhances environmental quality. Evidence in this respect has been mixed, depending on the environmental metric, the region, the geographic scale, and the modalities of interregional commerce. The regional policy aspects of the environmental Kuznets curve are considerable as it may offer an expedient rationalization for delaying the adoption of tighter environmental protection standards.

Following conventional economic development wisdom, natural resources are regarded as a blessing to well-endowed regions. After all, abundant coal deposits were instrumental in the success of the Industrial Revolution in narrowly circumscribed regions of the United Kingdom and Belgium in the eighteenth and nineteenth centuries. Yet the idea that natural resources may instead be an economic curse gained traction in the 1990s. Widespread evidence now exists in China, Africa, the Middle East, and other parts of the world that regions with natural resource abundance experience poor economic growth. This points to two significant insights. First, space and the region matter for the understanding of socioeconomic structures. Second, these structures are complex and multifaceted and cannot be boiled down to environmental determinism.

Location analysis

As pointed out earlier, regional science grew out of the nineteenth- and early twentieth-century traditions of location theory. This theory underscores the role of transportation costs, along with other costs related to shipping from sources to production sites and then on to markets (transaction costs), on the locational equilibrium of economic activities. Although Cairncross predicted the death of distance in the 1990s, distance remains a significant force in locational decisions at the local, regional, and global scales (McCann and Shefer 2004), yet under notably different modalities than before. Nodal access to communication networks and mobility systems for human, social, and financial capital (such as airports) has emerged as a dominant locational factor in postmodern economies.

By explicitly recognizing the existence of transaction costs associated with travel and shipping across the geographic space, and the monotonicity of these costs with distance, location theory marks a dramatic departure from conventional economic analysis, which is largely framed in terms of perfect competition. In fact, location theory has demonstrated that, because of the geographic space, imperfect competition prevails and spatial competition often boils down
to spatial monopolies or oligopolies (Thisse 2011). Markets are intrinsically spatial and their geography exhibits many of the properties of other geographic phenomena, particularly spatial dependence.

Since its inception, location theory has expanded from explaining the spatial organization of single economic activities to explaining why firms in various industries and households co-locate in the geographic space. Christaller’s central place theory and the many extensions of it that have sprung up since the 1930s to account for the spacing, number, and functional complexity of urban centers within a certain territory have been among the influential theories of modern spatial sciences. Explanations for co-location or agglomeration are multiple and include factors from exogenous first-nature elements studied extensively in geography (political geography, physical geography) to endogenous second-nature factors. The latter include customer behaviors (e.g., multipurpose shopping), as well as supply-side considerations such as localization and urbanization economies that materialize only where some degree of agglomeration is achieved. In all these cases, geographic proximity is the catalyst to generate savings through travel cost reductions, knowledge spillovers, more effective labor markets, and other means (Rosenthal and Strange 2001). These are precisely the triggers of the emergence of regional growth poles (Isard 1975), which exploit the input-output linkages between industries. Growth pole theory and its more modern version, industrial cluster theory, continue to shape regional economic development strategies across the globe.

**Regional analysis**

Regional analysis focuses on three fundamental questions about regional economic growth (i.e., the rise in economic wellbeing of populations of a region). It seeks to understand the processes and factors of regional economic growth, the longitudinal fluctuations in the rates of growth exhibited by regions (e.g., what may lead to a region’s decline), and finally the geographic concentration of growth in rather confined territories (e.g., the spikiness of economic wellbeing across the world). Factors of regional economic growth can be sorted into elements that are internal to the region itself, such as natural resource endowment, capital formation, and labor or human capital, which foster endogenous growth, on the one hand, and factors related to the commercial relationships entertained by the region with other regions, on the other hand.

Early research in regional analysis was in line with economic base theory, which distinguishes basic industries, those exporting from the region and bringing wealth from outside, from nonbasic industries, whose function is to support basic industries locally. The split of total employment between basic and nonbasic is what determines the multiplier effect in the regional economy, and thus the rate of growth. Input-output analysis (Isard 1975) extends economic base theory by explicitly recognizing the interdependencies between industrial sectors of the regional economy through matrices of aggregate transactions in the economy, along with estimates of imports and final demands. As a structural macro-economic equilibrium model of the economic system, it is a regional accounting system that simulates the cycling of money through the economy over the short term and the long term. When multiple regions are distinguished, transactions between regions as well as within regions are recorded. Input-output models have fixed prices for factor inputs, which precludes the estimation of relative price elasticity of substitution between pairs of factor inputs and restricts their usefulness for policy analysis. The
more recent computable general equilibrium (CGE) framework generalizes input-output analysis by allowing price variation among inputs; the relative price elasticity of substitution is estimated econometrically. The input-output and CGE frameworks both allow estimation of the direct, indirect, and induced effects of an exogenous stimulus (e.g., new investment, change in fiscal regime, change in transportation costs, etc.) within and between regions, while the dynamic characteristic of the latter enables an emphasis on technology changes over the long run (up to 100 years). Both regional accounting frameworks are in line with the more theoretically grounded new economic geography model. Particularly noteworthy is the common emphasis on transportation costs and on increasing returns to scale as factors structuring the socioeconomic landscape of regional systems.

A complementary perspective on regional economic growth has privileged the importance of labor-related factors of production. Under the Fordist paradigm of industrial organization and socioeconomic production and reproduction, industrialization through mass production is the benchmark of economic efficacy. Given the highly standardized tasks expected of labor in this context, the flexible availability of labor trumps other considerations. Conversely, in postmodern knowledge-based economies, human capital and social capital held in the region constitute the most prized assets for regional economic success. Workers must possess the capabilities to learn and adopt new processes, organizational forms, and technologies. In addition, entrepreneurship and new knowledge creation through innovation and invention are prime conditions in order to stay ahead of the competition, which is decreasingly localized. Research has shown that regional competitiveness and lasting economic success are enhanced by investment to expand human capital (from secondary education to college, and beyond), strategies to nurture socially and culturally diverse societies, and the formation of creative class districts. Creative milieux have been found to exhibit higher quality of life for the enjoyment of residents and to be conducive to more effective knowledge spillovers through formal and informal social networks.

Urban analysis

The urban phenomenon occupies a special place in regional science scholarship as it usually structures a region in and of itself according to its own complex socioeconomic logic, while inserting urban regions in a broader functional framework spanning countries and continents. The modern history of humanity is increasingly framed by urban life and over 50% of the world population now lives in urban regions. Systems of cities frame social organizations, whether they are regarded as market places as in Christaller’s central place theory, or as nodes of thick trade and financial flows, housing critical command and control business functions, as in Sassen’s global city networks theory (2011). Urban regions have arguably become the focal points of cultural, social, and scientific creativity and innovation. Armed with the theoretical paradigm of the new economic geography, regional science is in a position to explain the very existence of cities on the basis of second-nature principles (Fujita and Thisse 2002), namely the circular and cumulative growth inherent to locales exposed to increasing returns brought by agglomeration. This opens the question of economic efficiency of cities and the possible existence of an optimal city size, which remains hotly debated today.

Internally, the city has been conceptualized as space over which various socioeconomic agents compete for the highest and best use in relation to requirements of access to the city
center. As discussed by William Alonso, location theory explains the concentric sorting of land uses regulated by the bidding between agents who trade off land rent and transportation costs. The emerging structure of the polycentric city has also been studied in location theory, and persistent spatial differentiations in land rent, quality of life, and access to labor markets and other urban amenities continue to challenge our understanding based on single theories such as urban gentrification or spatial filtering.

The growing concern garnered by sustainable human development in contemporary societies has brought closer scrutiny on cities and urban regions as they epitomize excessive consumerism, loss of ecosystem services, and debauchery of energy use. Regional scientists have been actively involved in studying the relationship between urban form and sustainability and the policies and practices that may enhance urban sustainability. In particular, restating the inseparability of land use and transportation, new integrated models rooted in micro-behavioral principles and aimed at providing urban residents with the requisite accessibility to employment and other urban amenities without sacrificing social and economic wellbeing have become available to inform the policymaking process in urban regions.

Transportation and mobility analysis

The scientific discourse on socioeconomic structures at the scale of the region would be rather stale and incomplete without attention to the ability, and occasionally the lack thereof, to physically connect places separated by some distance from one another. Without transportation and mobility, regions do not trade, stores do not sell, workers do not commute. Transportation, along with the modern technological offshoot of communication, enables interactions and flows of commodities, ideas, and people. It is important to stress, however, that transportation differs from all other factors of regional organization of socioeconomic systems in one critical respect: the benefits afforded by transportation in enabling mobility and creating accessibility are network effects stemming from the connectedness of the infrastructure.

The ease of transportation influences decisions made by households and businesses. Nodes on a transportation system as well as at the interface between distinct modal networks (e.g., seaports or airports, train hubs) experience disproportionately good accessibility, which makes them desirable locations for households and businesses. It is also in this context that location theory explains that the long-term trend towards lower transportation costs has facilitated interregional trade, expanded market areas, and promoted regional economic specialization as agglomeration forces have seen their importance grow in relative terms. A politically contentious topic is whether investment in transportation infrastructure promotes economic development. While macro-economically the evidence is there to support such an assertion, the conclusion is much more nuanced at the regional scale. While under certain circumstances, transportation infrastructure investment has high regional multiplier effects, in others it may facilitate outside competition and put local businesses and workers at risk, and ultimately lead to a spiral of job losses and economic decline.

Regional science has been at the forefront of the study of urban transportation. This includes the assessment of land rent effects of highway and public transportation systems, on the supply side, and the estimation of the modal trip generation under alternative scenarios (including modal shifts in commute trips), on the demand side. The externalities stemming from imbalances...
between the demand and supply of transportation services in the form of traffic congestion have been a focal point of attention in regional science. Network-based equilibrium models have served to assess the efficiency and social and spatial equity implications of creating a market for such distortions through a regime of congestion pricing.

Methodological legacy

Being problem driven and policy oriented, regional science has contributed a number of techniques of data analysis and modeling to the social sciences, and to spatial sciences in particular. The following list introduces a selection of some of the most meaningful of these contributions. Several of them were tangentially mentioned earlier in this entry. A more complete overview can be found in Fischer and Nijkamp (2014).

Input-output and computable general equilibrium (CGE) modeling – These related modeling frameworks are macro-economic models based on the principle of general equilibrium to capture the interdependencies of economic sectors of a region (in the case of a single region model), or among regions (in the case of a multiregion model). They serve to evaluate and forecast economic impacts of various social, economic, trade, and environmental policies. Input-output and CGE simulations may involve thousands of equations and are computationally intensive. With CGE models, the relative price elasticities of substitution are estimated econometrically.

Spatial econometrics – Regional socioeconomic systems entail multiple entities with explicit geographic positions. Methods of spatial econometrics entail confirmatory models that account explicitly for spatial dependence in system variables, which enables regional scientists to test for distance-based diffusion and spillover effects, such as knowledge spillovers. Another operational concept of spatial econometrics is that of spatial heterogeneity, which relates to the nonstationarity of causal relationships across the regional systems according to the ambient socioeconomic context.

Spatial interaction models – Spatial interaction models form a family of models designed to quantify the magnitude of flows of interaction between individual agents (e.g., households and stores) or aggregates of agents (e.g., countries, counties) in different geographic positions. Flows are expressed as a function of intrinsic characteristics of interacting agents and of their spatial separation (e.g., economic distance). Many spatial interaction models are nonlinear and recent extensions account for spatial dependence issues stemming from the spatial layout of interacting agents.

Spatial optimization – Normative models of operations research seek to optimize decision variables in the context of scarce resources. In regional science, optimization models may serve to benchmark decisions and proposals on the basis of objectively quantifiable metrics. Alternatively, they are core elements of computer-based spatial (regional and multiregional) decision support systems used by various public and business organizations. For instance, they may identify the allocation of scarce land resources to multiple urban uses to achieve policy goals (e.g., accommodate a 20% population and 25% employment growth over a decade), enhance the spatial efficiency of a school system by selecting school locations and capacities that meet projected enrollment growth across an urban area, and design routes of hazardous material shipments so as to minimize risk to populations. Such problems
are well addressed by linear and nonlinear programming methods.

Recent methodological advances in the study of regional systems have been marked by two dominant emerging trends. The first is the multiscalarity of the analysis, in that its explicit purpose has been to better apprehend the diversity of factors that interface with regional socioeconomic structures. These would range from the individual and household attitudes, preferences, and choices, to the contextual and institutional effects at the level of the neighborhood, city region, country, and beyond. Multilevel modeling allows the effects to be sorted out (thus also capturing spatial dependence effects) and complex covariance structures to be accounted for. The second trend is the reliance on increasingly computationally intensive approaches. The greater availability of data at diverse levels of granularity and the advances in computing and information processing have opened new opportunities in spatial data analytics that the regional science community has embraced. As a result, microsimulation techniques and agent-based models (ABM) have emerged as viable analytical vehicles for research in regional science. The convergence of better data, better analytical and computational methods, and more comprehensive theories of regional socioeconomic structures may be the dawn of a new era for operational regional models, building on earlier generations of integrated transportation and land-use models.

Regional unemployment and regional labor markets

Nik Theodore
University of Illinois at Chicago, USA

Regional restructuring and employment change

Capitalist economies undergo the continual creation and destruction of jobs, leading to rising and falling levels of unemployment. New firms start up and existing firms expand, while old facilities are shuttered and some companies go out of business. These dynamics are exacerbated by cyclical swings in the economy, such as during recessions, but they cannot be reduced to the volatility of the business cycle. Rather, they are endemic to capitalism – and they produce profoundly uneven impacts across places, regions, territories, and scales.

Since the 1970s, economic geographers have developed and refined a distinctive approach to the study of regional labor markets and regional unemployment. The 1970s and 1980s were a period of tremendous economic uncertainty, and economic geographers in the United Kingdom and North America in particular, along with researchers in allied fields, sought to grapple with the dislocations that were gripping older industrial regions. Plant closures, mass layoffs, capital flight, and strike actions were widespread, clear signs that the established economic order was being radically unsettled. The tools of mainstream economics seemed to be increasingly unsuitable for the analysis of these phenomena; the discipline’s fixation with mathematical models and detached theorizing had exceeded its explanatory limits. A new approach was needed.

The analytical and methodological approaches developed by economic geographers, which evolved in contradistinction to the precepts of neoclassical economics, conceived of labor markets as being socially embedded, shaped by institutional forces and structured by power relations. A “market” like no other, the labor market does not adjust mechanistically, as described in economics textbooks, with price changes leading to the smooth balancing of supply and demand. Neither is labor simply just another “factor input” to the production process, one whose price – wages – will rise and fall depending on its availability. As David Harvey (1989, 19) put it, “The buying and selling of labor power deserves special scrutiny. Unlike other commodities, labor power has to go home every night and reproduce itself before coming back to work the next morning.” Economic geographers have in fact subjected capital-labor relations to sustained scrutiny, developing robust subfields such as labor geography, industrial geography, and global value chain analysis to analyze the shifting contours of capitalist economies.

This work has been guided by the maxim that economic restructuring – as well as labor market adjustment – is an inherently sociospatial process. Doreen Massey’s (1995, 3–4, italics in original) account in *Spatial Divisions of Labor: Social Structures and the Geography of Production*, originally published in the mid-1980s, succinctly summarized the evolving view from within economic geography: “New spatial divisions of labour (forms of uneven development) are
thorough re-workings of the social relations which construct economic space . . . . They are more than just new patterns of employment, a kind of geographical re-shuffling of the same old pack of cards. They represent whole new sets of relations between activities in different places, new spatial forms of social organisation, new dimensions of inequality and new relations of dominance and dependence. Each new spatial division of labour represents a real and thorough spatial restructuring. It marks a new form of regional problem; and more basically it marks not a new re-organisation of relations in space, but the creation of a new space.”

The differences in the approaches to the study of labor market change between economic geography and neoclassical economics perhaps could not be more stark. In contrast to the aspatial approach to studying the functioning of regional economies and labor markets found in neoclassical economics, which posits the notion that capitalist markets are self-regulating, that they tend towards a state of equilibrium, and that they lead to regional convergence over the long run, the emerging geographical perspective saw the dynamics of capitalist growth as perpetually disequilibrated and inherently prone to producing new patterns of uneven geographical development. Orthodox economic theory assumes that (i) the fundamental economic activity is exchange through competitive markets; (ii) exchange in free and unfettered markets will lead to the optimal allocation of resources; and (iii) the natural state of economic systems is a stable equilibrium. Geographical perspectives are founded on a critique of these assumptions.

Writing as the British economy was in the throes of a deep recession in the early 1980s, Doreen Massey and Richard Meegan’s (1982) *Anatomy of Job Loss: The How, Why and Where of Employment Decline* stressed that deindustrialization (the systematic reduction of industrial capacity in an area) produces geographically uneven patterns of decline. In articulating a geographical approach to the study of economic restructuring and employment loss, they urged researchers to probe beneath the broad statistical depictions of economic change that are commonly used to describe economic conditions – such as unemployment statistics, counts of business closures, and aggregate measures of income loss – and instead interrogate the underlying causes of the observed patterns. Based on research on more than 30 industries, Massey and Meegan identified three distinct forms of production reorganization that can result in substantial job losses: intensification, technical change, and rationalization. Intensification refers to a type of reorganization that aims to increase labor productivity without making major investments in capital and equipment. Intensification can be pursued through a variety of means, such as speedup, piecework, and the introduction of new forms of teamwork on the shop floor. Technical change occurs when significant investments are made in capital and equipment that result in alterations in the machines, techniques, and processes used in production. Rationalization refers to disinvestment that results in a loss of production capacity, usually due to a (relative) lack of profitability in an industry. “Rationalization … involves complete or partial plant closure, the scrapping of capital equipment and cutbacks in the labour force” (Massey and Meegan 1982, 87).

Crucially, these three causal drivers of employment loss differentially impact regional economies. Intensification, through tactics such as speedup, results in employment losses in situ; its impacts are concentrated in the places where production is currently located, and it does not imply a shift in the location of jobs. Rationalization, on the other hand, may result in changes in the distribution of employment if production
is selectively eliminated within a given industry, or if firms consolidate employment at certain facilities while at the same time others are shuttered. For regions that are reliant on a single industry or firm, or even those whose economic base is in a small number of industries, the impacts of rationalization can be devastating if plants close or if jobs are relocated to distant facilities, thereby gutting the local employment base. Finally, because technical change occurs through new investments in productive capacity, unless there is a commensurate increase in total output, these investments will lead to employment declines, either through the closing of less technologically advanced facilities or through in situ employment losses.

One of Massey and Meegan’s (1982, 88, 89, italics in original) key insights was that economic crises, ruptures in industrial production systems, and the decline of entire industries all are endemic to capitalist economies and not the result of exogenous shocks: “[E]xcess capacity … is continuously produced by the very nature of accumulation. […] There comes a point where too much capital is chasing too little profit. […] If accumulation is to continue then the capital structure must be reorganized.” In other words, the industry will be a target of restructuring, potentially with far-ranging effects on regional employment.

In *The Capitalist Imperative: Territory, Technology, and Industrial Growth*, Michael Storper and Richard Walker (1989) subsequently took up the question of how the nature of industrial restructuring impacts regional economies and the geographic location of economic activity. Like Massey and Megan, they sought to make “space … an active variable in the social system,” emphasizing the instability of cities and regions over time as processes of capitalist restructuring continually rearrange the geographical location of production as capitalists search for profit (9, 10). So too did they conceive of economic crises and spatial disequilibrium as being internal to capitalist economies, as opposed to being the products of exogenous shocks, as typically is portrayed in the orthodox economics literature.

Storper and Walker sought to advance a theory of capitalist growth and restructuring with a clear focus on their spatial expressions, one that, along with the penetrating analyses of David Harvey (1982, 1989), marked a further, forceful challenge to neoclassical economics. They placed industrial production and technical change at the heart of their analysis (as did Massey and Meegan (1982) and Massey (1995), though Storper and Walker as well as Harvey (1989) and Massey (1995) also emphasized the path-altering role of class conflict within capital–labor relations and its effects on industrial location), thereby displacing the primacy of exchange that is found within orthodox economics. They also challenged assumptions concerning the optimal allocation of resources that is said to occur through market mechanisms. And they argued, contra mainstream economics, that “industrialization, as linked to capitalist competition and the dynamics of capital accumulation, … generates a highly disequilibrated form of growth that repeatedly unhinges the existing economic order” (Storper and Walker 1989, 8). Centers of industry shift, driven by the “coercive laws of competition [that] force capitalists to search out superior technologies and locations,” producing a restless economic landscape that is shaped by cycles of boom and bust, of overaccumulation and devaluation (Harvey 1989, 136, 143). For these reasons, “equilibrium [in the sense posited by neoclassical economics] is always just out of reach” (Storper and Walker 1989, 38).

Storper and Walker then turned their attention to processes of territorial development. Like Massey (1995), they argued that through the
varied pathways of restructuring that are pursued within capitalist economies, industries produce their own geographies – in other words, they produce regions. “[I]ndustries create regional resources and not the other way around,” Storper and Walker (1989, 96) asserted, and it is in this sense that regions are constructed through socioeconomic processes (such as through flows of commodities, the mobilization of labor, and the exercise of power). Economic regions are not, in other words, naturally occurring areas that precede the actions of capital. Rather, “The spatial distribution of employment … can be interpreted as the outcome of the way in which production is organized over space” (Massey 1995, 65). But more than this, “‘space’ is not a passive surface on to which the relations of production are mapped, nor yet simply a negative constraint (in the sense, for instance, of distance to be crossed). […] In relation to production, spatial form and spatial strategy can be an active element of accumulation” (66).

Moreover, in this era of increasing international economic integration, leading firms have considerable latitude in selecting production locations and (re)organizing production over space, the scope of which has been greatly expanded with the emergence of globalizing production networks and their distended supply chains (Coe and Yeung 2015). Industries can make, remake, and mobilize space in the pursuit of profits. For example, successful industries are able to expand into formerly peripheral territories in the search for profits and market share, and lead firms are able to orchestrate supplier networks that span national borders and continental divides, often in the search for low labor costs. These processes in turn create greater regional differentiation – in labor costs, factors of production, power geometries, and so on – rather than the regional convergence posited by neoclassical economics. In short, they produce and rework patterns of uneven geographical development.

Regional unemployment

The processes of economic restructuring analyzed by economic geographers can produce upheavals in regional and local economies. Industrial reorganization; capital flight; layoffs due to intensification, technical change, and rationalization; and plant closures can undermine the employment base of regional economies, leading to economic decline and mass job loss. In studying these effects, economists commonly distinguish between three types of unemployment: frictional, structural, and cyclical. Frictional unemployment refers to the unemployment that occurs when job seekers move between posts, when students leave school to join the labor force, when workers switch careers, or when job seekers relocate to new areas. It arises because workers and employers have incomplete labor market information, creating time lags for workers who are trying to identify and secure job opportunities, and for employers who are trying to fill job vacancies. Employers must search among pools of job seekers to find an appropriate hire, and this takes time. Similarly, job seekers who are recently out of work usually must participate in multiple job interviews before accepting a position. Frictional unemployment is considered to be a feature of job-search and recruitment processes, and to some degree it is always present in the economy. Because it is taken as a sign of a dynamic labor market, and because it usually is short term, frictional unemployment is typically regarded as beneficial for the economy. It is a side effect associated with labor market dynamism and occupational mobility.

Structural unemployment is a second form of unemployment. It arises when there is a
mismatch between the type and skill requirements of job vacancies in the labor market and the qualifications of the unemployed. Under these circumstances, unemployed workers are unable to easily fill available vacancies. The mismatch might be the result of a shift in the jobs base caused by technological change which renders skill sets obsolete; the ratification of trade agreements that facilitate the relocation of industries, leaving former employees without jobs and without the prospect of fully utilizing their skills and experience; or an economy’s reliance on declining industries. Structural unemployment is a form of long-term unemployment, and it disproportionately impacts regions where economic restructuring has been greatest. The loss of manufacturing jobs in certain regional economies, for example, leaves former employees without work and unable to capitalize on skills that are no longer in high demand. Labor market adjustment and reductions in unemployment in the short to medium term are stymied because the supply and demand for certain job skills and qualifications are grossly out of balance. In depressed regions especially, less skilled and less educated job seekers may be greatly affected by structural unemployment if sectoral changes remove the jobs for which they might qualify from the local labor market. Though far less severe a problem, seasonal unemployment may also be regarded as a form of structural unemployment because economic activity in the local economy changes over the course of the year, leaving certain workers without appropriate employment. Some economists, however, consider seasonal unemployment a form of frictional unemployment because even if seasonal workers find alternative employment during the off-season there typically is a time lag before a job is obtained.

Cyclical unemployment, sometimes known as demand-deficient unemployment, is a third form of unemployment. It is associated with economic downturns – slowdowns and recessions – that occur as the economy contracts. Cyclical unemployment is caused by sharp declines in demand and it is a sign that aggregate demand for goods and services is insufficient to generate jobs for all those who want to work. When consumer and business demand falls, work orders are reduced, business revenues decline, and businesses respond by laying off workers in order to reduce costs and maintain profit levels. Unemployment rates can rise rapidly if demand plummets because spending across the entire economy can be affected, simultaneously impacting multiple industries. Under the assumptions of neoclassical economics, cyclical unemployment should be a short-term phenomenon. As the ranks of the unemployed swell, downward pressures on wages mount, making it possible for employers to hire on new workers. Keynesian economists, however, hold a different view. They contend that a rise in unemployment deprives the economy of consumer spending, creating a negative multiplier effect as this loss in spending leads to further job cuts and a corresponding rise in unemployment. Under this scenario, cyclical unemployment will be associated with high and sustained unemployment levels over longer time horizons.

During recessions, the composition of overall unemployment shifts. Cyclical unemployment rises because businesses lay off workers in response to falling demand. Frictional unemployment tends to fall because workers are reluctant to quit their jobs, fearful that they will have difficulty finding a new one. At the same time, there is a danger that structural unemployment will set in as firms feel the pressure to restructure production systems, integrate new technologies, or close their doors due to declining demand. Under these circumstances, the structurally unemployed could face extended
periods without work because their skills are no longer demanded by employers. When regional economies are beset by high levels of structural unemployment firms may be reluctant to bear the costs of retraining displaced workers, contributing to the mismatch between job seekers’ skills and the vacancies available in the labor market.

The long-run impacts of structural unemployment can be seen clearly in the coalfield areas of Britain, where employment in the mining industry plummeting from 220,000 jobs in 1985 to just 7,000 in 2004 (Beatty, Fothergill, and Powell 2007). Massive job losses in export-oriented industries (such as mining) set in motion additional employment declines in affected regions. As the multiplier effects of industrial decline took hold in these areas, the shocks of pit closures rippled through local economies, robbing them of income and spending that supports a wide range of economic activity. Employment losses led to declines in local consumer spending, which in turn undermined the locally serving sectors of the economy, which in turn led to further declines in local consumer spending, and so on. Rising unemployment followed, and when unchecked it led to rising long-term unemployment. The local economies of these areas were, by any measure, in decline (Beatty, Fothergill, and Powell 2007; Pike, Dawley, and Tomaney 2010; Theodore 2007). With little employer demand for their specific skill sets, and with local economies facing entrenched job deficits, miners found themselves structurally unemployed, most of them for the long term.

Employment statistics divide the labor market into three groups. The employed, the unemployed, and those who are not in the labor force. The unemployment rate typically counts only those job seekers who are actively seeking work. Therefore, especially during periods of high unemployment, official statistics tend to undercount the extent of joblessness in the economy. Job seekers are considered to be experiencing short-term unemployment if they have been out of work for fewer than 27 weeks, and they are considered to be experiencing long-term unemployment if the jobless spell is 27 weeks or more. As overall unemployment increases in a labor market so too does the incidence of long-term unemployment. During economic downturns, unemployment rises, increasing the number of job seekers at a time when vacancies are scarce. When job seekers experience extended periods out of work, employers grow more reluctant to hire them, reading lengthy unemployment spells as a sign of a lack of labor market qualifications or problems with their “employability.” Under these circumstances, weeks of unemployment can turn into months, or even longer. Some job seekers will stop their active search for work, frustrated by their lack of success in finding a job. They are referred to as discouraged workers. Workers may become discouraged when there is a shortage of job vacancies in their local labor market, or when they face employment discrimination on the basis of race, ethnicity, nationality, gender, religion, disability, or sexual orientation. Discouraged workers, who sometimes are referred to as the hidden unemployed, are not included in official unemployment statistics.

The 2007–2009 Great Recession provides a revealing window into various dimensions of unemployment. The recession had devastating, though socially and spatially uneven, impacts on job seekers in the United States. The economy shed more than 8.5 million jobs from the recession’s onset to the bottom of the cycle, losses that were disproportionately located in the manufacturing and construction sectors. As 2009 came to a close, approaching 16 million job seekers were officially unemployed, and
reports of worker discouragement dominated news headlines. Geographically, unemployment rates varied greatly state by state, ranging from 3.9% in North Dakota to 15.9% in Nevada. To make matters worse, the effects of the recession lingered. Approximately two years after the recession had been officially declared over, unemployment durations were at their historic highs, as was the share of the unemployed who were classified as long-term unemployed. Protracted periods of unemployment raised new concerns that deep structural unemployment was affecting large parts of the country, undermining the future job prospects of laid-off workers and weakening the job market for new entrants, particularly young people.

The social distribution of unemployment

In the mid-1990s, questions regarding the social structuration of labor markets, including which social groups bear disproportionate burdens of economic restructuring and job loss, were taken up in earnest by economic geographers. The publication of Gender, Work and Space by Susan Hanson and Geraldine Pratt (1995) and Work-Place: The Social Regulation of Labor Markets by Jamie Peck (1996) marked a theoretical, conceptual, and empirical advance in geographical analyses of regional labor markets. Building on the work of Massey, Harvey, and Storper and Walker, along with research by heterodox economists, Hanson and Pratt as well as Peck sought to “spatialize” heterodox labor market theories, in particular labor market segmentation theory. Labor market segmentation theory had been developed by economists who were dissatisfied with the predominant view within neoclassical economics that labor markets behaved like commodity markets. In opposition to theories in neoclassical economics that viewed the job market as a single, unified market in which (i) opportunities are ordered according to skills and other forms of human capital and (ii) wages correspond to human capital attributes, labor market segmentation theory proposed that the job market is comprised of noncompeting subgroups. In the broadest terms, the labor market could be conceived as having a “primary segment” where higher status, more secure, and better paid jobs could be found, and a “secondary segment” comprised of lower status, insecure, and poorly paid jobs. The allocation of workers to jobs, according to the theory, was largely based on ascribed characteristics, such as race and gender.

Economic geographers placed the local labor market at the heart of their analysis, conceiving it as far more than merely a catchment area or commuting shed for workers and employers, thereby elevating claims of its theoretical status. Peck (1996, 95, italics in original), for example, states that “it can be argued that all labor markets are ‘locally constituted’… . Although a broadly similar set of causal processes underpins the operation of every local labor market, each local labor market is unique in that it reflects a unique intersection of those processes. While all local labor markets are shaped by, say, gendered domestic labor or ethnic stratification and marginalization, ‘generic’ tendencies do not have universally even outcomes. […] Further, local labor market differences are magnified by the fact that these processes are not operating on a tabula rasa, but in their realization are affected by the inherited social, economic, and institutional geographies of the labor market.”

Building on labor market segmentation theory, these geographers sought to interrogate various forms of socioeconomic disadvantage and how these might be produced and reproduced through the operation of local labor markets. The labor market is not seen as a neutral medium
of exchange that balances adjustments in supply and demand. Instead, it is socially structured and structuring, consigning members of disadvantaged groups, such as racial minorities, to jobs in the secondary sector. There they endure low pay, little upward mobility, and frequent spells of unemployment.

The existence of a secondary sector provides a number of benefits to employers. For large and stable companies, access to workers in the secondary sector, for instance through subcontracting chains, is a way to boost profits by outsourcing low value-added work to lower cost suppliers. For more marginal companies, tapping labor pools in the secondary segments of the job market can be a core workforce strategy, and the difference between surviving in a competitive marketplace and going out of business. In both scenarios, firms rely on secondary labor markets to, among other things, achieve numerical flexibility. They hire workers when there is a need to increase output, and they lay them off when demand is sluggish. This means that job losses will be disproportionately concentrated within the secondary sector and unemployment will disproportionately affect workers who tend to be consigned to job opportunities there, in the process reinforcing their labor market disadvantage.

Regionalism

John Tomaney
University College London, UK

Regionalism is typically understood by human geographers as the identification and mobilization of divisions formed in relation to subnational, socioeconomic, cultural, or political territories. Regionalism can refer to efforts to organize government action at the subnational scale (such as “metropolitan regionalism” in the United States). In cultural terms, regionalism can refer to ideas of belonging and attachment to a particular territory expressed, for instance, through art, music, food, and literature. Political regionalism denotes the mobilization of actors around territorial claims. If regions are social constructions, regionalism is the means by which they are fabricated by administrators, intellectuals, and politicians. But regionalism is also reproduced in the practices of everyday life, for instance, through the use of dialect and accent, in media discourse, and in distinctive social practices. Regionalism is contingent and constantly being formed and reformed, negotiated and manipulated, promoted and contested. (A less common usage, used to describe macroeconomic and political blocs mainly by political scientists, is not considered in this contribution.)

Regionalism typically presupposes a regional identity. Regional identities are not pre-given cultural phenomena, but are constituted through cultural and political ideas, social movements, and modes of governance. Regionalism is a means of articulating the relationship between people and place. Regionalism is a narrative activity concerned with defining and acting upon boundaries – region-making – through the mobilization of political, cultural, and socioeconomic claims (Paasi 1991). For instance, interpretation of the past is a key element in the political and cultural construction of a region, often involving the search for a “usable past” as a guide to regionalist praxis.

Regionalism is a performativediscourse that seeks to achieve legitimacy for definitions in cultural, political, popular, and official understandings. Regionalism is also concerned with giving meaning to bounded material and symbolic worlds in an effort to create intersubjective meanings. Regionalism is frequently linked with “topophilia,” that is, to affective bonds between people and place. Regionalism in art and literature often gives expression to these processes, creating imaginative boundaries around particular territories exhibited, for instance, through a concern with dialect and landscape, which are intimately linked through topological nomenclature. Contemporary regionalism is often closely related to rising ecological awareness and the growing interest in more diverse and sustainable forms of living. The defense of regional cultures can occur alongside struggles to preserve biodiversity. On occasion, ecological concerns and cultural claims have proved the basis for political regionalism, although there is no necessary relationship between these factors. A shared regional identity, in both its cognitive and affective dimensions, does not have inevitable political consequences, but depends on whether this identity is used as a framework for perception and judgment of interests (Keating 1998).

Regionalists are at times criticized for emphasizing a topographical understanding.
of cultural and political geography. Regionalism tends to imply a territorial understanding of the production of space. Critics maintain that contemporary life does not take place in bounded territories, but occurs relationally in networks stretched through and beyond regions (Amin 2004). But the persistence of regionalism as a cultural and political form reaffirms the importance of the making (and unmaking) of territorial boundaries. There is a strongly normative dimension to the critique of regionalism, which is seen as tending toward chauvinism and exclusion of “the Other.” Regionalism, moreover, is criticized for offering a common geographical origin as a basis for solidarity in a way that obscures intra-regional inequalities. Escaping the particularist claim of territorial identities, such as regionalism, is a theme of those who advocate international solidarities and global citizenship.

Such normative criticism begs the question of why regionalism persists. The contrast between relational and territorial understandings may be unhelpful in providing an answer. The topographical and topological are perhaps seen best as being in tension. The appeal of regionalism may lie in its offer of moral particularity as a means to negotiate global networks. Regionalism may provide a means of politically and culturally “being at home in the world”; a sense of being grounded in a particular society while being open to the gains that arise from greater global integration. Regionalism may represent the search for rootedness and belonging and the valorization of local distinctiveness in the face of the universalizing claims of globalization (Tomaney 2013).

In practice, states are often compelled to accommodate regions in their political structures. Regional actors influence patterns of state formation and nation-building projects. The process of territorial integration is uneven, contested, and always incomplete. The resurgence of regionalism, which scholars identified from the 1980s, reflected a mix of old and new conditions and forces. The “new regionalism” signifies the reconfiguration of the nation-state in the face of global economic integration, on the one hand, and the assertion of regional identities on the other, resulting in an uneven process of political and administrative decentralization which can be identified across the globe. Regionalism developed after World War II in many countries as a reaction to processes of centralization and nationalization in economic and cultural life. The forms of regionalism that emerged from the 1960s were often based around language divisions (Flanders, Catalunya, Quebec). In some cases, regions have made secessionist claims. The line between regionalism and nationalism can be blurred. Wales, Brittany, and Bavaria can claim national identities within the context of larger states. The “new regionalism” became more widespread in the face of economic restructuring in the 1970s and 1980s. Modernization strategies of states were concerned with eliminating regional inequalities and integrating peripheral regions into national economies. Centrally directed regional policies and the regionalization of state structures were used to achieve these ends. But defining economic management in territorial terms fueled the growth of regionalism as actors mobilized around these institutions to make economic, cultural, and political demands. The new regionalism has become firmly founded on claims that economic restructuring is best managed by effective regional institutions (Rodríguez-Pose and Sandall 2008). These arguments, though, have been often most vigorously made by regions with strong regional identities. Indeed, it is claimed that such identities facilitate economic development through processes of “untraded interdependencies” at the regional scale, although the evidence for this is inconclusive. But, the growth of regional institutions
to promote economic development often has encouraged democratic regionalism – making regional institutions accountable to the populations over which they have jurisdiction.

The new regionalism has dominated contemporary debates about the salience of the region as a focus for economic, cultural, and political action and has been a fruitful site for the investigation of contemporary social change. It provides a powerful and resonant account of regional change since the end of the 1970s and one which has appealed to policymakers, as well as scholars. Critics contend that the new regionalism canonizes the region as a functional space for economic planning and political governance. The region is presented as having a special efficacy in the governance of the flexible, post-Fordist economy. But, according to the critics, such a viewpoint requires an overemphasis on the dynamism of an unrepresentative group of high profile urban agglomerations, where competitive advantage is embedded in civil and political networks characterized by “institutional thickness.” Such examples do not represent the “leading edge” of global change, but unique and irreproducible cases. Moreover, a focus on the internal characteristics of these places leads to a neglect of their position in wider economic divisions of labor and political systems and leads to little more than the elaboration of a set of stylized “success stories,” which obscure understanding of broader patterns of regional change and owe less to their explanatory purchase and more to their instrumental appeal to regional political elites searching for narratives to justify their actions in an era of enhanced territorial competition (MacLeod 2001). The simpler versions of new regionalism certainly underplay the complexities of the contemporary regionalization of business and governance and the changing role of the state in relation to these. By fetishizing the region we can overlook the contradictory nature of the reterritorialization of the state and the extent to which states and regions are entwined in multilevel systems of governance.

The power of regionalist narratives, however, cannot be ignored. The narrative construction of the contemporary regional world does seem to include a cultural and political reawakening of regional consciousness. Regionalism, therefore, remains a key concept in human geography. Practically, it continues to shape culture and politics, influencing patterns of state formation and nation-building and framing patterns of socio-economic development, albeit in diverse ways.

Regulation

Martin Jones
University of Sheffield, UK

Regulation – dictionary-defined as the action or process of regulating or being regulated, replete with associated categories of adjustment, control, management, balancing, setting, synchronization, modulation, tuning, and so on – is a geographical concern. Working on the interface between economic and political geography, regulation is an important category of geographical analysis, and it certainly warrants not just an entry here but also a sustained program of research inquiry and engagement with policy and practitioner communities.

The entry point for thinking about regulation is that mediation is needed in our economies and societies. Contra the thought processes of neoclassical economics and the assumptions of equilibrium and optimality, everything else is neither equal nor without visible and invisible hands. The economy, for instance, is “not an unmediated outcome of universal and trans-historical processes operating across a featureless” (Peck 2000, 61) and stateless isotropic plane, as perceived by the likes of J.H. von Thünen and followers in land economy modeling. The economy is a function of highly complex, messy, and geographically grounded processes in places and regions. In contrast to the somewhat “abstract, orderly, and mathematically regularized world envisaged by orthodox economics” and exhibited during the long tradition of location theory in geography, certainly from the turn of the last century up until the 1970s, in which synchronous processes and stylized facts hold sway, the contemporary geographer is reminded that the world is more concrete, institutionally occupied, sometimes cluttered, and above all geographically uneven (Peck 2000, 61). Contemporary economy and society is an unsettled dynamic, requiring different forms of intervention to ensure stability and coherence, and the various trends in terms of both academic analysis of economy–society–space interactions and societal challenges have been covered brilliantly over the years in the various editions of *Location in Space* and *Modern Western Society* by Peter Dicken and Peter Lloyd. Two distinctive branches of regulatory thought in geography have emerged: first, notions of “real” regulation; and, second, regulation theory and the regulation approach.

Given this concern for dynamisms and interventions, spatial processes and administrative practices offer one window through which to view regulation. Gordon Clark’s research has been considerable in this field and has enabled geography to consider “real” regulation where administration and space are not separable categories but are defined by interactions and relationships, which in turn require institutional-oriented, fine-grained case study research (Clark 1992). This tradition started with a theory of “local autonomy” offered in the early 1980s as a way of capturing institutional and relative geographical power vis-à-vis the different tiers, or scales, of the state, in this case local and state-level governmental relationships. A series of typologies were offered – type 1 (initiative and immunity), type 2 (initiative and no immunity), type 3 (no initiative and immunity), type 4 (no initiative and no immunity), and so on – to capture ideal interactive regulatory situations.
This typology was later put to work empirically on innovative research on the geographies of the capitalist state and the field of legal geographies. In the latter, regulation is considered deeply in relation to local autonomy, set within the context of the rise of US federalism and the shortcomings of standard empirical analyses of urban governance and policies. Clark’s geographical analysis in *Judges and the Cities* (1985) brings into play the fluid and evolving regulatory roles played by courts in giving expression to social heterogeneity and pluralistic values, thus revealing an uneven and evolving legal hierarchy landscape with both strong and weak forms of local autonomy.

“Real” regulation has been continued by Clark through later work on pension fund capitalism, and a more recent paper teases out US state-level differences in the provision and uptake of financial services. The authors are interested in the variegated geographies of US state and local public employee retirement systems (PERS), which utilize various models of contracting out. These differ both within and across states according to the roles played by investment management agreements (IMAs). Clark and Monk (2014) focus on the Illinois area PERS to highlight not just the processes of contracting out through IMAs but also the detailed forms that these regulatory contracts take and how precontract screening of potential suppliers effectively “sterilizes” investment manager services. This microgeography of regulatory processes and practices helps to produce and reproduce an “institutional ecology” of “real” regulation (Clark and Monk 2014).

A different and more embedded analysis of regulation has been offered by geographers through the lens of regulation theory and the regulation approach. This approach takes as its starting point the decline of the postwar Fordist model of growth and development that occupied North America and Western Europe until the 1970s, and the subsequent emergence and rise of new industrial spaces, based on niche areas of economic activity and underpinned and supported by new state and society regulatory arrangements. This Fordist regime of accumulation, that is a macro-economically coherent phase of capitalist development and its decline, required a particular form of analysis that could go beyond both neoclassical economics (noted earlier) and applied structural Marxism’s stress on indicative economic planning (popular in France at the time). What became known as the “regulation school” offered an analysis of socio-economic change that tried to understand the importance of rules, norms, and conventions at a number of spatial scales (local, regional, national, and supranational) in the regulation and mediation of capitalism. Regulationists go beyond “real” regulation and explore the regulation of economic life in its broadest sense, acknowledging that capitalist development does not possess its own self-limiting mechanisms or follow an exclusive economic logic. Regulationists instead argue that socially embedded institutions and their networks are critical to the endurance of capitalism, despite contradictions and crisis tendencies. This analysis is not restricted to Fordism, or any suggestions of post-Fordism; the regulation approach, as it developed in the social sciences through the 1990s and beyond, has been concerned with analyzing the institutional infrastructures around and through which capitalism proceeds. This infrastructure varies within and between nation-states, according to the different sets of economic, social, and political circumstances. Geography matters to this reading of regulation.

A good example of how geographers have used the regulation approach can be found in the work of Mark Goodwin and Joe Painter, who have looked at how the local state and
urban politics can act as sites of regulation. Goodwin’s research has focused on the changing institutional forms and functions of the local state and how these can act as both “agent and obstacle” to regulation. Building on this point, Goodwin discussed the ways in which regulation, its codes, and decision-making procedures, occur not in a national vacuum but through sub-national state agencies, which are often the very medium through which regulatory practices are interpreted and delivered. Goodwin and Painter (1996) accordingly explore the notion of regulation as process, where the institutional forms and functions of the state are seen as being associated not only with stability but also with managing fluidity, flux, and change, which are constituted geographically. This approach emphasizes the ebb and flow of regulatory processes across time and space by using a modified version of regulation theory that can explore the plethora of new institutions emerging in the local state. New institutional spaces have incorporated a wider variety of civil society and business sector groups, as opposed to the representational forces of labor, capital, and the state, into the regulatory frameworks of capitalism, as processes of depoliticization have been operating under a neoliberal regulatory regime of capitalism. In the area of economic development, these agencies have delivered specific rather than multifunctional policy remits, often also through smaller territories than those of elected local government.

Painter and Goodwin (2000) have deployed the term “regulatory capacity” to assess the effectiveness of such new institutional regulatory arrangements. Their case study research in Sunderland in the northeast of England claims that there is little evidence of new institutional state forms and their functions providing the necessary mechanisms for stabilizing what regulationists have called a “new mode of regulation.” Sunderland, in contrast, has a “deficit in local regulatory capacity” and some state forms and functions are “clearly counter-regulatory” (Painter and Goodwin 2000). This last point has been further explored by others, who suggest that state forms and functions are modified to regulate and deal with policy problems created by previous rounds of state intervention. Crisis of crisis-management situations can, in some circumstances, raise the issue of political legitimacy, ultimately threatening the state’s regulatory mode of operation. Jones (2010) has charted the rise of an “impedimenta state,” where the state and its regulation has become a form of bureaucratic ponderousness, with administrative inertia and modes of negative coordination. The state has baggage and is increasingly bag-like in its appearance, actions, and reactions. The trouble with bags, though, is that they demand to be filled, and impedimenta seem to replicate rapidly to create congestion and confusion.

Economic regulation is the political control and monitoring of activities involving the production and exchange of commodities. Commodities are goods and services that can be put up for sale, including land, money, and labor power. Regulators are vested specifically with the power to determine—often but not exclusively through legislative mechanisms—entry and exit to geographically defined markets; price floors and ceilings; subsidies for and the taxation of producers and consumers within these markets; mergers and acquisitions that may affect market entry or exit; and items that can be imported and exported from these markets. Entwined with economic regulations are social regulations such as traffic rules, pollution guidelines, and educational standards. These regulations enable social cohesion and, by extension, the smooth functioning of commodity exchange. In many respects, socioeconomic regulation is the de facto antithesis to ideal-typical “free markets”: producers have to adjust their strategies in relation to regulatory constraints in different locations and industrial sectors in order to continue operations, while consumers’ purchasing decisions are shaped directly by pricing controls and taxes. Viewed across a landscape of variegated socioeconomic regulations that are determined by geography, sector, and competing interest groups, the notion of ceteris paribus will inevitably remain an assumption in economic studies.

Deregulation refers to the removal of pre-existing restrictions on economic practices. It became a major political focal point in the hitherto highly regulated US economy after then president Richard Nixon resigned in 1974. His successor, Gerald Ford, almost immediately worked at removing constraints to production and trade in major industries such as banking, transport, and energy. A process of competitive deregulation ensued and became pronounced after individual state governments within the United States were allowed to deregulate industries and, consequently, trigger wholesale changes in other states without affecting existing regulations in those states. For instance, following the 1978 Supreme Court decision to permit an operating bank to export the usury law of its home state nationwide, the relatively deregulated South Dakota became a highly attractive location for banks to headquarter their US credit card operations. The action of one state engendered significant impacts on credit card use—and in turn effective demand—across the whole of the United States without changing existing regulatory constraints in other states. Deregulatory pressures soon extended to the United Kingdom—facilitated in large part by the election of Margaret Thatcher—and, to a lesser extent, Western Europe through the 1980s. Taken together, this process unraveled what was known as the Fordist–Keynesian mode of capital accumulation (more on this shortly). Increased competition impelled firms from these advanced capitalist economies to seek alternative locations of production and target markets in order to secure growing rates of profits. Viewed
REGULATION/DEREGULATION

in tandem with regulatory shifts that enabled economic liberalization in developing countries, deregulation in the capitalist “first world” arguably underpinned the new international division of labor.

At the superficial level, deregulation appears to be diametrically opposed to regulation because it removes constraints that were previously imposed on producers and/or consumers. Yet regulation and deregulation are not binary constructs in reality: the latter is an extension of the former. Regulation is necessary to establish rules for economic transactions and to ensure that laws are followed; deregulation not only entails the prior existence of regulation but is in itself an act of regulation. This is because the removal of regulations entails the a priori power of state agencies to determine how and to what extent an industry or market is to be regulated. For instance, the Airline Deregulation Act which jump-started deregulation in the US air transport industry had to be granted by the pre-existing legislative powers of the US government. And, starkly contrasting Nixon’s penchant for regulation, Gerald Ford created a “great hullabaloo” about deregulation after taking over the presidency (see Crain 2009, ch. 16). That this “hullabaloo” could set in motion deregulatory processes that were subsequently deepened by Jimmy Carter and Ronald Reagan was due to one a priori power – the political authority invested in the American presidency.

In a counterpoint to market fundamentalism, an ideology that espouses the intrinsic superiority of self-regulatory markets in the organization of socioeconomic relations, institutional economists have shown how producers and consumers do not always favor deregulation. Producers often form coalitions with other producers to lobby the state for the development and/or revision of regulations. This underscores the constitutive role of regulation in the process of capital accumulation. Since the 1970s, economists have characterized the way in which well-organized groups manipulate state power to capture rents at the expense of less organized entities as the private interest theory of regulation (also known as economic theory). Contrasting this is the public interest theory of regulation, a consumer-oriented (and, some would argue, welfarist) view of regulation as an intervention to correct or pre-empt market failure. A market is deemed to have failed when the quantity of a product demanded by consumers, such as adequate and clean drinking water, is higher than the quantity suppliers are willing to produce. The demand–supply gap – which, in neoclassical economic parlance, reflects a state of disequilibrium – is attributed to the lack of specific incentives that can be corrected by regulators in the name of social welfare. Despite their differences, the private and public interest theories share an underlying assumption that regulators are self-interested political maximizers who are susceptible to the influence of interest groups (either producers or consumers) during the regulatory process. The challenge for researchers, therefore, is to identify and/or predict the variables that enable regulators to maximize their interests in ways that simultaneously enable producers and/or consumers to attain their personal objectives.

Perhaps more interestingly, deregulation triggers and functions on the basis of new regulations. In an intriguing study termed The Utopia of Rules, the anthropologist David Graeber (2015) shows how the move toward more extensive market-like rule has not engendered a reduction of regulations; in fact, new regulations have emerged in order to support market transactions. This study not only explains the enlargement of the state bureaucracy but also the expanded pool of professionals – predominantly consultants and...
lawyers – who now advise producers and consumers how to negotiate these regulations. The enforcement of these regulations is not simply the remit of state agencies; it involves a chain of actors ranging from telephone advisers, front-counter sales staff, and third-party agents such as debt collectors or mortgage advisers. It is in this regard that the entwinement between deregulation and regulation becomes positive – deregulation may be a signal of tension in the existing regulatory framework, but, contrary to arguments (still) advanced by pro-market scholars and think tanks, it does not exemplify a zero-sum process that leads to an overall reduction of regulation.

**Economic-geographical engagements**

The private and public interest theories – and, more broadly, theories of regulation inspired by rational choice – did not strongly influence economic-geographical scholarship. Perhaps the closest economic geographers came to economists’ conceptualization of regulation/deregulation is the two-pronged approach to (i) map where deregulation has taken place, and then (ii) assess whether geographical shifts engendered greater socioeconomic “efficiency.” Another related approach is to evaluate the cost impacts of deregulation on the locational choices of producers. An example of this engagement, which takes deregulation as an isolated phenomenon to be studied (i.e., as not entwined dynamically with regulation), can be seen in the study by Goetz and Sutton (1997) on airline deregulation in the United States, in which deregulation is found to have led to the consolidation of the domestic airline industry and the formation of key domestic hubs and international gateway cities. At the global scale, Bowen (2002) shows how the deregulation of the global airline industry led to the relocation of air gateways which, in turn, further isolated specific parts of the world. Terms such as “spatial effects,” “spatial transfers,” and “core–periphery” were characteristic of this research stream, which overlaps the genres of spatial and regional science. Unsurprisingly, these studies largely construe space and place as passive containers of regulatory shifts; their primary goal is to map and evaluate the implications of emerging spatial patterns in firm-level responses to the removal of pre-existing restrictions in specific industries.

Economic-geographical research on deregulatory shifts in advanced capitalist economies were more strongly influenced by regulation theory (RT). RT was developed in France as an attempt to theorize changes in Fordist Keynesianism with reference to how these changes are shaped by and in turn impact the overall social structure. Fordism refers to a particular sociospatial division of labor that facilitates the production of standardized goods. Keynesianism refers to a state that actively manages aggregate demand and establishes wage relations to facilitate mass consumption. Taken together, Fordism–Keynesianism was a form of state-managed and privately led economic production that viewed social agents as more than simple labor power. Workers were viewed as consumption agents at the same time, and ensuring that workers were given the ability to consume was fundamental to the management of aggregate demand. In itself a response to the Great Depression of the 1930s, Fordism–Keynesianism experienced its golden era in North America and Western Europe in the two decades that followed World War II. It then encountered crisis in the 1970s.

Why this crisis came into being and how it undermined extant socioeconomic regulations became a primary research focal point of RT. To Michel Aglietta (1976), whose book *A Theory of Capitalist Regulation* was arguably the pioneering work on RT, the primary motivation for the
development of RT was a dissatisfaction with the (still) obdurate focus on “homogeneity” in two prevailing economic “sciences,” neoclassical economics and Marxism: “The neo-classical theory inspired by liberalism, which amounts to a representation of the system as a pure economy in a natural state of equilibrium, stretches the postulate of homogeneity to its very limits,” writes Aglietta, while

the Marxist view of the economy remains strongly homogeneous because capitalism is supposed to move in accordance with general laws which lead to its overthrow, whatever the nature of the society in which it develops. Furthermore, the overthrow of capitalism heralds the coming of a transparent and homogeneous system of perfect planning. (1998, 42)

RT regards as problematic the “naturalness” of the “pure economy” and the “general laws” of capital accumulation in framing politico-economic evolution. It makes the presupposition that there is no such thing as a pure, self-regulating economy that will always reach a state of equilibrium; if “equilibrium” is or appears to be reached, it is always a temporary period of compromise and consensus that is mediated by social institutions or agents. It also presupposes that the so-called general laws of capitalist accumulation would not engender a prophetic movement toward socialism or communism because society is somehow able to negotiate — or perhaps “tolerate” would be the more precise term — the problems engendered by capitalist exploitation. It was this emphasis on heterogeneous institutional formations that made RT such an attractive conceptual framework for examining the primary phenomenon confronting advanced capitalist economies between the mid-1970s and early 1990s — the previously mentioned pressures to dismantle the Fordist–Keynesian social compact.

Focusing on what Adam Tickell and Jamie Peck (1995, 357–358) term the “structural coupling” between the accumulation system (AS) and mode of social regulation (MSR), economic geographers drew on RT to understand what made individual economies work coherently across an uneven socioeconomic landscape. To follow Mick Dunford (1990, 305–306), an accumulation system is defined as “a systematic organisation of production, income distribution, exchange of the social product, and consumption.” The AS comprises (i) organization of production and workers’ relationship to the means of production; (ii) speed of capital circulation and valorization (yielding of its value); (iii) management principles; (iv) distribution of value (e.g., good wage); (v) composition of demand; and (vi) manner of articulation with noncapitalist forms. This system is in turn supported by noneconomic or extra-economic institutions (the state, trade unions, industrial associations, schools and universities, etc.) to constitute the MSR. As Mick Dunford (1990, 306) puts it, the MSR “defines the rules of the game … [and] guides and stabilises the process of accumulation.” The MSR examines the determination of (i) the wage relation (or wage nexus); (ii) forms of competition; (iii) monetary and financial regulation; (iv) the state and governance; and (v) the international trading regime.

The successful coupling of the accumulation system and the MSR in turn produces a regime of accumulation. At one level, this coupling follows the tradition in political economy by examining how economic surplus is produced, distributed, and accumulated within a class-divided society. A key difference is that it does not privilege the capital or the state as possessing the determining role in the last instance. Management of the wage relation is fundamental to the socioeconomic regulatory framework, and it is when this management
is transferred from the state to profit-seeking firms that aggregate demand changes. The incorporation of the MSR in the analysis of regulatory shifts differentiates RT practitioners from those incorporating rational choice economic theories to explain or predict (de)regulation. Crucially, there is no deregulation from an RT standpoint. Rather, regulations are strategically reconfigured – and this reconfiguration includes the removal of pre-existing restrictions – or their repurposing. Accumulation regimes are assumed to contain intrinsic tendencies for overheating and would thus require rolling series of economic and noneconomic regulatory interventions in anticipation of, or to ameliorate, these tendencies. For instance, it was because of overheating that the Nixon administration intensified industrial regulation across the United States during the late 1960s and early 1970s.

The primary concern for researchers working with RT, broadly referred to as regulationalists, is to ascertain and explain the institutional means by which this overheating occurred. RT identifies three types of crises that could potentially destabilize regimes of accumulation:

1. microcrises – affecting individual units of capital, e.g., the unprecedented £6.4 billion loss declared by the British retail chain Tesco in 2015;
2. conjunctural crises – linked to cyclical downturns, e.g., short-term decline in tourist inflows due to uncertain political developments, like the Bangkok riots in 2010;
3. structural crises – affecting the entire economy, usually framed within the nation-state, e.g., the Greek and Irish governments’ inability to service debts after the 2008 global financial crisis, which led to bailout packages from the European Union and the International Monetary Fund.

Since its “importation” by economic geographers, RT has been instrumental in demonstrating the constitutive role of non- or extra-economic institutions in the multiscalar (de)regulatory shifts toward an uncertain future known as post-Fordism. In attempting to understand a distinct economic-geographical transformation – the new international division of labor (NIDL) – Alain Lipietz (1982; 1987) critically evaluates whether the regime of accumulation known as Fordism can be exported to the global scale. Building on his analysis on the central tenets of RT, he argues that the system of capitalism is being expanded geographically because the “crisis” of the Fordist accumulation system (e.g., falling rate of profits, falling productivity, reduced demand) can be successfully deferred overseas. This success is contingent on an uneven reregulation of labor–capital relations in the former Fordist heartlands. Comprehensive defeats of labor unions in the United States and the United Kingdom (led by Ronald Reagan and Margaret Thatcher) led, at one end of the spectrum, to neo-Taylorism, which is effectively a fragile balance characterized by flexible employment conditions. At the other end, collective renegotiation in the Scandinavian economies led to a regime known as Kalmarism, which retains many of the characteristics of an ideal-typical Fordist–Keynesian prototype. Lipietz (1997) subsequently situated his conceptual framing through categorizing the effects of this rebalancing act – or, using Tickell and Peck’s term, “structural recoupling” – in Western Europe and North America.

This focus on structural recoupling fundamentally eschews the presupposition of or empirical focus on a deregulated end state. While Lipietz is not the only analyst to examine the relationship between Fordism, NIDL, and post-Fordist restructuring, his works in the 1980s established the agenda through which to
comprehend Fordist crises and how these crises are resolved and/or deferred through multiscalar reregulation. His central and highly prescient insight is that NIDL was never an autonomous process; nor did it lead to the absolute reduction of regulations in advanced capitalist economies. Rather, its geographical reach was contingent on how institutional reconfigurations in previously Fordist economies could lead – for capitalists and politicians, at least – to the export of the crisis overseas, as exemplified by deindustrialization in the United States and the United Kingdom, or trigger in situ industrial restructuring, which occurred in Scandinavia and, to a lesser extent, the former West Germany. These insights endure in contemporary analyses of variegated neoliberalization, uneven economic-geographical development, and what has emerged as a major phenomenon: the emergence of the Chinese political economy as a central site of rapid but highly uneven socioeconomic transformations.

For one, it offers a grounded twist to David Harvey’s (2010) recent conclusion that capital never overcomes its crisis tendencies but merely moves them around: some regimes of accumulation are more enduring than others, and, for capital to do the moving, certain regulatory preconditions must be established (more on this shortly).

Economic geographers’ sensitivity to regulatory changes in and through different spatial scales led to a dissatisfaction with the state-centric focus of RT. The key issue of debate during the 1990s was the possibility that different scales of socioeconomic regulation could occur within the same national space, and that RT must respond to the issues surrounding uneven development (Peck and Tickell 1995; Low 1995). Put another way, the constitutive role of geographical scale in RT is a key “missing link” (Tickell and Peck 1992; see also Collinge 1999) in RT-oriented work. This critique helped drive subsequent economic-geographical research on the tensions between regulation and deregulation, especially work on understanding the rescaling of capital accumulation in and through city-regions. Interestingly, the growing influence of RT in economic geography corresponded with an “institutional turn” within economic geography in the 1990s. This was spearheaded by Ash Amin and Nigel Thrift’s (1994) well-discussed work on the constitutive role of “institutional thickness” on regional economic development in Western Europe. To Amin and Thrift (1994, 15), institutions “mobilize the region with speed and efficiency,” and an institutionally “thick” region is characterized by:

1. an extensive institutional presence, from governmental bodies to banks and educational establishments;
2. intense interactions between these institutions;
3. well-defined structures of domination (i.e., unequal power relations are defined and accepted by the different institutions); and
4. a collective geographical imagination, which leads to a sense of shared interest in regional stability and growth.

Amin and Thrift’s (1994) highly influential, agenda-setting work addresses some of the key concerns that were further elaborated in economic-geographical research from the mid-1990s to the present, namely the importance of noneconomic support for workers (a key tenet of research on “sticky” industrial districts/clusters); the importance of social relations (a key focus of the relational economic geography debate in the early to mid-2000s); unequal power distribution (still ongoing in studies of production networks); and, through the focus on geographical imaginations, discourse, and identity (revived recently by Allen Scott through his work on cognitive-cultural metropolises). Throughout
the 1990s, they proceeded to advocate a socio-economic approach to understanding economic development in Europe. While not directly addressing regulation and deregulation, this approach led to economic-geographical research that underscores the constitutive role of socio-economic institutions in economic practices. Notable works include Michael Storper’s (1997, 27) work on the “holy trinity” of economic production (technology, organizations, and territories); Philip Cooke and Kevin Morgan’s (1999) formulation of the “associational economy”; and Henderson et al.’s (2002) global production networks (GPN) framework. Indeed, Amin and Thrift (2000) have so taken to the causal strength of MSRs that they actually considered dispensing with concepts from economics in toto. Viewed collectively, this new research wave was instrumental in shaping what Bob Jessop (1997, 514) terms the three new “innovations” in RT:

- **space**: the focus on the politics and constitutive roles of scale;
- **government and governance**: power relations and the shift in state–market engagement through the formation of new ruling coalitions involving both public and private actors and institutions;
- **discourse and identity**: geographical imaginations, discursive and practical performativity.

The incorporation of these three innovations within the RT framework underscores how regulatory scales are not simply constructed by capital. The expansion of Chinese economic influence at the global scale is instructive in this regard: through its fixed foreign exchange regime and one-party political system, the Chinese government operates at a variety of geographical scales to contour and react to the demands of capital. To make strategic use of its foreign reserves (accumulated as a result of its exchange rate regime), a sovereign wealth fund (the China Investment Corporation) was set up to explore investment opportunities at the global scale. State-owned enterprises (SoEs) are also encouraged to “go abroad” (zouchuqu). In turn, China’s outward FDI – which surged from around US$3 billion in 2002 to US$116 billion in 2014 – places the country within the world’s top five national sources of FDI (Lim 2010). This globally expansionist strategy, however, is an anomaly for a developing country where the per capita income is approximately a sixth of that of the United States. An outcome of a strategic macroeconomic policy (fixed exchange rate regime), the sudden growth in outward direct investments from China, exemplifies the direct impact of national-level accumulation regimes on global capital flows. That this expanding influence was and remains predicated on the prior willingness of the Chinese state to de- and reregulate the national economy in 1978 points again to the dynamic entwinement between regulation and deregulation.

**Conceptualizing the regulation–deregulation dynamic: future directions**

Despite its theoretical promise, the importance of RT gradually faded since the mid-2000s. In the late 1980s Allen Scott, David Harvey, and Michael Storper led the way in arguing that a new accumulation regime characterized by flexibility has emerged. This triggered a series of heated debates, during which Meric Gertler (1988) and John Lovering (1990) rebutted the claims that post-Fordism has become a byword for any flexible form of production. The fundamental problem, as Ray Hudson (2006, 174) puts it cogently, is that RT portrays the transition from one regime of accumulation to another as
a “seamless” process that overlooks the “messy complexity of the historical geographies of capitalist economies and their overdetermination as a result of struggles between social actors over (inter alia) the extent and form of state involvement in economy and society.” Because RT could not offer any predictions on what post-Fordism is or could be, Peck and Tickell (1995, 36) presciently predicted that RT could go down “the dustbin of Fordism.” Against the contemporary backdrop of transnational production and financial networks, very few economic geographers talk about post-Fordist restructuring anymore. And this means few – if any – economic geographers now draw on even the spatially reformulated RT to analyze and assess contemporary problems of (de)regulation.

Crucially, in view of the severely reduced faith in neoclassical economics following the devastating 2008 global financial crisis, this might mean missing a critical moment to seize the theoretical and even policy initiative in driving future discussions on economic regulation. For one, deregulation is no longer postulated as a utopic end state of economic efficiency. Indeed, Alan Greenspan, one of the surviving economic advisers who helped Gerald Ford launch the aforementioned deregulatory wave across the United States, even publicly acknowledged that he might have been wrong in his convictions about the self-regulatory market all along. What this acknowledgment amounts to is not simply a reminder that economic regulation remains important (RT-inspired economic-geographical research has long demonstrated this as a fact); it points to financial deregulation in multiple economies (e.g., United States, United Kingdom, Iceland, Ireland) as a specific regulatory failure that plunged multiple social formations into a financial crisis from which they are still trying to recover. It is to this second point that economic geographers are well poised to respond.

In spite of this opportunity, however, Peck and Theodore (2007, 762) identify a paucity of “institutional theories of the uneven development of capitalism” within economic geography. This observation points to the continued and urgent need to understand capital accumulation as a regulated process, deeply embedded within and simultaneously cutting across multiple sociopolitical structures. Perhaps more important is the continuing importance of the state – the primary scale of reference for theories on regulation – in determining and implementing legal parameters that determine the geographies of production, work, and consumption. Christophers’s (2016) work on the “leveling” effects of laws regulating competition and monopolies in the United States and the United Kingdom exemplifies the contemporary relevance of a state-focused framework that critically engages with and contributes fresh insights on RT. There is much to build, then, from the regulationist approach, notably in two areas of contemporary economic-geographical research: (i) variegated neoliberalization and (ii) primitive accumulation.

Expressing a dissatisfaction with the constraining effects of preconceived economic categories on understanding extant neoliberalization processes, Brenner, Peck, and Theodore (2010, 207) argue that “the variegation of neoliberalization processes involves a series of constitutively uneven, if cumulatively transformative, shifts in the qualitative form of regulatory uneven development itself.” This approach effectively addresses and builds on Hudson’s (2006) concern that RT only offers a vision of a clean break from one production system (Fordism) to another (an undefined post–Fordism). To Brenner, Peck, and Theodore (2010), the impacts of specific neoliberal projects – characterized by an emphasis on economic deregulation and the corresponding formation of a “small” state – need not dramatically transform regulations over an
entire economy over a fixed period of time. Rather, each round of reregulation tends to be responses to the contradictions of earlier rounds of market-oriented deregulation, and this plays out differently within and between state space. The bigger picture of regulation and deregulation can thus be determined only after studying these transformative shifts over an undetermined period of time. Put differently, a coherent and defined accumulation regime may appear only after a series of discontinuous and capricious shifts toward market-like rule are aggregated. Sometimes, the accumulation of these changes and shifts may be limitless and there may be no coherent system. Neoliberalization remains variegated across the global economy precisely because the regulation–deregulation process is not a zero-sum one; in spite of deregulatory pressures, states continue to regulate economic practices in order to attain non-economic objectives, while workers remain active in fighting to secure better terms of employment. The goal of future research is to ascertain and evaluate these dynamic responses to neoliberalization.

Concomitant with the global expansion of neoliberal logics is primitive accumulation, or what Harvey (2003) terms “accumulation by dispossession.” The central question of contemporary capitalism remains why a small group of people is able to seize an inordinately huge amount of resources to start businesses and begin exploiting fellow human beings (through employer–employee relations). In Indonesia, for instance, 3% of the population owns and arguably continues to appropriate 70% of the economy’s value. In the 1990s the Russian state allowed a few oligarchs to purchase “shares vouchers” from ordinary citizens and effectively sold off a sizable portion of the state’s wealth. The primary consequence of primitive accumulation is to disconnect a large pool of people from resources that would allow for self-determination; this in turn impels these people to put on sale their labor power in labor markets. How the primitive accumulative process is effected, the extent to which this process is institutionally mediated, and how the affected population are persuaded to accept “proletarianization” are key research questions that address and build on the regulation–deregulation entwinement. Primitive accumulation may appear to be an unintended outcome of deregulation, but it may also be a deliberate calculation to transpose social agents into abstract labor power. That primitive accumulation is allowed to happen at such a large scale suggests there could be global regulatory failure. Identifying the specific (de)regulatory mechanisms that facilitate primitive accumulation in both developed and developing economies would go a significant way to understanding the multidimensional relationship between labor exploitation, surplus extraction, and crony capitalism.

Relational assets

John Pickles
University of North Carolina at Chapel Hill, USA

“Relational assets” refer to the intangible, behavioral, and normative practices that influence interfirm behavior and firm and regional competitiveness. The concept was originally developed in two main contexts. In business and management theory, the idea emerged in response to the growth of multinational corporations and global sourcing practices, and the tendency to overlook the ways in which even multinational corporations and firms depend on acknowledged, unacknowledged, and untradable assets. The concept thus sought to deepen traditional economic and regional analyses focused on the factor endowments of emerging multinational corporations and international business activities by refocusing on the social and cultural practices that affect competitiveness.

Dunning (2002) identified three specific kinds of income-generating assets that shape the economic behavior of firms and regions: assets that are unique to specific firms; assets that are external to the firm but on which its performance depends; and assets that relate to the broader institutional and cultural contexts on which the first two depend. Historically, the relative importance of, and form taken by, such assets has changed. In agrarian economies, land and property ownership were crucial in shaping social relations, economic performance, and geographical outcomes. In industrial economies, the physical and financial assets of a firm and the institutions that protected financial property, regulated social and market norms, and managed labor markets and consumption norms were important. In contemporary globalizing economies, attitudinal attributes such as values, honesty, trust, cultural sensitivity, and reciprocity operating across spatial scales; firm-level attributes of reputation, experience, and openness to innovation; and characteristics of particular countries such as the rule of law, transparency, freedom from corruption, and the upholding of human rights are all crucial to economic performance (Dunning 2002, 476). For Dunning, firms with a greater number and intensity of linkages, such as multinational enterprises, tend to have more relational assets than those with fewer linkages, such as locally focused firms. The result has been a refocusing of the analysis of economic performance on the ways in which such cultural, regional, and institutional assets nurture or inhibit firm and regional competitiveness.

Regional geographers have complemented this business argument by turning to institutional analyses that focus on the ways in which regional economies can be understood as “stocks of relational assets” that rely on intangible institutional and cultural practices (such as trust and reciprocity). While Dunning focused on the growing complexity of relational assets in internationalizing businesses, geographers have shown how different regions enable different kinds and densities of relational assets, most notably in works dealing with Silicon Valley, the “Third Italy,” and metropolitan learning regions. For Storper (1995), the metropolitan economy possesses particular locational advantages in terms of the number, intensity, and diversity of linkages, networks, and relations they offer. Regional
RELATIONAL ASSETS

capabilities, information, and knowledge foster practices of conversation and coordination which enhance the activities of individual economic actors, both individual and collective, and intensify the effects of participation in regional economies to foster economic accumulation (Storper 1995, 3–4). Here:

the territorial element of the holy trinity (technologies, organization, territories) needs refocusing, from the geography of input–output relations – industrial complexes and spatial divisions of labor – and the economics of proximity in traded linkages, to the geography of untraded interdependencies and the dialectics of proximity and distance in them. (Storper 1997, 43)

A variety of related insights have emerged from this notion. Instead of “the region” being understood as a series of fixed material investments and technologies, the idea of relational assets has been important in the development of notions of institutional thickness, untraded interdependencies, learning regions, innovation regions, association economies, and perhaps most recently, from evolutionary economic geography, local buzz. For Henry Yeung, this marks a significant turn in the study of regional economies, where “a relational approach to regional development seeks to identify complex relational geometry comprising local and non-local actors, tangible and intangible assets, formal and informal institutional structures, and their interactive power relations” (2005, 48; emphasis original). In recent years geographers, anthropologists, economic sociologists, and cultural theorists have expanded this relational ontology by focusing on diverse and alternative modalities of power, economy, and life through their engagements with the importance of context. Yet, as Peck (2005, 133) warns us, when turning to issues relating to the social, spatial, and scalar constitution of economic systems, identities, processes, and development paths, we all too often leave “only fuzzily defined and un-theorized ‘context’ in the background.”

More recent efforts have engaged with this problematic of context. For Doreen Massey (2005, 110), the turn to concepts such as context and embeddedness are a recognition of “contemporaneous coexistence and becoming,” and for Larry Grossberg (2006, 4) what we mean by context must always be understood as “a complex, overdetermined and contingent unity.” From this same perspective, Pickles (2012) asks how an understanding of context and contingency help to develop a conjunctural analysis of economic and regional change. The result has been a rich array of investigations that show the many ways in which these relational assets are activated in firm and regional economies, and how social and spatial networks and linkages matter. By focusing on such networks, forms of access, information, and trust, economic sociologists, economic geographers, and regional economists have identified different kinds of networks and forms of governance – between firms in a particular industry, between buyers and suppliers, between one sector and others, and between manufacturing and service firms and venture capitalists and investment banks. Some have focused on the ways in which network resources obtained from prior alliances provide differential access and referral benefits, and also produce capacities that increase the proclivity of firms to form further alliances (e.g., Pickles and Smith 2015). Others have focused on the ways in which state and private actors have formed regional partnerships to enhance regional economic performance, integrate once fragmented production systems, and expand their role in regional trade systems.

Further reading

Since the 1970s there has been a lively scholarly exchange, principally among Anglo-American geographers, over whether and how academic geographers should seek to shape policy and influence public debates over pressing social, political, and environmental issues. These exchanges are commonly termed the “relevance debates.”

Since its institutionalization as a formal discipline, some academic geographers have had considerable influence in the public arena. In the early twentieth century, for example, Halford Mackinder advanced geopolitical ideas that influenced the orientation and practice of foreign policy in the United Kingdom and beyond. In 1919, Isaiah Bowman accompanied US President Woodrow Wilson to the Paris Peace Conference, where he headed the US scientific delegation that contributed to the redrawing of the political map of Europe. In the middle of the twentieth century, Gilbert White pioneered an approach to floodplain management that continues to be influential to this day.

Geography’s Quantitative Revolution opened up opportunities for academic geographers to contribute to transportation and urban planning initiatives, and to offer input on a variety of decisions with a locational dimension. By the turn of the 1970s, however, little geographic work, whether quantitatively oriented or not, spoke to the social upheavals, international conflicts, and growing environmental activism of the time. Against this backdrop, a number of prominent geographers began to draw attention to what they saw as geography’s lack of relevance. They argued that geographic theory had become abstracted from pressing real-world problems, and they called on geographers to undertake work aimed at solving those problems (e.g., Chisholm 1971). Because a particularly sharp debate over this matter emerged in Anglo-American geographical circles, the term relevance debates has come to be primarily associated with academic exchanges over questions of relevance that have occurred among North American and United Kingdom-based geographers.

In the wake of the growing calls for relevance at the beginning of the 1970s, debates quickly emerged about what constitutes relevance and what the goals of relevant research should be. Some argued that geographers should actively look for ways to contribute to the policy-making process, whereas others contended that a policy-driven geographical research agenda would subvert the discipline’s potential to contribute to an understanding of underlying social forces or challenge existing sociopolitical norms. In a particularly widely referenced article entitled “What Kind of Geography for What Kind of Public Policy,” David Harvey (1974) argued that most geographic efforts to inform public policy involved playing into an unjust status quo. Harvey did not argue against relevancy; instead he made the case for an approach to relevance rooted in the effort to counter the structural inequalities, racism, and ethnocentricism of the corporate state. For those sympathetic to Harvey’s perspective, the historical lineage of relevancy in the discipline of geography ran less through Mackinder,
Bowman, and White, than it did through the likes of Élisée Reclus, Peter Kropotkin, and (much later) Bill Bunge.

Geography’s relevance debate in the 1970s reflected fundamentally different views of the discipline’s social role. For some, that role lay in the contributions geography could make to promoting efficiencies and improving public policy; for others the discipline’s mission was to pave the way for the development of alternatives to unjust structures and arrangements. Those in the former camp sought to draw attention to the social costs of foregoing diagnosis and action in favor of what they saw as an abstract, potentially undemocratic revolutionary agenda. Those in the latter camp focused on such issues as the intellectual constraints that can accompany cooperation with policymakers.

During the last two decades of the twentieth century, debates over relevance took place against the backdrop of a growing body of geographical work that spoke directly to such issues as environmental change, urban restructuring, human responses to hazards, and planning choices with a locational component (the latter spurred in significant part by the rapid development and proliferation of geographic information systems (GIS)). As geographical scholarship with a clearly discernable sociopolitical dimension became more common, discussions of relevance came to focus increasingly on the practices and ethics that are appropriate to academic engagement with social, political, and environmental issues. A growing number of commentators called on geographers working with those in the policy realm to be explicit about their positional-ity and its influence on their work. Some argued that academics engaged in policy work should explicitly acknowledge their own values and beliefs, recognize their lack of independence, be willing to critique the status quo, and promote public accessibility to their work product. Others called on geographers to be attuned to ethical dilemmas that can accompany policy work, and be prepared for conflicts that might arise between them and policymakers with different agendas and priorities.

As the twentieth century gave way to the twenty-first, relevance came to be an expected feature of most geographic scholarship. Social and institutional changes were behind this development. The US National Science Foundation and other funding agencies began requiring applicants to explain in detail the larger social impacts of their projects. At the same time, the rapid growth in the use of GIS in the private and public sectors opened up rapidly expanding opportunities for geographers to address applied problems. Moreover, cutbacks in funding for higher education meant that geographers increasingly needed to justify their academic positions in terms of “real world” consequences and look for funding support from sponsors with an applied agenda.

An avowed commitment to relevance now runs through much geographical scholarship, but relevance debates are still very much in evidence. They center around three key issues: the long-standing question of what constitutes relevance, the obstacles geography faces in becoming more relevant, and the types of practices that are most likely to lead to constructive applied engagements. Turning to the first of these issues, a number of geographers have sought to broaden the concept of relevance beyond the policy realm. Kevin Ward (2006), for example, has argued that there are different types of geographies with an explicit relevancy component: activist, participatory, and policy-oriented. He and others have encouraged an expanded conception of the audiences geographical work should aim to reach. Borrowing from Michael Burawoy’s (2005) writings on “public sociologies,” the term “public geographies” has
gained increasing acceptance – referring to a variety of different types of audiences (publics) that geographic scholarship might address. The embrace of public geographies speaks to the need for geographers to recognize that there are important audiences for research that extend beyond social and political elites.

There is also a body of work highlighting the limited ways in which geography is having an impact beyond the academy and seeking to explain that state of affairs. Scholarship in this vein has drawn attention to the virtual absence of geography in major public debates over social and political developments, and the concomitant paucity of geographers who are public intellectuals. To explain this state of affairs, Castree and Sparke (2000) have highlighted some of the institutional barriers to public scholarship, Murphy (2013) has pointed to the hesitancy of geographers to engage grand narratives, and a number of other commentators have pointed to a dominant approach to writing that is inaccessible to the general public. Some commentaries in the latter vein have argued that geography’s post-modern turn had directed attention away from the types of grounded, empirical, and politically committed work that can influence policy. The latter claim has generated considerable controversy, even as it has drawn attention to a key contemporary element of the relevancy debate: is much geographical work in fact relevant, and if not, why not?

A final pillar of recent commentaries on relevance focuses particularly on the policy realm and concerns the advantages and pitfalls of conducting different types of policy-oriented research. Beaumont, Loopmans, and Uitermark (2005), for example, examine ways in which policy-oriented researchers can avoid clientalistic relationships with sponsors and retain a commitment to traditional academic standards in the face of social engagement. Interventions in this vein reflect a relevance debate that has moved from an initial focus on whether geographers should focus on relevance to an emphasis on how relevance is understood, and how it can be most effectively, and ethically, practiced.

The study of religion in human geography is a vibrant subfield of social and cultural geography that has grown significantly since being labeled a depleted and marginal field in the early 1990s. This growth is evidenced by the publication of key texts (Stump 2008) and edited collections (Hopkins, Kong, and Olson 2013). Geographies of religion have developed as a result of a range of different influences and interdisciplinary debates. Some of the earliest work in this area was shaped by the Berkeley School of cultural geography, with work on spatial patterns arising from religious influences and the impact that religion has in shaping the physical landscape. Much of the more recent work in this area was shaped by the Berkeley School of cultural geography, with work on spatial patterns arising from religious influences and the impact that religion has in shaping the physical landscape. Much of the more recent work in this area was shaped by the Berkeley School of cultural geography, with work on spatial patterns arising from religious influences and the impact that religion has in shaping the physical landscape. More recently, geographies of religion have diversified further through engagement with neighboring disciplines and different subfields of geography. For example, Knott (2005) offers a rich conceptual tapestry for understanding the spatial location of religion through her work, which draws on debates within sociology of religion and religious studies, and Brace, Bailey, and Harvey (2006) have proposed a framework for understanding historical geographies of religion. Moreover, researchers interested in political geographies and geopolitics as well as economic geographies have also started to explore what happens when debates about religion and faith intervene into landscapes of politics and finance. Within social and cultural geographies, an important focus of work about religion is on the mapping, measuring, and monitoring of patterns of religious affiliation and experiences of ethnic and religious residential segregation. This work emerged from long-standing debates within social geographies about the politics and spatiality of race and ethnicity. Research in this area has centered on mapping changes in levels of ethnic and religious segregation over time, as well as on the spatial distribution of congregations or places of worship, such as megachurches, and has tended to focus on minority religious groups in contexts where they represent a diasporic or migrant population. Research in this area has also looked at the existence of specific religious communities or areas – be these actual or imagined – such as the ummah (the global Islamic community) or the Jewish eruv and the political contestations associated with such spatial manifestations of belief. Some of this work has been useful for policymakers as well as academics, given that it has contributed to explaining patterns of segregation and has offered insights into changing population patterns over time.

Strongly related to the urban theme of these debates, geographers studying religion have also explored the construction and contestation of religious built environments and architectural styles in different contexts. Work here has focused on the spatial practices, social exclusions,
and contested politics associated with the location and use of religious buildings and places of worship. These often connect to debates about multiculturalism and citizenship, but have also included engagements with architectural research and discussions about urban design and planning. An important strand of this work has charted the racist and exclusionary ways in which the location and development of mosques, particularly in Muslim minority contexts, are resisted by national governments and local communities. This work has tended to look at officially sacred locations – such as mosques, churches, synagogues, and temples – although there is now more research emerging that explores how issues of religion and matters of faith come into play in locations beyond the officially sacred.

An interest in the cultural politics of identity among social and cultural geographers in the 1990s led to a series of important developments in geographies of religion, as debates within feminist geographies, children’s geographies, and political geographies and geopolitics emerged as significant strands of research. Work has drawn attention to the complex manifestations of religious identities and how these are performed by people of varying faith backgrounds in different geographical locations and contexts. In particular, such research has been sensitive to the intersection of religious identities with other social identities such as those related to gender, race and ethnicity, class, and sexuality.

Drawing on debates within feminist geographies and geographical studies of gender relations, a significant body of scholarship within geographical studies of religion focuses on the ways in which the politics and practices of religion and spirituality are intertwined with gendered expectations and relations. In particular, exploring the identities, practices, and attitudes of Muslim women in different contexts has been a key aspect of research (e.g., Gökariksel 2012). Work has focused on the contested politics of the Muslim headscarf in diverse contexts such as Turkey, Australia, and the United States, challenging dominant representations of Muslim women as oppressed and marginalized, and exploring their engagements with different private, public, and institutional contexts. Partly in response to this, an interest in Muslim masculinities has emerged, with research on the contested intersections of Islam and masculinity, as well as the spatial practices and exclusionary behaviors of Muslim men in the mosque, in public spaces, and at home.

Parallel with the development of gendered geographies of religion, the introduction into the discipline of children’s geographies and debates about young people and family life has created a rich set of insights into the religious lives of children and young people. Researchers have explored a diverse range of themes including young people’s engagements with religion through different (religious and secular) institutions such as schools; and the role of local and national geographies in shaping young people’s faith. Connected to debates about gender and home, research has explored the ways that young people’s religious identities and faith practices are shaped in complex ways by intergenerational relations (Hopkins, Kong, and Olson 2013). Research has also centered on different institutional contexts, including, for example, how young people who are members of the Scout movement in the United Kingdom engage with everyday informal expressions of “worship” that take place outside of formal religious space, and Christian students’ experiences of university life in England.

Debates about citizenship and rights to public space informed by political geographies, alongside the emergence of research about religious geopolitics, have played an important
role in shaping geographical scholarship about religion. An important example of work drawing on discussions of citizenship has been Nagel and Staeheli’s (2008) research about how Arab activists in the United States respond to political debates about integration and their complex positioning in relation to their place of settlement. Researchers within the subfield of geopolitics have also started to explore the role of religion, particularly with reference to Christianity and evangelicalism in the United States, and there are signs that this interest is now expanding to include other faiths and spiritual practices. A number of significant international (geo)political events (most notably 9/11, but also the bombings in Bali in 2002 and 2005, in Madrid in 2004, in London in 2005, and in Mumbai in 2008), as well as other national and local political occurrences, have played a highly significant role in shaping the everyday lives of people of faith, and this remains an important focus and contextual background for geographers researching religion.

Connecting with literatures about alternative spiritualities within sociology of religion and arising from a desire to engage with the unofficially sacred, a small strand of work within geographies of religion has focused on different forms of spiritual practice. Alternative spiritualities tend to refer to spiritual practices that distance themselves from mainstream traditional and institutionalized forms of religion. Many participants who engage in alternative forms of spirituality resist the institutionalized structures that they feel dominate mainstream systems of faith and belief. One example of work in this area is research with New Age spiritual seekers which has shown how everyday objects and actions are given spiritual meaning: this work suggests that geographers of religion could usefully open up the nature of the everyday to further scrutiny in order to understand more about the relationship between the sacred and the profane.

Interrelated with the debates in political geographies, and coupled with urban themes and an interest in the role of faith-based organizations, postsecularism is one of the most recent issues to emerge within geographies of religion. Connected with long-term discussions about secularization theory within the sociology of religion, research about postsecularism challenges assumptions about complete secularism and instead explores the ways in which religious actors and institutions have re-emerged so that there is a coexistence of religion and secularism. Olson et al. (2013) have recently offered a retheorization of the postsecular by suggesting that a focus on embodiment and transcendence challenges the solidity of traditional religious categories and their association with clearly defined spaces, thereby opening up the sacred and profane to deeper analysis.

Debates about affect and emotion have also recently found their way into discussions about religion, faith, and spirituality, partly as a result of debates about postsecularism and the blurring of boundaries between the religious and nonreligious. Holloway (2013, 205) observes that being spiritual or religious is “enacted through many different registers of emotion and affect – from quiet contemplation to ecstatic expression, from serious reflection to peaceful assurance, from joy to humbleness, from anger to awe,” and focuses on the spaces associated with ritual in order to explore these. Discussions about religion, affect, and emotion are likely to be an important feature of future research about geographies of religion. Furthermore, appreciations of the emotional landscapes of faith and belief have also provided a valuable context for the development of research about deathscapes and places of mourning. In particular, research has explored how geographies of death and bereavement are central to
understanding different patterns and practices of belief.

Aside from researchers, who seek to map, monitor, and measure patterns of religious affiliation and settlement, research in this field tends to rely on qualitative methods that engage with the experiences, feelings, and values of people who identify with particular religious or spiritual groups. Geographers of religion regularly employ methods such as focus groups, interviews, ethnography and participant observation, archive research, and participatory action research in their fieldwork. In addition to the complex ethical and methodological issues involved in researching geographies of religion, the issue of the positionalities of researchers in relation to matters of personal faith has been explored in research.

In a recent review of geographies of religion, Kong (2010) observed the significant advancement of the field since the early 1990s, commenting in particular on different sites of religious practice, different sensuous geographies, different constituents of population, different religions, and different scales of analysis. That being said, although geographical studies of religion have become increasingly diverse over the past couple of decades, most research still focuses on the cultural identities and religious practices of Muslims, with less work about Christianity and Judaism and less still about the other world religions or indeed about minority or alternative forms of religion or spirituality. Furthermore, geographies of religion tend to look at particular scales of analysis, especially those relating to cities, neighborhoods, and religious buildings, with some work showing appreciation of the multiple scales on which matters of religion come into play, from the micro- to the macro-geographical. The inclusion of debates about transnationalism, religious conversion, and suburbanization, coupled with a continued focus on the body and processes of embodiment, are useful reminders of the importance of considering the multiscalar significance of religion on social, cultural, and political relations.

Remittances

Philip F. Kelly
York University, Canada

Remittances are generally understood to be financial transfers sent by overseas migrants to households in their place of origin. With increases in the flows of both temporary and permanent migrants around the world, remittances have grown dramatically in the twenty-first century. While individual transfers are usually small, in aggregate they represent flows of resources that can have a significant impact. As a result, the movement, measurement, and consequences of remittances have been closely scrutinized by both development institutions and critical researchers.

In 2013 total migrant remittances to developing countries amounted to $414 billion, and it is these flows that have attracted the most attention. They represent nearly three times the aggregate value of official development assistance, and more than the total movement of private debt financing and portfolio equity investment to developing countries. While the largest total flows of remittances go to more populous countries, such as China, India, and the Philippines, in some smaller economies they represent a very substantial share of the country’s domestic economy. In Haiti, Lesotho, and Nepal, for example, remittances are worth well over 20% of their economy’s gross domestic product.

Remittances are, however, notoriously difficult to measure accurately. For example, money carried back home may be recorded as tourist spending rather than as migrant remittances; and, where gifts are sent instead of cash, they may represent an invisible transfer of wealth or may be recorded as imports. Some estimates suggest that the real magnitude of remittances may be twice the levels that are formally recorded. Exactly where remittances are coming from may also be ambiguous. A remittance agency or an international bank may route money through a third country before it reaches its destination, thereby distorting official records of remittance flows. In the case of systems such as honor-based hawala networks, which are widely used in South Asia and the Middle East, no money may flow across borders at all. And, of course, not all money transfers are remittances from migrants. Counting remittances is not, therefore, a straightforward process.

While remittances are difficult to count, there are nevertheless some precise international accounting standards that define them. Until recently, the definition combined “migrant workers’ remittances,” “compensation of non-resident employees,” and “capital transfers by migrants” (IMF 2009). With the development of a new set of standards in 2009 (known as BPM6), the International Monetary Fund redefined remittances so that the relationships involved, the reasons for sending money, and the duration of migration are no longer considered (IMF 2009). This formal definition now includes:

1 “personal transfers”: including all cash and in-kind transfers between individuals or households (not limited to migrant workers);

2 “compensation of employees” (minus taxes, social contributions, transport, and travel related to employment): referring to the
income of cross-border, seasonal, and other short-term workers who work in an economy where they are nonresident, and the income of resident workers employed by a nonresident entity (such as an embassy or a company based abroad);
3 “capital transfers” of assets between households from one country to another.

Together, these three items constitute “personal remittances.” Beyond personal remittances, international transfers of social benefits (e.g., pension payments) are added to give an amount referred to as “total remittances.” Finally, transfers to “non-profit institutions serving households” (NPISHs) are added to calculate “total remittances and transfers,” thereby including donations from humanitarian agencies, governments, or other organizations to charitable organizations in another country (IMF 2009).

There has been increasing recognition of the importance of remittances among international financial institutions and national governments for two reasons. First, it is clear that, although migrant remittances have always been a feature of international financial flows, they have increased significantly in the twenty-first century. In 1990 total global inflows of remittances were counted at $64 billion (in current dollars). This grew to $124 billion by 2000, and by 2013 total remittance flows had reached $550 billion.

A second reason for increased attention is that remittances are being seen by national and international policymakers as a promising source of development finance and welfare enhancement. In this respect, remittances are presented as having several advantages. First, as they are sent directly to households, they are less prone to capture by corrupt practices or political agendas. Remittances also provide some degree of immunity from the vagaries of business cycles and economic crises, especially in countries with migrant workers placed in very diverse locations and sectors around the world. Some analysts have also suggested that remittances are correlated with welfare gains such as lower infant mortality rates, higher life expectancy, better access to health services, and more equitable income redistribution. While remittances help a country’s balance of payments and strengthen its currency, they do not necessarily enhance a government’s fiscal position. Some governments, however, have sought the direct assistance of overseas migrants (and their descendants) by selling diaspora bonds, which provide low interest loans to a national treasury. In this way, migrant remittances can be used to invest in infrastructure and services. For all of these reasons, there has been a sense of optimism in relation to the developmental promise of migration, and much of the technical and policy discussion has therefore related to ways in which remittance transfers can be made easier and cheaper (World Bank 2006).

At the same time, critical research has drawn attention to the negative implications of a remittance-based development strategy. Some of these arguments concern the wider consequences of migration. For example, migrants with precarious residency status are more vulnerable to exploitation or abuse in their sites of employment around the world than workers with full citizenship rights. Remittances may also represent relations of subjugation for migrants, either because they are repaying creditors back home, or because they are fulfilling gendered expectations to support family members. There are also the social and psychological consequences for children who are left behind when parents migrate to work. The loss of highly qualified human resources – brain drain – has also long been a concern for sending nations. More broadly, it has been suggested that a migration-based development strategy is often a
way for governments to abdicate their responsibility to foster domestic economic prosperity and provide adequate public services.

Even the supposed benefits of remittances may have significant unaccounted costs. First, there is a long-standing debate over whether remittances lead to productive investment or just fuel immediate consumption – meaning that returning workers, and their communities, are no better off when they return than when they left. Second, several studies have shown that beyond the human capital lost to migration, the stay-at-home recipients of remittances may also change their labor market participation behavior (thereby withdrawing even more human capital). Third, it is clear in most contexts that the poorest segments of society generally do not have the resources to migrate and so remittances may actually increase income inequality in sending communities, as nonmigrants are left behind, in more ways than one. Fourth, remittances can have inflationary impacts on the costs of land, housing, schooling, and other everyday expenses in sending areas, thereby rendering migration a necessity rather than an option. These factors have all contributed to what some commentators have described as a new pessimism related to migration and development – in reaction to the optimism noted earlier (Gamlen 2014).

While migrating and remitting are, at one level, individual and familial decisions, they are also very much shaped by states. In some cases, states have actively promoted and marketed their human resources in global labor markets – the Philippines being the best-known example. Even where labor export policies have been less developed, governments have actively cultivated their overseas diasporas as investors, bond purchasers, returnees, and philanthropists (Mullings (2011) provides a Jamaican example). In some cases, governments have legislatively mandated remittances (e.g., the compulsory deferred pay program for miners from Lesotho in South Africa).

Migration and remittance processes have also attracted the attention of nongovernmental organizations and advocacy groups. Among international Filipino migrant groups, “zero remittances days” have been opportunities to express opposition to government practices and policies. Some organizations have also attempted to certify “ethical” remittance agencies that charge fair fees and to advocate boycotting those that are exploitative (www.remit4change.net). Activism around remittances has also taken the form of community-based economic initiatives in which remittances are harnessed for collective rather than private benefit. An example is the development of cooperative enterprises using remittance capital in the Philippines (Gibson–Graham 2005). Remittances are perhaps most effective where collectives such as hometown associations finance the creation of clean water, health care, and education infrastructure.

While the economic significance of remittances attracts most attention, a great deal more than money is usually being transmitted. To those sending and receiving them, remittances may symbolize the obligations and power relations inherent in parenthood, marriage, filial piety, debt repayment, entrepreneurship, and many other social and cultural relations. Similarly, the impact of remittances may go beyond the economic sphere. Remittances may rework power relations (based on class and gender, for example) in the places where they are received, and may have significant impacts on the cultural landscape in both rural and urban areas (Lopez 2015).

Rent gap

Jean-Paul D. Addie  
*University College London, UK*

Rent gap theory is a Marxian explanation of gentrification introduced by Neil Smith in 1979. The rent gap denotes the disparity between the actual ground rent being capitalized on a plot of land and the potential ground rent that could be realized if the site were developed to its “highest and best” use. The theory refers to the value of land (separate from improvements made on it) as appropriated through economic transactions in the form of ground rent. Potential and capitalized ground rents align immediately following the development of a site since land is employed in an optimal manner and intensity. Yet over time, the depreciation of capital fixed in the built environment and shifts in the social or physical condition of the surrounding area may prompt changes in a given location’s highest and best use. As the proportion of ground rent able to be capitalized under current uses diminishes, landlords divest in or abandon their buildings to avoid losses arising from rebuilding or maintenance costs. When capitalized ground rent falls sufficiently below potential ground rent, renewed opportunities for profit-making challenge rates of return available elsewhere and provide incentives for capital to flow back into devalorized inner-city neighborhoods. According to Smith, rent gaps represent a historical discrepancy arising from uneven patterns of investment and disinvestment in the built environment. They are a structural product of capitalist land markets that provide the necessary economic conditions to catalyze processes of revalorization, rehabilitation, and renewal, including gentrification.

The theoretical and empirical validity of rent gaps have been broadly contested, notably in a series of debates between Smith and his critics in the 1980s and 1990s. Chris Hamnett (1991) criticized rent gap theory for dismissing the role of individual agents in shaping gentrification, and reducing demographic factors and structural changes in (postindustrial) employment to consumption preferences. Feminist scholars further pointed to the need to supplant single causal mechanisms with a diversity of processes to explain inner-city redevelopment. Critics, including David Ley and Steven Bourassa, were more critical of Smith’s conceptual foundation, claiming that the rent gap lacked antecedents in Marxist analysis of land rent and failed to offer any significant insights relative to neoclassical land economics. In response, the theory’s proponents asserted that the rent gap concept should not be reduced to a simple deterministic economic model, but rather needs to be contextualized within a more general theory of uneven development (Clark 1995). Smith (1996) refined his account of the rent gap to address the intertwined cultural, political, and economic processes that unfolded along “gentrification frontiers.” His reformulations stressed that housing and other preferences are socially and collectively constructed and expressed by real social individuals. The rent gap does not then determine property development, but reflects ongoing social and political struggles over the appropriation of value from the built environment within capitalist space economies.

Representation: 3-D

Sisi Zlatanova
Delft University of Technology, Netherlands

Approaches to 3-D representations have been independently developed in two broad domains: the real world and the design world (Zlatanova and Prosperi 2006). Modeling of real-world objects has developed quite differently with respect to the objects of interest and the associated application domain. Real-world objects above the surface, such as buildings, streets, terrain, rivers, and so on, have been the conventional focus of geographic information systems and represented as 2-D objects (vector or raster) for many years (Longley et al. 2005). Subsurface modeling of geological and geotechnical phenomena has long recognized the need for 3-D representations (voxels and 3-D surfaces). The design world, that is, computer aided design (CAD), computer graphics, architecture engineering and construction (AEC), and building information modeling (BIM), on the other hand, has always dealt with 3-D representations and, naturally, many of the developments are currently being investigated for applications to represent the real world.

Several tendencies can be observed, as follows.

• The previously sharp boundary between real-world and design-world applications is diminishing. All systems, regardless of their origins and foci (GIS, database management systems, BIM, AEC, computer graphics, serious games, virtual and augmented reality), attempt to extend their core functionality to handle 3-D geographical data.
• The demand for 3-D applications is increasing (Billen et al. 2014). Cities grow and the dependencies between buildings, transportation, infrastructure, green and water areas, and so on are becoming more elaborate, which cannot be solved on 2-D maps. Numerous examples demonstrate the demand for 3-D, such as large civil engineering works (Tegtmeier et al. 2014), urban planning, environmental monitoring, and utility management (Figure 1).
• The importance of integrating data from different environments (indoor/outdoor, above/below), applications (cadaster, urban planning, water management), and domains (GIS, BIM) is becoming evident, which results in developing and investigating new approaches and frameworks for integrated data modeling, management, and visualization.
• Technological developments are moving fast: sensors decrease in size and weight and can be mounted on light platforms (such as drones). 3-D sensor measurements are becoming more accurate, cheaper, and faster. 3-D representations of the real world are closely related to the real-world phenomena being modeled. The interest in geosciences has traditionally been directed toward real-world objects with spatial extents, a.k.a. spatial objects. A spatial object refers to a real-world object with geometric and thematic (semantic) characteristics (Aronoff 1995; Longley et al. 2005). Lately, authors have drawn atten-
tion to a third group of characteristics, that is, radiometric characteristics of spatial objects, which have to reflect surface properties of the object. A further distinction is made between real-world objects with respect to discernible (determined) or indiscernible (undetermined) boundaries (Raper 1989). Usually, discernible objects are artificially constructed objects, such as buildings, bridges, and streets, and indiscernible objects are nature objects, such as geological formations.

Another aspect that influences the 3-D representations is the digital visual appearance of the 3-D object. In contrast to 2-D, 3-D visualizations require a certain level of realism, so that users are able to understand the model and the intended message. Digital 3-D models have been traditionally a topic of research and investigation of computer graphics and solid modeling (Mäntylä 1988). One of the main purposes of the 3-D modeling is to achieve maximum similarity to reality. The model may be visualized on a screen as an image or sequence of images (video or animation). The word “scene” is used to denote the rendered imagery on the screen. Several key components are necessary to achieve readable 3-D images on the screen or, in other words, to create realistic scenes: geometry, illumination, shading, texture, and camera position (or view) (Figure 2). These components attempt to capture features of real 3-D objects and represent them in accordance with human perception. 3-D geometry determines the position, shape, and size of the objects. Illumination and shading models control lighting from artificial light sources and corresponding reflections on the surfaces. Colors and textures aim to represent surface properties of the objects. Textures can be artificial or obtained from real-world images. The camera position specifies the location of the user inside the model and orients the model accordingly. The readability of the scene depends on the components used to render the model or part of it on the screen. In this respect, three basic techniques can be distinguished, that is, points, “empty” polygons (wire frame), and shaded (textured) polygons, containing information about the surface texture (or radiometric properties).

For digital representations, a description of real-world objects requires a priori clarification.
Representations: 3-D

of several aspects: (i) spatial subdivision; (ii) geometric primitives to define position/orientation, shape, and size of objects; (iii) levels of detail; (iv) appearance (realism, radiometric properties); (v) topology (spatial relationships); (vi) thematic semantics and attributes; and, last but not least, (vii) operations to be performed on the model.

Conventionally, two approaches to space abstraction are utilized in geospatial data modeling, that is, field oriented and object oriented (Worboys 1995). The field-oriented approach assumes complete subdivision of the space into smaller, often regular partitions, for example, a pixel. In the object-oriented approach, the space is “an empty container” and all the objects are placed (embedded) in it, that is, a house in a 3-D model. Both approaches have advantages and disadvantages and are appropriate for different applications. While the field-oriented approach is better suited for the representation of continuous phenomena, for example, elevation fields and rainfalls, the object-oriented approach represents better discrete phenomena, for example, buildings and roads.

The spatial subdivision and the geometric primitives have a large impact on the final data structure. Traditionally, within GIS, vector and raster approaches are most used. The CAD/AEC/BIM domain distinguishes between larger varieties of 3-D geometric representations, such as boundary representations (B-reps), meshes, constructive solid geometry (CSG), voxels, octrees, nonuniform rational basis splines (NURBS), and so on (Mäntylä 1988). However, they can be also subdivided into two large groups: 3-D vector and 3-D raster representations. These representations have been analyzed for 3-D GIS as well (Latuada 2006; Abdul-Rahman and Pilouk 2008).

3-D vector representations

This group of representations comprises approaches that describe the boundaries of objects. The used primitives are 0-D (points), 1-D (curves), and 2-D (surfaces) (Figure 3). Three large groups of representations can be further distinguished: boundary representations (B-reps), meshes (fishnet or raster representations), and CSG with parametric and freeform curves and surfaces, such as nonuniform rational basis spline (NURBS).

Boundary representation

Boundary representation (B-rep) is a relatively straightforward approach because the visible surfaces of the geographic objects are modeled. This approach comprises most of the data collection approaches, which also measure properties of visible surfaces. Therefore, it has been widely used, applied, and investigated for modeling of real-world phenomena above the surface (built and natural objects). However B-reps can result in very large datasets (in case of high resolution) and very complex data structures if validity and consistency has to be ensured. Many 3-D datasets modeled only with geometric data structures reveal many inconsistencies, which obstruct visualization and performing complicated spatial operations (Ledoux, Arroyo Ohori, and Meijers 2001).
B-reps have been largely employed for geometric representation in GIS. Each primitive is described by low-dimensional primitives subject to certain rules. For example, a curve is described by two points, a surface is described by three or more curves, and a solid is described by three or more surfaces. The primitives are utilized to describe objects such as buildings and streets. The objects are usually embedded in the 3-D space, that is, full subdivision of space is assumed rarely. A number of rules are applied to the geometric primitives and to the way they are combined to define the geographic object. Examples of such rules are: a curve (also called an arc) can be restricted to be the straight line between the two points or curves are not allowed to intersect. In the case of intersections, the curve has to be split. The two points of a line must not have the same coordinates. A surface (polygon) can be restricted to be composed of only three straight lines (i.e., triangle), or otherwise restrictions need to be imposed to ensure that it is planar. The order of the curves has to be specified to be able to define the orientation of the surface. The three points of a triangle must not be on one line. A polyhedron (a 3-D object) must have the following characteristics (Arens, Stoter, and van Oosterom 2005): (i) flatness – it consists of only planar polygons on the surface; (ii) all surface polygons together constitute only one 2-manifold, so that the polyhedron bounds only one volume; (iii) simplicity – tunnels are allowed but no inner rings, a line has only two points and all polygons must have area; and (iv) orientability – inside and outside must be specified. Ledoux, Arroyo Ohori, and Meijers (2014) provided tools for checking and repairing polygons.

The rules and relations between the primitives can be specified in a geometrical or topological data structure (see the examples of 3-D geometrical data structures shown later). The data structures take account of the space subdivision, define primitives, apply geometric rules, and explicitly store (or not) relationships. The difference between the two types of structure is that geometrical data structure coordinates define locations of individual primitives, while topology data structure maintains the spatial relationships among the primitives (Bilen and Zlatanova 2003). The geometric representation facilitates spatial indexing and metric operations and, hence, is commonly used in spatial data management. Topological structures, on the other hand, ensure object validity on editing and data manipulation as well as reducing data duplication. Development in boundary representation with rules for geometrical and topological structures is being extended to 3-D data models and data handling (Breunig and Zlatanova 2011).

The Open Geospatial Consortium (OGC; www.opengeospatial.org) has developed two standards for the representation of geometrical structures: abstract specifications (Topic 1 Feature Geometry, also ISO 19107) and implementation standards. The abstract specifications provide a guidance to what geometric primitives should be used for representing geographical features (Figure 4). The implementation specifications for simple feature access (SFA) are described for three different platforms: structural query language (SQL), common object request broker architecture (CORBA), and object linking and
Figure 4  OGC geometry package (ISO 19107, Feature Geometry; www.iso.org). Reproduced by permission of OGC.
embedding (OLE)/component objects model (COM). In 1999, the first implementations of the structural query language/spatial feature standards (SQL/SFS) became available; these marked a significant step forward in maturing spatial database management systems (DBMS). Currently, almost all commercial DBMS platforms support spatial data types, that is, Oracle, PostGIS, Ingres, MonetDB, Informix, IBM DB2, as most of them adopted OGC standards. Figure 5 shows a SQL geometric feature hierarchy of simple primitive points, curves, and surfaces according to OGC SQL/SFS. As can be observed, a much richer set of geometric primitives, including 3-D shapes (solid, cylinder, sphere, spline), is proposed in the abstract specifications (Figure 4).

Following the implementation specifications for SQL, two ways of storing geometries in DBMS can be distinguished: using the polygon and multipolygon data types (Figure 6). In the first case, a 3-D object will have as many rows as the number of polygons that constitute the 3-D object. The table for volumetric objects represented by tetrahedrons will be simpler and can be normalized. It can be organized as a table with five columns: one for the ID of the tetrahedron and four for the composing polygons (triangles). In general, such an organization can be seen as a partial topological model, as the 3-D object can be defined in reference to the composing polygons, which can be organized in a separate table.

The query shown in Box 1 retrieves the geometry of Polyhedron 1, Face 1 as stored in PostGIS. When multipolygons are of the data type to represent 3-D features, a 3-D object is stored in one row with its object ID and geometry (represented by one multipolygon). This case allows management of only one table, which will be composed of two columns: the ID of the object and the GEOM (an attribute field for geometry) for the spatial data type multipolygon. An apparent advantage of the 3-D multipolygon approach is the one-to-one correspondence between a record in a relational table and an object.

Presently, only a few DBMS platforms (e.g., Oracle Spatial, PostGIS) include a volumetric data type. The challenges to the type of volumetric objects, its validity, and the functions that have to be performed on it are numerous. A simple volumetric object can be represented by polyhedron, triangulated polyhedron, and tetrahedron, all of which can be realized with provided spatial data types of polygons and multipolygons (Zlatanova 2006). Moreover, there is no practical difference in the implementation of the polyhedron and triangulated polyhedron, since a separate triangle data type does not exist. Tetrahedrons would allow for a slightly simpler representation than polyhedrons or triangulated polyhedrons, as a tetrahedron has only four triangles.

User-defined spatial data types can be implemented using different approaches from the simple SQL create data type statement, to more complex implementations, using a procedural language (PL), Java, C++, and so on. The common drawback of such an implementation is that native spatial functionality (operations and indexing) of DBMS cannot be applied to user-defined spatial data types. Moreover, the user-defined spatial data types cannot be stored in the same column of the natively supported spatial data types. Visualization for front-end applications would be possible only by developing individual connections. User-defined spatial data types, nevertheless, are very useful for prototyping of new concepts. For examples Arens, Stoter, and van Oosterom (2005) showed implementation of polyhedron data type. Penninga and van Oosterom (2008) proposed an implementation of a tetrahedron data type.

**Constructive solid geometry**

Constructive solid geometry (CSG) has been seen by many as a modification of vector representation (Latuada 2006) because it utilizes parametrized primitives, such as cube, sphere, cylinder, pyramid, and so on, which are essentially described by their outer shell. Boolean operations (union, intersection, difference, complement, and cutting) may be performed on the selected initial primitives until the desired shape of the object results. A CSG tree is constructed with primitive solids at the leaves, operations at the inner nodes, and the final object at the top level. This approach to 3-D representation

---

Figure 6  Examples of storing of polyhedron/tetrahedron. Left: Multiple polygons (each polygon is a face) are used to represent a 3-D polyhedron (same idb) with coordinates in different lengths for each polygon (geom1, geom2, etc.); hence, each polygon with a string of $x$, $y$ coordinates is stored in one row in the DBMS. Center: When all faces are triangles, all polygons have three pairs of $x$ and $y$ coordinates; therefore, all polygons can be stored in an array of coordinate sets of three for all triangles in one row in the DBMS. Right: one multipolygon is used to represent a polyhedron; each geometrical object (e.g., geom1, geom2, etc.) corresponds to a set of multiple polygons.

has many advantages: the primitives are simple volumetric objects; the operators, such as drilling, cutting and gluing, are applicable to the CSG tree; and volumes can be easily computed. This modeling approach has been widely used in computer-aided manufacturing to construct machine components, for example. The CSG approach has also been used in software design and, specifically, in BIM (Revit, SketchUp). Many building components (e.g., walls and windows) are structured following the CSG concept.

CSG is of limited use to modeling of real world phenomena. While CSG is easy for design, the modeling of real-world objects is quite tricky and not intuitive. The shape of a real-world object has to be approximated and subdivided into predefined primitives. Only regularly shaped objects, such as buildings, might require less effort (e.g., CityGML LOD1 and LOD2). However, representation of a whole city will result in a complex CSG tree. A positive aspect of this way of modeling is that all objects must be represented by solids as in reality. Real-world
objects that are currently modeled by 2-D primitives (streets, digital terrain models) or even 1-D primitives (cables and pipes) can naturally evolve to 3-D objects. Research and development are needed to establish appropriate data management of CSG trees in DBMS. Alternatively, robust operations are needed for conversion of CSG trees to B-reps, and the data types currently available in DBMS (Figure 7). As mentioned previously, the OGC abstract specifications suggest that parametric shapes be considered for implementation, but whether the CSG tree should be stored in the database remains a question.

The first step towards utilizing CSG for modeling geographical objects is introducing parametric shapes such as cylinders, cones, and spheres. Such a representation is sufficient for performing numerous analysis but faces challenges when the depth has to be taken into consideration or they have to be visualized in 3-D environments, for example, in utility works. Three-dimensional lines alone may not be sufficient for 3-D visualization because they lack the volumetric appearance that is required to produce depth perception. Several approaches have been proposed in the literature. One approach is to model pipelines as 3-D lines in the database and only create their 3-D volumetric representation for visualization. Another approach is to store the centerlines and geometry of pipeline networks with parametric representation or their real 3-D representation. While all approaches have advantages and disadvantages, a smooth transition to manage real 3-D pipeline systems depends on the availability of parametric data types and corresponding spatial operations (Döner et al. 2011). Experiments with 3-D representation of pipelines have revealed that many intersection errors can easily be detected (Figure 8).

Figure 8  3-D visualization of underground pipes: intersection of two pipe segments (left) and pipes beneath the surface in the vicinity of silo foundations (right).

Freeform curves and surfaces

Another approach to 3-D representation is utilizing freeform curves and surfaces. There are several methods to represent freeform curves and surfaces. Bézier, B-spline, and NURBS methods are among the most commonly used in practice. They are all represented by parametric functions (Piegl and Tiller 1997).
Parametric functions have several advantages over triangulated and polygonal surfaces (meshes): parametric functions have more degrees of freedom to model shapes than predefined shapes; points on a curve or surface can be evaluated numerically and accurately; and they allow for more compact representations than meshes. The simplest of the three methods to represent a freeform curve is a Bézier curve. Its shape is defined by a sequence of \( n + 1 \) control points \( P_i (i = 0 \ldots n) \) in 3-D space. A Bézier surface is, similarly, defined by a grid of \( (n + 1) \times (m + 1) \) control points \( P_{ij} (i = 0 \ldots n, j = 0 \ldots m) \). To be able to keep the degree of the curves low (3 or 4) the objects are usually modeled by Bézier patches. Such an approach cannot ensure the smoothness at the edge of two patches. B-splines overcome this limitation, because the degree of the curve can be defined independently from the number of control points. A B-spline curve of degree \( d \), is defined by a sequence of \( n + 1 \) control points \( P_i (i = 0 \ldots n) \) in 3-D space, and a knot vector of \( m + 1 \) knots such that \( m = n + d + 1 \). Though Bézier and B-splines are widely used representations, the most popular method currently for representing freeform shapes is the NURBS method (Figure 9, right). The main difference between NURBS and B-splines is that the control points of a NURBS have weights that give extra degrees of freedom in modeling curves and surfaces. The important properties of NURBS curves include the following.

- A NURBS curve is a piecewise rational polynomial curve and has the same continuity conditions at knots as a B-spline curve.
- NURBS curves are projective invariant, that is, affine and projective transformations can be applied to the control points.
- NURBS curves can represent conic sections, such as circles and ellipses; that is, they can be used to represent parametric shapes.
- NURBS curves are, just like B-splines curves, locally modifiable and contained within the convex hull of their control points.

OGC has recognized the importance of freeform curves and surfaces and has included them in the abstract specifications, but currently no GIS software or DBMS supports them. They are mostly applied in the design phase. When the construction is built, the surfaces are modeled as

![Figure 9](image-url) A pavilion modeled with NURBS: building (left) and 3-D model (right).
simple surfaces and stored as meshes (utilizing the available data types) in the database. Zlatanova, Pu, and Bronsvoort (2006) demonstrated that NURBS can easily be stored, visualized, and analyzed at DBMS level (Figure 9). A range of questions have to be investigated. For example, the validation rules for freeform curves and surfaces have to be further specified. The present validation functions follow the mathematical definitions of freeform curves and surfaces. The function AnyIntersect, for example, has been implemented using the convex hulls of the control points of two shapes to identify intersections. Opportunities remain for improved accuracy in determining intersections of 3-D shapes. NURBS have been used in AEC and for approximation of underground geological formations. A broader implementation in GIS will improve 3-D GIS functions and utilities.

3-D raster representation

Another large group of 3-D representations is based on exhaustive enumerations: voxels, polyhedrons, tetrahedral, octrees, and so on (Figure 10). This approach assumes complete subdivision of space into equally shaped (voxels) or irregular shapes (tetrahedrons, polyhedrons) 3-D units. Spatial occupancy approach is appropriate for continuous phenomena, mostly natural objects such as geological formations, marine and atmosphere phenomena. As rasters in 2-D representation, voxels are popular in 3-D. Each voxel has distinct properties with which 3-D objects can be created based on a function of properties such as salinity, temperature, or pollution parameters.

Voxel representation has the advantage of using a simple primitive and simple data structure. The space subdivision schema can be optimized using octree and binary decompositions. Such schemas allow for flexibility of voxel sizes to account for local or regional homogeneity. In addition, voxel representation offers a convenient data framework for computing, such as calculating volume, intersections, and neighborhood analysis. However, they can result in high volumes of data, which need efficient management and indexing. Furthermore, the surface of the voxelized object can be rough, and hence cannot be textured with photo-images (as widely applied in B-reps). Tetrahedrons and polyhedrons are alternatives for better modeling of variant surfaces or boundary objects, albeit at the cost of trading the regularity of voxel data structures.

As mentioned previously, many natural phenomena have been modeled with 3-D rasters (i.e., voxels). Figure 11 shows the 3-D subsurface model of The Netherlands in a voxel representation. It is a nation-wide model covering 41 000 km² and the upper 500–1000 m of the subsurface. The size of the voxels is 100 × 100 × 0.5 m³. The information recorded per voxel describes stratigraphical unit, lithology, grain-size and hydrology, physical and chemical properties as well as associated uncertainty. This dataset is used for a number of applications, such as groundwater and pollution management, land subsidence studies, and infrastructural issues.

Voxels are commonly used to facilitate the processing of point clouds. Voxelization processes reduce the size of the point clouds and, at the same time, introduce regularization for ease of analysis. For example, Figure 12 shows a voxelized point cloud for the Anne Frank tree in Amsterdam, The Netherlands. The coloring of the tree (right) is based on the number of points per voxel. The higher the number of points, the greater the chance is that the voxel represents leaves. The voxels with the highest number of points are, hence, colored green. The result appears a good match of reality.
In recent years, voxel representations have attracted increasing attention due to their simplicity and flexibility in creating representations of different resolutions. Artificially-constructed objects, such as buildings, streets, and bridges, are increasingly being modeled with voxels in science, engineering, and entertainment. For example, Minecraft, the game, originally designed for children, is currently being investigated for serious applications in planning and public participation. The game has two modes: survival and building. The building mode allows a complete world to be designed with blocks of $1 \times 1 \times 1$ m$^3$. Figure 13 portrays a Minecraft model of the old city of Delft, The Netherlands.

Voxels can be created from existing 3-D vector models as well. However, 3-D vector-raster conversion requires accurate representations of geometry, topology, and semantics. Geometrically, voxelization algorithms should be able to deal with points, curves, surfaces, and solids. The semantics of the objects depends on...
the applied semantic model, such as the most commonly used CityGML. Figure 14 illustrates a complete voxelization of a building. Voxels are created from a 3-D vector of the model and the semantics of walls, floors, windows, stairs, and air is preserved.

The neighborhood relations in the vector domain are represented by the boundaries that completely enclose the objects. Since voxels do not represent boundaries explicitly, the closure of an object is determined by its neighboring voxels. The neighboring voxels give an indication of connectivity. Each voxel has six neighboring faces, 12 neighboring edges or eight neighboring vertices (Rosenfeld 1981). This results in six faces, 18 edges and faces, and 26 faces and edges and vertices connectivity in 3-D.

The type of connectivity relates to the shape of the voxelized object as well as the topological relationships between the objects. Figure 15 illustrates four cases in which the connectivity
may lead to disconnecting or penetrating objects in 2-D raster: 8-connectivity is favorable for crossing lines (a), but not for touching between a line and a polygon (b); on the contrary, 4-connectivity is favorable for touching between a line and a polygon (d), but may lead to discontinuity of line in case of crossing lines (c).

One of the best approaches for vector to voxel conversion is the topological method (Laine 2013). The method is intersection-based, which sets a voxel at an intersection target. A voxel’s intersection target is a spatial subset of the cubical space occupied by the voxel such as the quadrilaterals bisecting the voxel along its three axes. Intersection targets are chosen based on the desired connectivity level and the dimensionality of the input vector object. Since the proposed method is intersection-based, computational efficiency would be an issue.

3-D semantics

The word “semantics” is used to describe the meaning of things. Semantics can have different interpretations: as opposite to geometry (vector/raster), as a formal connection to reality (nature-oriented) or connection to usage (value-oriented) (Billen et al. 2014). In the text here, semantics is discussed in the context of reality, that is, the meaning of data objects representing geographical objects in an application.
model. Application models can emphasize different aspects of a geographical object, which can lead to associating a real-world object with different semantics. For example, a building can be associated with a building, settlement, construction, house, office, and so on in different models. The semantics used in 3-D city modeling is compatible with the semantics used for 2-D topographic maps. Few thematic semantic models for 3-D cities exist. A common understanding is that buildings and terrain objects are the most important features to describe. Therefore, the following are top-level object classes: buildings, streets, green areas, public areas and terrain surface or terrain, vegetation and built forms.

Models can be purely semantic (definitions and relations between the objects on the basis of a theme, e.g., geography) or might be related to spatial, topological, and appearance properties. For example, the vocabulary or taxonomy referring to spatial data types (e.g., polygon, multipolygon, solid) as well as topological relationships (intersect, overlap, meet) is also a kind of semantics. Many ongoing standardization initiatives (i.e., OGC, ISO) define semantics of geographical objects with respect to their spatial, topological, appearance, and thematic properties (geometric representation, time, accuracy). Examples of such standards are spatial schema (ISO 19107:2003, 2003), temporal schema (ISO 19108:2002, 2002), quality principles (ISO 19113:2002, 2002), quality evaluation procedures (ISO 19114:2003, 2003), metadata (ISO 19115:2003, 2003), schema for coverage geometry and functions (ISO 19123:2005, 2005), and the XML geometry encoding GML (ISO19136).

In 3-D modeling, semantics is commonly used to stress the meaning of the objects and not the meaning of geometric, topological, and appearance constructors. A number of semantics models have been defined for 3-D city modeling. Townontology is an example of ontology that deals with geographical (named physical), socioeconomical, and mental objects in an urban system with part-of relationships. It is possible to observe the first two levels of physical objects taxonomy (Caglioni 2006).

The INSPIRE “generic conceptual model” (http://inspire.ec.europa.eu/index.cfm/pageid/2) is another example of defining the semantics of objects with considerations of different application models called themes. INSPIRE has 34 different spatial data themes, which cover natural, built, administrative, and environmental objects. The nine themes (“Annex I,” completed by the end of 2009) has an elaborated semantics but is not specifically related to 3-D. One exception is the theme Cadastral Parcels, which refers to 3-D cadastral objects. Annex II (e.g., Elevation and Geology) and Annex III (e.g., Soil, Buildings, Atmospheric conditions, Oceanographic geographical features, and Energy resources) themes are being specified to contain more explicit reference to 3-D aspects. For example, the draft data specification on energy resources (INSPIRE TWG ER) mentions 2-D, 2.5-D, or 3-D geometries.

One of the most prominent semantic models for 3-D geographic objects is CityGML (Gröger and Plümer 2012). Work on CityGML was initiated by Special Interest Group 3-D, Germany, in 2002 and in 2008 it was adopted as a OGC standard. Since that time, many cities in Germany, France, the Netherlands, Switzerland, Turkey, Japan, and Qatar have been using and experimenting with CityGML to build their spatial data infrastructure or city models. Vendors such as ESRI, Bentley Systems, Autodesk, and FME provide import/export modules. A large number of 3-D viewers are also available: KIT Karlsruhe, BS Contact from Bitmanagement
Software, Aristoteles from the University of Bonn, LandXplorer of Autodesk, and so on.

CityGML maintains information about spatial, semantic, appearance, and topological properties of the objects. Semantics is defined for sites (buildings, tunnels, and bridges), transportation facilities, water bodies, digital terrain models, vegetation (areas, volumes, and solitary objects with vegetation classification), land-use type, city furniture, and generic city objects. The geometric representation is typical boundary representation, which follows the GML 3-D geometry model (based on ISO 19107 Spatial Schema). CityGML is also a multiscale model with five predefined levels of detail (LOD): LOD0 – regional landscape; LOD1 – city and region; LOD2 – city districts and projects; LOD3 – architectural models (outside) and landmarks; and LOD4 – architectural models (interior). The LODs have definitions referring to semantic and spatial properties of objects. In this respect, they can be seen as a vocabulary for LODs. The definition of buildings is most developed and tested among all definitions (Figures 16 and 17). The semantic hierarchy goes to windows, doors, and furniture. The buildings (or parts of buildings) can be represented by multiple geometries (solids or multisurfaces), depending on the purpose of the application. If individual texturing is applied for each surface, multisurface is recommendable, otherwise solid should be more appropriate.

As illustrated in Figure 17, the buildings LOD1 are “buildings”; LOD2 semantics is extended with “ground surface,” “wall surface,” and “roof surface;” LOD3 adds “window” and “door”; LOD4 includes “room,” “ceiling surface,” “interior wall surface,” “floor surface,” “closure surface,” “door,” “window,” “building furniture,” and “building installation.” Depending on the LOD, a voxel of a given size can have several different semantic tags, such as (building, roof), (building, room), (building, window), and so on. For example, the “wall surface” might need to be replaced with the notion of a wall between two rooms. The “room” is then represented by all voxels that can be placed between the walls.

As mentioned previously, a geographic object can be associated with different semantics. Here examples are given with the 3-D model of a building interior. It is differently modeled in three international standards: CityGML, Industrial Foundation Classes (IFC), and IndoorGML.

In CityGML, the building interior is represented in a similar way to the outdoor concept; that is, the visible parts of the interior are represented. WallSurface, CeilingSurface, InteriorWallSurface, and FloorSurface are identified per room and are represented by surfaces. A building is composed of Rooms; a room is composed of the surfaces representing the visible part of walls, ceiling, floor, doors, and windows. However, there is no explicit notation for story floors. IFC and IndoorGML take different approaches.

IFC is the mainstream standard of building information modeling (i.e., ISO PAS 16739, 2005). In contrast to CityGML, IFC centers on the key building elements (or construction objects), including beams (IfcBeam), columns (IfcColumn), walls (IfcWall), slabs (IfcSlab), and stairs (IfcStair) (Figure 18). A building is composed of story floors. Some building elements (i.e., walls, slabs) may contain openings (i.e., voids or holes). All objects are represented by constructive solid geometry or sweeping primitives. Boundary representation is used very rarely for individual elements such as stairs. The spatial relations are preserved in the form of spatial hierarchies with (spatial) relationship classes. IFC models a wall as a solid (physical wall) between two rooms. Therefore, the notation for a room does not exist. IfcSpace was introduced recently to represent the volume occupied by a space.
Figure 16  UML diagram of CityGML’s building model. Courtesy OGC CityGML. Reproduced by permission of OGC.
IndoorGML aims to provide a semantic, geometric, and navigation model for indoor navigation systems. IndoorGML takes an alternative view to IFC in the duality graph of indoor spaces and considers that spaces (instead of walls and other solid objects) are the most important building elements, which are used to automatically derive network for navigation. The interior of a building is subdivided into appropriate spaces, with respect to the user’s navigation profile (e.g., visitor, woman, or modes of movement) and the environmental characteristics (e.g., lights, crowds, renovation) of the interior. This subdivision can vary: some spaces can be united in larger units, for example, to represent areas which are not of interest for a visitor, or can be subdivided into smaller units to indicate some functional areas as “coffee corner” or “registration area.” The spaces are volumetric objects, conceptually very similar to ifcSpace of IFC. Regardless of how the spaces are defined, semantically they are distinguishable only with respect to navigation purpose into TransitionSpace, ConnectionSpace, GeneralSpace, and AnchorSpace (Figure 19). The spaces should not overlap. The connection space/connection boundary (i.e., doors) is used to derive the logical or metric network.

Indoor empty space (free air in a room) can be modeled as GenericSpace or TransitionSpace (in IndoorGML), ifcSpace (in IFC) and Room (in CityGML LOD2). The three representations differ geometrically and topologically and should be taken into consideration when modeling interiors. CityGML, IFC, and IndoorGML are also intended for different purposes. CityGML is intended to represent the real world as built,
IFC is intended predominantly for design, and IndoorGML is dedicated to a specific application (i.e., indoor navigation). Therefore, the semantics differs, which influences also the geometric representation of the topological relationships between objects.
3-D topology

Topological data structures are often referred to as B-reps. Topology is one of the mechanisms to describe relationships between spatial objects. Models utilizing the topological properties of spatial objects are usually called topological models and are considered best suited to maintain consistency and validity of objects as well as for performing certain type of operations. As mentioned previously, B-reps require strict rules to maintain consistency of data. They depend on space partitioning, the types and number of primitives, the explicitly stored and derived relationships, and the constructive rules. While in 2-D, several topological data structures have been developed and widely used (wing edged, wheel-chain), the 3-D data structures vary greatly and no 3-D topological structure has been implemented. OGC suggests a very general concept of topological data structures but no implementation specifications. The research in the last three decades has contributed to a number of 3-D topological data structures, such as the 3-D formal data structures (3-DFDS), unified data model (UMD), simplified spatial structure (SSS), tetrahedral network (TEN), and combinatorial maps. All data structures have advantages and disadvantages with respect to certain applications. Compared to geometry, topological structures are slower in metric operations, such as computations of area, length, and volume, or for visualization because the coordinates are stored with the nodes. Each metric operation will invoke a search of low-dimensional objects until the nodes with the coordinates are reached.

3-DFDS is the first data structure that aims at storing real-world objects and their spatial relationships. The model consists of three fundamental levels: feature (related to a thematic class), four elementary objects (point, line, body, and surface), and four primitives (node, arc, face, and edge). The model follows the concept of full space subdivision into nonoverlapping objects. Several relationships, that is, node-on-face, arc-on-face, node-in-body, and arc-in-body are explicitly stored. A number of rules specify the validity of objects and relationships. The data structure has been tested in research and has exhibited complexity that is difficult to maintain. For example, the faces must be planar, and the explicit relationships should be properly organized.

The tetrahedral network (TEN) was introduced initially by Pilouk in 1996 (Abdul-Rahman and Pilouk 2008) and later modified by Penninga in 2008. TEN has four constructive objects (tetrahedron, triangle, edge, and node). An ARC table stores arc-node relationships; a TRIANGLE table contains tetrahedron-triangle-edge links. A body object is composed of tetrahedrons, a surface object of triangles, a line object of arcs, and a point object of nodes. The general rule for creating the model requires that each node is a part of an arc, each arc is a part of a triangle, and each triangle is a part of a tetrahedron. Singularities are not permitted. This data structure simplifies significantly the 3-D representations, assuming that the world is partitioned into tetrahedrons and each object (its boundary) is embedded in the tetrahedronization. The first implementation of this data structure is in a relational data table. A later implementation of Penninga’s TEN model considers mixed geometry/topology description, keeping the coordinates of the primitives as attributes (Penninga and Oosterom, 2008). This representation speeds up the search and query of objects and allows spatial indexing to be applied.

The above mentioned models maintain all primitives, that is, node, edge/arc, face, and body. To improve model performance, several researchers suggest skipping maintenance of arc. Two data structures, the simplified spatial structure (SSS) and the urban data model
(UDM) have clearly demonstrated that search and visualization operations are significantly expedited. While SSS allows polyhedral representations, UDM assumes only triangles to represent the boundaries of all objects. These two data structures are quite similar to the most data structures used for meshes in CAD (e.g., Rhinorous). Data structures without explicit maintenance of arcs (while they still can be implicitly derived) will result in some deficiencies for operations on arc (e.g., “shortest path” operations). A number of alternatives have been developed to overcome the deficiencies to metric operations. However, the tendency is the same, that is, improving the performance of topological structures by either reducing the number of primitives or storing the coordinates as attributes of the primitives. More models are discussed in Zlatanova, Rahman, and Shi (2004).

No one data structure can account for the wide variety of 3-D objects and, hence, cannot be used for all kind of 3-D applications. The topological structures depend on many different factors: dimension of the embedding space (2-D, 2.5-D, or 3-D, time), used topological primitives (node, edge/arc, face, or body), and explicit or implicit relationships, topological rules (crossing, on, or in). Oosterom et al. (2002) proposed special encoding of the topological data structures similar to geographical coordinate systems; an example of such a coding is shown in Table 1. Each topological structure obtains a three-digit code (topological type) and six parameters, that is, dimension, primitives used, topological tables, explicit relationships, number of tables, and rules, which aim at providing all needed metadata. For example, TIN has a code 221, which means is 2-D and all the information can be organized in two relational tables.

Hybrid representations

As shown already, the 3-D geometry can be vector based or raster based but it could be combinations of the two. The interest in hybrid (vector-voxel) representation is becoming increasingly important. Seamless conversions between the two will bring benefits to the type of operations that can be performed. Voxel representations are favorable for volume computations and k-nearest neighbor operations. Vector representation are better for fast, realistic visualization, although much research is completed currently on visualization of (colored) point clouds. Figure 20 illustrates voxel and vector representation of the same building including interior rasterization. The voxel representation is obtained from the vector (CityGML LOD4), preserving the semantics of the original object. The semantics is added as an attribute to the description of each voxel. In this way, it is possible to select and visualize all the voxels with a tag “wall” (Figure 20, left).

The voxel representation allows for quick volume computations (rooms, walls) and various space-based simulations, for example, 3-D routing, wind/air quality analysis. The vector representation is more convincing for walkthrough, surface computations. The general performance can be improved if a hybrid model is used. Operations can be executed at the representation, which requires less computational complexity. The conversion between the two representations can be performed on the fly if parallel maintenance is not beneficial. Such a flexible voxelization allows work at various resolutions. Figure 21 illustrates the vector model and derived 3-D rasters with different voxel size. It clearly shows that objects with crisp boundaries (e.g., the house) need very high resolution to achieve acceptable visual appearance. In contrast, the shape of objects with undefined boundaries,

Current status and future research

This entry has provided an overview of 3-D representation and models developed to account for 3-D geometry, semantics, and topology. Presently, there is no single 3-D model that can support all applications. The models are still being adapted, extended or newly designed to address specific application needs or for general purposes (e.g., developing of a national 3-D topographic standard). This process affects all components of the 3-D representations in a variety of combinations. Most commonly, the semantics is adapted and the geometry is kept unchanged, such as extensions of CityGML and IFC (Tegtmeijer et al. 2014; Hijazi, Ehlers, and Zlatanova 2012; Isikdag, Zlatanova, and Underwood 2013; van de Brink, Stoter, and Zlatanova 2013). Geometric representation might be also changed but this is mostly for temporary purposes, such as integrating B-reps and 3-D raster. Very often 3-D topologically-structured data are converted to nontopological data but the semantics is preserved. Nevertheless, a strict internationally accepted mechanism for using, adapting, and creating new concepts for digital representation of the real world is needed. Figure 22 schematically illustrates linking concepts from different models. To facilitate this process, definitions, validity rules, and relations between objects in individual model have to be further clarified and strengthened in the description of the standards.

The discussion about which component of 3-D representation should be considered primary has been going on for decades. The most commonly accepted vision is that semantics is the very critical component, followed by geometry and topology. A general workflow for 3-D data modeling is outlined here.

- Semantic definition: investigate which objects are needed, including the required resolution, accuracy, and visualization; apply existing definitions and vocabulary as much as possible; introduce new semantics specifications only when no suitable semantics is available.
- Geometric definition: decide which representation is more appropriate and, if needed, apply hybrid models or on-the-fly conversions; consider which representations
are supported by DBMS. GIS-based software vendors and mainstream DBMS do not support parametric representations, CAD/AEC-based software vendors rely on them heavily.

- Topological definition: decide which extended 3-D topological data structure is needed; investigate options for building topology to check validity of objects or perform certain operations only; consider computational geometry libraries such as CGAL (the Computational Geometry Algorithms Library), which provide robust 3-D operations on polyhedra (e.g., Nef-polyhedra) (http://www.cgal.org/)

To conclude, 3-D modeling is entering a new phase that requires more attention and cooperation from different disciplines than ever before. The ultimate goal is to create a set of different core 3-D representations and provide tools for mapping, integration, and exchange. The first steps in this direction are being made by the many international organizations that created CityGML and INSPIRE, CityGML (OGC) and IFC (BuildingSMART), and Web3-D. Researchers face many new challenges in developing data structures, theoretical frameworks, and algorithms. New domains and cross-domains are emerging as well. A typical example is 3-D indoor modeling. Research in support of modeling interiors has been active for over thirty years but it has been mostly for design purposes. Governmental and commercial enterprises as well as individuals are beginning to apply indoor models in their business processes and applications. Is the technology developed for the outdoor world readily applicable for indoor? 3-D representations should be advanced to allow seamless transitions between indoor and outdoor spaces and between different application domains.

Representation, including the presentation of spatial patterns in maps and diagrams, is a core concept in the discipline of geography’s history and is particularly central to the history of cartography, which has long struggled with questions of how and in what ways to represent the world. This means that representation is also one of the most contested concepts in the discipline. Geographers, cartographers, and GIScientists employ very different theoretical and methodological approaches to the organization and meanings of geographic data, the representation of patterns and processes across geographic spaces, and the analysis of cartographic practice. All of these occur within larger conversations about the history of ideas in the discipline. Today, geographers do not employ one definition of representation, but instead offer up multiple ways of knowing and thinking about representations of space and place. This is particularly true within cartography, which remains wedded, on the one hand, to a scientific approach to representation, and, on the other hand, offers numerous challenges to that same scientific cartographic practice. Given the complexity of how representation is discussed in the discipline, this review sketches a variegated history of this concept and examines the multiple trajectories that define representation in the discipline today (Edney 2012).

Scientific cartography

In Western cartographic traditions, maps have a long history as both scientific representations and expressions of power. The emergence of modern cartography in Europe between the fifteenth and nineteenth centuries served the needs of exploration, state formation, and colonization (Edney 1997). Increasingly centralized governments used maps, as representations of territories, to organize, tax, and control both space and subjects. At the same time, through their creation and use, maps helped people living within these territories identify themselves as subjects, citizens, and, eventually, members of nations. During the same period, emerging capital and states sponsored expeditions that mapped trade routes and “new” lands for colonization. As technologies, practices, and representations, these maps — politically, culturally, and scientifically — wrote the world into the known and, in many cases, served as artistically enticing advertisements to attract investors and colonists.

Cartography became integral within geography as it emerged as a formal discipline in Western academies in the late 1800s. During the quantitative revolution of the 1950s and 1960s, academic cartographers established their craft as a spatial science with maps as both the products and subjects of scientific investigations. To that end, cartographers theorized maps as communication devices.
More specifically, Arthur Robinson and Barbara Petchenick, in 1976, described maps as representations of the milieu — a term chosen to encompass the cartographer’s environment in addition to the meaning of place. They and other academic cartographers drew from structural linguists and psychologists to theorize that maps’ accurate topological representation of reality make them more fundamental to human experience than language. As other cartographers formalized the communication model further, maps became defined as scientifically created presentations communicating a representation of reality formed within the cognitive realm of the cartographer to the cognitive realm of the map-reader (Morrison 1976).

As a result of the cartographic communication model, academic cartographers relied on methods borrowed from behavioral psychology to measure the effectiveness of different symbol sizes, colors, and typefaces in communicating information between the cartographer’s and map-readers’ cognitive realms (Gilmartin 1981). Examples of this work included controlled experimentation that tested the accuracy of one’s map-reading skills based on the use of different symbolic systems (Board 1978). In these experiments, both author and reader were treated as individuals that had the capacity to cognitively read and map the world around them.

In contrast, but still working with a scientific approach, is the work of Alan MacEachren, who argued that communication models should be replaced by models based on “visualization” (MacEachren and Ganter 1990). As developed more fully below, maps as visualizations focus on representing unknowns rather than the known geographies of communication models. The model of representation that underwrote both the communication and visualization approaches abstracted map symbols and other elements from the social processes involved in a map’s production and consumption.

Critical cartography

While scientific geography faced increasing criticism from humanistic geography, feminist geography, and Marxist geography in the 1970s and early 1980s, most academic cartographers continued to operate within scientific communication or visualization models to incorporate digital technologies — including nascent geographic information systems (GIS). By the late 1980s, a few voices began questioning the assumptions about how maps represented reality that undergirded scientific cartography. J.B. Harley (1989, 1990) and Denis Wood (1992) adapted Michel Foucault’s understanding of power and, in Harley’s case, a relatively narrow version of Jacques Derrida’s deconstruction to retheorize the relationship between the map, the cartographer, and the worlds they represent.

Harley’s efforts were intimately tied to a much broader trend in the discipline of geography, which was in the midst of a “crisis of representation.” Informed, in particular, by the development of a new cultural geography, which called into question the discipline’s role in the reproduction of systems of power and authority, a group of geographers began to question how and for whom geographic representations worked. Harley, working within this wider conversation, called into question maps as representations of the “real world,” instead suggesting that maps, like all geographic representations, were better theorized as part of a wider cultural politics. This move aligned with the discipline’s own interest in interrogating its history and historical geographies more generally, from the role geographic representations played in the building of empires to the ways in which geographic representations obfuscated subaltern experiences of space and place.

Denis Wood (1992, 2010), in slight contrast, built his critique of the limits of scientific
cartography out of an engagement with “mundane” cartographies, both examining maps that were often marginal to cartographic discussion because of their apparent lack of scientific rigor and producing maps that built on mundane experience. Wood’s work pushed the boundaries of what cartographers might consider as objects of their scholarly analysis as well as what sorts of data and representations geographers might use and produce.

The critical cartography that emerged out of the disciplinary debates of the late 1980s and early 1990s called on practitioners to look at the margins of the map and beyond. It focused attention on the ways a map’s symbols, titles, legends, pictures, and descriptive texts represent both absences and presences and posited that these, in turn, are representations of social power. Critical cartographers argued that maps and map-makers need to be understood within the complex social and political contexts of their production. As such, maps, like landscapes, film, and other representations, are defined as both parts and products of social discourses.

As some human geographers turned toward poststructuralism to challenge any reliance on fixed and external referents in theories of representation, some geographers challenged Harley’s work for positioning social power as such a referent. Sparke (1995, 4), for example, argues that understanding a map requires the critic to constantly go back and “look for other ways in which the map and what is supposed to lie outside of it – power relations, interpretation, the ‘real’ world, and so forth – might be still more complexly inter-related.” Indeed, poststructural geography sought to unhinge the notion that binaries, such as reality and representation or production and consumption, can be theorized as distinct concepts. Offered instead, was a constitutive understanding of binaries as coproducive.

GIS’s renewed scientific representations

While critical cartographers were radically retheorizing maps as representations imbued with social power, geographers, computer scientists, and others developed GIS – databases and automated tools designed to function as scientific models of reality. Technological advances in geodesy, remote sensing, and surveying increased the accuracy of maps’ topological representation of reality. New developments in database structures and algorithms were developed to represent geographic information digitally. The process required a formal logic describing the relationship of reality to the digitally coded data representing that reality as well as to graphic representations produced from those data (Brodeur et al. 2003; Schuurman 2006).

As in the communication model of cartography, in the emerging geographic information science (GIScience) reality was first represented by cognitive models of reality – although the cognitive science underlying these models involved
a better understanding of the neurological processes involved in perception and cognition than the behavioral psychology cartographers borrowed in the 1960s and 1970s (see MacEachren 1995). These cognitive models then required formalization into conceptual representations that can be coded. The actual coding of these concepts comprised the next step resulting in a digital database, which was used to produce spatial concepts that could be represented in a digital map. Schuurman (2006, 729) summarized this process by stating that in GIS, “representations of space are expressed conceptually, programmed in code, represented graphically, and then become the basis for environmental and other decision making.”

Some of the limitations of this formal and functional method to represent reality were acknowledged by GIS developers who, as early as the late 1970s, noted that there were severe constraints in the ways digital data models could represent how people experience and organize “space” (see Schuurman 2006). This is, in part, due to the limitations of traditional cartographic data models which often serve as the conceptual representations of space described above. Yet, these internal critiques had little impact on the ways GIScience conceptualized representation before the late 1990s.

By that time, GIS and GIScience were displacing cartography from geographic education. In addition, as maps became digital they became more flexible and ephemeral. And, increasingly, map authors were not classically trained cartographers. These factors led to the rejection of the idea that maps are only communication devices. Instead, Alan MacEachren (1990, 1995) and others theorized maps as scientific geovisualizations that can be employed in different ways depending on the purpose and context of their production and use.

In his model of cartography, MacEachren acknowledged that a map designed to represent known geographic information to a general public who are expected to interact with its content as traditional map-readers can still be usefully understood as a form of scientific communication. However, he argued that increasingly maps are not designed or used in this way. His model allowed for maps to represent previously unknown geographic information to a small number of people who interact with it in ways that may profoundly change this representation. This is a map as a geovisualization; it is a scientific tool that allows map-makers and users – often the same people – to represent spatial patterns in order to first explore, then describe, and then to explain them. Like the communication model that preceded it, however, maps and the mostly quantitative, topological data they represented remained fixed in a functionalist scientific epistemology. And, as operationalized through GIS, maps were often thought of as examples of developments in visualization technologies.

Critical GIS, participatory GIS, and qualitative GIS

External critiques of GIScience emerged within human geography in the early to mid-1990s. Early criticisms characterized GIS as a dangerous return to the overly abstract quantitative geography of the 1960s and described the ways GIS practitioners represented data and reality as undertheorized. Writing from perspectives informed by feminism, Marxism, and poststructuralism, these critics chastised GIS developers for assuming that their models could objectively represent reality and/or for utilizing a Cartesian epistemology that is inadequate for representing both human and natural phenomena. Others argued that GIS represented and reproduced
space as a system of control and surveillance in ways that served the needs of capital and the state. In summary, they characterized GIS as a representational process that abstracted data, and the visualizations based on those data, from the social relations they both represent and reproduce. In addition, such critics argued that the technological costs and expertise needed to work with GIS excluded and subjugated already marginalized populations (Pickles 1995; Sheppard 1995).

Many GIScientists questioned the practicality of these critiques and argued that the critics did not understand the abstractions and formalizations undergirding their discipline (Openshaw 1997). Yet, some researchers working within GIS recognized that few in the field had conceptualized their work in a social context (Schuurman 1999; Kwan 2002). Lamenting the “antiseptic” nature of GIScience and worrying that the critiques leveled by human geographers in the 1990s had been ineffective, Nadine Schuurman, Mei-Po Kwan, and others outlined a critical GIS that works to incorporate issues raised by critical human geography into GIS using language understood by GIScience (Schuurman and Kwan 2004). Questions of representations were especially central to two streams of critical GIS research.

Public-Participation GIS (PPGIS) developed independently and in parallel to the external critiques described above. Focused on on-the-ground, practical research, practitioners of PPGIS engaged with underprivileged social groups to develop GIS meeting communities’ needs and help people in particular places visualize the spaces they share and hope to change. Central to the development of PPGIS were questions concerning the authorship and ownership of both data and maps representing these communities (Elwood 2006). In other words, in a participatory GIS, the representation’s subjects are the same as the representation’s authors and, as such, are understood to control how and by whom the representation is used and interpreted. Such concerns connect the ways representation is utilized with PPGIS with methodological literature in human geography and with poststructural theorizations of maps in critical cartography.

Qualitative GIS emerged, mostly after 2000, in response both to calls for a critical GIS and to meet the needs of researchers and communities working with data representing situated and negotiated knowledge about space and place (see Jung and Elwood 2010). Rooted in grounded theory, feminist, or mixed method approaches, qualitative GIS requires the production of formal codes and techniques that permit existing GIS software – typically designed to represent quantitative and topological data – to represent qualitative data, such as interview transcripts, photographs, or audio recordings expressing more experiential understandings of space and place. At the same time, such representations must be in a form permitting the use of qualitative analytical methods that allow researchers to explore the “contradictions, commonalities, and nuances of data that are rich in contextual and process-based detail” (Elwood and Cope 2009, 4). Finally, researchers utilizing qualitative GIS techniques must grapple reflexively with the ways in which the data and visualizations with which they work both represent and reproduce relationships of unequal power between, for example, researchers and subjects.

Nonrepresentational theory and cartography

Within critical cartography and critical GIS, the poststructuralist turn presaged the interjection of nonrepresentational theory (NRT) into understanding map-making and map use. As Joe
GERLACH (2014, 26) summarizes, NRT is “at once a critique of the epistemological certitude of representational, and by the same token cartographic, reasoning, while also affirming a geography of things happening.” Building from the work of Nigel Thrift (1996), NRTs argue that the focus on maps, landscapes, and other representations inadequately captures the multisensory and emotional practices and experiences of ordinary lives. For many geographers utilizing NRT, the goal is to theorize affect or to acknowledge that “there is no stable human or nonhuman existence because so much of what happens in the word, what moves, what becomes, from day to day and throughout spaces, does so before it passes the threshold of cognitive recognition” (Gerlach 2014, 27).

As applied to maps, NRT foregrounds emergence, practice, and performance rather than the representation as a fixed object. Nigel Thrift calls maps “their own practitioners” (2007, 58), meaning that they are always parts of what they represent and that their producers and consumers are not separable from either each other or from maps as emergent, practiced, and performed.

Rob Kitchin and Martin Dodge (2007) develop this line of argument more fully. They argue against a map as either an objective, scientific representation derived from reality through cognitive processes or a representation of social power. Instead, a map – or mapping – is simply of-the-moment, contingent on how it is practiced in any particular context. Using a map derived from Irish census data as an example, Kitchin and Dodge state that the lines, colors, and other marks only take the form of, and are understood as, a map through mapping practices. These practices are learned “knowledge and skills [that] (re)make the ink into a map and this occurs every time they are engaged with – the set of points, lines and areas is recognized as a map; it is interpreted, translated and made to do work in the work” (Kitchin and Dodge 2007, 335). Thus, a map does not shape how we think about space and, thereby, does not make space. It is a co-constitutive production between inscription, individual, and world; a production that is constantly in motion, always seeking to be an immutable mobile, a particular representation that carries its relationship to reality and to its producers and consumers with it wherever it is engaged. In this way, a map is always ontogenetic; it is emergent.

From this point of view, the map is gone. Only mapping remains. Cartography becomes a “science of practices not representations” focused on how the acts or performances of mapping are produced and how different mappings do work in the world (Kitchin and Dodge 2007, 342). The study of how certain mappings appear to be ontologically secure is another focus in this radical rethinking of the subdiscipline.

A nonrepresentational cartography does have points of attachment with other theories of representation in cartography and GIS. As a science of practices, it engages with the formal logic of digitally coded geovisualizations – entities called into being as parts of scientific research rather than as finalized and objective representations of known spaces. And, like Del Casino and Hanna’s (2006) map space, Kitchin and Dodge’s mapping cuts through the binaries between representation and reality, production and consumption, representation and practice, and ontology and epistemology. While others criticize nonrepresentational cartographic theory as asocial and, therefore, useless for understanding how sociospatial power is deployed and reproduced, Thrift (2011) offers a possible way forward, arguing that maps, as processes/practices, are now inhabitable. Inhabitable maps, such as those found on Google Earth or in video games, are engineered to produce “defined experiences which can be commoditized” (Thrift 2011, 9).
As such maps or mappings can become means of achieving social assent. Thrift’s approach does not presuppose unequal social relationships or hegemony, but allows for mapping practices, theorized as emerging in particular spatial and temporal contexts, to assert ontological security as a means to enforce a particular sociospatial order.

The democratic potential of a new cartography

Professional geographers are not the only people to develop and distribute geographic representations of space in map form. The emergence of new technologies that allow a variety of users to collect and map spatial data has facilitated a much broader world of maps. The authority of the cartographer is challenged by these developments, as is the capacity of the discipline to manage the representational politics of maps. One such avenue of challenge has developed from the practice of “voluntary mapping,” which allows people to either build their own maps or represent themselves in map spaces, from websites such as Wikimapia to organizations mapping data in real time and space to focus their political agendas (Elwood 2008). Websites, such as Google Maps, have also redefined the term “map maker” by allowing millions of people to tag and upload data to a Google Map database. These technological changes, a function of the development of Web 2.0, have increased the capacity of everyday users to engage in mapping practices. According to Michael Goodchild (quoted in Thrift 2011), “we are, in effect, back to the days of the 1500s when it was possible for someone – a cartographer – but with no qualifications whatsoever, and no authority, to produce a map which led, in effect to the naming of America.” This new way of mapping challenges those traditional “map authors” – cartographers, GIS professionals, and massive data organizations, such as the US Census Bureau – who have long controlled the organization and representation of much spatial data.

On the other side of the everyday cartographer is the development of massive datasets situated within a new era of big data. Resting at the heart of big data analysis is a commitment to data visualization, which includes the use of mapping technologies. Some of these projects rely on voluntary data to help destabilize normative assumptions found in historical mapping projects, such as the US Census. In other cases, visualization projects are gathering data points from around the globe to investigate sociospatial networks, be it within transportation systems, urban greenspace systems, or criminal trafficking patterns. The turn toward big data also calls into question the traditions of positivist quantitative representations, which rely on historical variables, such as fixed locations and generic social and economic variables. In this new era, crowdsourced data provides a different cut at how we might map diverse spaces and processes (González-Bailón 2013). At the same time, big data representations make claims to “real data” in “real time” in ways that may prove equally problematic in relation to earlier scientific approaches to geographic representations, which, for example, seemed to marginalize the histories that undergird these data (Barnes 2013).

Conclusion

Cartography is a core subdiscipline through which the debates around representation in geography have taken place. At the heart of these debates are the questions of what it means to represent the world and whether we can even do that work appropriately. On the one hand, the model of mapping as a science remains central to
the discipline, finding its outlet in a revitalized visualization approach to cartography and the formalistic approach to modeling in GIScience. On the other hand, there is a constant re theorization of maps and their relationships to both the spaces they represent and the people who simultaneously are their makers, users, and subjects. While many of the applications of critical, poststructural, and NRTs to cartography and GIS are performed by geographers outside of these twinned subdisciplines, an increasing number of scholars claiming the identities of GIScients and cartographers are seeking ways to “re-wire” geospatial technologies to work with and represent alternative ways space and place are experienced and known.

Such developments, and the explosion of voluntary mapping and big data applications, mean that cartography cannot be contained by disciplinary boundaries that seek to delineate its meaning and practice, suggesting that maps are more than objects of geographic use and inquiry. Whether theorized as representations, visualizations, or practices, maps may be better imagined as art and not science. This can be seen, for example, in projects designed to challenge familiar geographic sensibilities by distorting space through maps. Projects have developed that are much more playful with spatial data, producing new representational mapping practices that are not beholden to the conventions of a communication or visualization model. These new cartographies are less interested in the theoretical or ontological questions found in critical cartography, on the one hand, and geovisualization and GIS, on the other.

Despite the explosion of maps, visualizations, and other cartographic representations, it is clear that the fields of cartography in particular, and geography more generally, will continue to support a wide range of representational theories and practices. What this suggests is that the concept of representation – of how we can represent the world – will remain highly contested, even as some seek to remove representation from geography’s conceptual toolkit.

Further reading

In the early days of geographic information systems (GIS), the “field” view of geographic reality prevailed. A field answers the question “What is here?” It gives a value for each possible location on a surface (ideally, a continuous surface). The alternative view in geographic data modeling is the “entity” view. It answers the question “Where is this object?” An entity-based data model sees entities (or objects) as independent from each other and assigns them a link to their location in space (Couclelis 1992).

The field/entity dichotomy usually adopted in GIS has its roots in philosophical ground. In Aristotle’s view, void space does not exist: bodies, with their extension, determine the existence of space; therefore, a parallel can be drawn with the entity view. In the earlier view of Plato and the Pythagoreans, space was a more abstract concept (geometrical figures); here a parallel can be drawn with the field view.

Several data structures, raster or vector, were defined to represent geographic data models in the limited memory of computers. It is commonplace to think of rasters as the most immediate data structure to represent a field, and of vectors to represent objects. This is, however, not always the case and can lead to misunderstandings. There exist vector data structures (such as triangulated irregular networks (TIN) and contour lines) that represent fields.

Likewise, objects can be represented as rasters (it is common practice in remote sensing and object-based image analysis (OBIA)).

Nonetheless, for representing entities, vector data is the prime choice to assure flexibility and scalability. From the early vector-based GIS, single objects could easily be represented as points, lines, or regions, but it was not so straightforward to represent collections of objects and their relationships. The latter issue produced a range of different data models categorized as spaghetti models, network models, and topological models. While spaghetti models were based on collections of independently represented lines, network models and topological models aimed to explicitly represent topological relationships among entities and avoid redundancy or duplication. Basically, network and topological models were graph-like structures composed of nodes and edges. Topological models in early vector GIS were associated to the idea of single-value maps or planar enforcement allowing only one object at a given location. Single-value maps can represent spatial objects of a single type (e.g., administrative boundaries or a road network). Hence, spatial data is organized in several layers, each one showing a single-value map. At the same time, topological models experienced challenges in representing objects of complex shapes, such as regions with holes (a region with a hole cannot be modeled as a face of a graph embedded in the plane) or complex lines (when two roads intersect, the roads must be split to obey the single-value map principle).

Topological models, even if they were vector-based representations of entities, could not capture the complexity of real geographic fea-
tured and failed to find an adequate representation for them. From the 1980s, a new data modeling paradigm emerged in computer science, the so-called object-oriented model (Atkinson et al. 1992). While in the antecedent relational data model information was typically fragmented over several tables, the object-oriented model considers objects of arbitrary complexity, which can be constructed via the repetition of abstract modeling primitives of classification, aggregation, and generalization. The object-oriented approach was introduced to GIS during the 1990s, when the use of the term “complex object” in spatial databases was also observed. According to Goodchild (Goodchild 1992), complex objects are incompatible with the field view of reality. Complex objects are the true realization of the entity-based view in geographic data modeling. Complex objects are able to represent both the complex internal structure of entities (e.g., the presence of holes or subparts), and the complex relationships between them (e.g., topological relations of crossing and overlapping).

The object-oriented paradigm is now well established in information technology. Complex geographic objects have been included in spatial data type specifications defined by the Open Geospatial Consortium (OGC). The adopted definition of data types representing complex objects is described in the Simple Features Interface Standard (SFS) (OGC 2006). Such data types are the basis for all interoperability standards for geographic information exchange, such as the Geography Markup Language (GML) (OGC 2007), the Web Feature Service (WFS) (OGC 2005), and the language for supporting geographic objects in the semantic web, GeoSPARQL (OGC 2012). These data types are rooted in the mathematical foundation of point-set topology.

Definitions of complex objects in point-set topology

A mathematical definition of complex objects is usually expressed in point-set topology. A topological space is generally described as a set of arbitrary elements (points) in which a concept of continuity is specified. A continuous mapping transforms a topological space $X$ to a subset of a topological space $Y$ subject to the preservation of the neighborhood relations between mapped points. Continuous mappings are also known as homeomorphisms or topological transformations and include translation, rotation, and scaling. Topological relations remain invariant under topological transformations. The study of topological relations between objects also depends on the embedding space, which is assumed to be $\mathbb{R}^2$.

In the following, the definitions of simple and complex regions, lines, and points are introduced. All the definitions were originally published in (Clementini and Di Felice 1996). Simple regions are equivalent to a disk and simple lines have just two end points. Complex regions have separations and holes, complex lines have separations, more than two end points, and possibly self-intersections, and complex points are a set of points. Complex objects are far more common than simple ones in geographic reality. The definitions are based on concepts of open sets, closed sets, and continuity of point-set topology.

Let $A$ be a two-dimensional point-set:

- the interior of $A$, $A'$, is defined as the union of all open sets contained in $A$;
- the closure of $A$, $\overline{A}$, is defined as the intersection of all closed sets containing $A$. If $A$ is a closed set, then $\overline{A} = A$;
- the boundary of a closed set $A$, $\partial A$, is defined as the difference between its closure and its interior;
the exterior of a closed set \( A \), \( A^- \), is defined as \( A^- = (\mathbb{R}^2 - A) \).

Throughout the entry, it is assumed that regions are regular closed sets.

**Definition 1** A point-set \( A \) is called regular closed if, and only if, \( A = \overline{A} \).

Regular closed point-sets are usually assumed in spatial data modeling because they allow particular cases to be got rid of, such as those shown in Figure 1a–c. Nonregular point-sets can undergo a regularization process to become regular (Figure 1d–f).

The notion of complex regions relies on the topological notions of connectedness and component. A *separation* of \( A \) is a pair of disjoint nonempty open sets \( A_1 \) and \( A_2 \) whose union is \( A \). \( A \) is connected if there exists no separation of \( A \); otherwise it is disconnected and \( A_1 \) and \( A_2 \) are called the *components* of \( A \). Separations and components refer to interiors of regions, while spatial features are represented as closed sets, in order to permit that a region also contains its boundary. Simple regions are defined as follows:

**Definition 2** A simple region is a regular closed (nonempty) two-dimensional point-set \( A \) with connected interior and connected exterior.

A simple region is illustrated in Figure 2a. A region with disconnected interior (Figure 2b), a region with disconnected exterior (Figure 2c), and a region with spike (Figure 2d) are not valid simple regions.

Now the above definition can be extended by taking into account holes. The exterior of a region with holes has separations. Separations of the exterior imply that there exists one *outer exterior* (unbounded set) and \( n > 0 \) *inner exteriors* (bounded sets). The outer exterior will be denoted by \( A_0^- \) and the inner exteriors by \( A_1^- \ldots A_n^- \). Their union makes up the entire exterior, that is, \( A^- = \bigcup_{i=0}^{n} A_i^- \).

**Definition 3** A region with holes is a regular closed (nonempty) two-dimensional point-set \( A \)

---

**Figure 1** Examples of nonregular closed point-sets (a–c) and their respective regularizations (d–f).
According to Definition 3, the case in Figure 3a is allowed, while the cases of disconnected interior (Figure 3b) and of nonregular closed point-set (Figure 3c) are not allowed. Therefore, in a region with holes, the closures of any two different exterior components cannot touch along a line, but they are allowed to touch at some points. Formally, their intersections must be empty or equal to a finite set of points \( \{p_1 \ldots p_k\} \):

\[
\forall i, j = 0 \ldots n, i \neq j : \\
(\overline{A_i} \cap \overline{A_j} = \emptyset) \lor (\overline{A_i} \cap \overline{A_j} = \{p_1 \ldots p_k\})
\]

Now, composite regions can be defined:

**Definition 4** A composite region is a regular closed (nonempty) two-dimensional point-set \( A \) with disconnected interior.

If the interior of \( A, A^\circ \), is disconnected, the components \( A_1 \ldots A_n \) of \( A \) can be indicated as the closure of the corresponding components of \( A^\circ \). For the components of \( A \), it holds:

1. each \( A_i \) is either a simple region or a region with holes;
2. \( A_i^\circ \cap A_j^\circ = \emptyset, \forall i \neq j \);
3. \( (\partial A_i \cap \partial A_j = \emptyset) \lor (\partial A_i \cap \partial A_j = \{p_1 \ldots p_k\}) \).

In other words, each component is either disjoint from the other ones or touches other components in single points: it cannot touch other components along a one-dimensional piece of boundary. Figure 4 shows an example of a possible composite region.

Now, the definitions of lines can be illustrated. Intuitively, a simple line in the plane corresponds to a single pencil stroke obtained by not passing twice on the same point. To define a simple line in point-set topology, a homeomorphism must
be considered from a one-dimensional interval to the plane requiring that the mapped points are distinct, as follows:

**Definition 5** A simple line is a closed (non-empty) one-dimensional point-set, $L$, defined as the image of a continuous mapping $f : [0, 1] \rightarrow \mathbb{R}^2$, such that $f(t_i) \neq f(t_j)$, $\forall t_i, t_j \in [0, 1], t_i \neq t_j$.

Figure 5a shows a simple line. The mappings of the endpoints of the interval 0 and 1 through $f$ are the two endpoints of $L$. These two endpoints form the boundary of a simple line in the plane; that is, $\partial L = \{f(0), f(1)\}$.

By relaxing the constraint of distinct points in the continuous mapping, the notion of line with self-intersections is arrived at. Self-intersections can involve either the endpoints or the interior of the line. Figure 5b–d shows three lines with self-intersections: the boundary of a line with self-intersections can be composed of 2, 1, or 0 end points.

Complex lines cannot be obtained by a single pencil stroke. They are composed of several simple lines or lines with self-intersections that can be disconnected or connected each other (see Figure 6).

**Definition 6** Let $f_1, f_2, \ldots, f_n$ be continuous mappings from the interval $[0, 1]$ to the plane. For this entry, a complex line is any closed (nonempty) one-dimensional point-set, $L$, defined as the union of the image of the functions $f_1, f_2, \ldots, f_n$.

Figure 5  A simple line (a) and lines with self-intersections (b–d).

The boundary of a complex line $L$ can be built subtracting from the set of endpoints of single lines $f_i$ all the endpoints that touch other lines.

The closure of a line, $\overline{L}$, is the set of all points of $L$, end points included; therefore $\overline{L} = L$. The interior of a line, $L^\circ$, is the set difference between the closure of the line and its boundary: $L^\circ = \overline{L} - \partial L = L - \partial L$. The exterior of a line, $L^-$, is the set difference between the embedding space and the closure of the line: $L^- = (\mathbb{R}^2 - \overline{L})$.

**Definition 7** A point is a (nonempty) zero-dimensional point-set, $P$, consisting of only one element.

As a generalization of the previous concept, the notion of complex points is introduced as follows.

**Definition 8** A complex point is a (nonempty) zero-dimensional point-set, $P$, consisting of a finite number of distinct elements.

The boundary of a complex point $P$ is empty (i.e., $\partial P = \emptyset$); as a consequence, the interior of a complex point $P$ is equal to the union of all the elements in $P$ (i.e., $P^\circ = \bigcup_{i=1}^n P_i$).
Other dimensions in conceptual modeling of complex objects

If facing the conceptual modeling of a complex geographic object, various components are involved in its definition. Not all of them exist at the same time nor might there be the actual need to consider all of them in the model. For this entry, the following possible dimensions are considered to be taken into account.

- **Compound definition of the spatial component.** The actual geometry of a geographic object might not be described with a single spatial component as described in the point-set topology approach. Therefore, a compound geometry, that is, an aggregate of various geometric types, might be needed.

- **Multiple representations.** A single spatial representation might not sufficiently represent a given geographic object. A road could be represented as a polyline at a small scale and as a region at a larger scale. Therefore, a complex object might allow the coexistence of several geometrical representations at the same time, that is, multiple representations.

- **Semantic and spatial properties.** Besides the spatial component, complex geographic objects possess a semantic component. Complex object representations include thematic attributes, functional requirements, and various types of constraints.

- **Temporal component.** A geographic object is rarely seen as time-independent. Time relates in various ways to geographic object definitions. For example, trajectories (of cars moving in town) cannot be modeled with a separate temporal component, but they exist in both space and time. In other cases, for example, a lake that cyclically shrinks and expands its boundary due to rainy seasons may associate the temporal component by adding time stamps to the spatial component.

- **Uncertain boundaries.** The point-set topology approach produces models with precise boundaries (also known as crisp boundaries), which are always an approximation of reality at a given scale. Geographic objects in a variable measure all possess a degree of uncertainty in boundary definition. Even human-made objects such as buildings would not have crisp boundaries at a sufficiently large scale. Natural objects such as mountains and islands have a greater degree of fuzziness than buildings. While currently not much implemented, models considering fuzzy or broad boundaries could significantly improve geographic modeling.

- **Aggregations.** Often complex objects are made of other objects, which can exist independently. A mall is made up of several shops. A building is made up of walls, windows, and stairs. Object-oriented modeling does not directly include such components inside the definition of bigger objects: it includes references (or “pointers”) to other objects, which therefore conserve their own identities.

- **Complex relationships.** Complex objects interact with other objects in various ways. A city “is the capital of” a country. A river “flows into” another river. In many cases, such complex relationships hide a spatial relationship between their geometric representations (an “inside” in the case of city-country and “touch” in the case of river-river). A considerable part of geographic data modeling, therefore, may be devoted to the description of complex many-to-many relationships between geographic objects.

**REPRESENTATION: COMPLEX OBJECTS**

A key theme in the scholarship on dynamic complex systems is that the system as a whole takes on characteristics and functions that are qualitatively different from (i.e., is greater than) the components, processes, and interactions that comprise the system (i.e., the sum of the parts). The idea that something unique exists at the system level that cannot be identified simply by enumerating, describing, and understanding its parts (i.e., reductionism) is not new in geography, and a holistic approach to understanding system dynamics has characterized the discipline from its earliest days (e.g., von Humboldt’s (1845, 4) “perception of unity of plan amidst eternally recurring variety of form” in Cosmos).

In the early 1900s, geographer Vidal de la Blache postulated that interactions among entities were the key to the emergence and evolution of system properties. He described processes on the Earth’s surface that were interrelated and affected others (such as “localized ocean currents, geological traits, and climatological attributes”) and wrote that these processes were interdependent and together formed an organism, a whole (Archer 1993, 501). Later, the Gaia hypothesis (Lovelock 1979) and the whole field of Earth system modeling (Falkowski et al. 2000) formalized the notion of the organic evolution of interconnected Earth systems.

Fascinated with the whole as an organism, Vidal de la Blache described parallels between the formation of biological organisms and the emergence of social, political, and industrial organisms from society (Archer 1993). He noted that emerging organisms are dependent on and influenced by the interactions among the animate entities that form their base. He also noted that geographical boundaries often unite and bond certain animate entities together through their interdependence and interactions (Vidal de la Blache, 1926, 165 – cited in Archer 1993, 502). In the case of humans, where interactions have increased over time as a result of improved communication and transportation, larger social organisms have emerged (Archer 1993).

Vidal de la Blache (1898, 102 – cited in Archer 1993, 502) described relationships of interaction between “two principal cycles, that of the inanimate and that of the animate world,” which corresponds to the typical division of phenomena into human and physical geography. The inanimate cycle refers primarily to deterministic relationships and interactions among geological, hydrological, climatological phenomena, and processes of nature; while geographically animate cycles are primarily nondeterministic and are concerned with living phenomena, such as humans, that have the capability to self-organize and adapt (Archer 1993).

Cutting across the traditional domains of geography as it does, it could be argued that the representation of dynamic complex systems is a necessary component of spatial reasoning and analysis. Based on Tobler’s (1970) first
law of geography, which explicitly incorporates spatial interactions, that is, “All things are related, but nearby things are more related than distant things,” spatial analysis is the study of emergent spatial patterns due to changes in the underlying properties of the local environment (i.e., first-order variation) or the interaction among observations (i.e., second-order variation). Spatial analysis in geography, then, seeks to understand complex systems in a way that explicitly incorporates space. Because spatial patterns emerge and evolve over time, understanding geographical processes requires a spatial analysis that is dynamic and can adapt to a changing environment (first- or second-order variation) to describe and compare patterns over time due to behavioral and interaction processes.

Studying dynamic complex systems requires conceptualizing and operationalizing approaches for representing relationships and interactions in space, over time, and at multiple scales that can produce emergent and aggregate patterns. This entry reviews these issues in representing dynamic complex systems in geographic research and identifies gaps and potential future directions for geographic research.

**Complex systems**

A complex system can be defined as a system that comprises many heterogeneous interacting parts that, when aggregated, produce system-level properties for which analytical solutions are intractable and cannot be easily deduced from the actions of the parts. Flocking behavior by birds is an example of a phenomenon that illustrates the behavior of complex systems. The movement of the flock and any one bird are difficult to predict. However, the pattern of flocking behavior can be reproduced by simulating individual birds that abide by three simple rules (i.e., follow the average heading and velocity of the flock, maintain space so as not to bump into other birds, and move toward the center of the flock) (Reynolds 1987). This representation of a complex system provides an existence proof (Waldrop 1990), demonstrating that representation of dynamic complex systems can provide understanding of the processes by which individual components of a system interact with each other to produce observed spatial and temporal dynamics.

Complex systems can be nonadaptive or adaptive. Self-organization of landslide dynamics, in which adding grains of sand to the pile affects the frequency and magnitude of landslides (Bak, Tang, and Wiesenfeld 1987), is an example of a nonadaptive system. Here, the grains of sand do not have the ability to change their behaviors or their goal. In some cases, however, complex systems are adaptive (termed complex adaptive systems or CAS), in which the system components are able to adapt (Axelrod and Cohen 2000) and change their goals and their behaviors depending on their state, the states of their neighbors, or the state of the system (i.e., autonomous agents) (Iglesias, Garijo, and Gonzalez 1999). These complex adaptive systems are more resilient to external perturbations and may change their structure to improve the functionality of the system components or agents and/or the system as a whole. Most geographic research representing dynamic complex systems incorporates both adaptive and nonadaptive components.

Interactions among nonadaptive or adaptive components of a system can produce feedback effects which result in systems that can exhibit complex spatial and temporal structure, including nonlinear dynamics and threshold effects, that are sensitive to initial conditions and may hold path dependencies, and that can produce multiple equilibria (i.e., the system does not necessarily
converge on a single equilibrium outcome. To represent these feedbacks requires understanding and describing cross-scale dynamics in complex systems, which involves understanding the micro-level processes that form system behaviors and the macro-patterns that emerge from those behaviors.

**Representing dynamic complex systems**

Geographic information systems (GIS) and spatial analysis approaches have been successfully used to represent, describe, and analyze the spatial macro-patterns of dynamic complex systems. However, until recently, these approaches have been limited in their ability to represent detailed knowledge of process and behavior, the drivers of dynamic interactions among features in a landscape, and how features change over time and through interaction with other features and the environment.

Instead, a variety of other approaches have been used to represent and model the processes inherent in dynamic complex systems. In some cases space–time statistical models have been constructed to represent behavior and change across a landscape (e.g., land-cover change or disease spread). Additionally, mathematical models, such as ordinary differential and partial differential equations, can be used to capture the dynamics and interactions of dynamic complex systems. However, mathematical models typically have difficulty representing heterogeneity among system components and the micro-level behaviors of those components.

Arguably, the preferred approach for modeling complex systems is the representation of system components, be they locations on a grid or mobile decision-making entities (e.g., agents), in a simulation model (Torrens and Benenson 2005). Cellular automata (CA) describe the former type of models, with fixed topological relationships, and agent-based models (in the social sciences) and individual-based models (in ecology) describe the latter case of entities with an evolving topological structure (hereafter both are referred to as agent-based models or ABMs). These models are able to capture most of the primary characteristics that describe the micro-level processes driving dynamics in complex systems, such as agent heterogeneity (Holland 1995), interaction (Anderson 1972), adaptation and learning, and agent–environment feedbacks, among others. The ABM approach is appealing because it allows for a one-to-one matching of real-world actors to virtual-agent entities that can facilitate model parameterization, calibration, validation, and communication of model results with system stakeholders.

Next, how the various components of dynamic complex systems are typically represented are described. While many of these representations can be utilized across different modeling approaches, the focus is specifically on CA and ABM as the key tools for representing these dynamics.

**Representing space**

The representation of geographic space in a dynamic complex system provides a measurable environment within which system dynamics evolve, through changes in the location of dynamic entities (i.e., absolute space) and in their topological relationships (i.e., relative space). Traditional concepts from geographic information science (GIScience) serve well to describe these representations. Absolute space is defined by a mathematical coordinate system, and typically a projection, that maps cartographic or modeled entities to locations on Earth. The dominant data models for representing the space of a dynamic
complex system are raster and vector data models, which roughly but not perfectly correspond to field- and object-based conceptions (Bian 2000) of spatial variability, respectively. The coordinate system provides information about the location of entities (e.g., cells or objects), about which there is usually also some attribute information (i.e., categories or quantities) that is either fixed to a location (in the field view) or fixed to an entity whose location can change (in the object view). Relative space can be defined through explicit description of spatial connections between entities, through concepts of adjacency or proximity, or through nonspatial connections that represent known social, hierarchical, or network-based interactions.

Cells, features and agents

The entities that implement the dynamics in these models can be either agents (in ABMs) or cells (in CA). “Agent” is a term adopted from economics (Holland 1995) and is typically used to represent real-world actors (e.g., individuals, firms, governance entities) (Rounsevell, Robinson, and Murray-Rust 2012). While agents can be reactive or deliberative (Doran 2001), agents can be thought of as any object (defined as a software object) that has the ability to satisfy internal goals or objectives through actions and decisions based on a set of internal rules or strategies (Iglesias, Garijo, and Gonzalez 1999). An agent may represent a single entity, such as a blood cell, or a collection of agents, such as a firm or organization.

The only real distinction between an agent in an ABM and a cell in a CA is that agents need not have a fixed location, or any location for that matter (as in the case, for example, of agents that represent institutional rule setting), whereas cells in a CA are explicitly fixed to a geographical location. This distinction is important when it comes to understanding the relationship between the entities in the model (agents or cells) and their referents in the real world, and has parallels in the object/field distinctions in GIS. The key advantage of agents is that they can be more flexibly associated with individuals or groups of people, animals, or other mobile entities, whereas cells in a CA are limited to represent particular locations or areas as the basic entities in the model.

In the object-based (or vector) data model, a feature represents entities in the real world. Real-world features, like a person, a road, a coastline, or an area of specific soil type, can be represented virtually in a GIS as points, lines, or polygons. Features can be defined as simple and independent, such that they have no relationship with neighboring features (adjacent or distance based), or complex, with defined and distinct relationships with other features around them (Longley et al. 2001). Features have attributes that describe their properties. As spatiotemporal information is increasingly incorporated in to GIS, changes to features and their attributes are represented explicitly, but they do not have explicit representations of behavior (i.e., descriptions of how those changes occur).

Interactions between agents and geographic features have been described through four specific relationships: identity, causal, temporal, and topological relationships (Brown et al. 2005). Identity relationships are one-to-one or one-to-many matches between the agents, which have explicit descriptions of behavior, and the geographic features. The agents implement change and the GIS manages geographic location and feature attribute data. In the causal relationship, the agents alter features in the landscape but may have no physical presence as a geographic feature. For example, they may alter attribute values of a polygon, such as water or soil quality. In a temporal relationship, change in feature locations or attribute values...
may be implemented through the creation of new time-stamped data layers or attributes that record the history of processes created by an ABM. Lastly, in a topological relationship agent movement is influenced or constrained by the topological rules given to a set of spatial features (e.g., exclusion of movement or spatial associations (e.g., features within proximity or view).

The field-based (e.g., raster) data model tessellates a space with nonoverlapping entities and assigns one and only one entity (e.g., cell) to each location. Attributes of these locations are then recorded. Because of the fixed nature of the locations, the spatial topology among entities is relatively easy to ascertain, simplifying definitions of relative location.

**Representing processes and behaviors**

Possible approaches to representing spatially explicit processes in a dynamic complex system can be partly understood by exploring descriptions from fluid dynamics, specifically the Eulerian and Lagrangian views. The Eulerian view focuses on change in state or attributes at a location and is well represented by field-based models of space. CA models implicitly use the Eulerian view, in which they describe change of state at a location as a function of the characteristics at that location, characteristics at neighboring locations, and some rule or algorithm implemented iteratively (and usually uniformly) at all locations. While rules describe the conditions under which the attributes at a location change, and there is no explicit representation of entities, fundamental work on CA dynamics has shown that some sequences of changes in interacting neighborhoods of locations can produce complex behaviors that mimic movement of an entity across a space, such as a fire or diffusion front (Yassemi, Dragićević, and Schmidt 2008).

The Lagrangian view offers an alternative perspective on spatial processes that focuses on modeling movement of entities through space, and corresponds to the object representation of spatial entities. Descriptions of processes are tied to entities and the processes themselves describe the movement of the entities (i.e., change in location), rather than change in attributes. An example of the Lagrangian view implemented in an ABM is a predator–prey relationship, whereby individual predators moving across a landscape search for prey and the prey attempt to avoid detection and move away from predators. In these models, movement, and the ever changing relative spatial locations of entities, is key to the evolution of system properties.

In practice, many ABMs of geographical systems include representations of both movement and change, combining aspects of Eulerian and Lagrangian dynamics. When the representation of the dynamic complex system increases in complexity it becomes more likely that these two perspectives intersect as the modeler requires some processes to be represented using an Eulerian approach (e.g., soil erosion) and other processes (e.g., farmer decision-making) to be represented using a Lagrangian approach (Parker et al. 2003). Additionally, it is possible to model the same dynamics using either perspective; the choice of approach will generally result in focusing attention on different aspects of the phenomena being modeled. Relating these perspectives back to the work of Vidal de la Blache, the inanimate processes can be thought of as primarily using an Eulerian perspective, whereas the animate processes relate most directly to a Lagrangian perspective.

As the value of the Lagrangian perspective has become apparent, and its computation more tractable, more examples of its use have become available. For example, Torrens (2014) provides a counterexample of inanimate processes, that
REPRESENTATION: DYNAMIC COMPLEX SYSTEMS

is, buildings collapsing in an earthquake, represented from a Lagrangian perspective. However, typically, what processes are represented (e.g., change or movement), and how, depends partly on the types of observation data that are available as well as how the structure and results of the model are communicated to researchers trained in a specific domain or to the system stakeholders.

Time

The representation of dynamic complex systems requires that entities interact and change across space and over time. The representation of time and the inclusion of temporal dynamics in geographic analysis have been ongoing research topics within GIScience (Kwan and Neutens 2014). While GIS and remotely sensed data can increasingly support the representation of change and movement in geographic data, the complex behaviors and processes driving change over time are typically represented in the context of spatial models.

A classic approach to representing time in geographic information, and one that continues to influence the field, is Hägerstrand’s time geography, whereby he mapped the movement of individuals across space in the x and y plane and the movement through time over the z-axis. This approach has been used not only to trace the activities of individual agents in ABMs but also to assess the collective behaviors of individuals to improve evacuation procedures (Torrens 2012), solve n–p complete routing problems (i.e., the traveling salesman problem), and understand activity chaining and accessibility in spatial analysis (Miller 1999). In these examples, time geography has proved valuable, but in many cases it merely provides an alternative approach to data visualization and analysis.

Early geographic research that involved representing the dynamics of complex systems and explicitly incorporated time and process started with cell-based (or CA-based) representations of change processes, for example in Hägerstrand’s (1967) work on innovation diffusion and Tobler’s (1970) work on city growth. Agent-based approaches began to be used to represent movement, along with change, in geography in the 1990s (Deadman and Gimblett 1994; Westervelt and Hopkins 1999). These spatially explicit CA and ABMs represented both logical and physical time (Ziegler 2000). Logical time is the operationalization and virtual representation and meaning of time intervals or increments used in a model. For CA and ABMs time progresses in discrete steps over regular time intervals, for example, a day, month, or year.

Discrete-event simulations use an alternative approach for representing time. Models of this type do not have a regular interval of time progressing over the course of a model run, but increment time based on the occurrence of discrete events, such that time appears to jump between events. Discrete-event simulations tend to have processes occur in a specified sequence and have irregular temporal resolutions that are often finer than models employing regular time steps. For example, in a model of agricultural farming agents, all farmers might plant crops, then fertilize, then apply pesticide, then harvest, all while seeking opportunities to pursue off-farm labor. As each of these processes occurs, a different amount of time is advanced and recorded.

Physical time refers to the real-world temporal period the model is representing. In some cases these may map one-to-one with logical time. For example, a CA or ABM of farmer decision-making might use an annual time step because it maps directly onto the annual decisions of farm actors in the real world. With the discrete-event simulation example, planting may take 20 days,
initial crop growth may take 30 days, fertilizing may take 7 days, and so on, such that all the activities on the farm comprise one year.

Issues related to time are particularly important in how representations of dynamic complex systems are implemented in geography. A key challenge in representing time in geographic analysis has to do with assumptions of temporal stationarity in modeling dynamic processes. Models of processes and dynamics developed and parameterized with reference to observations taken over a particular time interval will provide poor predictions of conditions in different time intervals (e.g., in the future). The degree of error in these predictions will be a function of how much the processes and dynamics represented in the model differ from the constantly evolving observed system, the degree of nonstationary in the system of study. This issue will continue to limit predictability of complex geographical systems.

The historical challenge for geographic science to formally link temporal and spatial elements of geographical systems (Harvey 1968) is being solved. The adoption and integration of concepts and methods from complexity science in the study of spatial phenomena has recently enabled the linking of temporal and spatial elements through explicit representation of the processes of change and movement. The iterative nature of spatial simulation permits the execution of processes, behaviors, and changes, and provides the ability to conduct virtual experiments and perform novel scenario analyses that acknowledge the potential uncertainties and nonstationarities that can affect prediction.

Scale

The choice of what scale to use in geographic analysis (i.e., the “scale problem”) has always been difficult and, in many cases, the basis for the choice still remains “intuitively rather than empirically based” (Harvey 1968). The intuitive aspect is often associated with constraints imposed by preferred analytical tools and approaches, whereas the empirical aspect has often been constrained by available data. Representing the temporal and spatial aspects of dynamic complex systems also presents challenges associated with choosing an appropriate scale, involving tradeoffs between specificity and generality.

While the reliance on aggregate data to infer micro-level components and their behavior, known as the ecological fallacy, has been a problem in geographical research in the past, the ability to simulate the process generating temporal changes in spatial patterns can alleviate these difficulties by allowing for the representation of cross-scale processes (and analysis) to occur. Furthermore, the modeling tools now available (e.g., CA, ABM) permit the representation of dynamic complex systems at multiple scales, and simulation experiments that can help determine the scale at which a particular process contributes greatest to a specific spatial pattern. In many cases these models are combined with empirical analyses that determine, for example, the spatial distance over which interaction occurs using semi-variograms or incremental spatial association statistics (Getis and Ord 1992; Goodchild 1986). Collectively, traditional spatial analysis and contemporary complexity modeling approaches are able to illustrate how behaviors and outcomes of the actions of micro-level agents can give rise to macro-level (i.e., aggregate system level) patterns.

Aggregation

The approach in complexity science of growing or generating macro-level behavior based
on micro-level processes and the interactions among agents (Epstein 1999) provides an important cross-scale bridge. In this case, the “scale problem” exists primarily as a linguistic delineation of scale as referred to the areal extent viewed by the observer, or a particular level of resolution within a representation. Any number of features or agents may be modeled at the lowest level of representation, and any number of features or agents may also be parts of groups or organizations that exist at potentially any aggregate level of analysis.

This approach provides a solution to the problem of determining the scale at which a particular process contributes most to a spatial pattern. Using contemporary modeling approaches, a process may be modeled at a given scale to determine if it creates a specific (existing) spatial pattern. These patterns, in turn, serve as a test of the ability of the model to represent actual processes operating in the world. The better patterns represented by the model match or reproduce observed patterns in data, the more evidence there is that the modeled processes generating the patterns are correct (Grimm et al. 2005).

The observable system properties and system dynamics of a complex system grown through simulation are the result of the aggregation of individual behaviors, interactions, and resulting feedbacks within the system. This aggregation is sometimes referred to in complexity science as emergence (Johnson 2001), whereby a macro-level outcome emerges from the micro-level processes, sometimes unexpectedly and in ways that could not be intuited from knowledge of the system components. However, because intuition can be trained and expectations updated, a preferable term in the conduct of scientific approaches to complex systems is aggregation.

In representing dynamic complex systems, two types of aggregation can be modeled. The first type of aggregation may be referred to as outcome aggregation, whereby individual actions (i.e., local processes) and their outcomes derive system-level patterns and measurable outcomes (i.e., regional-level trends). The field of land-use science, for example, has embraced this type of aggregation and has used ABMs to demonstrate how individual landowner decision-making and actions can give rise to regional-level land-use and land-cover change patterns (Bell and Irwin 2002).

The second type of aggregation, which could be termed structural aggregation, is the aggregation of objects or agents into meta- or super objects or agents (Holland 1995). These meta-agents are collections of agents whereby the individual actions of agents work together to complete a high-level goal. Representations of structural aggregation in dynamic complex systems are rarely used in geographic science, but this is a direction of opportunity and future research, for example, having individual voters comprising the system-level properties of governance and directing governance agent policy development that, when implemented, affects the subsequent voting of the individuals. Whereas outcome aggregation is unidirectional in its effects, structural aggregation is bidirectional.

Generally, for either of the two types of aggregation to exist, the processes by which cells or agents change or move within the system must be described in some formal way (e.g., equations or algorithms). Empirically describing the actors within the system and representing their dynamic behavior, situated among other actors and system processes and how they interact, is difficult but has been a focus of geographic research (Robinson et al. 2007). Vidal de la Blache used biological methods to try to move geography from a descriptive discipline to one that was more experimental and able to explain
how localized phenomena were interrelated and how they self-organized into a greater whole (Archer 1993). In transcribing Vidal de la Blache’s “greater whole,” sometimes referred to as an organism, Archer (1993) used the common phrase of complexity science that “the whole is greater than the sum of its parts.” This may be interpreted as a macro- or higher-level behavior that occurs as a result of lower-level interactions and behavior that do not explicitly lend themselves to the formation of the whole. Therefore, if the rules and behaviors of the agents and interacting entities were “added-up” they would not equal or produce the same macro-level outcome as that which emerges from the system left unto itself. It has been the case that this outcome aggregation (a.k.a. emergence) has fallen under the definition of organicism, where the organism is made up of acting and interacting components that yield an organism with autonomous behavior that differs completely from those components of which it is made.

Summary

Modern social, health, environmental, and political challenges require geographic science to synthesize traditional and contemporary geographic theory, methods, and data to study the processes driving observed spatial patterns. Key to solving this challenge is the representation of dynamic complex systems, which includes both representations of the dynamics of spatial patterns and explicit representation and simulation of the processes. Coupling of spatial models that explicitly represent processes of change and movement, with spatial data representing the state of system components and aggregate spatial patterns, provides a powerful platform for exploring and evaluating the mechanisms by which spatial patterns change. Such models, then, provide a tool for testing the possible implications of physical or social interventions within the system that might be proposed for solving some of humanities toughest problems.

At first glance it may appear that representation of dynamic complex systems requires both a holistic approach and a comprehensive representation of the system of study. A misguided expectation of comprehensiveness can overwhelm researchers both in terms of the intensity of data requirements and the large amount of time needed to represent dynamic complex systems. However, successful scientific research investigating dynamic complex systems and representing them in computational models often starts with simple existence-proof models and systematically incorporates data and adds complexity over time. Research that is able to represent dynamic complex systems with levels of detail that span a spectrum, from simple existence proofs to high-fidelity models, is able to employ a suite of models to gain understanding and make scientific advancements.

Furthermore, while high-fidelity models may be able to encapsulate a large number of relevant processes driving a system of study and potentially provide for greater realism, they are often difficult to validate against historical outcomes, generalize across space and time, and communicate to stakeholders and policymakers. In contrast, a parsimonious model (i.e., a simplification of reality designed to improve understanding) can be a more effective tool for communicating process behaviors and outcomes and can provide a more efficient platform for understanding general processes and identifying new data that need to be collected, deriving new theory and thought experiments, and testing new policies or interventions. “All models are wrong, only some are useful” (Box and Draper 1987, 424) and the tradeoff between realism and generality is a critical element determining their usefulness.
This entry has shown that the representation of a dynamic complex system requires attention to the multiscale relationships and interactions among spatial entities over space and across time, and to the spatial patterns that emerge through those interactions through aggregation. Explicit representation of system components and outcomes provides an opportunity for geographic science to capitalize on the holistic approach to scientific inquiry that reaches back to its origins and make significant spatially explicit advances in science and society.

While we all have a certain idea of what “space” is because we constantly interact with it, most of us would be hard pressed to give a definition. The nature of space has been debated for a long time, and no clear and uncontroversial definition exists because different disciplines (e.g., mathematics, physics, and geography) have different definitions, and these are context-related. However, we know that humans conceptualize space with two contrasting views: the object and the field views. The former considers space as being “empty” and populated with discrete entities embedded in space and having their own properties. We usually use this view when we reason about the spatial arrangement of the buildings and streets in our neighborhood, or about the pieces of furniture in our house. The latter view considers space as being continuous, and every location in space has a certain property (there is something at every location); entities are formed by clusters of properties. We usually use this view for geographical phenomena such as the amount of rainfall in a given province, or the temperature of a body of water.

When we want to represent and store a certain part of space in a computer, that is, to build a spatial data model and realize it with a data structure, the field-view approach is much more problematic than its counterpart. The causes of this are many. First, a field is intangible and is not part of our intuitive knowledge. It is easy for us to see and describe entities such as churches and rivers, but, although we can imagine a field, it is somewhat of an abstract concept. Second, fields are by definition continuous, while computers are discrete machines. Third, there is much confusion among users because for years the geographic information system (GIS) world has reduced each view to one of the two spatial models: “object = vector model” and “field = raster model.” Goodchild (1992), among others, explains that this standpoint is simply false as both views can be stored with either spatial model. For example, the elevation of a terrain can be represented with a raster or with a set of triangles, and buildings in a city with polygons or with a binary raster.

This entry begins with the definition of a field, as usually used in GIScience. It should be noticed that fields as found in GIS-related disciplines are not restricted to two dimensions, and we consider fields of three and higher dimensions (for spatial-temporal modeling). Different strategies to represent higher-dimensional fields in a computer are described under “Strategies to represent fields in a computer,” below. These strategies take into account the fact that while geographical fields are continuous, we first have to collect discrete samples to study them. The section “Samples + global interpolation rules” presents different interpolation methods that can be used to reconstruct the continuity of a field from its set of samples. The section “Piecewise spatial models” presents different spatial models to discretize a field into a finite number of parts; these spatial models can be based on the samples or be arbitrarily subdividing the space. For each of the spatial models, potential data structures for an efficient implementation in a computer are briefly discussed.
What is a field?

The definition usually used in GIScience is borrowed and adapted from physics. Physicists in the nineteenth century developed the concept of a force field to model the gravitational force, where a force (a vector with an orientation and a length) has a value everywhere in space, and changes from location to location. For most GIS applications, the vector assigned to each point is replaced by a scalar value, and we obtain scalar fields; unless otherwise explicitly stated, in the following all fields are scalar.

A field is a model of the spatial variation of an attribute $a$ over a spatial domain; we assume this domain to be $\mathbb{R}^d$, the $d$-dimensional Euclidean space. It is modeled by a function mapping one point $p$ in $\mathbb{R}^d$ to the value of $a$, thus

$$a = f(p)$$

The function can theoretically have any number of independent variables (i.e., the spatial domain can have any dimensions), but in the context of geographical phenomena the function is usually bivariate $(x,y)$ or trivariate $(x,y,z)$.

Bivariate functions are commonly used in GIS to model the elevation of a terrain. However, it should be noticed that the dependent variable $a$ (the elevation in this case) can have one and only one value for each location $(x,y)$. This restricts the real-world cases that can be modeled because, as shown in Figure 1, vertical surfaces (e.g., walls of a building if we model all human-made objects with the terrain to construct a digital surface model), overfolds (e.g., the balcony of a house), and caves are impossible to represent. Modeling the elevation (or other attributes) with a bivariate function is sometimes referred to as “2.5D GIS”; we model the function with a surface (i.e., topologically a two-dimensional (2-D) object) but we embed this surface in $\mathbb{R}^3$.

Geographical phenomena tend to vary over time, and, as a consequence, we obtain dynamic fields. If we assume that time is continuous and linear, it is possible to incorporate it as an extra dimension, perpendicular to the spatial ones. It becomes a new independent variable, and if we already had a trivariate function $(x,y,z)$ then it becomes a quadrivariate one $(x,y,z,t)$. A dynamic field representing the salinity of a body of water over time is thus modeled in $\mathbb{R}^4$.

The value of the attribute $a$ can be measured according to different scales, and depending on the scale used different types of fields will be obtained. We distinguish between two types of field.

**Continuous fields**: the scale of measurement is a real number $R$. Most fields studied in the geosciences fall into this category: temperature, precipitation, or salinity are examples because they can be measured precisely. The measurement scales “ratio” and “interval” are of this type.

**Discrete fields**: the possible values of an attribute $a$ are simply labels. An example is a map of Europe where each location contains the name of the country. The labels can also be

![Figure 1](image)

Top: a profile view of a terrain, with one tree and one house with a balcony. Bottom: the profile view if the elevation is a dependent variable of the $(x,y)$; notice that the walls of the house and the sides of the tree are not fully vertical (dotted lines).
ordered; for example, a certain region can be categorized from 1 to 5 according to its suitability for producing wine, 1 being poor, and 5 excellent. These are respectively the scales “nominal” and “ordinal.” It should be observed that in the former case the only comparison possible between two values is whether they are the same or not; in the latter case, operations such as “greater than” and “less than” can be made, but no arithmetic operations are possible. Discrete fields act also as objects because each region can be modeled as a unique object.

Notice that the terms “continuous” and “discrete” can be misleading because in mathematics continuity has a slightly different meaning. Here they refer only to the scale of measurement, and not to the spatial continuity of a field. Indeed, both types of fields are spatially continuous, since they are represented by a function and there exists a single and unique value at every location in space; this is called a \( C^0 \) function in mathematics. For the representation of fields, it is, however, often desirable to have a function for which the first or second derivative is possible everywhere; such functions are respectively referred to as \( C^1 \) and \( C^2 \).

**Strategies to represent fields in a computer**

The representation of a field in a computer faces many problems. First, fields are continuous functions, and, by contrast, computers are discrete machines. Fields must therefore be discretized, that is, broken into finite parts. Second, in practice it is usually impossible to measure continuous phenomena everywhere, and we have to resort to collecting samples at some finite locations and reconstructing fields from these samples. The discretization task therefore begins at the acquisition phase, and is affected by the acquisition tools and techniques. This fact is aggravated for fields as found in GIS-related disciplines because, unlike disciplines like medicine or engineering, we seldom have direct access to the whole object of interest. Indeed, to collect samples in the ground we must dig holes or use other devices (e.g., ultrasound penetrating the ground); underwater samples are collected by instruments moved vertically under a boat, or by automated vehicles; and samples of the atmosphere are collected by devices attached to balloons or aircraft. Moreover, because of the way they are collected, geoscientific datasets often have a highly sparse and anisotropic distribution: as shown in Figure 2, the distribution can be, for instance, dense vertically (with a sample every 2 m in that real-world case) but extremely sparse horizontally (water columns are located at about 35 km from each other). Even if a sensor is used to collect samples, the result (e.g., an image with pixels) is not a complete representation since each pixel usually averages the value of the studied phenomenon over the pixel area, or each pixel represents the value for one location inside the pixel. Third, another peculiar property of geoscientific datasets is that the samples they contain represent the spatial variability of a given attribute only at time \( t \), and many geographical phenomena in geosciences change and evolve relatively quickly over time.

**What is needed to represent a field?**

To represent a field in a computer, two things are needed.

1 A set of samples that were collected to study the field; for example, these can be the elevation of a terrain obtained with airbone laserscanning or the humidity of
REPRESENTATION: FIELDS

Figure 2 An oceanographic dataset in the Bering Sea in which samples are distributed along water columns. Each red point represents a (vertical) water column, where samples are collected every 2 m.

the soil collected with a certain device. This set forms the “ground truth” of the field, and its importance is such that it has been dubbed the meta-field by Kemp and Věkovskí (1998).

2 A set of rules to obtain one and only one value for the attribute studied at any location, in other words, to reconstruct the continuity of the phenomenon studied from the discrete samples. This operation is referred to as spatial interpolation.

The section “Samples + global interpolation rules,” below, presents the first strategy: storing the original samples with the parameters of the global spatial interpolation method that is best suited to the distribution of the samples and their accuracy. Notice that this strategy permits us to reconstruct the continuity of a field from the samples by calculating the value of the attribute, but that this value is not persistently stored in the computer.

The section “Piecewise spatial models” presents an alternative strategy: the spatial interpolation function used is piecewise (instead of being global). That is, the field is tessellated, or partitioned, into several pieces, and for each of these we assign an interpolation function describing the spatial variation. Piecewise models imply that a supporting data structure is constructed, and stored, to represent the tessellation (it is, however, possible to construct on-the-fly some well-known structures only when they are needed since they have formal rules). Some of these tessellations partition arbitrarily the space, while some are based on the set of samples that were collected.

Incomplete representations

In the GIS literature, different representations for 2-D fields are often listed. For instance, these six are common:

1. regularly spaced sample points;
2. irregularly spaced sample points;
3. contour lines;
4. rectangular cells (raster);
5. triangulated irregular networks (TIN);
6. planar partition with arbitrary polygons.

While these are by no means exhaustive, they represent how a typical practitioner would store her 2-D fields. Theoretically, these representations all generalize to three and higher dimensions (these are discussed in “Piecewise spatial models,” below).

Although the first three representations are commonly used, they are incomplete: the set of rules to reconstruct the continuity of a field at unsampled locations is not explicitly given. These should therefore not be considered valid representations of a field. It should be noticed that while finding a spatial interpolation function suitable for the first case is simple (a few are discussed below), for the third case it is a complex task. Indeed, Dakowicz and Gold (2003) demonstrate that using simple rules (nearest-neighbor for instance) yields fields that are not realistic and
have bad slope, which is in practice problematic for several applications. Obtaining good slope from contour lines is possible, but is in practice a complex process.

Samples + global interpolation rules

We consider as “samples” any data that were collected to study a phenomenon. In practice, these data can take different forms.

1. A set of scattered points.
2. A set of lines. The most common case is a set of contour lines coming from a topographic map.
3. A set of scattered polygons (or polyhedra or polytopes) to which one value is attached. Although this case is theoretically possible, in practice this is very rare. It is nevertheless always possible to discretize each primitive into a set of points, and then perform interpolation.

Observe that it is also possible to collect directly a raster image, coming from remote sensing, where the value of each pixel represents the temperature of the sea, for instance. The value is the average of all the values within the pixel, and this case is considered as being already tessellated (the pixels) and is discussed in the next section.

Interpolation methods are rather difficult to categorize because they are based on different paradigms, and some methods fall into more than one category. No attempt is made in this entry to introduce categories; the reader is referred to the entries Interpolation: inverse-distance weighting and Interpolation: kriging.

The following are a few examples of “global” interpolation methods, that is, the same function is applied everywhere to a subset of (regularly or irregularly spaced) sample points (and the function is not piecewise, as in the section “Piecewise spatial models”). Observe that these methods can all be used in three and higher dimensions.

Nearest neighbor: the simplest interpolation method. The value of an attribute at location \( x \) is assumed to be equal to the attribute of the nearest sample point.

Inverse-distance weighting (IDW): as described in the entry Interpolation: inverse-distance weighting, it requires different parameters to define which points are involved in the interpolation at a given location, and also the power must be defined. The parameter to define the points is usually a searching radius, which can be used in higher dimensions.

Kriging: as described in the entry Interpolation: kriging, while the modeling of a dataset is a difficult and time-consuming task, the output of the modeling process (a function characterizing the dependence between the attributes of any two samples that are at a given distance from each other) can be simply stored as a string.

Notice that while it is theoretically possible to find a polynomial function of high degree for any set of real-world samples, in practice this is very rarely used because, as the degree of the polynomial increases, so can the error at unsampled locations. That is, the error at the samples is zero, but between two samples the function returns a value that can be far higher or lower than the two values of the samples (known as the Runge’s phenomenon). Piecewise functions formed by many polynomial functions, known as splines, are usually preferred and used in GIS (see Mitasova and Mitas 1993 for instance).

Storing explicitly, the interpolation method is efficient because in practice only a few parameters have to be stored. For instance, in the case
of IDW, it suffices to store the search radius and the power used (two numbers). Finding the appropriate values for interpolation parameters is a difficult and time-consuming task, as the user must have a good understanding of the spatial distribution of the samples, and of the details of the method. A vivid example is kriging, with which experienced users can obtain very good results, but which also leaves newcomers clueless with its many parameters and options. Using kriging with the appropriate parameters leads to results having statistically minimum variance; however, simply using the default values for the parameters will most likely lead to unreliable results. Thus, it is better to let specialists perform the modeling of a dataset and find the best interpolation method (and the parameters to use), and store only the results of that modeling. The practitioners can then reconstruct the field without having to find the optimal parameters, provided they have access to software to perform the interpolation.

Piecewise spatial models

In this section different spatial models needed to represent tessellations of space (this space can be in our case two-, three-, or four-dimensional) are presented and discussed. While the same spatial models can in theory be used in any dimensions, their implementations with a specific data structure for the three- and higher dimensional cases are more complex than the 2-D case, and for this reason, potential data structures are also briefly discussed.

Once the \( d \)-dimensional space covered by a field is tessellated, the field function becomes piecewise: to each \( d \)-dimensional element of the tessellation – which is named a cell in the following – a function is assigned describing the spatial variation in its interior. This function is usually a simple mathematical function:

- a constant function: the value of the modeled attribute is constant within one cell, for example to represent a discrete field;
- a linear function;
- a higher-order function.

In general, we classify the tessellations of space into three categories (as shown in Figure 3): regular, hierarchical, and irregular.

Regular tessellations

In regular tessellations all the cells have the same shape and size. The most common regular tessellation by far in GIS is the grid (or raster representation), in which the cells are squares in 2D (usually called pixels, a portmanteau of “picture” and “element,” as an analogy to digital images). However, while they are not common in practice, other regular shapes are possible, such as hexagons or triangles. Regular tessellations generalize to higher dimensions: for instance, in 3D, instead of squares we have cubes (called voxels; “volume” and “element”), and tesseracts in 4D.

Observe that a regular tessellation often arbitrarily tessellates the space covered by the field without taking into consideration the objects embedded in it (the samples) or the nature of the phenomenon modeled. This is in contrast with irregular tessellation in which, most of the time, the cells constructed are constrained by the samples. Kemp (1993) states that “[a 2-D grid] requires us to enforce a structure on reality rather than allowing reality to suggest a more appropriate structure for our analysis.” In practice this means that, unless a regular tessellation is obtained from an image sensor (remote sensing or photogrammetry), we can
Figure 3  Types of tessellations and one example for each in two and three dimensions.
assume that it was constructed from a set of samples by using spatial interpolation. Converting sample points to cells is not optimal because the original samples, which could be meaningful points such as the summits, valleys, or ridges of a terrain, are not necessarily present in the resulting grid.

Concrete example: a 2-D grid. A 2-D grid, stored for instance with the GeoTIFF format, is thus a piecewise representation of a 2-D field: a regular tessellation where each cell has a constant function. The value assigned to each cell is either an estimation previously obtained by spatial interpolation, or, in case of aerial imagery, the average values inside that cell. However, for a given grid, it is usually unclear if the value of a cell is for its center, or for one of its vertices (and if the latter is the case, for which one). Different formats have different rules, and converting a field represented with one format to another one (while retaining the same cell resolution and spatial extent) can shift the value from the center to the top-left corner for instance.

Concrete example: a 3-D/4-D grid. As is the case for 2-D grids, 3-D/4-D grids are piecewise representations, and usually a constant function is used for each cell. Several implementations of a voxel-based GIS exist, notably the open-source system GRASS (Geographic Resources Analysis Support System; http://grass.itc.it) in which diverse operations such as interpolation and visualization are possible. Also, most of the earlier attempts at building 3-D GISs were made using voxels. Four-dimensional grids can be stored, among other ways, in the netCDF format (http://www.unidata.ucar.edu/software/netcdf/). It can actually be used for d-dimensional grids, with different spacing for different dimensions. They are binary and spatially structured, which means that parts of a dataset can be efficiently retrieved and processed.

While the function assigned to each cell is often a constant, other functions can be used. Notice that a linear function is impossible (unless, for instance, in 2D, the four vertices of the cells are coplanar), and instead bilinear interpolation is used. The method, which can be seen as an extension of linear interpolation, performs linear interpolation in one dimension (e.g., along the x axis), and then in the other dimension (y axis). The result is independent of the order in which the axes are used, and can be generalized to higher dimensions.

The wide popularity of regular tessellations in 2-D and 3-D GIS applications is probably due to simplicity and to the fact that they permit us to easily integrate 2-D remote sensing images and fields. Indeed, a grid is naturally stored in a computer as an array (each cell is addressed by its position in the array, and only the value of the cell is stored), and thus the spatial relationships between cells are implicit. This is true for any dimensions, thus, contrary to other tessellations, grids are very easy to generalize to higher dimensions. The algorithms to analyze and manipulate (Boolean operations such as intersection or union) are also straightforwardly implemented in a computer. On the other hand, grids also suffer problems. First, the size of a grid can become massive for data at a fine resolution; this problem gets worse in higher dimensions. Second, grids scale badly and are not rotationally invariant, that is, if the coordinate reference system used is changed, then the grid needs to be reconstructed to obtain regular cells whose boundaries are parallel to the axes of the reference system. To assign a new value to the transformed cells, spatial interpolation is needed, which is often performed not by reusing the original samples, but by using the values of the
neighboring cells. Unfortunately, each time a grid is transformed its information is degraded because what is used is not the original samples but interpolated values.

Hierarchical tessellations

Hierarchical tessellations attempt to reduce the number of cells in a tessellation by merging the neighboring cells having the same value (thus yielding cells of different sizes). While both regular and irregular tessellations can be hierarchical, in the context of the representation of fields, the former is more relevant and is often used in practice. Irregular hierarchical tessellations, usually triangulations, are used for obtaining multi-resolution models (De Floriani and Magillo 2002), or act as a spatial index for efficiently accessing triangles. Their use as a support to construct a piecewise function is not necessary since, as shown in the section “Piecewise spatial models,” irregular tessellations have cells of different sizes and shapes. Consequently, only hierarchical regular tessellations are discussed in the following.

A commonly used hierarchical structure in two dimensions is the quadtree, which is a generic term for a family of tessellations that recursively subdivide the plane into four quadrants. As is the case for grids, quadtrees are relatively easily implemented in a computer because they are trees in which each node has exactly four children, if any. Different variants of quadtrees exist, but the most relevant type in the context of this entry is the region quadtree. As shown in Figure 3, it indexes and merges adjacent grid cells to save space by recursively subdividing the space into four squares of equal size, until every square contains one homogeneous region (based on the attribute of every grid cell, the color in the figure). A region quadtree offers a more adaptive subdivision of space than a regular tessellation because smaller cells are present only when needed (to capture more details).

The region quadtree generalizes to higher dimensions. For instance, in three dimensions, the space is recursively subdivided into eight octants, and thus the tree is called an octree (each node has eight children). In four dimensions, space is recursively subdivided into 16 cells (each one of them being a tesseract).

Examples of the use of regular hierarchical tessellations in GIS for representing fields are more numerous in 3D than in 2D, probably because the space issue (i.e., space used to store a field in a computer) is more critical. However, it is possible that a GIS stores and handles internally 2-D grids as region quadtrees – the user does not need to know as no information is lost in the conversion, and important space and processing gains can be achieved.

The shortcomings of regular hierarchical tessellations are similar to those of regular tessellations: the rotation and scaling operations are difficult to handle. The main advantage of using them – saving memory space – is present only when there is spatial coherence between cells having the same attribute value, that is, when they are clustered together. Indeed, the size of a quadtree is not dependent on the number of cells but on their distribution. The quadtree of a 2-D grid having no two adjacent cells with the same value contains the same number of cells as the grid, and its size would most likely be worse because of the overhead to manage the tree.

Irregular tessellations

The cells of an irregular tessellation can be of any shape and size, and they usually “follow” – or are constrained by – the sample points that were collected to study the field, albeit this is not a requirement. Subdividing the space based on the samples has the main advantage of producing a tessellation
that is *adaptive* to the distribution of the samples (and thus to the complexity of the phenomenon studied). The subdivision is potentially better than that obtained with quadtree/octree (which subdivide arbitrarily the space without any considerations for the samples).

The most known examples of the use of irregular tessellations in GIS for representing fields are arguably the choropleth map, the triangulated irregular network, and the Voronoi diagram.

A choropleth map subdivides the plane into arbitrary polygons, and a constant function is used within each polygon. They are mostly used to model and visualize discrete fields, such as densities, rates, or proportions. Figure 4 is an example that shows the percentage of people above 65 years of age per neighborhood in a part of the Netherlands. Observe that since the field modeled is discrete, using other functions (linear or quadratic) would not make sense. Operations that are possible with continuous fields, for example interpolation, are also impossible.

The generalization to higher dimensions of choropleth maps, that is, of an irregular tessellation of space into cells of different shapes and size, is possible. In three dimensions, the cells are polyhedra, and these are used, among other areas, in geological applications where one type of rock is attached to each polyhedron. In four dimensions, the cells are polytopes, and can be conceptualized as polyhedra modeled over time.

The storage of a discrete field such as a choropleth is done with one of the data structures described in the entry Data structure, vector, as this is simply a set of polygons to which one attribute value is attached. For the three- and four-dimensional cases, more advanced data structures have to be used. One example is the structure *generalized maps*, as first introduced in Lienhardt (1994). It is capable of representing a wide class of objects in arbitrary dimensions. Practically, it also has the advantage of having been implemented in higher dimensions, and of being used in different systems in three dimensions (e.g., it is used in RING (Research for Integrative Numerical Geology; www.ring-team.org) for geological modeling and in Moka (http://moka-modeller.sourceforge.net/) for geometric modeling).

As shown in Figure 5, a triangulated irregular network (TIN) refers to an irregular tessellation of a 2-D field into nonoverlapping triangles (whose vertices are formed by three sample points), and to the use of a linear interpolation function for each triangle. While in theory any 2-D field can be modeled with a TIN, it is in practice mostly used for representing the elevation of an area because the lifting of each sample point to its elevation creates a surface, embedded in three dimensions, approximating the morphology of the terrain. The value of the attribute of a field at an unsampled location $x$ is obtained by linearly interpolating on the plane passing through the three vertices of the triangle containing $x$. TINs are the most popular

![Figure 4](image-url)
alternatives to 2-D grids for modeling elevation; both representations have advantages and disadvantages.

Given a set of points in the plane, there are several ways to construct a triangulation. A TIN usually refers – although this is not a strict requirement – to a Delaunay triangulation (DT) of the set $S$ of sample points projected on the 2-D plane. A triangle respects the Delaunay criterion if the unique circle on which its three vertices lie does not contain any other point in the set $S$ (see Figure 5). This also means that, among all the possible triangulations of a set $S$ of points, the DT maximizes the minimum angle (the max–min property) and minimizes the maximum circumradii; in other words, it creates triangles that are as equilateral as possible. This property is useful in applications where interpolation is necessary (such as the reconstruction of a field) since with long and skinny triangles the estimation of the field attribute at location $x$ by linear interpolation in the triangle will use samples that can be far away from $x$. In a DT the three vertices of the triangle containing $x$ will most likely be close to, and around, $x$.

A TIN in which a linear interpolation function is used yields a $C^0$ piecewise representation, that is, it is a continuous function but at the edges of the triangles the first derivative is not possible. Akima (1978) shows the advantages of using higher-order functions in each region of a TIN, to construct a $C^1$ or $C^2$ field. In other words, if elevation is the attribute modeled, the slope of the terrain will be “good,” which is important for several applications, for example flood modeling.

Storing a TIN can be done with any of the data structures described in the entry Data structure, vector since a TIN is formed by a set of triangles. However, more efficient data structures, in terms of storage space and in terms of complexity, exist. The simplest of these, the triangle-based data structure, considers the triangle as being its atom and stores each triangle with three pointers to its vertices and three pointers to its adjacent triangle; it can be easily implemented in an array. Shewchuk (1997) reports the implementation of his program to compute the DT to be nearly twice as fast when this structure is used instead of a generic structure for polygons. It is being used in several packages, notably by the open-source project CGAL (Computational Geometry Algorithms Library; www.cgal.org). It is also possible to see a TIN as a graph and to compress that graph, see for instance Blandford et al. (2005). The data structure is more complex to construct, but can take five times less memory than the alternatives mentioned above. It should, however, be noted that, from a practical point of view, if the triangulation used is Delaunay, it is easier to store only the sample points and reconstruct on the fly the DT when needed since the DT is unique for a given set of points (if no four or more points are cocircular). This is conceptually equivalent to the solution described in the section “Samples + global interpolation rules,” and it is known that the DT of a set of points can be reconstructed very efficiently (Snoeyink and van Kreveld 1997).
The generalization to three dimensions of the Delaunay triangulation is the Delaunay tetrahedralization: each triangle becomes a tetrahedron that satisfies the empty circumsphere rule. However, obtaining nicely shaped tetrahedra that can be used for linear interpolation of a field is more difficult than finding good triangles because the max–min property of 2-D Delaunay triangles does not generalize to three dimensions (nor to higher dimensions). A 3-D DT can indeed contain some tetrahedra, called slivers, whose four vertices are almost coplanar, and thus have a volume of nearly zero. (Observe that slivers do not have 2-D counterparts.) For the reconstruction of a 3-D field with linear interpolation inside a tetrahedron, these tetrahedra are not optimal and should be removed. This is unfortunately a rather convoluted operation. However, it should be said that in most cases Delaunay tetrahedra have a more “round” shape than arbitrary tetrahedra.

The DT generalizes to four and higher dimensions; the circumball around each simplex (the simplest element in a given dimension: vertex, edge, triangle, tetrahedron, etc.) is empty of any other points. It can be constructed, among other ways, with the algorithm and the implementation described in Barber, Dobkin, and Huhdanpaa (1996).

Storing a 3-D or 4-D Delaunay triangulation is simpler than storing higher-dimensional arbitrary subdivisions of space, and can be done with a straightforward generalization of the triangle-based data structure: the atom is a $d$-dimensional simplex having $d+1$ pointers to its vertices and $d+1$ pointers to its neighbors. However, as is the case for the cases in 2D and 3D, the reconstruction on the fly is a simpler alternative in practice.

Another example of an irregular tessellation is the Voronoi diagram (VD) of a set of points in a $d$-dimensional space, where each point is mapped in a one-to-one way to a cell representing the space closer to the point than to any other in the set. Figure 6 shows an example, and more details about the properties of the structure are discussed in the entry Spatial modeling: Voronoi diagrams.

The VD is the geometric dual structure of the Delaunay triangulation (DT), and that in any dimensions. In brief, it means that both structures represent the same thing, but from a different viewpoint. The sample points collected to study a field are not on the boundary of the cells of a VD, but are rather the points generating each Voronoi cell (they are “in the middle”). As is the case with the DT or other irregular tessellations, perhaps the main advantage of the VD for representing fields is that it permits us to preserve the original samples. The main advantage of the VD over the DT is that, for the three- and higher dimensional cases, the shape of the cells is always “good,” that is, even if slivers are present in the DT, the Voronoi cells will still be “relatively spherical” (which is an advantage for interpolation).

If a constant function is assigned to each Voronoi cell, the VD permits us to elegantly represent discrete fields. Indeed, if sample points were collected to study a discrete field, it makes little sense to use spatial interpolation functions such as IDW; the VD offers a natural way to reconstruct the field. To know the value at a location $x$, one simply has to find the Voronoi cell containing $x$ and query its attribute value. Observe that this is conceptually equivalent to

Figure 6 The two-dimensional Voronoi diagram. The cell in gray represents the space closer to the point in the middle of the gray cell than to any other point.
storing the sample points and using a nearest neighbor function, as explained in the section “Samples + global interpolation rules.”

To reconstruct a continuous field from a set of samples, more elaborate functions are needed since the VD creates discontinuities at the border of each cell. An interesting one is the natural neighbor interpolation method (Sibson 1981; Gold 1989) because it has been shown by different researchers to have many advantages over other methods when the distribution of samples is highly anisotropic: it behaves consistently whatever the distribution of the samples is, and it is an automatic method that does not require user-defined parameters. The method is entirely based on the VD for both selecting the samples involved in the interpolation process, and to assign them an importance. The neighbors used in an interpolation are selected using the adjacency relationships of the VD, which results in the selection of neighbors that both surround and are close to \( x \), the interpolation location. A field reconstructed with the natural neighbor function will be smooth and continuous everywhere (\( C^1 \)), except at the samples themselves. It is possible to use that method in any dimensions (see Ledoux and Gold 2004).

Since the VD and the DT are dual structures, the knowledge of one implies the knowledge of the other. In other words, if one has only one structure, she can always extract the other one. Because it is easier, from an algorithmic and data structure point of view, to manage simplices over arbitrary polytopes (they have a constant number of vertices and neighbors), constructing and manipulating a VD by operating only on its dual structure is simpler and usually preferred. In the context of representing fields, there is therefore no need to store a VD. When the VD is needed, it is extracted on the fly from the DT. And since the DT is rarely stored in a computer as far as the modeling of fields is concerned, neither is the VD.

**In brief**

The choice of a spatial model to represent geographical phenomena is a fundamental issue of spatial data handling, and unfortunately one that is more than often overlooked by GIS practitioners. For a given task, practitioners tend to simply use the spatial models, and data structures, available in commercial GISs, without assessing the consequences of their choice. This is particularly problematic for the representation of fields as found in GIS-related disciplines because, regardless of a few notable models developed in academia, the only solutions available are grid-based models, and this is especially true in dimensions higher than two. The popularity of grids is probably due to their conceptual simplicity and to the fact that they are easily and naturally stored in computers. However, as was demonstrated in this entry, they have many shortcomings, both conceptually and technically. They tessellate arbitrarily the space without taking into consideration the objects embedded in that space (or the phenomenon being studied), which yields an unnatural discretization. Moreover, grids need to be resampled each time the cartographic projection used is modified, and each resampling degrades the information stored in the file, and can lead to errors and misinterpretations during the analysis.

The alternative representations presented in this entry are often more complex to construct and store in a computer, but practitioners should consider them because they would often permit them to better represent the phenomena they are studying. Irregular tessellations indeed permit us to obtain a subdivision that is based on the samples collected (which are preserved, by opposition to grids where they are “lost”), and the cells constructed are adaptive to the spatial distribution of samples, which is crucial when
dealing with highly anisotropic distributions such as the ones found in the geosciences.

Flow is the collective movement of energy, matter, or related concepts. Energy and matter flow includes electromagnetic fields, gravity fields, gases, liquids and solids, and self-changing organized matter in the form of biological entities. Matter flow is affected by the local energy field, that is, gravity or electromagnetism. Likewise, some energy flows, for example wind, are mediated by mass flow. Flow can also be used in a very conceptual way, such as flow of genes or flow of ideas. Biological entities, ranging in size from blue whales to viruses, can act as a conduit for genes of their own or genes from infectious agents such as parasites, bacteria, or viruses for larger organisms down to virophage infections for viruses. Biological entities also can drive flows of learned memes, ranging from simple behaviors to complex concepts. Nevertheless, in geographic domains, flows commonly refer to the continuous movement of water, air masses, lava, population, and traffic, as well as a diversity of dynamic fields in physical and human environments.

Flow can be tangible or intangible. Intangible conceptual flow, such as memes, requires carriers to transmit the concepts to other entities. The carriers interact in physical space or cyberspace mediating the flows of information, impalpable commodities, or concepts. The total flow is the result of both the changes in positions of entities that act as carriers and communication among entities. Flows may or may not be subject to rules of conservation: energy, matter, financial instruments, or commodities should account for everything throughout the courses of flow; yet, information communication or social constructs may experience gains or losses in flow.

Flow is represented either continuously or discretely. Physical fluids, for example atmospheric and surface water, are composed of innumerable individual constituents with viscosity and plasticity to move as a continuous whole. Representation of physical fluid is most common as two-dimensional or three-dimensional grids of data fields. In contrast, flows of people or other discrete entities are usually treated as a collective whole (e.g., people to population and vehicles to traffic) that moves in defined paths between end points. A common representation for discrete flows (e.g., a migration) is in the form of interactions between the two end points, using both arcs and nodes to show the magnitude of flows (e.g., the volume of traffic) from point to point or in an interaction matrix to enumerate the flow magnitude from origins to destinations.

Discrete models of arcs and nodes are popular in map representation of geographic flow. This tendency has continued in geographic information systems (GIS). An early geographical flow map was compiled by Henry Drury Harness (Robinson 1955; Figure 1) for railroad traffic analysis in the Atlas to Accompany the Second Report of the Commissioners Appointed to Consider and Recommend a General System of Railways for Ireland in 1837. Travel was shown as the actual rail path traveled between nodes of locations. Harness used a dasymetric method to calculate population densities for areas around the nodes.

The flow maps of Harness were simplified when Charles Joseph Minard produced the map of “Napoleon’s Russian campaign of 1812”
in 1861. The path information in the maps of Harness were removed to provide space for other variables. Tufte and Graves-Morris in their 1983 book *The Visual Display of Quantitative Information* highlighted the six variables captured in the map, with the two most important being line width to portray the number of troops and nodes to portray skillfully significant events in space and time. Algorithms for creating Sankey maps have been developed to create unique flow maps by selecting relationships and aggregation levels for nodes. The System for Automated Graphics and Explanation (SAGE) created a dynamic “March on Moscow” Sankey map by selecting relations.
among space, time, temperature, and troop strength (Friendly 2002). In addition, other research resulted in algorithms that enabled dynamic aggregation of nodes to simplify navigating the map and enable zooming in and out (Riehmann, Hanfler, and Froehlich 2005).

Tobler (1981) considered both discrete and continuous representations of flows in modeling geographic movement. Discrete flow maps illustrate flows using arrows with widths to show directions and magnitudes. The arrows do not fill the corresponding regions but connect a sequence of objects on the map. Continuous flow maps use vector fields that fill the region to represent continuous flow patterns that are defined at all locations. Vector fields are associated with physics and meteorology where they represent the flow of fluid through space. The vector field requires the formation of streaklines to determine where a fluid parcel travels with the passing of time. A continuous flow map of migration using streaklines has a very different appearance from that of a discrete map with weighted lines of thickness representing the movement of groups of people. Expanding upon Tobler’s work, discrete flow representation has been used by human geographers to model human migration flows, commuting patterns, traffic flows, commodity flows, and information flows. The idea of flows is instrumental to Paul Krugman’s economies of scale that produced flows of goods between regions as a result of production concentration.

The idea of flows is also common in the study of physical geography. Physical geographers use continuous flow representations to portray near-surface ocean currents in coastal waters, wind direction on meteorological maps, and glacial movement on geomorphic maps. Continuous data is often aggregated to create a discrete representation. Aggregation simplifies the data representation and analysis while providing feature abstraction that lessens the generalization required for map legibility. Extending flow maps beyond representing aggregated matter flow described in external data sources requires the ability to model dynamic systems within GIS. Cellular automata and vector raster operators have been integrated with GIS in an effort to represent and map dynamic systems.

Besides meteorology and oceanography, hydrology research also involves many kinds of flows, such as two-dimensional groundwater flow, runoff routing, and particle tracking in streams. Different perspectives of dynamics complicate the ways in which hydrological flows should be represented in GIS (Gold 2006), especially the need to simultaneously accommodate both Lagrangian (following a particle) and Eulerian (particles passing a cross-section) views of flows. Nevertheless, the current GIS framework for hydrological flow modeling starts with a hydrologically conditioned digital elevation model (i.e., a digital elevation model adjusted with known streams, water bodies, and other notable hydrological features) to calculate slope, flow directions, and flow accumulation. Flow direction is determined as being from the focal cell to its neighbor with the steepest slope. Flow accumulation is determined by the sum of the total land units (cells) along the path of steepest slope up to the point of interest. Results commonly are summarized into a vector representation, with nodes representing intersections and arcs representing flow paths. Often, underground flows have only origin and destination connections determined, with no path information.

Flows of concepts, ideas, and beliefs influence behaviors, ideology, and culture. Behavioral memes flow through generations and beyond and eventually contribute to the formation of social norms and cultures. Cultural memes, or singular cultural concepts, are transmitted as flows by humans who can consciously or accidentally
modify them. Flows of cultural memes can be traced back to the group of origin and can displace a region’s original culture. Nevertheless, cultural flow may be resistant to change as it is an intragenerational and intergenerational transmission of ideas that are realized in modes of cultural behavior. Political resistance can modify a cultural flow by importing cultural flow from a different region to show resistance to local control.

Flow representation is shaped by the need to abstract and generalize the idea that some quality and quantity may vary along with a movement or displacement between two locations. The flows between discrete nodes represent spatial interactions between sources and destinations. Conventional flow matrices do not record the travel paths but merely the start and end of the aggregated objects. Creating a flow map from the interaction matrix is possible but is of limited use. Further simplification can be achieved by using the gravity model to define interactions between all possible pairs. Gravity models are likely the most widely used spatial interaction representation.

GIS does not model flows well due to a lack of a suitable spatiotemporal representation to capture the transition of varying quality and quantity along the paths of movement. Temporal representation solutions have utilized domain-specific ad hoc conceptualizations to enumerate and characterize the relationships and rules. Yuan (2001) reviewed the five main approaches to temporal GIS modeling and found that all build on the scalar data of location, objects, and events. This focus makes it difficult to represent dynamic fields based on data derived from partial differential equation models of physical processes such as water-flows, sediment transport, pollution and waste diffusion, and cyclones. Many real-world spatiotemporal phenomena go beyond the representation of object-oriented or event-based data models. Mapping these phenomena is a challenge due to the lack of GIS continuous flow representation.

A map is a scale model of a geographic area. Maps work because they clearly present the geographic layers of interest and follow cartographic conventions that everyone recognizes. Motorists easily navigate road maps with highways, residential roads, and dirt roads identifiable by their common line symbols. Contour lines effectively visualize slope angle by bunching up along steep mountainsides and spreading wide on the plains. The extent of a watershed on a surface can be found by deriving ridgelines around the stream that drains an area.

A map portrays geographic information through a series of thematic overlays – streets, buildings, water, terrain, and imagery. A GIS displays a map by rendering a collection of thematic overlays. The entities in each thematic overlay (points, lines, polygons, imagery, surfaces) are drawn with symbols representing attributes such as feature types, heights, and quantities.

A geographic database is a collection of datasets containing the data within each thematic overlay. Geographic databases store sets of features by extending tables in a relational database with shape fields for point, line, or polygon geometries. These are called feature classes. Nonspatial entities that are related to features are stored as rows with attributes in a table. Imagery and continuous data are stored with efficient raster data structures scalable to large data volumes. Surfaces are represented with triangulated meshes built from many sampled points with elevation values. Upon these core datasets – tables, feature classes, rasters, and surfaces – higher spatial structures can be overlaid to provide a framework for sophisticated modeling of natural and constructed systems.

Representing discrete entities with simple features

When geographers compile maps, they make many decisions about how to represent features on a map. While geographic reality is infinitely complex, they build finite models of features in a geographic database, detailed enough to create maps and perform geographic processing tasks, yet simple enough to keep data modeling and collection costs manageable.

The spatial types of geographic features drawn on maps can be sorted by dimension – points, lines, and areas – and are described by annotations on the map. Point features on a map represent geographic entities that are too small to be depicted as lines or polygons, or locations at which a dimensional measurement is made. Line features on a map represent geographic entities that are too narrow to depict as areas at the map scale of compilation. Line features are also used for computed lines, such as survey traverses and graticules or isolines of a given attribute, contour lines being an example. Sets of connected lines form networks, such as roads and streams.

Polygon features on a map enclose areas that represent the shape and location of homogeneous areas, such as lakes, forest stands, and soil types. Polygon features are also the foundation for divisions of land, ranging from country
boundaries to land parcels. A parcel fabric is a system in which every point within a jurisdiction is covered by exactly one polygon.

Sets of point, line, and polygon features are represented in distinct feature classes which are grouped by thematic content such as transportation, hydrography, and so on. As with other database tables, every row in a feature class has a common set of attributes. Point, line, and polygon features are the components of the simple feature information model. Features, as represented in a geographic database, have several prime qualities: they occupy a geometric shape in space, they have attributes stored in a table, they have rules to enhance data integrity, they have associations with other features and nonspatial objects, and the simple feature information model can be extended in a variety of ways for rich data modeling.

A feature class is a collection of features. It is persisted in a geographic database as a relational table with a special field for shapes. Each feature shape has one or a set of \( x, y \) or \( x, y, z \) coordinates which is spatially referenced on the Earth’s surface through a coordinate system. Line features can also have measurement values for calibrating route systems. Line and polygon features are made of segments and each segment can (depending on the GIS software implementation) be a straight line, circular arc, elliptical arc, or Bézier curve. Features in a feature class are tied to locations on Earth through a coordinate system, which defines the map projection used and its parameters. All features in a feature class have the same spatial reference.

A feature class has a set of attributes for each feature in a table. Fields define feature attributes and can be numeric, textual, or descriptive. Some fields are predefined; most are user defined. Attributes can store rich content such as photographs as blobs (binary large objects). Features in feature classes and rows in tables can have attribute relationships established between them through a common field called a key. A key is an attribute of a table that uniquely identifies each record in that table. Many attributes represent measurements. Types of measurements are commonly classified into four levels: nominal, ordinal, interval, and ratio, with progressively more functional sets of operations. Operations on measurements range from equality and inequality to mathematical functions. These levels of measurement have been formalized by Stanley Smith Stevens in his landmark 1946 paper “On the Theory of Scales of Measurement.”

Nominal data values are used to classify, identify, and categorize data. The value is arbitrary and represents a quality, not a quantity. Values are considered labels with no comparative meaning. The only valid comparisons among nominal data values are equality and inequality. Maps that present nominal data values include soil maps, land-use maps, parcel code maps, and countries of the world. Field types used for nominal data are integer and text.

Ordinal data values determine the rank of an entity versus other entities. As well as equality and inequality comparisons, ordinal data values allow greater-than and less-than comparisons, but no mathematical functions such as addition or multiplication. Maps that display ordinal data values include street maps symbolized by road type and maps of marketing territories shaded by sales ranking. Field types preferred for ordinal data are integer, but in practice, text is used as well.

Interval data values represent a measurement on a calibrated scale, but with an arbitrary zero point, like the Fahrenheit temperature scale. Interval data values support addition and subtraction. Multiplication and division are performed on differences of values. Because the zero point is arbitrary, negative values can be used. Maps that depict interval data values include temperature isoline maps and contour elevation...
maps. Appropriate field types are floating-point values and dates, with values sometimes rounded to short and long integers.

*Ratio data values* represent a measure on a scale with a fixed and meaningful zero point. Length, area, and the Kelvin temperature scale are examples of ratio data. Ratio data directly supports multiplication and divisions and negative values are usually not allowed. Maps that visualize ratio data values include weather maps with barometric pressure and rainfall, and chemical analyte concentration maps. The best field types for ratio data are floating-point values, but sometimes values are rounded to short and long integers.

To validate the accuracy of attribute data collection, each field of a feature class can have a *domain*, which is a numeric range or list of valid values. Fields can also be set with a default value when an object is created.

Features have associated behavior through rules. Rules enforce data integrity within and among datasets. Rules apply to feature shapes, attributes, and relationships. You use attribute rules to apply a domain to a field, relationship rules to constrain valid cardinality in relationships, topology rules for spatial relationships such as touches, contains, and overlaps, and network rules for validating which features can be connected. Attribute domains are rules that describe the legal values of a field type, providing a method for enforcing data integrity. Attribute domains are used to constrain the values allowed in any particular attribute for a table or feature class. A domain is a set or range of acceptable attribute values. Whenever a domain is associated with an attribute field, only the values within that domain are valid for the field.

All geographic objects have some relationship to other objects. Features can be related on-the-fly through joins on keys in tables. When necessary, you can define *relationship classes* among geographic objects in different feature classes and tables, such as the relationship between a house and its owner. Relationship classes can store many-to-many relationships between features in separate feature classes. Relationship classes help ensure data integrity. For example, the deletion or modification of one feature could delete or alter a related feature.

Spatial relationships can be discovered or defined among features. Spatial joins discover associations among features using spatial relationships such as “within,” “.touches,” or “overlap.” Spatial rules can also ensure that features maintain spatial integrity such as “not intersecting” or “not having gaps.” Higher-level structures built on the simple feature information model can also manage spatial relationships among features. For example, a network model can be used to find features that are adjoining, upstream, or downstream. A parcel fabric can find neighboring parcels or parcels within a jurisdictional area.

**Representing connected linear systems with networks**

Networks are simple. They are comprised of two fundamental components, edges and junctions. Examples of edges are streets, transmission lines, pipes, and stream reaches. Examples of junctions are street intersections, fuses, switches, and the confluence of stream reaches. Edges connect at junctions, and the flow from one edge – automobiles, electrons, and water – is transferred to another edge.

To analyze networks, geographers use a branch of mathematics called *graph theory*. Graph theory keenly interests us because it provides rigorous theorems concerning properties of networks and algorithms to solve network-traversing problems. For example, one set of related algorithms for solving a problem in graph theory known as the Chinese Postman Problem provides optimized
solutions for many applications such as postal delivery, street sweeping, bus passenger pickup and drop-off, and garbage collection.

To understand the geographic application of graph theory, contrast it with a surface representation. A surface can be considered an infinite set of points on which you can sample continuous varying phenomena, such as elevation, precipitation, temperature, soil moisture, and spectral reflectance at many wavelengths. But other phenomena are not continuous across a surface. People, manufactured goods, water, energy, communications, and commodities are transported in a constrained way, channelized by streets, railroads, pipes, fiber optic lines, and shipping routes. The set of paths and where they join is a network, a subset of the infinite points on a surface.

Graphs can represent systems that move along natural or constructed linear networks. For example, the interstate highway system can be abstracted to a set of edges representing sections of the interstate highway between interchanges and junctions representing the interchanges at cities. A graph is the set of edges that connect at junctions. Two junctions span an edge. A junction can connect to one or many edges. A graph can be directed or undirected. (A directed graph is also called a digraph.) Directed graphs model systems where each edge has a fixed direction of flow, such as a river network flowing downstream inside hydrologic channels. Undirected graphs model systems with no preferred direction of flow, such as street networks which predominantly allow travel in both directions.

A graph can be planar or nonplanar. Planar graphs connect on a two-dimensional plane at junctions, without any crossing edges. Nonplanar graphs have edges that cross. On a street network, nonplanar graphs can model a bridge over a road. A graph can be cyclic or acyclic. A cycle (or circuit) is a set of connected edges that eventually return to a junction (in the case of directed graphs, a further condition is that the edges line up in flow order to close a cycle). A graph without cycles is called a tree graph (or acyclic graph) in graph theory. Examples are local area communication networks and river systems. A graph with cycles is called a cyclic graph. Application examples are streets and water utilities.

Whether a graph is directed or undirected and cyclic or acyclic are important graph properties when planning the application of GIS network models. These types of graphs are optimally stored with different internal data structures and have separate classes of algorithms for network analysis.

Representing undirected networks with network datasets

A type of network model, the network dataset, represents undirected networks, particularly transportation networks. Network datasets encapsulate decades of GIS modeling experience on optimizing street datasets for network analysis. You can see this in the network dataset’s attribute model representing cost impedances, connectivity rules and groups, hierarchy, elevation fields, one-way restrictions, and turns. This model enables sophisticated analysis such as optimal routing and allocation, even on multimodal systems such as combined street, subway, and pedestrian traffic. A network dataset in a geographic database can have zero or more junction sources (point feature classes), zero or more edge sources (line feature classes), and zero or more turn sources (line feature classes with turn attributes).

Turns are essential for modeling transportation networks. An undirected network allows vehicles to travel freely in any direction. In reality, our street networks have many restrictions on left turns, right turns, and U-turns. Turns
model these restrictions. Turns are also useful for assigning additional travel costs on a maneuver. If making a turn between two major streets is constricted and slow, a turn can be added with that additional travel time.

Network elements are discovered from features when a network dataset is built by finding geometric coincidences of points, line end points, and line vertices. The network elements and connectivity information are stored in a graph, a set of element and index tables inside a network dataset.

Edges are network elements that connect to junctions. Edges are the links over which resources flow. Each edge has exactly two junctions. Junctions connect edges and facilitate navigation. A junction may be connected to one or more edges. Turns record information about a sequence of two or more connected edges. Turns model turn restrictions such as no left turns or turn impedances.

Network elements do not have any geometry but combine to form a nonplanar network graph. Streets generally meet at surface level, so the transportation system is mostly planar. When roadways split elevations, such as at bridges or tunnels, this can be modeled by using nonplanar features for the overlapping lines or planar features with elevation fields marking the elevation levels at both ends of a line. While network datasets accommodate nonplanar networks, much commercial street data is mostly or completely planar.

The idea of connectivity groups is used to model multimodal systems, such as combined street and subway systems. Elements in different connectivity groups cannot connect except at shared junctions such as subway stations. For junctions, a connectivity policy sets whether a point for a junction must be located at an end point or whether it can be at any mid-span vertex along a line. For edges, a connectivity policy determines whether junctions are added when vertices from different lines coincide or whether junctions are added only at line end points.

When creating a network dataset, one can identify special attributes from network sources with information about hierarchy (road classification such as highway, major road, minor road levels), elevations (setting the physical levels of roadways, like stories in a building), one-way or vehicular restrictions (such as no trucks or no pedestrians), and cost of travel time or distance traveled. With variations on implementation, commercial data vendors include these and other attributes on street networks.

Hierarchy in a network of datasets is used to optimize compute performance and to find the likely quickest routes. Sometimes a path found may not be the shortest in distance but the shortest in travel time.

**Locating features on networks with linear referencing systems**

Linear systems such as roads, streams, pipelines, and railroads have many attributes that are defined at discrete locations or sections and these attributes often change with time. In a geographic database, these complex systems may be represented with a simple model called linear referencing. This model is based on routes, which are line features with a defined measurement system. Linear referencing extends line feature classes for modeling events along routes and provides a framework for dynamically managing, displaying, and analyzing all the types of information that can occur at points and sections along routes.

Linear referencing is about locating features on routes. A route can be any linear feature such as a highway, river, pipeline, or GPS track. With linear referencing, features are located on routes by measurements made relative to a starting location.
instead of an x, y location. Measurements most often represent distances, but can also represent other values such as time.

Organizations such as highway departments, government agencies, and pipeline companies manage their asset inventory and incident data along linear networks by measurement systems such as mileposting. Examples are finding an accident at highway milepost 12.4, a navigational buoy at river kilometer 61, or a pumping station at 40 km from the start of a pipeline.

Linear referencing provides two key benefits: it is a natural way to work with linear features and incidents that are recorded using measurements such as distance and time and it allows the modeling of many overlapping attributes on a route without splitting features. Linear referencing is widely used in transportation agencies to manage highways and streets for assessing pavement conditions; maintaining, managing, and valuing assets such as traffic signs and signals, guard rails, toll booths, and loop detectors; organizing bridge management information; and reviewing and coordinating construction projects.

The principal challenge of managing information along route systems is how to handle the many types of attributes that occur along a common set of lines. Along a highway route, a department of transportation manages diverse attribute data such as number of lanes, pavement material, speed limit, and roadway quality. A section of a route that represents a speed limit value rarely coincides with another segment of the same route modeling a certain pavement condition, roadway quality, or number of lanes. Simple line features to represent these attributes on a route must be split whenever an attribute changes. But with the linear referencing model, the underlying line features do not have to be split when an attribute such as pavement quality changes.

Another benefit of linear referencing is that it follows a natural method for location along routes. It is easier for maintenance crews to locate themselves using odometers and signs rather than interpolating coordinates from a map. While GPS receivers now make it easier to find coordinate-based locations in the field, these organizations continue to use linear referencing because field personnel find it natural to use odometers and signage.

Routes are a special type of line features that have measure values, also known as m-values. M-values are used to designate relative positions along routes for linear referencing. In addition to (x, y) or (x, y, z) coordinate values that all features have, measure values (called m-values) are stored at each vertex of a route feature. Measure values can represent any unit of measurement you choose, including miles, kilometers, meters, and feet for distances, or hours, minutes, and seconds for time intervals. Measure values are independent of the coordinate system of a feature class, however, it is not uncommon for the measure unit to be the same units as the line feature class’s coordinate system.

Point events, such as accident locations, and line events, such as pavement conditions along a section of highway, can be stored in event tables with a unique route identifier, measure values, and other attributes of events.

Representing imagery and continuous phenomena with rasters

Rasters are a sampling of one or many attributes of continuous phenomena on a rectangular array of equally sized cells. These cells, when taken as a whole, capture imagery, thematic, surface, or picture data. Raster data can represent everything from qualities of a land surface, such as rainfall, elevation, temperature, or vegetation, to satellite images, scanned maps, and photographs. The raster data model is very simple but supports
the modeling of a wide variety of geographic phenomena.

While the structure of raster data is very simple, it is exceptionally useful for a wide range of applications. Within a GIS, the uses of raster data fall in four main categories: rasters as base maps to provide a photographic background display, rasters as surface maps to enable spatial analysis and relief mapping, rasters as thematic maps to present analytic results through derived classifications, and rasters as feature attributes to link a place with a photograph, document, or drawing.

The most common use of raster data in a GIS is as a background display for other map layers. Images drawn below other layers provide the map user with confidence that map layers are spatially aligned and represent real objects. Three main sources for raster imagery are satellite imagery, orthophotos from aerial photography, and scanned maps.

Imagery, such as aerial photography or some satellite imagery, provides an easily recognizable view of the Earth's surface. People trust imagery because it is an actual view of the Earth. Much of the information about our environment – such as vegetative and soil type, distribution of pollutants, extent of urban development – is best detected using imagery. A key advantage of imagery is it can be the most current source of geographic data in a GIS.

Many satellites and aerial sensors are constantly collecting imagery over parts of the Earth every day. Some types of imagery, such as weather, are available in real time. Imagery can also provide three-dimensional information. Stereo pairs of images provide topographic information and height information for building and other features.

A raster can comprise thematic data derived from analyzing other data. A common analysis application is classifying a satellite image by land-cover categories. This activity groups the values of multispectral data into classes (such as vegetation type) and assigns a categorical value. Thematic maps can also result from combining data from various sources, such as vector, raster, and terrain.

Rasters model the surface of the Earth with cell values for elevation. These rasters are known as digital elevation models (DEM), digital terrain models (DTM), and digital surface models (DSM). Elevations are just one of the surfaces that can be modeled with rasters. Other continuous surfaces modeled with rasters include rainfall, temperature, contaminant level, groundwater level, noise, gravity, and population density. Continuous surfaces can be captured through sensors such as radiometers, derived from geostatistical analysis, or calculated from a geoprocessing model.

Many continuous surfaces change over time. Contaminant plumes spread from a source, precipitation falls with the passing of a storm, and temperature is a field continuously varying in space and time. Rasters with time-variant surface values can be stored as separate raster datasets for each point in time.

The cell size determines the resolution of raster data. Features identifiable in a raster cannot be located more precisely than the resolution of the raster. The size chosen for a grid cell of a study area depends upon the data resolution required for the most detailed analysis. The cell must be small enough to capture the required detail, but large enough so that computer storage and analysis can be performed efficiently. Cell resolution also determines the largest map scale at which this data can be properly displayed.

The value associated with a cell defines the class, group, category, or measure at the cell position. Cell values are numbers, either integer or floating point. Cell values can represent a measured or derived quality of a location, such as reflectance, density, precipitation, or elevation.
These values are either integer for reflectance or floating point for many other measurements.

Cell values can also represent categorical values such as land classification, which may be calculated from a geoprocessing model with many input geographic datasets. These values are always integer numbers. Cells can also have a no data value to represent the absence of data. While each cell has a single value and a color has three components (red, green, and blue values), color is associated with a raster most commonly by using raster bands for RGB composite display, or in the case of thematic maps, colormaps that associate an RGB color with a thematic index value.

Representing surfaces with terrain datasets and digital elevation models

The surface of the Earth is modeled in a geographic database with terrain datasets. Terrain datasets can handle many millions and even billions of points with x, y, z values and produce realistic scenes of a landscape. Terrain datasets are well suited for careful shaping of features such as roads and rivers. Terrain datasets can generate elevation rasters to support surface analysis such as stream and watershed delineation and improved cartographic display such as elevation gradient and hillshading combined, as shown on this map.

Terrain datasets can be in the form of triangulated irregular networks (TINs). The TIN representation models a surface from a set of points from which triangles are formed, or triangulated. Triangles are made from three points that occur at irregular locations. Each triangle stores topological information about its neighboring triangles, thus forming a network.

The edges of TINs form contiguous, nonoverlapping triangular facets and can be used to capture the position of linear features that play an important role in a surface, such as ridgelines or stream courses. Because nodes can be placed irregularly over a surface, TINs can be sampled more densely in areas where a surface is highly variable or where more detail is desired and a lower sample density in areas that are less variable.

A terrain dataset may be a multiresolution, TIN-based surface built from measurements stored as features in a geographic database. Terrain datasets are made from data sources such as stereo-captured photogrammetric features and mass point collections of 3-D data such as LiDAR, sonar, and bathymetry. Terrain datasets in the geographic database are designed to handle voluminous sets of point data from many sources. Terrain datasets can also integrate other 3-D data, such as lake boundaries and breaklines for edges of roads that are collected with GPS receivers and other methods.

Feature integrity with topology rules

Topology rules assure accurate topological relationships among features. Topology rules can be stored in a geographic database as one or more relationships that define how the features in one or more feature classes relate to each other, including shared geometry, containment, and so on. Topology rules have long been a key GIS requirement for data management and integrity. In general, a topological data model manages spatial relationships by representing spatial objects (point, line, and area features) as an underlying graph of topological primitives – nodes, faces, and edges. These primitives, together with their relationships to one another and to the features whose boundaries they represent, are defined by representing the feature geometries in a planar graph of topological elements.

Topology rules are used to ensure data quality of the spatial relationships and to aid in data
Topology rules are also used for analyzing spatial relationships in many situations, such as dissolving the boundaries between adjacent polygons with the same attribute values or traversing a network of the elements in a topology graph. Topology can also be used to model how the geometry from a number of feature classes can be integrated. Some refer to this as vertical integration of feature classes. Features can share geometry within a topological association, such that area features can share boundaries (polygon topology) and line features can share end points (edge-node topology).

Managing cadastres with parcel fabrics

A parcel fabric stores a continuous surface of connected parcels or parcel network. Parcels are made up of polygon features, line features, and point features. Parcel polygons are defined by lines, which store bearing and distance measurements. These measurements should ideally or eventually match recorded bearings and distances from the record of survey or plan. Each parcel has its own set of lines, which means there are two lines that define the common boundary between adjacent parcels.

Parcel lines have end points, which are common between adjacent parcels. Common points between parcels establish connectivity and maintain internal topological integrity in the network. Parcel points store x, y, z coordinates which locate the parcel on the ground. Line points are assigned to parcel points that lie on an adjacent parcel boundary but do not split the boundary. Line points constrain the parcel point to lie on its adjacent parcel line. Control points are assigned to parcel points when running a fabric adjustment. Control points constrain and pin down the parcel point in the adjustment.

Connection lines can be used to link isolated blocks of parcels to each other or link parcel corners to control points. Because each and every parcel is either linked or connected, a seamless network of connected parcel boundaries, or parcel fabric, is formed.

Finding places with locators

Locating a place by address is the most common geographic task that people engage in. Every organization has databases with tables containing addresses for customers and facilities. With a GIS, an address locator is designed to locate addresses on a map in a geographic database. An address locator contains reference data and methods for interpreting addresses. The reference data is most often a street network containing street names and address ranges for each street segment. The methods in an address locator encapsulate the addressing rules for a specific area or country. Geocoding is the process of transforming a description of a location — such as a pair of coordinates, an address, or a name of a place — to a location on the Earth’s surface. The resulting locations are output as geographic features with attributes, which can be used for mapping or spatial analysis.

There are various kinds of locations through geocoding. The types of locations include points of interest or names from a gazetteer, like mountains, bridges, and stores; coordinates based on latitude and longitude or other reference systems, such as the Military Grid Reference System (MGRS) or the US National Grid system; and addresses, which can come in a variety of styles and formats, including street intersections, house numbers with street names, and postal codes.

Addresses are the most common form of geographic information and are an essential
data source for many geographic information systems. Practically every residential and commercial location has an address. Ideally, each address is unambiguously associated with a unique location, but in practice, addresses have several characteristics that present challenges for automating their placement on a map. Some of the issues with finding locations for addresses are errors and misspellings in data entry, variations in address elements (“Avenue,” “Ave,” and “Av” may be found in a street address), variations in how houses are numbered (such as the rule of odd-numbered addresses on one side of a road and even-numbered addresses on the other side), changes in street names over time, and primary street names versus alternate street names (such as “Route 66” or “Main Street”). In a GIS, all of the geocoding rules and geographic information necessary to find an address is stored in the geographic database as an address locator. An address locator encapsulates the rules for interpreting addresses (such as “odd house numbers are on the right side of a street”), lists of standard street components and their abbreviations (such as “Avenue,” “Ave,” “Boulevard,” “Blvd,” and so on), plus the reference map data needed to find addresses.

Address locators are designed to handle the many possible variations of a valid address. If incorrect or insufficient information is provided in an address, the suspect address matches can be manually inspected and used to refine the address locator rules or improve the reference data.

While address formats vary considerably around the world, every address consists of several address elements, presented in a particular address format recognized within that region. Address locators are built to recognize the address formats and types of address elements that are particular to a region or country.

Representation: indoor spaces

Imad Afyouni
Wadi Makkah, Umm Al Qura University, Saudi Arabia

Cyril Ray
Christophe Claramunt
Naval Academy Research Institute, France

The range of geographical information system applications is progressively evolving from large outdoor environments to small-scale indoor environments. A new generation of opportunities in indoor environments has recently emerged. These can take advantage of low-level sensor data at the local scale, as well as events and activities that can be inferred from mobile phones or sensor-based data. At the root of the development of indoor space applications, one of the preliminary research questions is closely related to the availability of an appropriate spatial data model and data management facilities. Such spatial data models generally share several levels of abstraction as well as discrete and continuous data layouts. At the normative level, the development of spatial data standards surely will help and favor the development of exploratory applications. Next, and although indoor spatial data models offer unprecedented opportunities, several research challenges are still to be addressed. Indoor spaces are by their nature complex systems, as the phenomena that happen range from moving objects acting and behaving within these spaces (humans, artificial or virtual objects), to the distribution of intelligent sensors, and the delivery of collaborative and context-oriented services. Overall, the integration, storage, management, search, visualization, and analysis functionality in space and time can be considered as complex data integration and manipulation issues. Moreover, designing a comprehensive spatial data model for indoor environments requires the integration and combination of data from diverse sources in addition to the user’s context. The role of contextual dimensions is primal and also offers additional opportunities, as sensor-based data and collective social data provide additional knowledge-based opportunities.

While presenting a survey of current spatial data models developed for indoor spaces, this entry also discusses a number of research challenges related to the integration of context-aware data models, continuous query processing, as well as semantic location-based services. The potential of indoor spaces is illustrated by a concept of an extended context model, as well as several open challenges for context-aware queries closely related to navigation services. A concept of semantically annotating users’ trajectories is also presented. Several application perspectives associated with the future of indoor-based systems from academic and industrial points of view are highlighted.

The remainder of this entry is organized as follows: current indoor spatial data models are briefly reviewed; the data management and query processing techniques closely related to the manipulation of indoor moving objects are addressed; application perspectives are discussed.
Indoor spatial data models

Indoor spatial data models are important foundations for the development of human- or robot-based navigation and the delivery of context-aware services. Such models should help to locate static and moving objects in indoor spaces, and support users interactions and the different levels of behavior that emerge. Indeed, a better understanding of location information and the relationships that might exist among spatial entities, either acting or located in the environment, should be taken into account. As shown in Figure 1, many components that contribute to the design of a context-aware system should be reflected by the spatial model underneath. Therefore, the integration of an indoor spatial model into a context-aware system implies considering the environment as a dynamic system that should represent:

- the features that populate the environment: a feature can refer to either a person (i.e., mobile users and other social entities/human beings that are located in the vicinity and are of interest) or an object of interest. (An object of interest (OOI) may be either communicating or not, mobile or static, physical or virtual, attractive or repellent. Examples of such OOIs are sensors, exits, etc.).
- their spatial properties, that is, locations of the objects of interest and the spatial relationships that relate them.
- the actions that emerge from them (i.e., physical interactions and communications).

Moreover, specific properties of the spatial data model retained for the representation of an indoor space influence the manipulation, visualization, and computational capabilities of the system.

Two main approaches have been so far considered for indoor space models: symbolic and geometric spatial models (Afyouni, Ray, and Claramunt 2012a). Geometric-based approaches model an indoor space using a series of geometrical primitives, that is, points, lines, areas, and even volumes for 3-D representations. Symbolic-based approaches retain a sort of qualitative representation rather based on some points of interest (e.g., room, corridor, etc.). While geometric models can efficiently integrate metric properties to provide accurate location and distance information, symbolic models maintain an abstract view of space where the structural properties of an indoor space are more appropriately represented. Over the past few years several indoor spatial data models have been developed and applied to different domains (e.g., robotics, GIS, ubiquitous computing) with often a combination of geometric and symbolic approaches (Walton and Worboys 2012). Such approaches favor the application of indoor spaces to a large spectrum of applications, as suggested by the spatial semantic hierarchy (SSH) as initially introduced in Kuipers...
This provides a support for advanced functionalities such as human reasoning and robot-centered activities, and even sensor-based interactions within the environment.

A brief summary of different modeling approaches is given here, along with a discussion of their use from an application perspective.

**Geometric-based approaches**

Amongst geometric approaches, grid-based models decompose space into regular cells and can efficiently integrate metric properties, thus allowing precise locations, direction information, and distances. Free-space tessellation and Voronoi-based diagrams aim at providing an adaptive decomposition of space that is suitable to exactly represent the complexity of the environment being studied. Free-space tessellations are less suitable for localization but they are more compact (Mekni 2010). Boundary-based models represent the obstacles’ boundaries of an indoor space with sequences of primitive geometries such as points, lines, curves, and so on. Boundary-based models are less suitable for navigational services but provide accurate location data. Overall, geometric models require an integration of semantic annotations to achieve a higher degree of location- and context-awareness.

**Symbolic approaches**

Symbolic approaches have frequently attempted to model indoor environments using topological-based structures, graphs by capturing the connectivity and reachability between spatial units, and hierarchies (Jensen, Lu, and Yang 2009). Symbolic models are generally less accurate but context-awareness is easier to achieve as it favors human-recognizable descriptions. Thanks to their hierarchical structure, set-based models achieve a good level of efficiency and flexibility, but lack topological relationships such as connectedness (Becker and Durr 2005). Graph-based models are widely used in applications at a coarse-grained level of abstraction thanks to their richness and variety (Jensen, Lu, and Yang 2009). The major shortcoming of symbolic models is the lack of geometric details on entities and places represented in space.

**Application perspectives**

Symbolic-based approaches are often preferred, from an application perspective, over conventional geometric-based approaches and have been recently used in many application scenarios because they can capture the semantics of entities and places represented in an indoor space. In particular, graph-based and semantic models constitute the most common approaches used, so far, in many application areas ranging from emergency management and safety control in microscale environments to indoor context-aware navigation services, and especially those adapted to users with special needs. Applications that aim at providing intelligent emergency responses mainly employ simple place graphs, which capture topological relations between structural entities, because they are more concerned with network-based models that allow nearest or optimal exits to be discovered. In contrast, applications that support contextual elements, such as user preferences and capabilities, tend to favor semantically-enriched data models, either by designing an ontology-based model or by employing a hybrid model that combines a graph-based with a semantic model of space.
Towards context-aware indoor spatial data models

On top of an indoor spatial data model, several service-oriented and efficiency-related requirements can be developed (Afyouni, Ray, and Claramunt 2012a). The delivery of appropriate services in an indoor space implies that not only are static and mobile objects represented in their environment but that the semantics of the environment and context-based properties are also to taken into account. This is a mandatory requirement to deliver advanced services and navigation facilities to users.

Different dimensions still have to be considered when integrating context-awareness with an indoor spatial data model. There is clearly no generic answer for the choice and the modeling of contextual dimensions. While some dimensions are common to many context-aware services, others might be application-dependent. Such contextual dimensions can be gathered through different ways, using physical as well as virtual sensors. Physical sensors embedded in mobile devices provide basic raw data, and other virtual sensors (agenda, profile, social network activity, etc.) can also help an indoor system to track the user context.

Context-based spatial data model

Most of the principles presented in this entry have inspired the development of a hierarchical and context-dependent multigranular indoor spatial data model that provides a flexible representation of an indoor space (Afyouni et al. 2012b). The modeling approach developed integrates different levels of granularity and considers several contextual dimensions that emerge from space and time as well as user profiles. It supports continuous- and discrete-based location-dependent queries, and has been implemented by a series of algorithms that support navigation and range queries (Afyouni et al. 2013a). Context dimensions considered can be classified as follows (Figure 2).

- The environmental context comprising the spatiotemporal dimensions, as well as other environmental parameters (light, temperature, etc.). The spatial dimension includes the location, direction, and orientation in an indoor space. A user trajectory is another important element of the data representation, as well as another context dimension to consider. A trajectory and more generally movement patterns can be represented by different modalities, for example, a series of locations and/or directions as well as qualitative representations. The temporal dimension depicts the time stamp for a given event or activity within an absolute time reference or using high-level time and date indicators (e.g., morning). This temporal dimension is incorporated in most of the monitored and scheduled events in a context-aware system.

- The user-centered context includes user activities and his/her personal context. The user activity is an important context dimension that reflects the task or process performed by the user when acting in an indoor space. Taking into account such activities provides a step forward to develop truly ambient intelligent systems. For instance, a user activity recognition technique based on accelerometer data can be used. Such a system can identify different activities, such as running, walking, going upstairs, going downstairs, sitting, standing, in an elevator, and so on, and considers them while re-evaluating the answer to a given query.
