In addition, the intersection of globalization, gender, and development encompasses many aspects of women’s labor and rights within the agricultural sector. Boserup’s work on women in agriculture, Agarwal’s (1994) research on gender and land rights in South Asia, and studies about the impacts of neoliberal policies on women and rice production in the Gambia (Carney 1992) demonstrate the gendered nature of agriculture and agrarian transformation in developing regions. These studies highlight the social aspects of what constitutes women’s and men’s labor in agriculture, as well as gender differences in the rights to land and other rural assets. Moreover, women’s involvement in subsistence production is essential to rural households in times of fluctuating income, climate change, and political conflict.

Finally, globalization is the focus of critical discourse surrounding the body and gendered violence in areas where foreign capital has invested in the manufacturing and service sectors. Wright (2006) develops a compelling story of women in the border industries of northern Mexico who are subject to violence as a consequence of gendered, racialized, and ethnicized discourses of female workers. This research demonstrates that the Mexican and US political economies construct the notion of disposable bodies among poor women in this area. Similarly, Gibson-Graham’s (1996) work on feminist political economy shows that gendered constructions of women in the hegemonic discourse of globalization are related to cultural and economic identities. They argue for an anticapitalist imaginary that represents a politics of economic transformation with an array of diverse economies at multiple scales.

**Community-based development**

Another theme in the field of gender and development focuses on local and community-based models of development designed to empower marginalized women. These models draw from gendered dimensions of economic and social empowerment that rely heavily on women’s active engagement with, and input to, the development process. Two areas of community-based economic organizing and empowerment are microfinance and microenterprise initiatives. Microfinance models such as the Grameen Bank in Bangladesh exemplify initiatives to raise people, and especially women, out of poverty in developing countries. The small-scale savings and investment programs are often successful, partly because women have higher rates of repayment than men, and have been replicated in many developing countries.

Additionally, microenterprise and community-based livelihood strategies are the focus of considerable research in many parts of the developing world. Oberhauser and Yeboah (2011), for example, argue that women’s roles, and especially their access to assets and other resources, shape their livelihood strategies in West Africa. Many women have developed microenterprises and small-scale businesses in both urban and rural areas as a means of supporting households (Figure 1).

These livelihoods in turn inform policymakers and development workers about effective and appropriate support for women’s empowerment strategies. Critics of microfinance efforts by global and national institutions, however, cite the potentially exploitative nature of this model, where women are forced into repaying high-interest loans in order to invest in these
small-scale activities. According to some critics, women are also subject to strict timetables for repayment of these loans and are thus at risk of increasing their debt load.

Other areas of community-based development that incorporate gender identities are the cross-border practices and collaboration situated within transnational feminism. Alexander and Mohanty (2010, 40) describe this approach as solidarity work (albeit tense and uneven) that is “brought into ideological and geographic proximity with one another in ways that produce connectivity and inter-subjectivity.” Research in this area involves praxis or a combination of practice and theory that destabilizes the binaries often established by the academy on one hand and community-based organizations on the other. For example, Pratt’s (2012) work with Filipina migrant laborers in Canada, and Peake and de Souza’s (2010) research with Red Thread on violence against women and community organizing in Guyana, are illustrations of transnational praxis. Additionally, India’s Self Employed Women’s Association (SEWA) is a group that has organized women in informal and marginalized work of all kinds in a feminist trade union model. Thus, local organizing and collective action across national and transnational boundaries serve a critical role in advancing gender equality in a variety of contexts.

Gender and health

The health and wellbeing of people in developing countries is a growing area of emphasis in the gender and development field. International and intergovernmental organizations such as the United Nations and the World Bank, along with nongovernmental organizations such as Médecins Sans Frontières (Doctors without Borders), have implemented extensive initiatives and invested considerable resources in order to help eliminate diseases that continue to plague developing countries. Global indicators and comparisons of fertility rates, life expectancy, and infant mortality are commonly used to identify gender inequality and often relate to other indices of wellbeing. According to the Earth Policy Institute, for example, high fertility rates are linked to low levels of education among girls (Fitzgerald Reading 2011). Figure 2 illustrates that girls and women with higher levels of education tend to have fewer children, which makes it easier for them to engage in paid work and to make choices that will improve their overall wellbeing (UNDP 2013). In developing countries, however, girls are less likely than boys to be in school, partly because of the cost of enrollment and expectations that girls contribute more to families by working at home. These gendered aspects of health-related issues have direct outcomes for the social and economic wellbeing of these societies.

Gender also plays a role in the provision of health care in families and communities. Women are often responsible for prevention
Figure 2  Female secondary education and total fertility rates (Fitzgerald Reading 2011). Reproduced from Earth Policy Institute.

and for taking care of family members, and therefore shoulder a disproportionate amount of the emotional and physical burden. The rise of HIV/AIDS in developing countries highlights this gendered aspect of health care. Women are often primarily responsible for care of HIV-infected family members, which impedes their economic activities and increases their risk of contracting the virus (Schoepf 1997). The historical legacy of male migrant labor systems in regions such as sub-Saharan Africa has affected the transmission of this disease, especially from urban areas to rural villages and households. The high incidence of HIV/AIDS in many developing regions also contributes to labor shortages due to poor health and high morbidity among the working-age population (UNAIDS 2013). Finally, females tend to have a lower but more rapid increase in their rate of HIV/AIDS infection than men in many regions, partly because of risky sexual behavior between men and women, such as that associated with the sex industry in these regions (Momsen 2010).

Another topic that has brought attention to health issues in developing countries is research into sanitation and toilets. The spread of disease and the overall health of a population are closely linked to sanitary facilities such as toilets; therefore strategies to improve health must involve the provision of these services. Many researchers examine the rise of neoliberal policies and specifically cutbacks in public services as negatively impacting the health of impoverished people. Furthermore, Gershenson and Penner (2009) show that access to and use of public toilets is gendered, as women tend to value the availability and quality of these services more than men.

The final health-related topic in this discussion is gender-based violence and its impact on development. Interpersonal and self-inflicted violence
tend to reflect power dynamics and coercion that contribute to injury, death, or psychological harm. Interpersonal violence, which includes family and partner harm that is often embedded in gendered relations, is the leading cause of death in persons aged 15 to 44 years (Krug et al. 2002). Gender-based violence is considered a human rights violation and is gaining global attention, with recent incidents related to what some refer to as the “rape culture” in India and “honor killings” of women in some South Asian countries. Cultural patterns that tolerate domestic violence often make such violence difficult to report and consequently lead to the widespread neglect and physical and sexual abuse of not only women but also children. The World Health Organization has extended the negative impact of violence to national economies that suffer from losses to health care, law enforcement, and worker productivity (Krug et al. 2002).

**Women, gender, and the environment**

Access to and control over natural resources and the environment have a long history in the field of gender and development. In many cases, women don’t have equal access to or use of energy resources, food, or raw materials, and have therefore organized around these issues at both the local and international scales to expand awareness of and attention to gender and the environment. The Earth Summit in Rio de Janeiro in 1992 was one global forum that launched efforts to mobilize groups around topics that included gendered aspects of biodiversity, sustainability, and climate change (Momsen 2010). It led, for example, to the creation of the Women’s Environment & Development Organization (WEDO) as an international network of women’s environmental groups.

Subsequent global forums such as the Rio + 20 United Nations Conference on Sustainable Development in 2012 reflect growing concern about effective ways to reduce the impact of environmental degradation on impoverished people in developing countries, and to produce a more sustainable and equitable use of resources. In addition to these efforts, women are active at the local scale organizing against the destruction of forests: for example, the Chipko Movement in India (Shiva 1988), the Green Belt Movement in Kenya (Momsen 2010), and action against water contamination in Bangladesh (Sultana 2009). Critical feminist analyses of gender and the environment examine how gendered subjectivities “influence the responsibilities, roles, rights and norms that constitute the relations that men and women have to natural resources” (Sultana 2009, 427). This increased focus on the gendered aspects of nature–society relations is partly due to the contributions of feminist political ecology (Rocheleau, Thomas-Slayter, and Wangari 1996). According to this approach, gender, as well as other social and economic power relations in society, influences access to and control over resources. Both activists and scholars in this field make a point of grounding their research in a local context.

The field of environment and development also includes growing attention to climate change, and specifically increased variability in rainfall and temperatures which leads to flooding and drought, rising sea levels, and erratic weather events (Momsen 2010). These climate fluctuations and their unpredictability have consequences for livelihoods, food security, the spread of disease, and infrastructure. Some scholars and activists argue that gender is a central concern in this field because women are more vulnerable to the impacts of climate change, especially given the gender divisions of labor in agricultural production and gathering resources such as water and fuel wood (Dankelman 2010).
Additionally, a gender-sensitive approach to mitigating the negative impacts of climate change applies to the implementation of agricultural practices that include planting drought- and flood-resistant crops above rising flood waters in coastal and low-lying areas. Thus numerous aspects of nature–society relations, environment, and development are closely intertwined with gender roles and access to resources.

Future directions of gender and development

Looking forward, the field of gender and development will build on research, policies, and activism that have increased awareness of and improved conditions for many women and girls in the developing world. Critical issues in this field, however, highlight persistent inequalities in social, economic, and political arenas that reflect institutional biases concerning gender and other social axes of power. This discussion concludes with analyses of three issues that will most likely shape the future of gender and development – information and communication technology, global security, and sexuality. These topics are by no means exhaustive, but reflect some of the ways that feminist approaches to development will advance gender-sensitive and other forms of equality and empowerment.

The growing use of information and communication technology (ICT) has the potential to impact economic activities for women at all scales and in a variety of sectors. For example, increased access to ICT, especially through the use of mobile phones in many developing regions, reflects and changes gender dynamics in the household and the workplace. This expanded access entails not only job creation but also efforts to organize women across social and spatial boundaries through networks and support groups. Furthermore, widespread access to social media and other forms of information is a means to diffuse consumerism and cultural practices. However, the rapid growth of ICT also has the potential to maintain social and economic inequalities in terms of access to resources and skills needed to further women’s advancement in society (Asiedu 2012). Negative aspects of what some refer to as digital inequalities expand beyond spatial divides to include diverse socio-economic divisions such as gender, class, caste, and race/ethnicity. These inequalities are evident in the disparities between the ability of countries to invest in infrastructure and communications. Growing attention to the role of ICT in the development fields focuses on digital inequalities as a more holistic way of examining the complexities of the use of digital technologies.

Second, militarization and security issues are gaining attention in the global political and economic arena, with widespread implications for women and gender roles in society (Enloe 2007). Terrorism, military intervention, and despotic governments construct discourses of resistance to power and domination that are embedded in racial, ethnic, and gendered forms of repression and marginalization. For example, certain masculinist identities of Middle Eastern men are depicted by Western media in ways that reinforce stereotypes of extremism and violence. Likewise, the post-9/11 world has impacted transnational migration with mechanisms of exclusion and gender inequality (Marchand 2009). Feminist postcolonial analyses of the “war on terror” effectively situate these gendered representations within sociospatial inequalities and uneven development in the Global North and South.

Third, axes of difference based on sexuality draw attention to a form of discrimination and
harassment that is constructed through histories of colonial and postcolonial relations. Homophobic laws and attitudes are evident in certain areas of the Global South, with sometimes brutal forms of marginalization. Growing mobilization against these attitudes and practices often situates the lesbian, gay, bisexual, transgender, and queer (LGBTQ) community in alliance with postcolonial feminism in order to advocate for equality and social justice. For example, queer theorists argue that many homophobic practices stem from colonial attitudes such as British laws in colonial India that made nonheterosexual practices illegal. These histories of sexual norms often counter claims that homosexuality is a practice imported by Western ideals and norms. Thus, feminism and sexuality provide a framework for rethinking power relations and identities in gender and development.

In conclusion, pressing issues in gender and development require feminist perspectives and gender-based analyses to further understand inequality and uneven spatial patterns in the developing world. Public policy, scholarship, and activism must draw from rigorous research and grounded practice in this field to establish a socially just and sustainable world.

Gender, work, and employment

Helen Jarvis
Newcastle University, UK

While the definition of employment is well grounded in labor process theory and law, what counts as “work” is socially and culturally constructed. How we talk about women and men and the work they perform, and how this discourse appears to judge and prescribe “proper” behavior in a given context, have to be understood through social norms and conventions of language as much as through laws and state regulation. The market for labor is also rooted in socially constructed ideas, such as those of money, capital, and trade: an individual sells his or her time, sweat-effort, and skills in exchange for payment. Yet, inasmuch as these earnings are taxed and recorded as a barometer of national competitiveness, in the form of gross domestic product (GDP), paid employment tends to be recognized in a way that informal and unpaid activities of work are not. Efforts to critique and transform systematic gender bias in the international standard of measuring economic growth, and the ways in which women’s unpaid work have been excluded from what counts as “productive” in the economy, have contributed to a significant and growing body of feminist scholarship on gender, work, and employment (Waring 1990; Campbell 2014).

It is important to differentiate and qualify the terms and concepts used in academic debate and policy because both work and employment are segmented, structurally and culturally, in diverse ways to reflect persistent inequalities between women and men. This is to say that the prevalent notion of work as employment overlooks a wide range of tasks performed as a function of love, duty, subsistence, and voluntary association, or as reciprocal exchanges between friends or neighbors. Nor is this distinction limited to money; more crucially, it involves identity, status, and “worth.” In societies where a measure of gender equality is perceived to exist, financial reward continues to signal to society that work as employment is “real” and “useful,” in contrast to the concept of the “unproductive” and “dependent” housewife. This is readily apparent in the way that people introduce and define themselves by a paid occupation, by what they are qualified and paid to do in contractual terms. Similarly, to be unemployed is to be branded “workless” even though lack of income obliges the unemployed single mother, for example, to work very hard to get by and to make do on limited means. In societies where gender roles and divisions are entwined with religion and tradition, where daughters are valued less than sons, these distinctions between “productive” and “reproductive” roles heavily circumscribe women’s life chances and status. Viewed this way, activities and sites of work in the broadest sense span multiple and diverse economies that variously trade through currencies of money, sex, bartered goods, reciprocal assistance, gifts, extortion, and exploitation.

This introduction demonstrates that “work” and “worth” are circumscribed in dominant public discourse by a gender bias in the way economically productive activity is defined and measured. Consequently, it is not possible to make sense of what constitutes work and
employment without first drawing attention to unequal power relations between women and men. For this purpose, gender is widely used as a concept that accounts for the varied and complex arrangements that encompass the organization of reproduction, the sexual divisions of labor, and cultural definitions of femininity and masculinity (Bradley 1996).

Gender is distinguished from sex because the latter confines social difference to biological characteristics. Explaining the differences between male and female lived experience and behavior by recourse to sexual (genital) characteristics is widely dismissed as a form of essentialism whereby male and female characteristics (dressing up in blue or pink, fixing things or talking about them, exhibiting strength or nurturing) are read off from sex as “in essence” “already there” from birth. By contrast, feminist scholarship has developed a more culturally nuanced frame of analysis that draws attention to the multiple and fluid performance, language, meaning, display, and popular representation (on TV and in magazines, for example) of different forms of femininity and masculinity. Feminist scholars challenge the policy discourse that treats labor as a generic, disembodied commodity.

While gender is widely recognized in feminist scholarship as a major axis of social difference, one that especially affects the segmentation of work and employment, it is important to recognize the significance of other intersecting social axes, such as class, race, ethnicity, and sexuality. It has not always been the case, for instance, that labor market research has taken adequate account of gender inequalities or of difference and diversity. A crude distinction is usefully made between the “structural” accounts of sex/gender systems of discrimination and constraint which dominated Euro-American scholarship in the 1970s and 1980s, and poststructural and postcolonial accounts that emerged from a splintering of radical, moderate, and “new” feminisms in the 1990s.

Classical studies from the 1970s, especially those in economic geography and sociology, tended to focus narrowly on those social changes associated with male-dominated major industrial sectors. This emphasis on working-class paid employment overlooked the significance of gendered work considered outside the relations of production, including the messy, fleshy lived experience of diverse service occupations and domestic work. Labor market segmentation was explained by grand narratives of patriarchy (literally the rule of the father) and the dual systems of capitalism and patriarchy. Subsequent decades witnessed growing confidence among feminist scholars to challenge androcentric and ethnocentric bias and to “recover” excluded and marginalized subjects (women, ethnic minorities, plural and fluid femininities and masculinities, “bodywork” and emotional labor) through poststructural theory and methods. Women of color were especially critical of structural theories that privileged certain types of (white, middle-class) knowledge and experience by employing gender as an imperializing category.

Poststructural critique has led to greater awareness of intersecting axes of social difference. For example, Geraldine Pratt (2004) introduces the figure of the racialized Filipina maid as a way to challenge white middle-class feminists to face their privilege, and draws attention to the gains in gender equality in affluent societies that often rest on the availability of poorly paid domestic labor as migrants from lower-income regions. Nevertheless, “gender” continues to be central to debates on work and employment as a means to challenge the dominant discourse on what counts as economically productive activity. This deployment of gender effectively opens up the black box of socially constructed ideologies
of work and worth; and it does not preclude recognition of multiple axes of exploitation.

The global economy has been fundamentally transformed in recent years by the increased international mobility of people, products, and money around the world. The term “globalization” is widely used to describe the growing interconnectedness of people and places on a global scale, while the term “economic restructuring” describes the transition to a different phase in the what, how, and where of GDP. Economic restructuring is widely used as shorthand for a shift from making things to selling services: while this top-down view of the world has a tendency to desex the social and spatial profile of inequality, these trends are intimately gendered in the cultural norms and microsociological practices enacted within and between households, firms, local labor markets, industrial sectors, and regional economic specialization.

Around the world, but especially in the Global North, there has been a dramatic reduction in the proportion of well-paid, skilled jobs in male-dominated manufacturing and primary industry (from 1 in 4 in the 1970s to fewer than 1 in 10 by 2010) (BLS 2012). Parallel growth in poorly paid and elite jobs in the service sector has been reinforced by hugely significant advancements in technologies associated with cheaper and more efficient transport alongside new and extended capacity for real-time, virtual, and time-shifted interactions via digital media and mobile telecommunications. It was in 1992, for instance, that the World Wide Web (WWW) was made available to home users for the first time, ushering in the rapid expansion of Internet use in all aspects of work including not only paid work at a distance but also the remote coordination of coworkers and people and activities in public and domestic spheres of daily life.

In affluent economies, the restructuring of work and employment tends to be understood in terms of laissez-faire market forces. By contrast, the restructuring of economies in the Global South has been, to a considerable extent, imposed by the policy decisions of supranational bodies such as the World Bank. Offers of financial assistance in the form of structural adjustment programs (SAPs) have come with harsh conditions attached. These conditions reflect systematic gender bias in that they do not recognize or protect the productive aspects of women’s unpaid work. It is assumed that the unpaid work done by women to care for the family, including raising children, gathering fuel, nursing the sick, preparing and processing food, will continue regardless of deep cuts in public expenditure and the pressure for women to participate in greater numbers in low-paid employment in the export sectors. There is evidence that male bias results in disproportionately high rates of poverty among women in the Global South, especially women-headed households. This is because cuts in public expenditure (state support for health, education, transport) intensify the workload for women, who are likely to sacrifice their own health and wellbeing to feed and educate their children (Perrons 2004, 57).

The number and quality of jobs created in affluent economies have been permanently altered by economic restructuring, whereby the ideal of a “job for life” has largely disappeared. This new precariousness can be understood in terms of four distinct employment trends, all of which reflect persistent gender inequalities in the social construction of work and associated identity and reward: (i) a more competitive international division of labor (multinational employers; jobs and production facilities outsourced to low-cost countries); (ii) an emphasis on flexibility (deregulation that enables firms to hire and fire employees based on their willingness to learn new skills and adapt to changes in working conditions); (iii) “feminization” of
job descriptions that emphasize “high-touch” provision of care services (interactive bodywork, washing, dressing, caring); and a casualization of the terms of employment (e.g., freelance portfolio workers replacing full-time employees, and “zero hours” contracts replacing fixed and stable working hours).

While the feminization of new service sector jobs appears to favor women over men, more women than men are concentrated in poorly paid, temporary, and insecure jobs. This concentration of women into particular sectors (e.g., hospitality, health care, education, factory production) and occupations (waiting on tables, nursing, primary education, component assembly) describes a horizontal segregation of jobs constructed as “women’s work” or as “mother-friendly” (e.g., based on part-time hours or shifts that can be reconciled with a “second shift” of child care and housework). Women who participate in paid work outside the home frequently work alongside other women in jobs that look remarkably like those of caring, domestic, and emotion work long performed inside the home as labors of love and duty. Vertically, too, women are concentrated in jobs or cultures of work that frequently offer limited access to promotion. This apparent barrier to women achieving equality of seniority and decision-making power is popularly described as a “glass ceiling” and it is readily observed in the absence of women from annual report photographs of the boards of directors of major firms. The glass ceiling derives from multiple causal factors, including the impact of maternity leave on opportunities to demonstrate commitment to career, as well as tacit sexism in the cultures and practice of recruitment and promotion.

A persistent gender pay gap is evident, which reflects the impact of both horizontal and vertical structures of gender inequality and segregation. Current wage data indicate that women in full-time management, professional, and related occupations in the United States are earning 72 cents for every dollar earned by men in equivalent employment. Across Europe the annual gender pay gap between men and women in full-time employment is stuck at a similar point and the gender gap in pension earnings is even greater at about 50% (Campbell 2014). This contributes to a pronounced feminization of poverty and vulnerability in later life. Further structural inequalities in pay are attributed to segregations by race and ethnicity as well as gender. This intersection adds to the complexity of the picture; for example, in 2012 Asian women who were full-time wage and salary workers had higher median weekly earnings than women of all other races/ethnicities, as well as African American and Latino men (Catalyst 2012). While feminist scholars acknowledge that gender functions alongside race and class in mutually reinforcing ways as part of a “wicked triangle” of structural inequality, these intersections reflect complex geographies of inequality (Grünell and Saharso 1999).

The jobs that have been created since the 1990s typically represent two different extremes of financial reward, and similarly contrasting experience of fulfillment, autonomy, and status. On the one hand, new jobs have been created in areas of high-technology, new digital media, and the knowledge economy. For the (predominantly male) workers in the high-tech sector, these new jobs are skilled and generally fulfilling, offering high wages to compensate for expectations of long and typically unsocial hours, as well as time spent away from home working on projects overseas. Research and policy in this area draw attention to issues of masculinized institutions, self-exploitation, and the negative impact on health and family life of intensely work-centered, goal-oriented lifestyle practices and identifications. This serves to reinforce divisions between
working mothers’ time and men’s time whereby it is rarely possible for a dual career working family household to practice a dual carer arrangement, except perhaps in Scandinavia where shared care is more likely to be supported by progressive child-care and egalitarian parental leave policies (Gornick and Meyers 2003).

On the other hand, a substantial and rising proportion of jobs have been created in service sectors that are notorious for low pay, temporary and seasonal working, variable hours, and poor working conditions. Examples include the hospitality, retail, health care, and personal service sectors. While these poorly paid jobs are classed as “unskilled,” the (mostly female) workers recruited to them are increasingly required to perform intimate bodywork (cleaning, caring, serving) and emotion work (dealing with other people’s feelings), which represent undervalued (underpaid) “soft skills.” Feminized interactive service employment tends to offer not only low wages but also poor job satisfaction and little influence over the conditions of speed, stress, and safety under which tasks are to be performed. Research and policy action in this area draw attention to the human costs of very low wages and the erosion of autonomy and dignity. Some of the emerging issues have been brought to light by ethnographic methods of documentary journalism involving firsthand insights of the social indignities and economic realities of women living and working on minimum or “poverty” wages. Two examples are Barbara Ehrenreich’s (2001) searing account of working as a waitress, hotel maid, house cleaner, nursing home aide, and Wal-Mart salesperson in the United States and Polly Toynbee’s (2003) equally vivid portrait of life in low-pay Britain.

Economic competitiveness and growth have become paramount in public discourse on the demand for, and supply of, labor. The imperative that states and firms are globally competitive has repeatedly been used as justification for dismantling the terms of employment protection that were previously negotiated in struggles between organized (mainly male) labor unions and the interests of capital (firms and the state). Arguments about the impact of economic restructuring on new articulations of patriarchy through socially stratified gender divisions of labor tend to distinguish between optimistic and pessimistic narratives.

The optimistic narrative is of “detraditionalized,” mobile, educated portfolio workers who use social networks and technologies to escape from conventional gender and class divisions. Thus Beatrix Campbell (2014) observes that neoliberal competitiveness tolerates girls being astronauts or bankers but resists dismantling deeper structures of sexism and misogyny. The pessimistic vision points to a disillusioned and exploited “reserve” labor force (women working part-time, women of color, migrant men and women who are poorly represented by trade unions) and, beyond that, a permanently excluded underclass of NEETS (Not in Employment, Education, or Training). For example, there are competing viewpoints concerning the extent to which “flexible” labor market practices allow workers to choose when and how much to participate in employment whereby so-called zero hours contracts allow employers to hire staff with no guarantee of work: employees are only paid for the hours when their services are required (often at short notice), without incurring overheads for the workers on standby. Critics point out that promoting these contractual arrangements as mother-friendly attempts to disguise new articulations of modern slavery.

Economic restructuring has been accompanied by a parallel trend of diversity and change in the social characteristics of the labor force and the structure and geography of household employment. The quantity and quality of
spouse employment tend to be multiplied within working family households whereby work-rich (time-poor) dual career, dual income, or multitask households are significantly advantaged compared to households where none of the working-age adults is earning a living from paid employment. A combination of increased job insecurity and escalating housing costs motivates the majority of couples to believe that both partners have to work. In households with young children it is increasingly common for both parents to participate in paid employment but the cost of commercial child care imposes significant constraints on the working hours and times that mothers, in particular, can balance or reconcile with family care. It is not uncommon for parents of young children to work opposite shifts (such as night and day) or for mothers to fit part-time paid employment around the demands of child care, whether by working from home in the hours when children are sleeping or by working when older children are at school. Moreover, the hours that people work vary far more than in the past: nonstandard schedules are increasingly associated with a 24/7 economy whereby large grocery stores remain open 24 hours a day to service a customer base made up of workers who are also working shifts that would otherwise prevent them from shopping for their families during traditional 9 to 5 retail opening hours.

Time is a significant resource with respect to the coordination and reconciliation of the activities and identities of work with the rest of life – which is not gender-neutral. For many years the overwhelming preoccupation has been with time allocation as a function of the organization of employment, where time is conceived according to a featureless plane – of working hours (length of the working day) and working times (extended office hours and nonstandard shift arrangements), using categories such as full-time and part-time to differentiate levels of career salience and labor market participation. This emphasis on time as the essential currency of production coincides with a “workification” or work-centeredness of contemporary life. Attention has turned more recently to the gendered experience of time, such as feeling harried. Inequalities are variously explained by the pressure, intensity, and disruption of time that women feel more than men. Time pressures are imposed by scheduling constraints for specific tasks (such as collecting a child on time from daycare) and in relation to managing child-care providers and children’s daily schedules. While men are observed to help out and fill in with child care and to organize time in chunks to undertake a discrete domestic project, women typically experience time with greater intensity: activities are typically being done in combination or all at once. Women are also more likely than men to have their leisure time interrupted by domestic tasks. At the same time, social changes that have developed in affluent economies alongside popular struggles for work–life balance (e.g., “wraparound” child care and online shopping) further contribute to the socially unequal gendered experience of time.

A significant trend in recent years is the prevalence of in-work poverty, which is associated with problems of underemployment (part-time or variable hours) combined with low pay, especially where wages do not cover the cost of child care and the rising costs of living, notably housing and food. This is in a context in which the assumption in neoliberal states is of a “universal worker” model of citizenship. In order to maintain national productivity and international competitiveness, governments assert that all prime-age women and migrants should participate in paid employment on whatever terms the market will bear: this pressure is reinforced by the dismantling of protective legislation which in the
past served to reward one member of a house-
hold (typically male) with a family wage that
was sufficient to compensate another household
member for unpaid work at home. Economic
restructuring has exerted a downward pressure
on wages in nonprofessional service sector jobs,
especially where previously secure public sector
jobs (catering, cleaning, and security) have been
transferred out to private subcontractors who
typically rehire staff at a reduced rate of pay. In
some sectors and places this new paradigm of
insecure employment has triggered the forma-
tion of new grassroots community unionism and
campaigns and coalitions (scholars, activists, and
nonprofit organizations) to raise awareness of
issues concerning corporate social responsibility,
for example campaigning for a living wage can
be an efficient and effective tool for reducing
gender pay inequality (Wills 2009).

Evidence that women tend to be confined
to the most vulnerable categories of employ-
ment both in the formal interactive services of
affluent economies and within poorly paid and
informal sectors in developing countries has
motivated action for change within women’s
groups and transnational feminist movements
around the world. The Global Women’s Strike,
for instance, is a transnational network of direct
action intended to seek recognition for women’s
unwaged caring work in different settings around
the world, building on the seminal radical cam-
paign Wages for Housework, orchestrated by
Selma James in the 1970s (Jarvis, Kantor, and
Cloke 2009). Promoting decent and productive
employment and income opportunities equally
for women and men is one of the key priorities
of the International Labour Organization’s (ILO)
Decent Work Agenda. Another example is the
Clean Clothes Campaign, which raises awareness
of women’s working conditions in the global
garment industry, notably in Bangladesh. The
vast majority of workers in garment factories
worldwide are women, and the campaign is an
international alliance of trade unions and labor
rights activists working together to demand that
garment workers in Asia are paid a living wage
(Clean Clothes Campaign 2014).

Despite a huge expansion of academic analyses
in the field of waged work, a range of questions
arguably remain unresolved, most notably con-
cerning the intersection and co-constitution of
multiple dimensions of paid and unpaid work.
Gender is a highly politically charged concept
around which the notion of patriarchy has been
used to describe the systematic privilege and
domination of men over women. The language
and theory of patriarchy are less widely used in
feminist scholarship today because gender and
poststructural theory have a greater capacity to
reflect fluid and multidimensional relations that
are constructed, performed, and inhabited in
complex and changing ways. This is not to deny
the enduring structures of constraint in women’s
access to power and representation. Women
remain underrepresented in parliaments, judicial
systems, and the senior civil service.

Indeed, since the development of detailed
who-does-what studies of housework, child
care and money management in the 1970s,
time budget surveys have consistently revealed a
gendered sociospatial distinction between indoor
“wifework” and outdoor, “macho” home con-
struction and maintenance, typically involving
machinery (Nelson and Smith 1999, 125).
Enduring norms of behavior are reproduced
through the gender stereotypes represented in
magazines on cookery, cars, home decoration,
needlecrafts, home improvement projects, and
power tools. According to 2012 data from the
American Time Use Survey, on an average
day, women in the United States spent more
than twice as much time preparing food and
drink, almost three times as much time doing
interior cleaning, and four times as much time
GENDER, WORK, AND EMPLOYMENT

doing laundry, as men did. Men spent more than twice as much time doing activities related to lawn, garden, and houseplants, and doing interior and exterior repairs and decoration as women did (BLS 2015). While survey data continue to be reported in the news media, the focus of academic research has shifted away from time budget surveys toward more culturally nuanced ethnographies of how bodies, places, and biographies are gendered today.

Conceptual developments in gender performativity have been especially fruitful in recent studies of the workplace. Focusing on how gender identities are constructed through daily interactions at work allow questions to be asked about workplace cultures and the policy changes that are needed in order to challenge tacit as well as overt discrimination and disadvantage. From the mid-1980s a growing number of studies on gender and work (gender at work as a process) began to explore the ways in which gender-specific traits and characteristics are attributed to men and women through the work they do in particular settings. Increasingly it was understood that jobs are not gender-neutral but instead constructed as appropriate for men or for women. Likewise, gendered identities are created and recreated at work, rather than being held as fixed and unchanging attributes that individuals bring with them to the labor market. This gives rise to the potential in the workplace context for workers’ bodies to be controlled and regulated to create a particular brand or commodity that reinforces expectations of hypermasculinity, for instance, and the sexually available female body. An example of the latter would be the US sports bar Hooters, which requires female waiting staff to wear provocative cropped tops and short shorts. Further illustrating this point, a recent recruitment drive for an international clothing retailer specified that the new store they were opening would be employing “store models” rather than shop assistants. From the words and images used in the advertisement, the underlying message was clear: only young, slender, bright, beautiful people need apply (Jarvis, Kantor, and Cloke 2009, 18). In the new 24/7 consumer-led service economy the physical attributes of the body providing a service are part of the exchange that occurs at the point of sale (McDowell 2009).

Another significant body of recent research explores the intricate chains of exploitation binding some individuals in servitude while at the same time linking them, indirectly, to more affluent households (especially working parents in global cities), who themselves seek solutions to time pressures and the squeeze on social reproduction work. Motivations and driving forces behind the growth of private personal services (help in the home) can be attributed to the rise in women’s paid employment, such as with the normalization of a dual income household, as well as the growing complexity of home-work–family life (including long-distance commuting) balance. In her book The Time Bind, Arlie Russell Hochschild (1997) explored the repercussions of a work-driven lifestyle, highlighting the marital tensions in dual income couples where parents worked longer hours and husbands rarely contributed their share of the housework, all in a climate of rising cultural expectation of intensive parenting, labor-intensive home decoration, and high standards of cleaning and garden maintenance. This is the demand-side explanation for increasingly complex chains of exploitation. The supply-side explanation has also attracted considerable attention through issues of migration, low pay, human trafficking, and bonded labor.

One of the largest domestic maid services, Molly Maid, operates through thousands of franchised businesses in towns and cities across Europe and North America. Every aspect of
the brand (pastel pink with a frilly maid’s cap) is gendered in a stylized way. A number of handyman agencies have also emerged (notably in Australia) which similarly adopt stereotypes that reinforce the idea of a new division of labor. The question of who does what in the home is no longer limited to a man or a woman but is instead extended to “a cleaner.” The cleaner is positioned in this new division of labor as of such low status that he or she is desexed, less than man or woman – barely a human machine (Ehrenreich and Hochschild 2003). Marriage counselors popularly recommend that dual career couples hire a cleaner (a cleaning lady) to shore up the myth of gender democracy in their relationship and as an alternative to squabbling over whose turn it is to empty the dishwasher. These are profoundly gendered systems of occupational segregation at work – but they are global, intersectional, and increasingly also dehumanizing (Jarvis, Kantor, and Cloke 2009).

The concept of emotional labor is often used to help explain gender divisions of labor in the service sector that emphasize the significance of social characteristics including ethnicity, skin color, body shape, and other markers of difference. Examples of emotion work may include a parent’s efforts to keep children happy, a nurse comforting a bereaved relative, or a trade union leader rallying members to strike for fair wages. Historically the display of emotions has been denigrated as a feminine attribute. With economic restructuring and the proliferation of service sector employment, workers are increasingly expected to display (or convey) tightly scripted emotions as part of their job. Examples of workers whose job it is to follow a fixed script and embodied performance include call center employees “smiling down the phone” and shop staff wearing the shoes and clothing that are for sale in the store – masquerading as living mannequins.

Work and employment can be viewed in a number of ways, as structured events in people’s lives and as powerful sites of identity formation. Terms like “transition,” “reconciliation,” and “coordination” have been used as a way of thinking about multidimensional and dynamic identities and events. Viewed this way, the movement by an individual in and out of employment may correspond with movements in and out of education or to accommodate life events (such as taking time out to care for young children or older relatives) or because of injury or long-term limiting illness. The picture of individual employment is made more complex by home and market lives that are interlinked through family and household relations: the nature and extent of work and employment that any one individual undertakes have a significant bearing on the quality of life not only of that person but also of family members and other people in the same household. Indeed the changing landscape of work and employment is often seen as a challenge for family life, but largely for women as mothers because of the complicated and difficult acts of juggling competing demands of making a living and caring for a home and family. It is widely acknowledged that, even as more women have entered the paid labor force alongside men and are working increasingly similar hours over a lifetime, men have not shifted to an equivalent extent to pick up the tasks of unpaid work required at home (Presser 2003).

There are a number of specialist academic journals devoted to the study of gender, work, and employment in various combinations of emphasis: Work, Employment & Society (a British Sociological Association publication); Gender, Work & Organization; Gender, Place & Culture; and the Labor Studies Journal. These journals and the continuing production of knowledge and debate in this field attest to continuing speculation about the future of work (Green 2005).
GENDER, WORK, AND EMPLOYMENT

As a general trend, academic interest in work has become more integrated with ethnographic studies of social difference, social justice, and social movements. This has led Halford and Strangleman (2009) to conclude a broad trend of marginalization with respect to the academic (especially theoretical) interest in the way work is rooted in classical notions of social change. They argue that the study of work has become dis-embedded from wider social theory. A number of new research directions appear to contradict any suggestion of declining scholarship. These include questions associated with the social and economic impact of the 2008 global financial crisis and the decade of recession and state austerity measures that followed. The scarring effect of unemployment is one area of growing policy relevance, alongside new concerns around issues of intergenerational equity and the inter-connection of income and employment, debt (including student debt), and the uneven quality of individual life chances (health, notably mental health) where these are co-constitutive with diverse household employment structures and unequal access to livelihood amenities including housing, wealth, social capital, and welfare.

Gender

Robyn Longhurst
University of Waikato, New Zealand

Geographers have employed the concept of gender differently over time and space. It is a concept that is fluid and overlapping, therefore, presenting a chronological narrative that represents categorically different and progressive understandings of gender throughout the history of feminist geography is not without difficulty. Having said this there are some general trends worthy of note.

In the 1970s the concept of gender was introduced into the study of human geography. While sex was understood to describe fixed biological differences between men and women, gender was used to refer to socially constructed differences that are amenable to change. A small but growing number of geographers were becoming increasingly interested in how gender differences impacted on people’s, especially women’s, lives. Gender, it was argued, could be used as a concept not just to comprehend differences in men’s and women’s identities but also to recognize that societies and spaces are structured in a manner that is patriarchal. Patriarchy, like the term gender, has a variety of meanings but feminist geographers in the 1970s and 1980s were using it mainly to refer to men’s domination of women. The stereotypical roles played by women (e.g., homemaker) tended to be devalued compared to the stereotypical roles played by men (e.g., breadwinner). Topics such as gendered inequalities in relation to access to facilities, women and development, and the interdependences of men’s paid and women’s unpaid labor began to be addressed. Also, with a growing awareness of gender issues, geographers began to critique sexism and anthropocentrism in the discipline. Women were largely absent as the subjects of research. They were also absent as geography teachers, lecturers, and researchers.

Toward the end of the 1970s and early in the 1980s gender geography groups started to form. For example, in 1981 the International Geographical Union (IGU) held a session at a meeting of the Commission on Rural Development at California State University, Fresno, in which seven papers on women were offered. It was not until 1988, however, that the IGU Executive Committee finally approved a Study Group (later to become a Commission) on Gender and Geography. While the IGU represents an international group, national groups were also forming. For example, in the United Kingdom in the 1970s an informal group, and then “working party” within the Institute of British Geographers (IBG) was formed called the Women and Geography Study Group (WGSG), a group which became formally recognized in 1980 (Morin 2009). These groups were important in helping to constitute a new “field” known as gender or feminist geography. Gender was, and still is, at the heart of feminist politics and scholarship, including feminist geography.

Over the decades, however, understandings of the concept have changed. In the 1970s and 1980s when gender tended to be used in contrast to the concept sex, the emphasis fell heavily on the way men and women are “made” or socially constructed providing a route for challenging what seemed like essential and immutable differences in the stereotypical roles...
played by men and women. Women, it was argued, occupy widely differing positions in the roles they perform, both within and outside the home. Women are often the caretakers of children, elderly, and other family members, responsible for housework, active workers in various community roles and engage in paid work. Regardless of the varied roles women take on, however, they tend to be seen as less important than those played by men. It became apparent that in many areas such as geographies of employment, urban geography, and political geography there was a tendency to adopt perspectives that subsumed women’s activities into those of men. This recognition of women’s invisibility gave rise to a number of studies that used the concept of gender to identify the nature of women’s contribution to the home, workplace, and community.

Documenting the different and unequal gender roles played by men and women challenged the assumption that men’s work, lives, and the public spaces they occupy are the norm against which women’s work and lives are measured. This research paved the way for further scholarship in the 1980s and 1990s that focused less on gender roles and more on gender relations. Rather than understanding gender in terms of socially ascribed roles, the concept of gender relations enabled a deeper examination of the reasons why roles take the form they do, and how roles are contested and change over time and space. Gender came to be seen as a relational concept. It was no longer just about women per se but about power relations between men and women.

This shift from gender roles to gender relations in the mid-1980s led some to draw not just on feminist but also Marxist concepts to tease out intersections between gender and class politics. Feminist geographers began to question Marxist and political economic understandings of the labor process arguing that the position of women needed to be conceptualized not just in terms of labor relations but also gender relations. Arguments about the merits of this approach were rehearsed in 1986 and 1987 when geographers debated the concept of patriarchy in the journal Antipode (McDowell 1986). It was important to understand not just how capitalism alone creates and perpetuates unequal power relationships but also how it intersects with patriarchy to oppress women.

From the mid-1980s, then, geographers became increasingly interested not just in understanding the roles played by men and women but in the systematic gendered and capitalist power relations produced through, and producing, particular constructions of femininity and masculinity. Research addressing contexts such as the home, community, workplace, city, and rural spaces was carried out in an attempt to understand more about the gender relations and identities constituted within these spaces. It became apparent that gender- and class-based power relations result in women having for the most part access to fewer resources and opportunities than men. Their disadvantage in the labor market combines with responsibilities for childcare limiting women’s opportunities, especially in full-time and professional employment. Focusing on gender relations enabled geographers to understand how patriarchy and capitalism within different contexts leads to women’s inequality. Feminist geographers aimed to draw attention to the unvalorized role of the reproductive sphere within the largely hidden worlds of home, childcare, elderly care, and other community spaces. Gender relations began to be theorized as spatially variable and at a range of scales, not just regions, cities, and nations, but also the home and community.

In the late 1980s and early 1990s feminist geographers started to conceptualize gender not just as a role or a relation but as a complex and shifting
subject position. Feminist poststructuralist work of theorists such as Judith Butler (1990) gained in popularity prompting debate about issues such as performativity, embodiment, essentialism, representation, discourse, and heteronormativity. It was becoming increasingly evident that the way in which some women’s identities differed from the assumed dominant form (heterosexual, white, Western, middle class, able-bodied) mattered. Butler’s argument that gender emerges out of repeated gender performances, brought into effect through discourse, captured the interest of geographers who were keen to show how these repeated and unstable practices are enacted in different ways, at different times, and in different places.

In early feminist geographical scholarship there tended to be an assumption that whiteness and heterosexuality were the norm; however, in the 1990s there was growing recognition that not only do gender differences between men and women matter but so too do differences among women. Feminist geographers moved from the using “grand theories” to explain women’s “universal” oppression to instead examining smaller-scale, more localized expressions of gendered subjectivities. It was becoming increasingly apparent that gender is a fluid concept marked by some similarity but also by difference. Geographers started to question what were seen as the priorities of white, middle-class, Western feminists in the academy and instead encouraged recognition of the multiple and varied lives of women marked as “Other” (Kobayashi and Peake 1994).

The 1990s saw increasing diversity of representation as women of color and researchers from outside the Anglo-American center began to add their voices to the body of work on feminist geography. That is not to say that all parts of the world are now represented, far from it (Garcia Ramon and Monk 2007); however, as feminists from different countries, notably India and more recently Japan, and regions, particularly continental Europe, Southeast Asia, and Latin America, began to discuss gender issues the extent to which place and positionality shape knowledge became increasingly apparent (Monk 1994). Questions began to emerge about the Anglo-American hegemony of feminist geography including use of English as the *lingua franca* in publication outlets. Questions were also raised about what constitutes useful feminist theory or challenges inequalities in different places and spaces. The universal and essentialist category of “Woman” had by the 1990s been subject to critique and could no longer be used unproblematically as the foundation for feminist politics. Criticisms of feminism as a white, Western, and middle-class phenomenon made it clear that differences among women were at times more important than similarities.

Also in the 1990s and 2000s it became increasingly obvious that the concept of gender is not just about women and femininity but about men and masculinity. There was a growing body of work in feminist geography on masculinities, men, and male subjectivity. Examples of topics addressed include hegemonic masculinity, alternative masculinities, masculinities at work, men and empire, soldiers and masculinities, and masculinities and disability. There was also a great deal of research focused on sex and sexuality, especially gay male identity.

As the concept of gender was re-theorized by feminist poststructuralist scholars in the 2000s it became increasingly problematic to prize apart gender and sex. Butler (1990, 33) argues gender is “the repeated stylization of the body, a set of repeated acts within a highly rigid frame that congeal over time to produce the appearance of substance, of a natural sort of being.” When gendered and sexed performances in different times and places do not align in ways that are
GENDER

considered normative, when people “do” their gender differently, the result is “gender trouble” (Butler 1990). Many feminist geographers began to embrace this definition of gender as something that people “do” recurrently, embodied acts and gestures when repeated come to take on the appearance of the “real” or an “essence.” Not only gender but also sex and sexuality became increasingly evident in human geography in the later 1990s and 2000s (Domosh 1999). It was argued that if gender and sex are understood to have ontological status but are produced by repeated performances (Butler 1990) heterosex is clearly constructed rather than “natural.”

Another linked strand of scholarship that began in the 1990s is that of embodied geographies (Longhurst 1995). The body’s association with femininity has provided a route for feminist geographers to deconstruct gendered binaries such as sex/gender, mind/body conceptual/corporeal, and essentialism/constructionism thereby disrupting hegemonic masculinist structures of knowledge production (Rose 1993).

Over the past decade as feminist geographers have increasingly paid attention not just to gender per se but to the body and how gender intersects with class, race, ethnicity, masculinity, sex, sexuality, and more recently health, (dis)ability, body size, and age, questions have been raised about according primacy to gender as the central analytical category and whether there are instances in which gender ought to be decentered. Critical geography, which often addresses the intersections between different subjectivities, began to gain ground in the late 1990s. The Inaugural International Conference of Critical Geographers (IICCG), held in August 1997 in Vancouver, British Columbia, Canada helped propel interest. In 1999 Routledge began publishing a new series entitled “Critical Geographies.” In 2001 a new online international journal ACME An International E-Journal for Critical Geographies began publishing. While these initiatives did not signal the end of gender as an important analytical category they did prompt discussion about an exclusive focus on gender.

Gender, for more than four decades has been a central concept in shaping how feminist geographers think about place and space. Given, however, that feminist geography is a heterogeneous subject area that encompasses multiple understandings of gender these understandings do not necessarily map neatly onto different decades and spaces although there are some trends which are worth reflecting upon. To recap, in the 1970s gender tended to be equated with women and was understood in terms of roles. In the 1980s the focus shifted to gender relations in the hope it would offer more explanatory potential for understanding patriarchal relations and the oppression experienced by many women. In the 1990s geographers, informed by feminist poststructuralism, began to conceptualize gender as an embodied performance that could not be separated from the sexed body. Geographers increasingly questioned the priorities of white, middle-class, Western feminists instead recognizing the multiple and varied lives of women. The 1990s and 2000s saw increasing diversity of representation beyond the Anglo-American center. Masculinity, sexuality, and the body were also put on the agenda. Today, gender is still an important concept but questions have been raised about when it ought to be accorded primacy as the central analytical category and when it ought to be decentered or seen as intersecting with other subjectivities such as class, “race,” ethnicity, sexuality, age, and ability.

Gentrification

Brenda Kayzar
Kate Derickson
University of Minnesota, USA

Gentrification is the transformative process whereby lower-income and working-class households are subjected to higher rents and eventual displacement as higher-income households purchase and rehabilitate inner-city residences. In similar fashion, lower order businesses are pushed out as the character of the neighborhood changes and commercial space is renovated. From its introduction, however, gentrification has been a politically charged and less than simple term.

Concern over the displacement of lower-income households from London’s older inner-city neighborhoods prompted Ruth Glass (1964) to coin the term gentrification five decades ago. Her intent was to describe succinctly not only the outcome of the acquisition of inner-city residences by middle- and higher-income homebuyers and subsequent demographic shifts, but the impacts upon the former occupants of these properties as well. As Slater (2011) suggests, because the term “very powerfully captures the class inequalities and injustices created by capitalist urban land markets and policies” (2011, 571), this transformative process has been the subject of ongoing inquiry and debate.

Advocates for greater equity in property markets have sought to maintain Glass’s focus on the class shift and loss of affordable housing and commercial space inherent in gentrifying processes. They argue gentrification should be a planning and social concern. The loss of affordable housing in gentrifying communities is not offset by the production of affordable housing in proximate communities, making the advent of displacement even more arduous for the lower-income households and small businesses that are forced to relocate. Advocates for revitalization of the inner-city have sought to lessen this focus by highlighting the benefits of reinvestment such as aesthetic improvement to the neighborhood and increased property values and tax revenues. Gentrification is reconfigured and offered as a solution to the degradation of disinvestment in older parts of the city.

A myriad of arguments populate the continuum between these two perspectives and include disagreements pertaining to displacement and neighborhood improvement measures, the character of the actors involved, and the proper methodological approaches to understanding processes of neighborhood change. The contentious and often intense discourse around gentrification has drawn together scholars from political science, sociology, geography, anthropology, housing studies, planning, and economics. In the main, their collective efforts have sought to define gentrification, explain why it occurs, describe who is impacted and in what way, and to suggest what market, policy, or social justice effort presents the best mitigating outcome.

Production and consumption

There are two primary points of entry to the study of why gentrification occurs. The first focuses on the political economic processes
that produce the market conditions conducive to gentrification ("production"); the second focuses on the cultural and social relations that render the inner-city a newly desirable place for the middle-classes to consume ("consumption"). Work that focuses on production is typically rooted in Marxist theories of land markets. Defined by Smith (1996) as a rent gap, this perspective suggests gentrification is a result of uneven development, in which capital is withheld from inner-city properties as the appropriateness of their use diminishes. This capital is invested elsewhere as demand and profit opportunities dictate (i.e., suburbs, commercial property). Disinvestment, which reduces property values over time, enables reinvestment. Devalued properties can be purchased with less capital outlay for redevelopment to the benefit of inner-city property owners, investors, and developers. Work that focuses on the consumption of the city seeks to understand the process whereby a new middle class eschews the suburbs and seeks an alternative aesthetic and lifestyle in the city (Ley 1997). A succession of gentrifying actors have been introduced as a result of studies employing this demand-side approach from the early pioneers looking for more affordable housing with historic character, shorter work commutes, and racial and class diversity, to artists in search of affordability and the ability to practice their craft without complaint from neighbors, to the less expected middle-class minority and family households. While some scholars have resisted integrating these competing explanations, Lees, Slater, and Wyly (2008) note that by the fourth decade of the gentrification debate most scholars were accepting of a multiplicity of causal factors. Competing understandings of the causes of gentrification have generated a wide range of methodologies for studying it, leading to different and often contradictory outcomes.

Methodologies and outcomes

Bondi (1999) notes the consumption and production perspectives of gentrification processes represent “cultural and economic imperatives” that remain important frameworks of scholarly inquiry (1999, 261). Within these frameworks, scholars have proffered numerous theoretical and methodological approaches in an effort to enrich the discourse regarding the sustained transformation of older neighborhoods.

Various data resources such as census and government surveys have been used to discern the existence of gentrification and its spatial extent, as well as the scope of demographic change. Pull and push factors ranging from proximity of amenities to the tenure status and incomes of existing residents have been examined to discern predictors of gentrification. Interview and ethnographic methods have provided further insight into the motivations of new, existing, and departing residents. Collective resistance has also been studied to comprehend the success or failure of these mitigation efforts.

While economic theories such as the rent gap continue to be revisited, there has also been an effort to broaden the theoretical discussion with regard to race and gender. Recognition of the imprint of historical exclusionary practices on policy and the material landscape offers an important contextualization to the current gentrification debate as it demonstrates the impact of power relations favoring white middle and higher-income households. Past practices fostered inequality in housing opportunity and segregated populations. Disinvested neighborhoods, depicted as frontiers of financial opportunity for wealthier majority households, cannot be viewed without contemplation about who already exists in – or was relegated to – these spaces (Smith 1996). This figurative “emptying” of the urban landscape intimates...
revanchist desires or a recolonization of the city for the privileged classes, at the expense of lower-income and often, minority households.

Scholars have discussed the oppression of suburban development and the emancipatory space of the city for many women. Research on gentrification also addresses the role of women, noting that single-woman and female-headed households with children have been evident in gentrifying neighborhoods and that the rent gap presented an opportunity for career women to build sweat equity in real estate while residing near their employment. Bondi (1999) provides a comprehensive review of this research through the end of the millennium and offers her own empirical analysis of three communities in varying stages of change; interweaving life course into the equation of gender and class as an additional structural factor in women’s participation.

In general, the differing measures and deeper contextualization of the past five decades of research further established the complexity of gentrification. While there is wide-ranging agreement around the consideration of a multiplicity of structures and contingencies, there remains disagreement around the positives and negatives related to who is impacted and in what way.

For example, the results of a study and subsequent book by Freeman (2006) proposed that the high rate of mobility of low-income households was due to their already tenuous economic status and was not increased by gentrification. Freeman’s argument against displacement, along with studies signifying deconcentration as a positive outcome for poor households are antithetical to Glass’s aim, but they also reflect a shift in the way gentrification is perceived by policymakers as well as some scholars. While early studies and policy actions resonated with Glass’s concern about the potential for displacement, and thereby continued segregation and social disconnection for lower-income groups, Lees, Slater, and Wyly (2008) note that gentrification is now embedded as a goal in urban policy in North America and Europe under the assumption that it will foster less segregated and more sustainable communities. Cautionary narratives “have been overtaken by a global neoliberal discourse of regeneration and renaissance” (2008, xvii).

USA Today’s interpretation of Freeman’s study resulted in the pro-gentrification headline “Studies: Gentrification a Boost for Everyone” in 2005. Terms such as revitalization, renaissance, and redevelopment have replaced gentrification in policy and scholarly lexicons, and they imply progress while obfuscating the reality of displacement and social disruption as patronage to a pro-growth agenda. The pro-growth argument draws on deindustrialization as the impetus for cities to re-envision economic futures as centers of consumption and entertainment. Historic preservation, smart growth, and sustainability efforts further bolster the discourse in favor of reinvestment in older housing stock and the design and aesthetic appeal of older neighborhoods. Further, cosmopolitan and creative workers in the new knowledge and creative economies are expected to demand revitalized urban centers in which to live, work, and play, prompting “how to” guides for civic leaders and planners. Wilson (2007) argues that concern about gentrification has been recomposed as a civic necessity, conflated in globalization and competitive city rhetoric while the spaces of low-income minority households are further compromised.

**New spaces of gentrification**

Recently, research has sought to broaden our understanding of the actors involved and the places impacted by housing mobility and displacement, rethinking the process of
GENTRIFICATION

gentrification as displacement by the white middle class, and from the urban core. Singles, dual-income households, empty nesters, artists, the creative, and gays have all been suggested as consumers of gentrifying neighborhoods, and scholars are noting a further evolution in the gentrifying population. More recent studies explore the return of black middle-class households to urban communities in decline, challenging the commonly held belief that gentrification is driven by white middle- and higher-income households.

The remaking of inner-city neighborhoods as historic and cultural centers has been expanded to include studies of the postindustrial rural west and older industrial suburbs and urban districts. Lees, Slater, and Wyly (2008) explore the way in which the notion of gentrification has been expanded, “mutated,” and applied to spaces beyond the urban core, fostering different types of displacement. For example, they discuss the liability of students on a place, the role of new construction, as well as forms of mobility and displacement generated by hyper-financialization. They argue, however, that all of these “mutated” forms have in common “a socio-economic and indeed cultural transformation due to middle-class colonization or recolonization” (Lees, Slater, and Wyly 2008, 133).

Finally, scholars of gentrification have turned their attention to the increasing pace of gentrification beyond world cities, to the more quotidian spaces of the Global South, as a generalized strategy of urban policy and development. According to Smith (2002), gentrification is “no longer isolated or restricted to Europe, North America, or Oceania, the impulse behind gentrification is now generalized; its incidence is global, and it is densely concentrated into the circuits of global capital and cultural circulation” (Smith 2002, 202, 427). Lees (2012) proposes a postcolonial approach to studying “mega-gentrification” in the Global South and suggests productive intersections between new work on assemblages and policy mobility and the rise of gentrification in the Global South.

A return to the social justice agenda

While ways of knowing about gentrification and associated scholarly inquiry differ, much work (though not all) in this tradition in geography is united by a critique of the enduring vulnerability of the working classes and minority households to displacement, whether due to circuits of capital running their course or changing preferences of the middle- and upper-classes. This critique is borne out in the activism of the “Right to the City” movement, which has strong ties to academic geography. David Harvey, Peter Marcuse, Nik Theodore, Don Mitchell, Ed Soja, Mark Purcell, and Susan Fainstein have all been actively involved in collaborating with activists and citizens’ groups to produce the political language and scholarly studies that critique class-based urban precarity. A phrase attributed to Henri Lefebvre regarding the “right to the city” asserts the rights of everyone, including the poor, marginalized, and disenfranchised, not only to live in the city free from the threat of displacement, but to participate in shaping or “making” the city.

Geoarchaeology

Lisa Maher
University of California, Berkeley, USA

Definition

The subdiscipline of geoarchaeology has come a long way in the last few decades in terms of research scope and focus and, today, it frequently plays a central role in archaeological research design. Much ahead of his time, British prehistorian Colin Renfrew noted that “… since archaeology … recovers almost all its basic data by excavation, every archaeological problem starts as a problem in geoarchaeology” (Renfrew 1976, 2). Now, archaeology as a discipline widely recognizes this statement. As such, geoarchaeology today is defined as the study, at all scales, of the direct interrelationships between past humans and the landscape/environment, where the landscape can be viewed as the intersection of physical processes and cultural activities. Notably, this definition includes the social, economic, technological, and ideological (including symbolic) aspects of human interactions with the environment. It covers a wide range of topics and deals directly with: (i) material culture (how physical objects were made, obtained and/or used); (ii) cultural attitudes and perceptions of landscape (such as the symbolic status of artifacts or landscape features); (iii) landscape modification and other human impacts; and (iv) issues of subsistence (i.e., how resources were culturally manipulated; how economy affects and is affected by the patterning of resources and their human and nonhuman exploiters), settlement (i.e., how relationships between patterning in landscape and patterning in distributions of settlements vary over time), daily activities (i.e., identifying single and repeated activities or routines), and sustainability (i.e., examining the temporality of specific human activities). The focus is placed on human–environment interactions and cultural aspects of the environment such that research is driven by questions about human behavior, activities and practices, and related social phenomena. A key aspect of geoarchaeological research today is that consideration of these issues is highlighted in research design from the outset.

Geoarchaeology has become a subdiscipline recognized as necessary to any study of the human past (Goldberg and Macphail 2006, ix). Archaeologists realize the importance of understanding the context within which the material culture record is found and understood. Environmental scientists, ecologists, geologists, and geographers likewise realize the role humans have played in landscape creation, modification, and management over millennia and the importance of reconstructing human–environment interactions today and in the past. With the realization of the long-term impact that people had on the landscape and issues of climate change, environmental sustainability, and resilience being on the forefront of scientific research today, the contributions of geoarchaeology as a science based on human–environment interactions over time cannot be understated. Recognition of the importance of the subdiscipline within anthropological research comes in many forms. These include the creation of several interest groups within larger archaeological or other
science societies, such as the geoarchaeology interest group of the Society for American Archaeology, the archaeological geology division of the Geological Society of America, and the developing international geoarchaeology (DIG) group. Geoarchaeology-related research features prominently on the websites of the National Geographic Society, Royal Geographic Society and the US Geological Society. The establishment of geoarchaeology laboratories within university departments is becoming commonplace, such as Boston University’s microstratigraphy laboratory, the Charles McBurney laboratory for geoarchaeology (University of Cambridge), the geoarchaeology laboratory at the University College London, the scientific archaeology research group at the University of Reading, the laboratory of geoarchaeology and soils at the University of Haifa, and the geoarchaeology laboratories of Washington State University, University of Washington, Washington University at St Louis, University of Arizona, and the University of California, Berkeley. Annual workshops, such as the international soil micromorphology working group, University College London’s archaeological soil micromorphology training course, and the annual International Symposium on Archaeometry, provide training and conference venues for geoarchaeological research. Finally, there are now several peer-reviewed publication venues for geoarchaeology-focused research, including *Journal of Archaeological Science*, *Environmental Archaeology*, *Archaeometry*, *Journal of Human Evolution*, and *Geoarchaeology*.

**Historical background and modern perspectives**

As a subdiscipline of environmental archaeology, geoarchaeology historically sat at the crossroads between the earth sciences and archaeology. However, early geoarchaeological research followed a somewhat different trajectory than other types of environmental archaeology, such as archaeobotany, which always kept human activity at the forefront of research design. Borrowed from geology, early focus was placed on stratigraphy and aimed at clarifying relationships between and among strata at an archaeological site to establish the contemporaneity of deposits and material culture associations, as well as identify various site-formation processes in order to provide an environmental backdrop to culture change. Early practitioners of geoarchaeology were typically earth scientists or archaeologists with some earth sciences training, brought into archaeological projects already underway to answer specific questions about sediment matrix, stratigraphy, and natural processes operating on the archaeological record. Therefore, early conceptions of geoarchaeology focused on the application of earth science techniques to the solution of discrete archaeological problems. Essentially, it was archaeology done with the use of geological methods.

Early practitioners of geoarchaeology came to the field from archaeology, geography, geology, environmental science, and pedology and their research reflected these divergent backgrounds and covered a range of topics. In North America, early archaeology was heavily influenced by a number of scholars who bridged both geology and archaeology. Ernst V. Antevs was an American glacial geologist largely responsible for compiling United States and Canadian varve sequences that comprise the varve chronology used to reconstruct Pleistocene glaciations (Antevs 1954). Beyond this, he was also acutely interested in the relationships between glacial episodes and the peopling of North America. Along with K. Bryan and E.H. Sellards they instigated a long tradition of research on early
human–environment relationships and the study of early Palaeoindian sites in America (Haynes 1990).

Much of this early work was focused on chronology and stratigraphy. In the 1950s and 1960s, earth science approaches were being better integrated into archaeological lines of inquiry beyond dating and identifying deposits. While developments in dating techniques were proving revolutionary, archaeologists were also focused on provenance and petrographic studies for examining lithic and ceramic raw materials to address production and trade and exchange. Theoretical stances were also being taken on the necessity of integrative collaboration between geologists and archaeologists (Rapp and Hill 2006). Researchers began to explore the role of earth science approaches to understanding the different contexts of archaeological material and sites and for reconstructing human adaptations to changing environments. This work went under the guise of many names, including archaeological sedimentology, archaeological geology, geological archaeology, Pleistocene ecology, Quaternary geography. However, the goals were always the same – relating archaeology to the environment over time (Rapp and Hill 2006).

Beginning in the 1960s, C. Vance Haynes Jr brought geoarchaeology to prominence in the American Southwest and has remained active in research throughout North America ever since. Early geoarchaeological work in Europe included the study of Pleistocene geochronology by F.E. Zeuner (1959) at University College London. Ian W. Cornwall’s work on the interpretative contributions of sediment and soil analyses from archaeological sites was one of the earliest systematic attempts at geoarchaeology (Rapp and Hill 2006). In Soils for the Archaeologist (1958) Cornwall argued for the importance of context within the framework of understanding the sedimentological and soil processes responsible for the creation, modification and preservation of the archaeological record. Taking this even further, his work is considered by many today as revolutionary for the introduction of micromorphology, then a strictly pedological method developed by W. Kubiena (1938), into archaeology (Cornwall and Hodges 1964). Francois Bordes brought the study of geological context to Palaeolithic archaeology in France (Bordes 1954).

From the 1960s to the 1980s, archaeologists were concerned with understanding the depositional contexts of sites. However, it was the work of Karl Butzer, C. Vance Haynes Jr, G.W. Dimbleby, and a few others, who worked towards developing programs of research focused on geoarchaeological questions, as well as developing the appropriate methods and techniques to undertake this research (Goldberg and Macphail 2006). Haynes, appointed jointly in the departments of geology and archaeology at Arizona State University, continued to do much to improve our understanding of American Southwest Palaeoindian geochronology. G.W. Dimbleby (1962) reconstructed past vegetation and soils to understand Bronze Age monument construction. Working on valley fill sequences in the Mediterranean Basin and palaeosols at prehistoric sites in Italy, respectively, C. Vita-Finzi (1969) and M. Cremaschi (1987) explored the interrelationships between settlement and land use and landscape change. The work of Davidson and Shackley (1976) is particularly relevant as they are often credited as the first to pull together various aspects of geoarchaeological research under one name and published their approach in the book Geoarchaeology: Earth Science and the Past. Since the 1960s, Karl Butzer has focused on human–environment interactions in

Geoarchaeology today is a multidisciplinary approach to understanding the archaeological record, its environmental context, and site formation processes. Taking a broad approach to human landscapes and archaeological sites, geoarchaeology has come into its own with microscale approaches to the archaeological record. Explorations of microstratigraphy (Matthews et al. 1997; Matthews 2012) and microarchaeology (Weiner 2010) now highlight the invaluable contributions of geoarchaeology to reconstructing daily activities, individual events, and cycles and episodes of use and re-use of features at levels of detail unknown in the discipline previously. As a result of the new, integrative questions geoarchaeologists now address, rather than being a rare specimen who managed to navigate the blurred intersections between the hard and social sciences, geoarchaeologists are growing in number and many academic programs offer training in geoarchaeology from the undergraduate level. Goldberg and Macphail (2006, 2) situate geoarchaeology as providing “... the ultimate context for all aspects of archaeology from understanding the position of a site in a landscape setting to a comprehension of the context of individual finds and features. Without such knowledge, even the most sophisticated isotope study has limited meaning and interpretability.”

Scales of analysis

Perhaps one of the most significant points to be taken from the definition of geoarchaeology provided above is that geoarchaeologists operate at a variety of analytical scales, often sliding between macro-level regional and landscape studies and micro-level scales of investigation that involve examination of features, deposits, particles, and even individual molecules and elements in high resolution (Figure 1). The techniques employed for each scale are somewhat different, but the research questions often remain the same. Notably, whether we are discussing macroscale or microscale issues, we are really interested in understanding dynamic human–environment interactions in both spatial and temporal dimensions.

Macroscale studies usually involve regional landscape studies, palaeolandscape reconstruction, identifying landforms, mapping site locations, reconstructing climate change, and so on. These studies often incorporate a range of techniques designed to detect and map archaeological sites and landscape features, such as remote sensing, geophysical prospection, and ground surveys designed to identify and sample landforms and depositional environments, map and define soils and soil catenas, and locate and characterize archaeological sites. With these techniques the geoarchaeologist can establish the relationships between deposits and human activity to track landscape transformations and land use and settlement change over time. This often involves creating local and regional stratigraphic relationships between locales within a survey frame and correlating these deposits across space. With a theoretical shift towards human impact on the landscape, geoarchaeology intersects with historical ecology (Crumley 1994; Balée 2002) and human eco-dynamics (Kirch 2007).
Micromorphological analysis of archaeological deposits requires analyzing deposits at a variety of scales, from documentation and sampling of sections in the field (a) to the description, analysis and interpretation of thin-section slides (b) at a variety of magnifications (c) (Tell Seker al-Aheimar, Syria; images courtesy of Y. Nishiaki, University of Tokyo Museum).

**Figure 1**

Intermediate and microscale analyses involve investigation at the site level and below, such as individual archaeological features (i.e., hearths), particles contained within features (i.e., ash), and even molecular and elemental levels of analyses (i.e., elemental compositions of obsidian). Here there is overlap in techniques used at the macro and microscale, including the use of geophysical prospection to locate features within a site (e.g., houses, burials), sedimentological and pedological analyses of on-site deposits to establish stratigraphy and to assess preservation potential of deposits. The recent book *Microarchaeology* by S. Weiner (2010) is an excellent example of the sliding microscales of analyses performed by the geoarchaeologist, amongst other specialists. Similarly, W. Matthews’ (2005, 2012) and Twiss et al.’s (2008) approach to building construction, maintenance, and abandonment at Çatalhöyük provide a benchmark for the kinds of high-resolution interpretative power of microstratigraphic analyses, as does the examination of Paleolithic bedding material at Sibudu Cave, South Africa (Goldberg et al. 2009).

**Methods and techniques**

Geoarchaeology is both a field and laboratory-based endeavor. Geoarchaeologists employ methodologies and techniques from a wide range of fields, including archaeology, geology, geography, geomorphology, ecology, pedology, climatology, geochronology, geochemistry, and geophysics. Geoarchaeological methods can also include the reconstruction of past human activity through the analysis of biological datasets, such as archaeobotanical remains or marine and freshwater shells. Integrated organic and inorganic datasets allow palaeocological reconstructions that shed light on past human land use and practices, and landscape transformation at the
GEOARCHAEOLOGY

hands of humans. Many geoarchaeological tech-
niques focus on examining the composition and
origin of material culture, including ceramics,
metals, lithics, and building materials (e.g.,
plaster, mudbrick, adobe, stone, and cement).
Those who employ geoarchaeological methods
and techniques include researchers in university
settings, museums, and governmental agencies,
cultural resources management companies, and
private sector geoarchaeology consultants.

Perhaps one of the most long-standing and
well-known applications of geoarchaeology is
identifying, documenting, and analyzing strati-
graphy, sediments, and soils. Geoarchaeologists
make a clear distinction between sediments and
soils and, thus, require a firm understanding of
the different processes responsible for each and
how each interacts with and impacts the archae-
ological record. For sediments this includes
knowledge of the processes of sediment produc-
tion, erosion, transport, and deposition in order
to observe and record their characteristics and
as a means to understanding landscape history
and depositional environment (Goldberg and
Macphail 2006). As clastic, chemical, and bio-
logical sediments are all relevant to reconstructing
the contexts of human activity, geoarchaeologists
study colluvial deposits, riverine, estuary, and
alluvial deposits, aeolian environments, coasts,
and caves and rock shelters. Documentation
and interpreting sediments involves assessments
of their composition, color, grain size, shape,
roundness, sphericity, sorting, density, surface
texture, fabric/packing, and structure (bedding,
bedforms). Field techniques include trench and
column sampling, augering, coring, and archae-
ological excavation. Laboratory techniques
include particle size analysis (granulometry),
bulk density and mineralogy, organic matter (loss
on ignition), calcium carbonate content, iron
or magnesium content, magnetic susceptibility,
phosphate content, trace element geochemistry,
clay mineral analysis, and analyzing biological
and bioclastic inputs (e.g., ostracods).

Soils are usually formed over long periods
and conditions that entail some degree of land-
scape or landform stability and, thus, can prove
extremely important for understanding human
settlement and interpreting human–environment
interactions. Geoarchaeology thus often includes
a basic understanding of the processes of soil
formation and how humans can complicate
these processes, including anthropogenic inputs
and impacts. Activities such as terracing slopes
to control erosion can deepen soil profiles and
increase moisture content, and stock manage-
ment in highland soils can alter soil catena
development. In many past societies, especially
agricultural ones, soils were essential resources
that were mined, managed, and modified in a
variety of different ways. They can be seen as a
key factor affecting human occupation and land
use and, in some areas, particular soils were likely
foci for early farming activities. Hunter-gatherers
were also impacted by variations in soil, which
affected settlement location and instigated land
management practices. Palaeosols have some-
times proven useful indicators of past land
surface stability and can serve as likely indicators
of human occupation potential (Maher 2011).
Beyond the exploration of human–environment
interactions, soils, like sediments, can be involved
in the preservation of archaeological sites. Field
and laboratory techniques for soil analyses often
overlap with those conducted for sediments,
but also include the identification and docu-
mentation of soil profiles, soil (ped) structure,
boundaries between soil horizons, as well as the
analysis of pH, fertility (cation-exchange
capacity, N, K, and P content), sesquioxide
accumulation, and magnetic susceptibility.
Methods include the chemical, elemental and
mineralogical analysis of samples through X-ray
diffraction (XRD), electron microprobe analysis,
X-ray fluorescence (XRF), instrumental neutron activation analysis (INAA), atomic absorption (AA), Fourier transform infrared spectrometry (FTIR), Raman spectrometry, and inductively coupled plasma atomic emission spectrometry (ICP-AES). Micromorphology has proven to be indispensable to geoarchaeology for elucidating the complex relationships between sediments, soils, and anthropogenic activities.

Palaeosols can overprint archaeological stratigraphy and can preserve archaeological sites and, conversely, their formation can be sped up or slowed down by anthropogenic activities. An excellent example of the contributions of a geoarchaeological approach to soil analysis and the impact of anthropogenic input into soil forming processes is the study of dark earth (Macphail 1994; Macphail, Galinié, and Verhaeghe 2003), an organic-rich soil found at many Medieval archaeological sites in Europe. Despite being found in archaeological-rich urban contexts, these soil deposits exhibited a complete lack of stratigraphy and the processes responsible for their formation were largely unknown. Detailed microscale analyses of these deposits through micromorphology have shown them to be anthropogenic soils formed over very short periods of time as the addition of high levels of organic matter compounded by microfauna activity (namely, earthworms) accelerated the processes of soil formation and obliterated all pre-existing archaeological stratigraphy.

Characterizing on-site and off-site deposits allows the geoarchaeologist to identify and disentangle natural and cultural processes operating on the archaeological record and establish stratigraphic relationships between deposits, including correlating them across a site or several sites in a landscape. Together, the analysis of soils and sediments from on-site and off-site contexts provides a means for reconstructing palaeoenvironments and palaeolandscapes, identifying the possible locations of archaeological sites (by identifying landforms likely to contain archaeological material of particular ages), identifying human impacts on a landscape scale, and characterizing deposits and features within sites at high resolution. These direct and proxy data are powerful tools for contextualizing human activity across space and time.

Remote sensing and mapping

As technology becomes more sophisticated, portable, accessible, and affordable, field techniques for detecting and mapping landforms and sites are greatly improved and now almost standard preliminary survey methods. Remote sensing and satellite imagery, including open source platforms such as Google Earth, have aided immensely in landscape characterization and targeting specific landscape features (Comer and Harrower 2013; Ur 2006). Geophysical prospection, namely ground penetrating radar (Conyers 2013), electrical resistivity, and magnetometry (Aspinall, Gaffney, and Schmidt 2009), to name but a few, have revolutionized the way landscape potential is assessed and features located within sites to help target and refine excavations. Geographical information systems (GIS) are proving to be an invaluable tool for building models of land use and landscape change and developing and testing specific hypotheses regarding human settlement patterns and landscape modification (Conolly and Lake 2006).

Dating techniques

Chronological assessment and control, both in terms of relative (e.g., stratigraphic correlations) and absolute (e.g., radiometric methods) dating
have long been a pursuit of geoarchaeology (Aitken 1990). Radiocarbon dating, uranium series dating, K–Ar dating, optically stimulated luminescence (OSL), thermoluminescence (TL), electron spin resonance (ESR), and palaeomagnetism, in particular, are useful for archaeological deposits over a wide range of ages, from the very recent (Kirch and Sharp 2005) back to fossil-bearing deposits over one million years in age (Liritzis, Singhvi, and James 2013). Commercial and university-based radiocarbon laboratories, such as the Oxford Radiocarbon Unit, Weizman Institute, University of Arizona, and Beta Analytics, permit high-quality dates to be obtained at affordable prices with quick turn-around times. With interest in the age of landscapes, the age of sites contained within them, and the age of components within sites, geoarchaeologists employ dating techniques that date a wide variety of different types of materials at different resolutions (with different errors). All of these techniques require an in-depth understanding of archaeological context, laboratory preparation techniques and analysis, and how to interpret the results. With this knowledge, the quality of the sample collected and its appropriateness for a particular research question can be determined. In particular, it must be ensured that the sample material and technique used will not result in a date with uncertainties (errors) that are larger than the chronological resolution needed to solve the research question.

**Microscale analyses and daily practices**

Sometimes traditional geoarchaeological methods are not appropriate for archaeological deposits on a small scale. With developments in analytical techniques that permit examination of increasingly small samples, it is now possible to take microscale approaches to the archaeological record that can detect and identify human activity at the level of individual events. Rather than only assessing broad patterns in human activity and behavior within a site or feature from sedimentary or soil units, specific events, repeated activities, and daily practices within these individual units can now be discerned (Boivin 2000; Matthews et al. 1997). These microscale approaches fall under many names, including microstratigraphy, micro-artifact or microdebris analysis, micromorphology, and molecular analyses (such as isotopic analysis or residue analysis). These microstratigraphic approaches are unique in their ability to reveal specific human activities, such as in situ occupation, construction, and maintenance of floors, hearth cleaning, and dumping.

In particular, the introduction of soil micromorphology to archaeology has revolutionized the way archaeologists approach microscale analyses. Micromorphology is the examination of the composition, texture, structure, and arrangements of sediments, soil, and archaeological deposits at a variety of scales, mostly of high resolution. It involves the collection of undisturbed blocks, approximately 10×10 cm in size, of a deposit of interest. These blocks are then impregnated with a hardening agent (often a clear epoxy resin) in order to allow the blocks to be prepared into thin sections. Thin section slides are usually 5×7 cm in size (although this varies) and 30 μm thick, and are then examined and described at a variety of magnifications (Figure 1), often with binocular and petrographic microscopes. Like with artifacts, the context, distribution and composition of archaeological sediments is informative. With this technique, the geoarchaeologist considers sediment as material culture for the information it can provide on human activities, behaviors, and practices. A micromorphologist examines the composition...
and character of the coarse and fine fractions of a deposit, voids, organic matter, pedogenic activity, and anthropogenic input or traces. The advantage of micromorphological analyses over field observation of anthropogenic deposits is that human activity can be identified and examined at a completely different scale, often invisible in the field. Focus is placed not just on the identification of individual features or components within a slide, but on understanding the arrangement of these components with respect to each other for the information they can elucidate on the nature and relative sequence of processes of deposition, erosion, post-depositional alterations, and human activities (i.e., individual episodes of floor re-plastering).

Of particular relevance to archaeology, micromorphology allows one to look at occupational deposits, material culture, patterns in the use of space and object discard, and site-formation processes at a very high resolution usually invisible in the field. Micromorphology allows a high resolution view of time and space for understanding the activities of people within houses and settlements, including daily, seasonal, annual, and life cycle timescales. Building phases, levels, and repeated daily activities can be examined in more detail. Beyond the site, micromorphology contributes to studies of landscape and landform change due to human impact (e.g., farming practices like irrigation, manuring of fields, intentional burning, deforestation, overgrazing). In essence, it can provide a variety of types of information on human activity at a variety of scales. It has proven particularly useful for identifying and interpreting anthropogenic deposits, such as the construction, maintenance, and abandonment of buildings (resurfacing) (Matthews 2012; Rosen 1986), activity areas (food processing, flint knapping, sleeping, storage, middens), and changing use of areas/features over time (clean versus dirty spaces; sweeping) (Matthews et al. 1997), combustion features (Albert, Berna and Goldberg, 2012; Berna et al. 2012; Goldberg et al. 2012), bedding and matting (Wadley et al. 2011), human-induced modifications to soil regimes (agricultural practices) (Beach et al. 2006; Fisher et al. 2003; Macphail 1990), and site-formation processes (Rosen 1989; Tsatskin and Nadel 2003).

Key issues/current debates

Perhaps one of the most visible and common issues in geoarchaeology, as with any archaeological research design, is the issue of sampling strategy – deciding where, how, and how much to sample. Deciding on an appropriate sampling strategy depends on the research questions and is an issue at all scales of analysis, from regional landscape studies to reconstructing building phases or maintenance within one house. A golden rule of sampling provided by Matthews et al. (1997, 285) is that “in order to understand the complex pre-depositional, depositional, and post-depositional histories of occupation deposits, it is important to adopt research designs which raise these questions during excavation, recording, and sampling, and which enable integration of a range of field and laboratory characterizations, each of which has its own advantages and limitations and potential for different ‘readings’ of macroscopic, microscopic, chemical and physical attributes.”

Given the time-consuming nature of many analytical techniques, the key issues regarding sampling include decisions on the extent and intensiveness of horizontal versus vertical coverage, whether to sample all deposits or only key deposits, and whether to collect bulk samples or in situ, undistributed blocks (e.g., for micromorphology). These decisions have significant impact on the interpretation of archaeological
deposits, which can vary considerably spatially and temporally. While bulk sampling can be conducted expediently in the field, allowing coverage of a large portion of excavated area at a site or across a landscape, micromorphological sampling in the field is very time intensive and more destructive of archaeological sections and deposits (especially notable for small, thin deposits). This means that micromorphological sampling is often restricted to particular locations and deposits and often cannot intensively cover a large area across a site. However, the resolution afforded by micromorphological analysis often outweighs the time constraints and destructiveness of the technique in the field. Sampling strategies will also vary depending on the particular nature of individual deposits and the archaeological questions related to them. Bulk samples (for soil/sediment analyses, pollen or phytoliths) require samples to be taken within individual strata, while micromorphologists are also often interested in capturing and analyzing the transitions between strata. Thus, micromorphological sampling often requires a combination of systematic column sampling and purposive sample selection.

Another key issue faced by geoarchaeologists is ensuring consistency and continuity between field observations and microscale sampling and analyses. There are currently no accepted standards for presenting and publishing geoarchaeological data, but practitioners have over time developed certain guidelines to good practice for reporting and publishing results (Goldberg and MacPhail 2006). Full documentation must be ensured throughout every scale of sampling as it must be possible to clearly link each scale of analysis in order to maximize the interpretative power of each sample (Figure 1). Sometimes the sampling strategies of archaeological excavation must, thus, be modified to accommodate geoarchaeological sampling requirements that usually entail collecting more sediment/soil samples than might otherwise be done. This attention to consistency and continuity is carried into the reporting and publication of geoarchaeological datasets. Work must be presented in a clear and logical manner, readable and interpretable to the nonspecialist, and providing the reader with the possibility of tracing the exact locations of samples and sources of individual data (Goldberg and MacPhail 2006). This includes everything from including full field documentation details to ensuring scales are present on all images. Geoarchaeological interpretations are rarely, if ever, stand-alone datasets and, thus, should be written in consultation with other archaeological specialists (as the original research design was put together). Just as context is important to the geoarchaeologist, contextualizing geoarchaeological datasets with other lines of evidence provides the most robust conclusions and interpretations.

Future directions

With a focus on human–environment interactions over a great time period, and increasing global concerns with climate change, resource sustainability and ecological resilience, geoarchaeology has much to contribute to understanding of the long-term impact of human activities. Burgeoning areas of geoarchaeological research include the incorporation of historical ecology, sustainability studies, and resilience theory approaches to the environment. The interdisciplinary, multiscalar nature of geoarchaeology is well suited to tackling these issues in conjunction with many other environmental scientists. Particular contributions include examining the landscape modification brought on by long-term occupation (Beach et al. 2006; Matthews et al. 1997; Matthews 2010), small-
and large-scale land management practices (Fisher et al. 2003; Glaser 2007; Macphail 1994) and the development of experimental geoarchaeology and ethnoarchaeology (Cabanes, Weiner, and Shahack-Gross 2011; Friesem et al. 2011; Goldberg and Macphail 2006; Goodman-Elgar 2008; Matthews, Hastorf, and Ergenekon 2000).

Geocoding

Daniel W. Goldberg
Texas A&M University, USA

Geocoding is most commonly considered to be the process of converting postal address data into geographic coordinates, for example converting text such as “123 Main Street, AnyTown, Texas 12345” into the latitude/longitude representation “−118.23, 32.01” (Rushton et al. 2006; Goldberg, Wilson, and Knoblock 2007). Geocoding techniques and geocoding systems have been in existence since their earliest invention in support of the US Census Bureau activities in the 1970s (Jaro 1984; O’Reagan and Saalfeld 1987). Today, there are dozens of commercial, open source, and federally supported geocoding services available to serve the multitude of scenarios, applications, and users (Zhan et al. 2006) that need to convert textual information with a locational component into a geographic representation.

Geocoding plays an important role in many business, governmental, and research settings ranging from analyzing patterns of crime to perform predictive policing and planning (Ratcliffe 2004), to analyzing the spread of disease cases to reveal unfolding outbreak scenarios (Higgs et al. 2007; Gao et al. 2008) and understand chronic conditions (Costello et al. 2009; Rushton et al. 2004), to providing the base data necessary for enabling location-based services such as “search nearby” functions in many smartphone and scientific application scenarios (Adams, Ashwell, and Baxter 2003; Boulos 2003; Dao, Rizos, and Wang 2002). In these and many more instances, the process of geocoding serves as the enabling technology that transforms large databases of locationally relevant textual information into digital geographic data usable within mobile, desktop, and enterprise applications, services, and analyses (Goldberg, Wilson, and Knoblock 2007; Hill 2006). Because of this critical role, both the science of geocoding technologies and the science of using geocoded data have undergone in-depth research over the past four decades or more since the technology was first invented (Rushton et al. 2006; Goldberg, Wilson, and Knoblock 2007).

The purpose of this entry is to describe the past, current, and future of geocoding technologies. It begins by describing the internal processes of a geocoding system. It next describes the means by which users can interact with geocoding systems to process their data in secure and convenient manners. It concludes with current and future issues related to geocoding technologies and the use of these tools for scientific, business, and administrative purposes.

Components of a geocoding system

In general, geocoding systems can be divided into six major components (Goldberg 2008). These are: (i) the input data provided to a geocoding system; (ii) the parsing and normalization processes which are applied to those input data; (iii) the reference data repositories which contain the geographic objects that link input data to real geography; (iv) the feature matching algorithms which link input data to reference features; (v) the feature interpolation algorithms which identify the location along or within a reference...
feature where the output should be placed; and (vi) the output data resulting from the process of geocoding.

Input data

The input data provided to a geocoding system are most typically postal address data; however, this is not a requirement (Whitsel 2006; Levine and Kim 1998; Wieczorek, Guo, and Hijmans 2004). Most geocoding systems available today can process many types of textual data that contain some form of location reference within them. These alternative textual inputs can include the names of cities or states alone (without a postal address included), the names of official or colloquial locations, and the names of businesses or buildings. With the rise of social media, and Twitter in particular, the geocoding systems of today must now handle a wider variety of possible input which must now include highly abbreviated and nonpostal address structured references to geographic locations (Davis et al. 2011). In the vast majority of cases today, the data provided to a geocoding system must take the form of a string of text characters. These data can be passed either as a series of parsed address components such as “123,” “Main,” and “Street,” or as a single nonparsed string “123 Main Street.”

Parsing and normalization

Upon receiving an input string of characters to be geocoded, the first step of the geocoding process is to begin to identify what pieces of the input data relate to what types or attributes of geographic features (Boscoe 2008). This process is known as parsing, or recognizing and separating each of the components of the input address into its geographic type and attribute. For a nonparsed address-style input such as “123 Main Street, Anytown, Texas 12345,” the parsing process would use white spaces and other text separators (commas in this case) to separate the input data into a series of tokens each associated with the type of geographic object and feature. This input address would be separated into the following components: Street Number=123, StreetName=Main, StreetType=Street, City=Anytown, State=Texas, ZipCode=12345. To accomplish this task, parsing engines may utilize deterministic approaches where finite state machines process each token of text against known databases of synonym terms with look-back and look-ahead scanning to determine the correct types for each of the components of the input data string (Hutton 1992). Other approaches include probabilistic methods such as neural networks and hidden Markov models (HMMs), which are machine learning techniques that rely on annotated training sets and produce statistically based classifications for geography and attribute types for each of the input data items (Blakely and Salmond 2002; Christen and Churches 2005; Christen, Churches, and Willmore 2004).

Following the assignment of each term in the input data to a geography and attribute type, the next step of the input data massage process is to convert the recognized attribute types into the standard values which are expected by the feature matching and reference data components of the geocoding process. This process, known as address normalization, converts raw input data values into the official standardized versions following an address standard (Fonda-Bonardi 1994). This process results in, for example, the street type component “Street” in “123 Main Street” being converted into the official abbreviation “ST” when following a particular address standard that contains this official abbreviation.
Applicable address standards include the United States Postal Service (USPS) Publication 28 (US Postal Service 2015), which defines the official standardized values for address components for postal delivery in the United States, as well as the data format utilized by the US Census Bureau’s Topologically Integrated Geographically Referenced (TIGER) data files (US Census Bureau 2015), and many others utilized by local addressing authorities. The differences between address standards typically relate to the level of granularity of attributes available. For example, the parcel files maintained by the Los Angeles (LA) County Assessor separate the article of an address where the USPS Publication 28 standard does not. For an address as “123 La Brea Ave,” the LA County Assessor would store the components StreetNumber=123, StreetPreArticle=La, StreetName=Brea, StreetType=Ave, whereas the USPS Publication 28 would include the pre-article and the street name as a single attribute and identify them as StreetNumber=123, StreetName=La Brea, StreetType=Ave.

Reference data

The reference data sources included in a geocoding system represent all of the knowledge that the geocoder has about geographic objects in the real world (Gilboa et al. 2006; Zandbergen 2008). These data sources serve to link input data to real-world geographic objects that have known locations which can be assigned to the output data from the geocoding process. Reference data sources included in modern geocoding systems encompass the full spectrum of administrative geographic data items such as countries, states, cities, streets, buildings, and all forms of named geographic entities. These reference databases include one or more point, line, and polygon geographic representations for each of these administrative geographic data types that can be matched to during the geocoding process.

The most commonly utilized reference data sets include street centerlines, parcel boundaries, address points, and building footprints (polygons) (Goldberg, Wilson, and Knoblock 2007). The accuracy of a geocoding system depends heavily on what types and qualities of geographic reference sets are available to the system, because these define the types of objects that can be matched to in the real world (Zandbergen 2008). For example, if a geocoding system only contains the centroids of cities in the United States, it will only be able to produce output matching to the geographic accuracy of city centroids across the United States. Instead, if a geocoding system contains building footprints for a city, this geocoding system could be capable of producing output to the level of building centroid, which is dramatically better than simply matching to the center of a city for the same input postal address.

In the United States, the US Census TIGER/Line files (US Census Bureau 2015) represent the most accurate freely available reference dataset available for geocoding purposes at no cost. This dataset contains the street centerlines for all streets in the United States and includes the address attributes necessary for geocoding, such as street name, street type, from address, and to address by side of street. A multitude of commercial options also exist which are capable of providing building footprint and address point data for the whole of the world, but in many instances exceed the cost deemed reasonable by users who need to geocode their data. The United States does not maintain a publicly available national parcel dataset such as those maintained by other countries around the globe, for example, the United Kingdom (Ordnance Survey 2015) and Australia (Christen, Churches, and Willmore 2004; Paull 2003). As
such, national parcel-based geocoding in the United States is limited to purchased datasets. However, parcel datasets are rapidly becoming very available at the county level across the United States, allowing geocode users to build regional parcel-based geocoding options where this is the case.

Feature matching

Once processed through the address parsing and normalization components of the geocoder, an input data item will have been broken into several components representing different types and attributes of geographic data objects which can be found in the real world. The purpose of the feature matching component of a geocoding system is to identify possible candidate reference geographic data items, also known as reference features, within the reference datasets available to the geocoding system, score the correctness of the various matches, and determine which of all matches should be treated as the best possible match (Hutton 1992). To accomplish this task, two approaches have been implemented within the published literature on geocoding systems to date: deterministic matching approaches and probabilistic matching.

Both approaches begin by querying the reference data sources available to the geocoding system to identify possible candidate matches. In many geocoding systems, this involves generating and issuing Structured Query Language (SQL) queries to the relational database management systems (RDBMS) which store the reference data layers. Text-based query techniques such as word stemming and phonetic algorithms such as Soundex are utilized by geocoding systems to generate queries to the reference data layers which can account for common misspellings found in address and other location data. These queries are issued to each of the reference data layers in the geocoding system and result in a series of zero, one, or more reference geographic features that have attributes which exactly or partially match the components of the input address (Goldberg 2008).

Deterministic matching approaches will assign a weight to each of the attributes of a geographic feature and penalize candidate matches when the values on the reference features do not exactly match those of input location requested by the user to be geocoded (Goldberg, Wilson, and Knoblock 2007). These weights and resulting penalization factors are used to assign a score, known as a match score, to each of the candidate matches. Probabilistic approaches take into account the distribution of terms in a reference dataset along with the co-occurrence of terms to compute a match between the input data and every reference feature in the reference dataset (Jaro 1984; Christen, and Churches 2005; Christen, Churches, and Willmore 2004). In both cases, the match score associated with a reference data feature describes the likelihood that the candidate is the appropriate and correct match for a given input data item. The candidate matched feature with the highest match score is then used to pick the most likely best matching candidate which is then selected for use to produce the eventual geographic output from the geocoding system. A user-defined minimum match score is typically used within a geocoding system to determine a cutoff point under which a candidate feature will be treated as a nonmatch and not considered as a candidate from which to compute an output location (Boscoe 2008).

Feature interpolation

Once a candidate reference feature has been selected as the most likely candidate, the feature interpolation algorithms within a geocoding system compute the ultimate location at, along, or within the reference feature that is returned
as the final geographic output of the geocoding system. The type of feature interpolation algorithm employed relies primarily upon the type of geographic object stored in a reference data layer, and secondarily upon any ancillary information that is available about the distribution of an attribute of interest at, within, or along the reference feature (Goldberg and Cockburn 2012). For example, if the reference data layer is composed of address points with a latitude and longitude (lat/lon), the feature interpolation process is typically to directly return the lat/lon associated with the reference feature.

If the reference data instead contain polygon representations for ZIP code boundaries, cities, or counties, a feature interpolation algorithm will need to take some approach to compute a lat/lon output from a polygon representation. Several approaches have been documented in the literature for computing the centroid of a polygon including bounding box centroid and geographic centroid, which both have benefits and drawbacks (Goldberg and Cockburn 2010; 2012). However, if, as in most use cases of geocoding, the location data to be geocoded are associated with the addresses of people, a third approach, which uses population distribution within a region to bias the output toward where the majority of the population live, may be a better option.

If the reference data are street centerlines (the most common dataset utilized in free geocoding systems) the address interpolation algorithm must locate appropriate output-based street address attributes associated with the input address and the reference feature (Bakshi, Knoblock, and Thakkar 2004). Street centerline interpolation, also known as linear interpolation and address-range interpolation, utilizes the odd/even, side of street, and start and end address associated with the street segment in order to compute a proportional distance from the start of the street to place the output. This approach suffers from a number of documented shortcomings included an over-estimation of the number of houses on any street segment, non-contiguous address ranges between contiguous street segments, and nonstandard address numbering schemes or odd/even address street-side distributions (Zandbergen 2008; 2011). When additional information about the number and orientation of houses on a street is available from ancillary data sources, address-range interpolation techniques can be augmented to produce more accurate outcomes (Bakshi, Knoblock, and Thakkar 2004).

Output data

Traditionally, the output data from a geocoding system has been limited to simple lat/lon pairs with metadata information describing the quality of the match. In the literature on geocoding, the metadata from geocoding systems has been defined as match rates, match scores, and match types (Boscoe 2008; Rushton 2003). Match rates describe the proportion of input data records that could be geocoded to any level of geographic output of a total number of records in the input dataset (Zhan et al. 2006). This metric is an overall representation of the success rate of the geocoder, on a dataset-specific scale.

As discussed above, a match score is a value that describes the likelihood that a matching candidate feature is in fact the correct match for an input address. These scores are quantitative measures of correctness of a match and may be either deterministically or probabilistically based. In the former, the match score represents a measure of the similarity between the attributes of the input data item and those of the reference feature matched to. In the latter, the match score represents the probability that the correct selection was made from all reference features.
in a reference dataset. In both cases, the weights assigned for computing penalties and the distribution of attribute values in the reference dataset have enormous impacts on the resulting scores generated for candidate matches (Bichler and Balchak 2007). If incorrectly judged, it is easy for a geocode user to misinterpret the match score value and either accept false positive matches (matches that are not correct are included as correct in the output data), or reject false negative matches (matches that should have been included as correct in the output but are not).

The match type metric describes the level of geographic data object that a geocoding system is capable of matching to. The value that this metric takes for a geocode output is primarily dependent upon the type of reference data source that a candidate match is drawn from. If a candidate can be determined in a parcel data layer, the output match type in many systems will be “parcel”; if a candidate comes from a ZIP code layer, the match type will be “ZIP code,” and so on. Although the Open Geospatial Consortium (OGC) has developed many standards for geographic data, there are none that define the types of match types that are possible as output from a geocoding system. This situation has led to a proliferation of service- and community-specific match type schemes, with each geocoding service and community developing their own standards. For example, the North American Association of Central Cancer Registries (NAACCR) has devised a geocode match type scheme used throughout the cancer registry and cancer research communities (Goldberg 2008). This “geocode coordinate quality (GCQ)” includes the most commonly encountered geocode output types ranging from address point to state centroid level geocodes in an ordered hierarchy with a clear ordering of better and worse geocode match types.

The primary drawback of such systems is that they imply that all geocodes of certain match types are better than all geocodes of another match type. For example, the NAACCR GCQ hierarchy implies that all ZIP code level matches are better than all city-centroid level matches. In urban areas where ZIP codes are small and cities are large, this hierarchy arrangement makes sense. However, in rural, less populated areas where ZIP codes are large and cities are small, this assumption breaks down (Goldberg and Cockburn 2010).

A secondary drawback of the match type geocode quality metric is that it assumes that all geographic objects of the same type are of the same quality. Following from the rural/urban example above, it should be clear that a ZIP code in a highly populated urban area will represent a smaller geographic area than a ZIP code in a sparsely populated rural area. Geographic objects of the same type vary in size across and between geographic regions, meaning that one qualitative measure of “ZIP code level accuracy” does not mean the same thing in two different areas (Beyer, Schultz, and Rushton 2008; Drewnowski, Rehm, and Solet 2007; Grubesic 2008; Krieger et al. 2002). In one area it may match to a highly precise, geographically small area, while in another it represents a large area and thus highly imprecise geocode output.

Geocoding use cases and considerations

As of this writing, end users wishing to utilize geocoding technology have an extremely rich set of options available for accomplishing this task. Geocoding tools are now built into classic desktop geographic information system (GIS) packages such as ArcGIS and Google Earth, and are readily accessible via web services provided by commercial firms (Google, Microsoft Bing,
Here.com), academic institutions (Texas A&M University), and governmental agencies (US Census Bureau). The primary differences between these systems are cost (free versus paid), reference data layers included (parcel, address point, building footprint, etc.), and privacy and confidentiality guarantees (Health Insurance Portability and Protection Act (HIPPA) compliant versus non-HIPPA compliant) (Armstrong and Ruggles 2005; Cho 2008). In general, geocoding services with highly accurate, commercially based, or proprietary reference data layers are not free, and many cloud-based commercial options cannot guarantee HIPPA compliance or other requirements such as that data must remain within the borders of the United States during transit and while being processed (Goldberg et al. 2013). However, to a casual user of geocoding with a small number of records to geocode that are not of a confidential nature, many geocoding options exist. The primary decision that these users face is what means they should utilize to geocode their data. These users can choose from an array of available desktop/web and batch/single geocoding options.

Desktop versus web geocoding

The first decision a user must face when choosing a geocoding solution is to determine if they wish to use a desktop or web-based geocoder. A desktop geocoder runs locally on a user’s machine and requires that they have a complete geocoding system available and installed including all necessary reference data. In this scenario, the user opens the geocoding application on their local computer, points the geocoding system to their file containing location data to be geocoded, and clicks a button to begin the geocoding process. The lead up to this process may include the construction of a reference data layer-specific geocoding instance that is built by preprocessing a series of reference data layers to make them accessible and usable by the geocoding system. Processing data on one’s own local desktop ensures that one’s data never leaves one’s computer, thus ensuring confidentiality and security. However, desktop processing can involve high costs, to purchase the geocoding software and a license for reference data, and may require a high degree of technical knowledge and ability to be able to get the geocoding system functioning properly. In most desktop geocoding systems, it is possible for the user to tune the parameters of the geocoding system to optimize processing to meet the specific characteristics of their input data.

Web-based geocoding services operate through a series of web applications and/or web-based application programmer interfaces (APIs) that allow systems running in one’s web browser or on one’s desktop to call a remote geocoding service to process their data. In these scenarios, one’s location data are transmitted over the Internet to the geocoding service provider who processes the raw input data and returns geocoded output data as a result. There are numerous options available for web-based geocoding, ranging from free to very expensive, each of which provides a varying degree of options for tuning the geocoding process options, ranging from no ability to set parameters to complete ability to set all parameters. The primary benefit of utilizing a web-based geocoding solution is that it removes much of the expertise required to build and maintain a geocoding system from the end user, placing this burden instead on the service provider. Other advantages include scalable architectures at the service provider ensuring rapid processing of large amounts of data. As noted, the primary drawbacks of web-based geocoding solutions are cost and security. Many of the most accurate web-based geocoding providers charge nontrivial fees for using these
services and may include additional terms and conditions which limit what the end user can do with these data following their processing. All data sent to web-based geocoding services are transmitted over the Internet, so security may be an issue if proper security procedures are not in place or not followed during data processing. For example, at a minimum, if using a web-based geocoding system operating over the hypertext transfer protocol (HTTP), that is, anything that is a webpage, the HTTPS (secure HTTP) protocol should be used to verify the identity of the sender/recipient and provide a minimum level of encryption while the data are in transit. For health data of any kind, the geocoding service provider should be HIPPA and HITECH (Health Information Technology for Economic and Clinical Health) certified, which means that appropriate security practices, policies, and procedures are in place to protect an end user’s data while in transit and while at rest at the service provider.

### Batch versus single geocoding

The next main consideration for most geocoding system users is whether to use a batch geocoder or to geocode addresses one at a time (Zhan et al. 2006; Goldberg et al. 2013). In the vast majority of cases, users will need to geocode a data file that contains more than one address, such as a list of the addresses of study participants or a list of business names and addresses within a particular industry. As such, batch processing services are typically of more use for end users than single data entry forms that process one address at a time. In batch processing systems, users either upload a database of records to a web-processing service or point a geocoding system locally installed on their computer at a database of records. The next step is to identify the fields in the input database to the geocoding system, so the system knows which fields contain the full address as a single field or which fields represent parsed portions of the input data. It is typical for these systems to require one field to be a unique key which can be used to associate an output geocode with an input record. Geocoding systems will process the file of input record either serially (each data item in a row, one after another) or in parallel to increase processing speed and system throughput. The output of the geocoding process can either be appended as additional attribute fields in the input database or as a separate output file that can be linked back to the original file via the unique key associated with each data record.

### Geocode correction

The final process undertaken in many geocoding endeavors is the manual review of geocoded results which may or may not include manual inspection and correction of geocodes with less than desirable output qualities (Goldberg et al. 2008). These processes are built into many geocoding systems, desktop and web, and automatically prompt an end user to review output results where geocodes could not be found with high match scores or where match types are typically considered of low quality (state centroids, city centroids, ZIP code centroids, etc.). In these systems, a user is presented with an input address, the current output geocode, and the other match candidates which were found but not selected (Boscoe 2008; Abe and Stinchcomb 2008). At this point, the user can choose to accept the current output, choose a different matched candidate as output, or perform additional research to attempt to understand and correct any errors with an input address that prevented it from finding a more suitable match.
If additional data sources are available, such as DMV (Division of Motor Vehicles) records, social security records, or voting records, research has shown that nongeocodable records such as Post Office (PO) Boxes can be transformed into valid postal address for individuals which can be successfully geocoded (Gilboa et al. 2006). Similarly, Internet searches are often capable of translating the PO Box address of a business into a valid mailing address which can be geocoded. These same Internet searches are also quite successful in translating named places such as nursing homes and apartment complexes into valid street addresses which can be geocoded.

Manual geocode correction has been shown in recent years to greatly improve the quality of geocoded data, but also has been shown to be extremely labor-intensive and thus expensive. These expenses are due to the fact that very little of the research process can be automated, and it often takes a bit of detective work to understand the history of a person, address, or place to determine what a correct address should have been. In all cases, it is advisable for geocode users to retain both the raw input address and the corrected address discovered through a research process.

Current issues in geocoding research and practice

Despite the fact that geocoding techniques and technology have been in continuous use for more than four decades, many challenges remain which must be noted by the geocoding developer and user communities. Many of these have been challenging issues since the initial development of the field of geocoding, while others have emerged in recent years as new services and systems have increased the user base and use cases in which geocoding is applied. The following sections provide a discussion of just a sampling of all pertinent issues.

Spatial accuracy

Of primary concern to most geocode end users is the quality of the geocoded data they receive from their geocoding system. Of all aspects of quality possible, these users are primarily interested in spatial accuracy, or the distance between the computed geocode location and the true location of the object on the surface of the Earth (Davis and Fonseca 2007). Large spatial errors in geocoded data mean that all analyses, services, and/or conclusions based on these geocoded locations may be suspect, resulting in poor services and ill-derived conclusions (Jacquez and Rommel 2009). As noted, geocode accuracy primarily depends on the reference data layers available to a geocoding system, that is, a geocoder with better reference data will result in better output geocodes. However, geocoding accuracy has been shown to be the result of many factors beyond this simple technical observation. Most important, research has shown that geocode accuracy is not stationary across space or type of person (Krieger et al. 2002; Karimi, Durcik, and Rasdorf 2004; Oliver et al. 2005). Specifically, data from urban areas will result in better geocodes than data drawn from rural areas. Equally important, research has demonstrated that location data associated with minority populations and those less well-off across any measure of the socioeconomic spectrum are more likely have geocodes of lower quality than those in nonminority and/or more well-off circumstances. Users of geocoded data must be cognizant of these facts when using geocoded data for research or practice, and must be equally aware that simply removing low-quality
GEOCODING

geocodes from one’s dataset is not an appropriate method of dealing with low-quality data.

Security and confidentiality

As noted above, web-based geocoding services in particular may expose researchers and/or practitioners who need geocoding to a host of security and confidentiality concerns. Most important, users of geocoding systems need to be aware that their data are being shipped to a third party for processing when they are using these services. Depending on one’s dataset, this may or may not be an issue, but it does at least warrant some consideration if for no other reason than the terms and conditions of some providers state that they will keep a copy of all data submitted to their services (Curry 1999).

There is wide acceptance that submitting patient medical information (test results, disease stage, etc.) to one of these services would break confidentiality and/or privacy rules unless the service has signed a Business Associates Agreement (BAA) with the user and the service provider has HIPPA and HITECH polices, practices, and procedures in place to guarantee the safety and security of the user’s data in transit to/from the service and at rest while being processed by the service (Armstrong and Ruggles 2005; Gittler 2008). However, there is less clear guidance when no information other than an address is submitted about the patient. In this case, no personally identifiable information has been submitted to the geocoding service, nor has any disease or other medical information about the person. The Institutional Review Boards (IRBs) at academic institutions currently have no clear policies as to whether these data are considered personally identifiable information or protected health information (PHI), since the only data being transmitted are an address with no personal information included. Users of geocoding systems should be advised to check with their local organization’s IRB or IRB equivalent prior to sending any data to web-based geocoding services.

References

Since the advent of scientific computing, geographers have been engaged in building more sophisticated analytical methods and models. The so-called “quantitative revolution” of the 1960s and early 1970s paved the way for computers to become widely accessible, enabling a range of previously intractable problems to be studied across many research disciplines, including geography. At the start of this period, there were no geographic information systems (GIS) as such and no spatial statistics applications, so the practitioners of the day had to write their own code. The programming language Fortran and punched cards were the technologies of the day, and our forebears rose to the challenge and pioneered many new statistical methods and data structures that explicitly addressed the spatial nature of data – methods that are still used to this day. One result of this research activity was the development and ongoing use of several new spatial association methods. The aftershocks of this computationally-powered revolution can still be felt across the field of academic geography (an interesting account of the somewhat turbulent philosophical debates that followed is given by Macmillan (1997)). Geocomputation continues this tradition of leveraging the latest capabilities afforded by state-of-the-art computing methods and platforms.

Geocomputation, at its heart, is focused around two specific, sometimes overlapping challenges:

1. improving accuracy or predictive power by developing or adapting new approaches to analysis and modelling and
2. increasing the computational scalability of analysis and modelling methods.

The founder of geocomputation, Stan Openshaw (2000), was equally fascinated by both of these challenges.

For some researchers, the analytical inadequacies or size limitations of current GIS are still a challenge that must be overcome. And there are still weaknesses in the established statistical methods currently used, for example their ability to accurately model nonstandard distributions or to work robustly in the presence of noise (Gahegan 2003). Fueling this desire for greater predictive power and better scalability is the exponentially-increasing volume of spatial data at our disposal. Big data is by no means a new obstacle for spatial analysis; ever since the start of the quantitative revolution challenges have been faced based on data size and data complexity when compared to the performance of available computer platforms and analytical methods, and it is likely that they always will. Ultimately, it is the same technologies and needs that power both the supply and the demand side of big data!

The first international conference on geocomputation, hosted by the School of Geography at the University of Leeds in 1996, heralded the
launch of a new research agenda in geographical analysis and modelling (Openshaw 2000). A measure of the interest generated in this field is that the conference quickly became established as an international event (Otago, 1997; Bristol, 1998; Virginia, 1999; Greenwich, 2000; Queensland, 2001; Southamton, 2003; Michigan, 2005; Maynooth, 2007; Sydney, 2009; London 2011; Wuhan, 2013; Texas, 2015). There has been a steady production of new textbooks on geocomputation over this timeframe: from Longley et al. (1998) to Abrahart and See (2014).

As originally coined, geocomputation was not intended as a synonym for GIScience, nor for spatial information theory: these being somewhat orthogonal to the original and ongoing vision and having their own conference series and research focus. In its original sense, it is closer to spatial analysis, with a clear focus on spatial data, as shown in Figure 1. The focus is on computational geography – building on the best that scientific computing, machine learning and statistics have to offer, within the explicit context of geographical problems and data: hence the term “geocomputation.” However, over time, there has been a blurring of meaning, as geocomputational techniques have gained more mainstream appeal, perhaps also because many problems require a combination of analytical approaches to be successful.

**Challenge 1: Improving analytical insights**

Extending analysis and modeling capabilities beyond the established methods of spatial analysis has been a recurrent theme for geocomputation. Researchers have explored many newer analytical approaches, for example based on machine learning, agent-based simulation, and exploratory geovisualization (Brenning 2005;
An excellent summary of these new approaches is provided by Cheng, Haworth, and Manley (2012). In practice, most of the efforts are a translation of progress made in machine learning, simulation, artificial life and information visualization (infoviz) into an explicitly spatial or geographical context. This translation is not necessarily straightforward, given the complexities and subtleties of both the methods themselves and the geographical data to which they are applied (hence, the tongue-in-cheek definition of geocomputation by McNoleg (2008) as: “Geocomputation: the application of impossibly sophisticated methods to fiendishly complex datasets by hopefully optimistic researchers.”). For example, machine learning tools typically place a complex set of “controls” onto the behavior of a learning algorithm that subtly change the inherent bias towards accentuating different kinds of patterns or distributions. Selecting these parameters so that the algorithm performs well on a specific geographical dataset, with all of the subtleties that pertain, is a very complex task. The theory that would “map” the behavior of these new methods onto the understanding of geographic space, patterns, associations, and categories is still largely absent. It is precisely this gap in theory that Couclelis (1998) urges geocomputational researchers to address, and many have (Fischer 2006; O’Sullivan 1999). However, the most common approach to date is still trial-and-error, working methodically through a range of parameter settings whilst evaluating the change in predictive performance. Such an approach is common to many applications of machine learning and is an example of computing power being used as a substitute for theory.

It is worth noting that the focus of geocomputation to date has instead been on improving the predictive power of analysis, though not necessarily improving the explanatory power of any resulting model. Improvements to fitting of distributions typically require the use of more functions, or more complex functions, or both. So the cost of better prediction is often a more complex model that may be more difficult to understand, or to “mine” for useful generalizations. It could perhaps be argued that the spatial domain is complex and it is time we moved on from simple, over-generalizing assumptions.

Progress to date has yielded tangible improvements in the theory and applications of geocomputation: by reducing prior statistical assumptions, improving the tolerance to noisy data, and providing more flexibility in modelling distributions. There have been many published examples of significant improvements in predictive power, or some other form of accuracy gain when moving from established statistical methods to methods based on machine learning (Lasaponara et al. 2014; Beekhuizen and Clarke 2010).

However, it has sometimes been a challenge to gain acceptance for these methodological changes outside of the geocomputational community. Conceptually, researchers must move from a statistical mindset – where distributions are declared and understood in advance and any analysis will always produce exactly the same result – to a stochastic/heuristic mindset where distributions are constructed (learned) from data examples, not assumed, and where results can vary due to the nondeterministic nature of many machine learning approaches (often caused by randomized start conditions employed by the underlying algorithms). (The variation is usually not large (if it is, it usually shows the learning process is not yet configured reliably), but no such variation exists with most parametric statistical approaches. So a different means of reporting is needed, to allow for variation in the results, and a different expectation is needed on behalf of the researcher.)
Challenge 2: Scaling up analysis and modeling

There are many unsolved scientific computing problems embedded within spatial analysis. Often, the price paid for improvements in analysis methods is an increase in the computational complexity, requiring commensurate increases in processing power. Similarly, the drive towards using bigger and more complex datasets places increasing demands on data storage design and efficiency. However, almost all analysis in commercial GIS takes place within laptop- or desktop-sized computers, and much of it runs in a single processing thread, on a single central processing unit core. Even in research settings, most spatial analysis algorithms do not yet scale well to more complicated computing architectures, leading to hard limits on the data volume that can be addressed and the complexity of analysis tasks that can be supported (Wang 2013).

To achieve better performance or scalability, the underlying problem must be broken apart into smaller-sized processes that can be solved concurrently, that is, in parallel. Such decomposition can address either the algorithm itself (task parallelism) – for example, by distributing the algorithm (or parts of it) across a set of processors, or by distributing the data to be processed across a set of processors (data parallelism). Also worthy of note is data distribution design, the fragmentation of data across a set of distributed and fault-tolerant storage devices that can be accessed in parallel (see the entry on CyberGIS).

This approach now plays an essential role in managing large spatial data collections, such as the tile caches to support web mapping applications such as Google Earth (Zhang and You 2012).

Some problems are easier to decompose than others, depending on how tightly coupled the task is, that is, how much communication is needed during execution between the set of processes. Tightly coupled problems require specialized, high-speed interconnections between processing units to support intensive message traffic. At the other end of the spectrum are embarrassingly parallel (EP) algorithms; these are simple to parallelize because they have no internal coupling or coordination needs. A common example is a parameter sweep, where the same process is executed multiple times with a different set of initial values. The calculation of local spatial regression at multiple locations and scales is embarrassingly-parallel, so it can be moved onto a grid or cloud infrastructure with relative ease (Harris et al. 2010). Many problems fall somewhere in between, and may require a mix of decomposition approaches and some refactoring of the original algorithms in order to achieve a radical improvement in performance (Guan, Kyriakidis, and Goodchild 2011).

Even once these decomposition challenges have been solved initially they need to be periodically revisited to align with advances in: (i) computing architecture, (ii) algorithms and scientific computing libraries, and (iii) storage design and optimization.

Summary

Geocomputation is a conscious effort to explore new analytical techniques from the wider computer and statistical sciences – particularly the machine learning and high-performance computing communities – that can be applied to quantitative geography. Its aims are: (i) to enrich geography with a broader toolbox of methods that are more accurate because they are able to adapt to the geographical nuances of the specific data used to train them; and (ii) to address the computational scaling and decomposition needs that will allow geographers to move beyond artificially small and simple problems and work with a more realistic level of detail and complexity.

Geodemographic profiling

Paul A. Longley
University College London, UK

A person’s identity is defined in part by their conception and expression of their individuality, and in part by their affiliations to groups – for example, to nations, cultures, social classes, or even soccer teams. In each respect, geography tells us that a fundamental part of “who you are,” is “where you are.” National, regional, or other cultural affiliations link identities to a single or a small number of unique places on the Earth’s surface, whereas components of identity that arise out of social, economic, or demographic circumstances are likely to recur across multiple different locations. The study and classification of human identities thus corresponds to the two dominant traditions in the history of geography as a discipline: the idiographic tradition that emphasizes the unique shaping characteristics of places, and the nomothetic tradition that emphasizes the observable similarities of process outcomes upon different locations on the Earth’s surface.

Geodemographic profiling (or “geodemographics”) is the neighborhood-scale analysis of people by where they live. Traditionally, it has fallen into the nomothetic approach to geographic inquiry – emphasizing the shared social, economic, and demographic characteristics of different types (or classes) of neighborhoods, independent of their locations relative to unique places. As such, a type of neighborhood may be widely scattered across a territory or jurisdiction. Geodemographic profiles thus provide summary indicators of the commonalities of social structure that link different locations. Yet each neighborhood is embedded, from an idiographic standpoint, in a unique place on the Earth’s surface.

Geodemographic profiling systems are used by businesses organizations to understand consumer purchasing behavior, lifestyle, and social attitudes, with the goals of finding and retaining profitable customers and identifying the best locations from which to serve them. Public service organizations use the same kinds of systems to facilitate resource allocation decisions of public goods, such as law enforcement, schooling, or health care. Figure 1a presents the “super groups” and their constituent groups that make up the UK Output Area Classification (OAC; www.cdrc.ac.uk). This classification is based on 60 variables selected from the 2011 UK Census of Population (a framework data source that is open to reuse by anyone). The typology was derived using k means cluster analysis, which is a method of data reduction and data mining. Figure 1b presents an equivalent classification, derived from 2010 US Census of Population data.

Figure 2 presents two illustrative radial plots that each identify the 60 UK census variables clustered in order to create the classification shown in Figure 1a. The overall classification shown in Figure 1a comprises eight major classes (termed “super groups”), and these plots profile the values of the variables for two of them. It is clear that very different values of the 60 variables characterize these two super groups. Interpretation of plots, standardized cluster scores, and other diagnostics arising from the cluster analysis enables analysts to devise user-friendly summary “pen portraits” of the prevailing characteristics of each class within a

geodemographic classification. Two illustrative pen portraits from the London Output Area Classification (LOAC; www.cdrc.ac.uk) are shown in Box 1. Web mapping also makes the dissemination of geodemographic classifications accessible and readily intelligible to users, providing useful, detailed, and generalized summary information about the characteristics of human identity at the neighborhood scale of analysis.

Most geodemographic classifications include many more than the eight classes shown in Figure 1a and the nine shown in Figure 1b. Typically, each of the high level classes (“super groups” in the terminology of the classifications shown in Figure 1a) will be subdivided into lower-level classes (e.g., “groups”), and each of these may in turn be further subdivided (e.g., into “subgroups”), and so a national geodemographic taxonomy will often number 60 or more classes in total. These geodemographic classifications are said to be “open”: the methodology that was used to create the classifications shown in Figure 1 and Box 1 is published, the analysis method is fully documented, and the data that were used to create each of them are readily accessible to all (Gale et al. 2016; Spielman and Singleton 2015). However, many other geodemographic classifications are “closed”; that is, at least some of the data sources used to create them are not in the public domain, or undocumented and commercially sensitive methods were used in the data analysis.

A number of issues of spatial analysis underpin the creation and use of geodemographic classifications. First, it is assumed that the choice of variables used to specify social similarity has some intrinsic merit in representing the distinctive identities (defined in social, economic, and

demographic terms) of different neighborhood classes, and that the analysts that created the classification have selected and weighted the variables commensurate with their relative importance to the classification. Second, there is an implied assumption that the pen portrait (Box 1) of any class represents the modal identity of households in the neighborhood and that, by implication, other households are either small in number or similar to the modal subgroup. Third, there is an assumption that the units of analysis, such as UK census output areas or US census tracts, are appropriate for capturing the spatial heterogeneity of neighborhood structure, either alone or through aggregation. Finally, users will assume that the classification is up-to-date when they use it, and thus that there is temporal stationarity between the time of data collection and when the classification is utilized.

History and current state of the art

The conceptual roots to generalized representation of neighborhood characteristics and differentiation between small neighborhood areas can be traced to the work of Park, Burgess, and other members of the “Chicago School of Urban Ecology” from 1916 onwards. The root metaphor to this work was biotic competition and vegetation succession in ecological systems. Seen from this perspective, neighborhood communities were fashioned by subsocial forces, and “society” was a cultural superstructure above the more basic competitive level of the community. By analogy to ecological systems, the dynamics of invasion and succession were community-level forces, as vividly captured in Burgess’s famous (1923) concentric zone model of Chicago.

Much of the enduring appeal of this work originates in Burgess’s ascription of explicitly spatial terms such as “neighborhood” and “district” to areas whose residents shared collective identities and which drove urban expansion and change. Thus, the city came to be envisioned in cross-section as a mosaic of subareas, defined in terms of the patterning of socioeconomic and demographic groups and differences in built form. The root biological metaphor provided the dynamics that underpinned this cross-sectional view, and was deemed to drive the kaleidoscope of change that characterized the Chicago metropolitan area in the 1920s and 1930s. This image is both vivid and enduring, with some writers (e.g., Saunders 2001, 42) suggesting that the ecological analogy retains greater relevance (at least in empirical terms) to our understanding of residential structure than subsequent models of urban differentiation, such as those in the urban managerialist or Marxist traditions.

Powerful and enduringly relevant though the dynamic ecological metaphor may have been, subsequent empirical work focused rather repetitively upon the measurement task, elevating detailed description of the urban mosaics of different cities to an end in itself. This humdrum, unimaginative, and normal science endured as “factorial ecologies” during the quantitative revolution of the 1960s, as advances in computing made possible reduction of large and complex datasets, such as those arising out of censuses of population, for the first time. But geographic science is itself driven by change, and the routine nature of such data reduction exercises meant that interest in factorial ecology waned during the 1970s, although not before the approach was used by the UK Department of the Environment (DoE) to devise a UK neighborhood classification as the basis for prioritizing different inner-city policy initiatives. By 1979 the DoE’s system was used by some fifty local authorities.

It was this applied policy analysis that provided the template for the generalized geodemographic
GEODEMOGRAPHIC PROFILING

neighborhood classifications that were developed in the following 20 years. However, analytical refinement in the specification, estimation, and testing of classifications became the preserve not of urban sociologists or geographers, but of marketeers working in large commercial organizations (Harris, Sleight, and Webber 2005). At first, these commercial applications were created exclusively using population census data, but they subsequently broadened to include data harvested from social surveys and other sources of business data. This development in data very much reflected the preoccupations of the new business applications over those of government policy and planning. The societal mandate for population censuses is very much in response to government needs for relevant indicators of deprivation and hardship, whereas the new commercial classifications were more attuned to discerning differences in consumption behavior within more affluent socioeconomic echelons.

A consequence of this changing locus of activity in geodemographics was that, in a period of rapid and accelerating development in computation, the principal refinements in technique largely took place outside of academia and government. Private sector sources of data, of largely unknown provenance, were used to supplement and partially replace framework population data sources such as censuses. The motivation for this was at least twofold. First, the somewhat stale diet of census variables was not conducive to segmenting increasingly sophisticated consumer-led markets. Second, the decennial nature of census data collection (along with delays in making the resulting data available) meant that classifications based exclusively upon census data were deemed out of date even before they appeared. It also served commercial ends that the new classifications were “black box,” in that the content and lineage of many of the constituent datasets were unknown, and the precise methods used to cluster them were closely guarded commercial secrets.

The archetypal end use of a geodemographics application in the 1980s and 1990s was to improve segmentation in retail markets, for tactical or strategic gain. Within academia, there was little attempt to develop new and innovative applications, and no clear vision of the ways in which neighborhood classifications were integral to linking and summarizing the increasing range of administrative and survey datasets. The few academics who maintained active research interests in business and service planning felt “locked out” of developments that utilized private sector “lifestyle” data to augment census sources. The inevitable consequence was that geodemographic profiling remained rather rudimentary in the academic and public sectors. The archetypical public sector application of the 1980s and 1990s was the deprivation indicator, which standardized and summed census indicators to identify areas that were experiencing hardship.

Whether devised in the public, private, or academic sectors, geodemographic classifications of this period remained focused upon cross-sectional outcomes – good marketing prospects and deprived communities alike were deemed to be static outcomes. There was little interest in representing the dynamics of change in the way the Chicago urban ecologists originally envisioned neighborhood transition and secular change. While geographers were interested in patterns of spatial interaction, these were usually framed using coarse zonal geographies, or did not develop sophisticated taxonomies of human identity or neighborhood type.

The early years of the new millennium saw a renaissance of interest in academia and government in the use of neighborhood geodemographic profiling. This was driven by the turn of the millennium, by a number of Western governments, to “evidence-based”
policies, improved access to and distribution of turn-of-millennium censuses, and the development of a performance culture in local public service delivery. The focus of the archetypical geodemographic application shifted to public service tasks, such as improving preventative communications programs (e.g., in health and policing) and the opportunities to improve efficiency by targeting neighborhoods most at risk from social ills. There was also renewed academic interest in the importance of local context in understanding the responsiveness of local communities to policy initiatives. By this time, however, the analytic skill base of many parts of local and central government, and of academia, had been hollowed out as a consequence of shifts in academic focus. Consequently, many public sector applications and academic studies were, in effect, consumers of the sophisticated yet black box classifications created in the commercial sector – which was fleet-footed in spotting the opportunity to rebadge existing classifications for new public sector clients. This raised a number of issues of research practice and ethics, some of which were discussed in John Pickles’s (1995) edited collection on the social implications of geographic information systems (see also Longley 2005). Commercial applications of geodemographic profiling are very much driven by predictive success in improved targeting of potential customers, and the black box nature of classifications remained of little concern in achieving this end. Yet all citizens are stakeholders of public services, and the motivations for social policy are much more broad-based; thus, any failure of commercial classifications to represent the interests of stakeholder groups in social organization presents important issues of ethics and accountability.

More recently, a number of governments have come to understand the value of public services and government in the creation of quality data. This could provide a much improved context to decision-making but hitherto has been neglected by (or even hidden from) potential users. The open data movements of many countries, worldwide, are leading to the greater dissemination of data collected about the public to organizations that represent the public. Open data from administrative sources are thus beginning to provide important elements of an inclusive socioeconomic data infrastructure, and hence for geodemographic classifications. This is a significant development, particularly given that the response rates to conventional sample social surveys appear to be in inexorable decline in many countries. This brings with it concerns about the nature of response bias in the data that are collected. On a more positive note, data from the most recent censuses suggest that they have not been vulnerable to this attrition effect (completion is a legal requirement in many countries), and they have been made more readily available for download than ever before. Although the limited remit of the short census form in the United States gives cause for concern about the accuracy with which a full range of population characteristics can be ascribed to small areas (using the American Community Survey) (Spielman and Singleton 2015), the future of censuses in the United States and United Kingdom does now seem assured.

Publicly funded data collection nevertheless now accounts for a reduced share of the totality of routinely collected digital data pertaining to household lifestyles – particularly when social media and transactional “big data” sources are taken into account. In the spirit of the private sector developments of the 1980s and 1990s, there is obvious potential for use of new data sources assembled in the course of business-to-customer transactions, and also through reuse of geographically referenced social media data such as Twitter. The provenance and
population coverage of these sources remains a very under-researched issue; much work remains to be done in order to open up access to such sources. Yet the potential benefits to geodemographic profiling are enormous, in terms of the range of variables that might become available, and the temporal granularity with which human activities might be measured.

Taken together, the availability of new and open sources of geographically referenced data is ushering in an era in which the creation of application-specific geodemographic classifications is becoming routinely possible for a broad constituency of spatial analysts. This is making it possible to build geodemographic classifications tailored to the widest range of end uses, using data that are detailed, pertinent, and up to date. Yet for this to make a significant contribution to evidence-based policy, data sources must be of known provenance, with sufficient endeavor to accommodate bias in their coverage.

Prospects: toward geotemporal demographic profiling

Viewed retrospectively, it is clear that the practice of geodemographic profiling of neighborhoods has been guided by two overriding considerations – one substantive, the second procedural. In substantive terms, nighttime residence has always been seen as key to generalized understanding of the relationship between human identity and the spatial organization of society. This assumption is increasingly outmoded given the fission of lifestyles in societies that are manifestly differentiated in many other ways, such as by measures of family structure and kinship, consumption, education, or employment. Residential structure is but one (albeit very important) indicator of social structure that needs to be considered alongside indicators of activity patterns on a daily, weekly, seasonal, or still longer-term basis. The nature and pace of change in the production and reuse of the built environment may make change monitoring important at greater frequencies than decadal census intervals. All of these issues will come to the fore as classifications for emerging economies are developed, and it is also likely that new big data sources (such as social media) will be particularly important in recording activity patterns in these new and dynamic settings.

The second, procedural, issue is the use of small area aggregations in order to preserve respondent confidentiality. This gives rise to the well-rehearsed arguments of ecological fallacy (confounding the characteristics of areas with particular individuals who live within them). As lifestyles become ever more differentiated, so patterns of individual behavior in space become increasingly central to defining what makes any person or group distinctive. From a geodemographic perspective, the zonal geographies of residence are by no means the only ones that shape identity at the level of the human individual, and a more appropriate representation of individual behavior should seek to capture more of the spatial trajectories and exchanges of information that are central to identity.

Some recent censuses have gone some way toward addressing these issues by providing small area workplace statistics, broken down according to a limited range of social, economic, and environmental variables. Although providing important local economic indicators, human identity encapsulates more than the duality of work and residence – many people do not undertake paid work, and for many others the rhythm of day-to-day activities is about more than the journey to and from work. It is thus increasingly the case that applications of geodemographic profiling need more information – for example, in order to measure and monitor the changing
convenience culture of retailing that continues to redefine the mission of retail store location analysts.

Geodemographics can rise to this challenge by incorporating the temporal dimension, at temporal scales from the dynastic to the diurnal. Over the most expansive timescales, biosocial research is providing context to the origins of populations and providing benchmarks for estimating the cumulative genetic effects of migration upon unique places over the entirety of human history (Leslie et al. 2015). While biological genotyping remains a prohibitively expensive means of establishing the biological uniqueness of places, family names have been used as a surrogate indicator of place effects, since many family names were first coined at unique locations (typically between the twelfth and fourteenth centuries in Anglo-Saxon cultures). Thus, Cheshire and Longley (2012) and Mateos, Longley, and O’Sullivan (2011) use Anglo-Saxon family names to analyze distributions of cultural, ethnic, and linguistic groups, present day and historic, at scales from the local to the international. Linkage of this work to biosocial markers provides valuable indicators of the cumulative effects of migration over the last 900 or so years, and hence of unique ancestry profiles of populations in different places. However, the efficacy of this approach is likely to depend upon the efficacy of naming conventions in representing the accumulated effects of language and culture in the period since family names came into common parlance.

This analysis provides context to the more recent and more generic patterning of social similarities that are measured using census and related survey data, and which have been overlain upon these unique historic biosocial landscapes. Bringing together the long-term biosocial place characteristics with the much more recent geodemographic profiling makes it possible to view patterns of social similarity in relation to historic place formation.

At the other end of the temporal spectrum, social media data are being used to capture the formation and sustenance of place effects through the measurement of social interactions. Thus, Birkin, Harland, and Malleson (2013) and Longley, Adnan, and Lansley (2015) use georeferenced Twitter data to capture the movements of individuals and draw conclusions about the sociospatial characteristics of the flows of people and information within cities. This evolving research agenda uses social media data to address issues such as:

- geographic variability in the connectedness of locations, and the creation of geotemporal profiles of (a) the connectedness of neighborhoods to others that are similar in terms of quantifiable characteristics and (b) the timescales on which people at a unique place become aware of, or react to, external events;
- diurnal, weekly or seasonal variation in the connectedness of systems of locations to one another;
- summarizing the locus of daily activity patterns, and the impacts of trip chaining behaviors upon place formation – such as the multipurpose trips of working parents, or the routing behavior of public services such as police patrols;
- the functional interdependencies between places in terms of volumes of interaction generated by different social, economic, and demographic groups.

What is defining about all of these applications is not just the infusion of the temporal dimension into representations but also their recourse to the human individual as the unit of enumeration and analysis. This is becoming central to understanding the short- and long-term dynamics of how
human societies and their settlement structures function. This also brings focus to human identity as shaping, and being shaped by, the information flows and population movements that define both unique and generalizable characteristics of places. It also brings sharp focus to ethical issues of disclosure control and anonymization in an age in which geographic information technologies facilitate the potential linkage of diverse data sources from the administrative, business, and service delivery domains.

The granularity of time-stamping that can be achieved through new sources of social media data is far greater than anything that hitherto has been incorporated into geodemographics. Less immediately apparent is that the coverage is very much less complete than has traditionally been the case with census-based analysis; sometimes heroic assumptions must be invoked at the individual level in order to assign attributes to individuals. The issue of coverage also applies to monitoring the biosocial characteristics of populations; cost issues restrict the size of samples and it remains unclear what constitutes, in practice, a “good” sample of the biosocial structure of any place.

From the perspective of geotemporal demographics, places are social constructs defined by the cumulative effects of highly distinctive interactions between population characteristics and environmental attributes over space and time. The fundamental challenge remains to filter the shared social similarities that can be generalized between different locations – as with the mosaics of urban areas identified by commercial geodemographics – while remaining cognizant of the uniqueness of different places when doing so. Place effects may reveal shared elements over the very long term (as revealed through biosocial analysis or migration history) or the very short term (as revealed through indicators of spatial interactions and activities gleaned from social media).

Geography tells us that widely scattered places (e.g., in Washington, California, Florida, or Illinois) share important social or physical similarities that are manifest in different ways and to differing degrees. Geotemporal demographic profiling offers the prospects of using standardized quantitative measures to measure the repetition of place effects across space, while also posing questions about what is unique, or unquantifiable, about places. The geotemporal profiling of places begs important questions, not just about data science and the potential of big data, but more fundamentally about the hypothesis-driven research designs that will underpin geodemographic profiles that are efficient, effective, and, above all, safe to use.

Geodesign

Thomas Fisher
University of Minnesota, USA

What is geodesign?

Geodesign combines the analytical capability of geography with the synthesizing characteristic of design, giving those responsible for shaping the built environment the geographical information systems (GIS) they need to make more informed decisions. Geography and design may seem to have little to do with each other, with one rooted in the social and physical sciences and the other based in the arts and humanities. However, these two fields have a lot of overlap.

Consider their names. Geography means to write (graph) on the Earth (geo), studying the traces of the cultures, movements, and flows of humans across the world and their natural and built environments. Meanwhile, design means to mark (sign) out (de) something, which includes the spaces, structures, and paths that people have placed on the planet. Geography, in other words, has long studied the designs of human beings and the designs that they have had on the places we inhabit.

As such, geography and design have many traits and interests in common. Both fields, for example, have a strongly spatial focus, studying how people construct, use, and interact in space. Both also look at the activities and institutions of people around the globe, attending to cultural differences and community coherence. And both use many of the same analytical tools, from maps and plans to databases and documents of all sorts.

The significant distinction between geography and design – and the value of combining them in geodesign – lies in their different temporal focus. A good deal of geographical work helps us understand the world as it was and as it is, while design offers a way of envisioning the world as it could be. Geodesign, in other words, marries our grasp of the past and the present with a desire to imagine a better future. It also ties into related geographical endeavors, such as the development of spatial decisions support systems or multi-criteria evaluation tools, which use geospatial technologies to envision possible futures.

Another distinction has to do with the difference between studying a situation and changing it. That distinction comes out in a recent definition offered by leaders in the field, Carl Steinitz, Stephen Ervin, Michael Flaxman, and Tess Canfield at the Geodesign 2014 Summit: “Geodesign applies systems thinking to the creation of proposals for change and impact simulations in their geographic contexts, usually supported by digital technology.”

Why geodesign?

Several forces have prompted the emergence of geodesign. Technology has evolved to the point where GIS software and 2-D and 3-D visualization tools can now interact in ways not possible in the past. Geodesign tools not only give a data-rich understanding of particular places, but also provide an immersive way of envisioning and depicting the changes we want to make to those places.
At the same time, geodesign reflects the emphasis in recent decades on interdisciplinary interactions and the new knowledge that can come from intersecting fields once thought of as distinct. Technology has helped prompt this trend as the web has become not just a place to seek information, but also a metaphor for reality as increasingly the world is seen in networked ways.

A further motive for geodesign has come from a realization that we can no longer justify or sustain many features of the world that we have designed for ourselves. With the built environments in which most humans live having such a negative effect on global ecosystems, endangering our own species along with millions of others, the design community has recognized the need for a new approach and new tools that enable us to make better decisions based not only on short-term needs but also on long-term impacts, locally and globally.

The history of geodesign

Geodesign, in some sense, has existed ever since people first made decisions about what we do on and with the land. As Steinitz observes, “people have designed and changed the geography of their landscape for thousands of years, often without the participation of design professionals or geographic scientists” (Steinitz 2012, 9). Steinitz traces the more recent history of geodesign to the work of the landscape architect Warren Manning, who first overlaid maps on light tables as the basis for his design decisions. The landscape architect Ian McHarg greatly extended that process, described in his ground-breaking (1992) book Design with Nature, using map overlays to determine where and what type of development should go where. Geography in their hands became an essential design tool.

The intersection of that work with computers occurred in the mid-1960s in the Harvard Laboratory for Computer Graphics founded by Howard Fisher. There Carl Steinitz and Peter Rogers conducted some of the first digitally based geodesign work, using early computer graphics software to develop scenarios for the future of the Boston region. Jack Dangermond, a graduate student in the Harvard laboratory during that period, went on to combine his education in landscape architecture and computer graphics to establish ESRI, which has led the development of geodesign. Other geographers also contributed greatly to GIS and, ultimately, geodesign. They include Roger Tomlinson, who created the first GIS: the Canadian Geographic Information System or CGIS to inventory Canada’s natural resources, and David Dickmore in the United Kingdom, who pioneered computerized mapping. Goodchild (2010) notes that, indeed, one of the original, primary goals of GIS was to support better landscape design and planning that fits the mold of geodesign.

Geodesign’s leadership

Geodesign itself dates from the first decade of the twenty-first century, arising out of Jack Dangermond’s conviction that we needed “a framework for understanding the complex relationships between human-designed settlements and the changing environment” (ESRI 2013, 44). Since then, geodesign has flourished, with many people contributing to its evolution. In addition to Dangermond, several colleagues of his at ESRI, including Bill Miller, Shannon McElvaney, Eric Wittner, and Bernie Szukalski, have all played key roles in the development of geodesign tools.
In the design and computational community, Carl Steinitz remains the primary theorist of geodesign, along with colleagues and former students of his, like Tess Canfield, Stephen Ervin, Michael Flaxman, and Juan Carlos Vargas. Geographers such as Michael Batty, Michael Goodchild, and Diana Sinton have also influenced the development and direction of geodesign.

Architects, landscape architects, and planners have played a major part in the evolution of geodesign, as well. They include academics such as Thomas Fisher, Kelleann Foster, Tom Paradis, Ryan Perkl, David Pitt, Janet Silbernagle, Ron Stolz, and Paul Zwick, as well as practitioners such as Doug Olsen, Keith Besserud, and Elliot Hartley. That group, along with a growing number of regular participants in the annual Geodesign Summit, has helped define the field and expand its reach.

Geodesign Summits

The annual Geodesign Summits that ESRI has hosted, beginning in 2010 at its headquarters in Redlands, California, have served to gather the leading practitioners of geodesign, to enable them to share best practices, and to hear about the latest geodesign tools under development. What started as a relatively small group of geographers and designers has since grown to a much larger and more diverse group of people. By 2014, the Geodesign Summit had grown to over 250 registrants representing 19 countries and 33 states. Geodesign had, by that time, gone international, with the first Geodesign Summit in Europe attracting 250 people to The Netherlands and the first one in China gathering 500 people in Beijing, with an estimated 50,000 watching it online.

During those summits, keynote addresses by some of the leading thinkers of our time have helped shape geodesign as an intellectual inquiry. Bran Ferren of Applied Minds described geodesign as a form of storytelling that can reveal the global challenges faced and raise the level of public discussion about them. And Janine Benyus of Biomimicry 3.8 spoke about the relationship of BIS — biological information systems — to GIS, suggesting that we need to embed our understanding of how the natural world works into geodesign. The intellectual diversity apparent at the summits demonstrates both the breadth and depth of inquiry necessary for successful geodesign research and practice.

Who does geodesign?

While some geodesigners see it becoming its own field, separate from either design or geography, others see it differently, as a method, a process, and a set of tools rather than a separate field. Steinitz has argued that geodesign “cannot and should not become its own full-fledged profession … rather … all the relevant design professions and geographic science should adopt and adapt geodesign ideas and methods, and then collaborate as needed on the world’s most serious geodesign challenges” (Steinitz 2012, 11–12).

Geodesigners have come, initially, from the ranks of geographers and geographic information scientists on one hand and design fields like landscape architecture and urban or regional planning on the other. However, like GIS itself, geodesign has begun to pervade a wide number of fields as a growing number find themselves having to devise creative alternatives to the way they do things now.

At the 2014 Geodesign Summit, for example, attendees represented 16 different disciplines, including architecture, biology, design, ecology, forestry, finance, health care, insurance, landscape architecture, mining, marine science,
planning, parks and recreation, transportation, urban design, and water resources. Whatever their differences, these diverse fields – and many more – have begun to recognize the value of geodesign methods and tools.

How geodesign works

That value comes down to what geodesign has to offer that neither geography nor design can. Unlike much of geography, geodesign offers a powerful way of not just understanding a place, but also imagining something there that does not yet exist. And unlike design, geodesign provides a means not just to shape the spaces we use and inhabit, but also to assess the results of design decisions based on relevant information about a place.

Geodesign, in other words, combines the data-rich capabilities of GIS with the visualization capacity of drawing and modeling software. It also links the critical analysis of geographers with the creative imagination of designers. The intersection of these fields lets us reframe the questions we ask and the assumptions we make about a situation, knowing that, as Albert Einstein observed, we cannot solve our problems with the same thinking we used when we created them.

Geodesign also promises to alter the way in which both geographers and designers will work in the future. It provides a readily accessible and highly visual way of understanding complex information and relationships. This enables everyone from policymakers to community members to see the consequences of our actions and decisions, broadening the ability of the public to participate in planning and providing opportunities for all involved in or affected by a proposed change in the physical environment to test different options and to see where various scenarios might lead.

While both geographers and designers work at multiple scales, examining situations from various perspectives and moving back and forth from one frame to another, the two fields approach scales from different directions. In his book – *A Framework for Geodesign* – Steinitz sees geodesigners operating in the overlap between geography, which generally starts at the scale of the planet (1:1 000 000) and goes down to the scale of infrastructure systems (1:5000) and design, which typically starts at the scale of the person and the building (1:100) and moves up to the scale of the region (1:250 000). “Geodesign activities,” writes Steinitz, “range from a large development project … through to a … city … (or) regional watershed, in the 1:5000–1:250 000 scale range” (Steinitz 2012, 5).

A geodesign framework

The framework that Steinitz lays out in his book offers a rigorous way of approaching geodesign and builds on earlier work (1995). He rightly sees design as an iterative process and he envisions it involving at least three passes through a set of six questions and six models. The first pass entails scoping out the situation: describing it, understanding its operation, evaluating its performance, defining the extent of its possible change, considering the impact of that change, and deciding how to make the change. In many ways, that first pass parallels the stages of a typical GIS analysis.

The second pass, as Steinitz describes it, involves a methodological phase that geographers rarely get to and designers rarely discuss, involving who needs to be participate in decision making, what issues a design needs to address, what strategies a designer should use in making
change, what criteria should be used in evaluating alternative designs, what process a designer should follow, and what scales the design needs to encompass.

The third pass involves the design phase, in which the geodesigner devises alternative scenarios with those who must implement the design and, ideally, those most affected by it giving their feedback along the way. Here, too, the steps involve describing the design, determining its operation, assessing its functionality, deciding what needs to change, why, and how. In a typical design process, this third pass may occur several times and, as Steinitz observes, it may also require looping back to the first two phases, changing the scale, assumptions, or methods in order to arrive at an optimal solution.

How to geodesign

Steinitz identifies nine different ways of designing, which represents a substantial contribution to the design-thinking literature as well as that of geodesign. The first, anticipatory approach involves leaping to a final result and then retracing the route to arrive at that foregone conclusion. Too many designers take this approach, applying their signature style to a problem, often in inappropriate ways, and Steinitz’s analysis shows how this has merit only in situations where the designer has “a sufficient and adequate amount of experience” (Steinitz 2012, 56).

The second, participatory approach incorporates multiple design options from a number of participants, leading to a consensus design that includes elements of several proposals or an agreement about one proposal that best meets the needs of a situation. Here, Steinitz recognizes that this process, like all participatory processes, takes more time and demands a shared sense of what is appropriate to a place in order to recognize the most suitable end result.

The third, sequential way of designing entails a step-by-step process in which decisions get made in order, leading to an optimal end result. This requires what Steinitz calls an “abductive logic” (essentially a reasoned guess based on evidence) in order to have the clarity and confidence needed to ensure the correctness of each decision along the way, and it demands adequate criteria to ensure that it does not go off in the wrong direction.

The fourth, constraining approach works best when a situation lacks adequate criteria. The design effort involves seeking out constraints when too many options exist at every stage of the process, with designers problem-seeking in order to find the best solution in a given situation. This approach often leads to discoveries that no one fully understood at the beginning.

A combinatorial approach constitutes the fifth of Steinitz’s categories. When faced with uncertainty about the relative importance of various criteria or different options, designers will resort to making as many reasonable combinations as possible in order to test them according to their success in meeting the main objectives of a project. Digital tools have greatly enhanced this approach by increasing the pace and complexity of possible combinations and improving the efficiency with which a designer can assess their validity.

The sixth option, which Steinitz calls “rule-based,” entails the application of a set of agreed-upon rules to identify and assess alternatives along the way. In a process like this, many designers employ informal rules-of-thumb or heuristics, based on experience, although geodesign and other digital tools also allow the use of algorithmic rules.
A seventh, optimized approach works best, as Steinitz acknowledges, when everyone agrees on beforehand “the relative importance of each of the desired requirements and also its decision criteria” (Steinitz 2012, 58). This applies to situations in which one measure, like maximizing economic return or ecosystem health, dominates all other criteria.

The eighth, agent-based approach, which Steinitz sees as “necessarily computer-intensive,” applies “independent ... rule-based actions of independent agents” to each stage of the process, with the design adjusting as it proceeds (Steinitz 2012, 59). Geodesign lends itself to this method, given the ability of GIS to handle the complexity of interactions that exist within a particular geography.

A final mixed approach involves various combinations of any of the above strategies. While this may appear to lack rigor, it often characterizes complex design processes in which designers have to switch methods and alter approaches when one proves unworkable or inappropriate.

We tend to judge a design process, as we do the outcomes of a scientific experiment, according to its outcomes. Steinitz’s change models reveal the diverse ways in which we can get to those outcomes, with different approaches more or less relevant to different situations. In geodesign, the choice of the right method can matter as much as the arrival at the best solution.

The process of geodesign

Steinitz’s framework shows how design, rightly understood, involves a process as systematic and rigorous as the scientific method. Because most people go through their entire education without ever learning about the design process, the rigor that it requires may surprise those who think of it as something intuitive and subjective. Knowing when to use what method and how far or fast to use it may depend upon a geodesigner’s experience and the intuitive understanding that comes from that. But as Steinitz shows, the design process itself depends upon the ability of multiple people to engage in it, understand it, and communicate it, and that requires a discipline as demanding as that of science.

At the same time, Steinitz’s framework demonstrates to designers the methodological complexity that often goes undiscussed in the design community. Too many designers often end up using a favorite process or approach, whether or not it fits the requirements of a situation, because it has worked for them before or because they have become comfortable with it. Steinitz’s change models show that every situation requires an assessment of the best approach to the problem, with each method having its place.

Geodesign, in other words, reveals a lot about design to geographers as well as to designers themselves, while affecting the ways in which we think about both geography and design. It can help bring geography more into the center of public- and private-sector conversations by providing not just the critical analysis of a situation but also the alternative scenarios in response to it. Geodesign also enables designers to make more informed choices by giving them access to information about the impacts of their ideas at a rapid enough pace to affect what they explore and what options they ultimately propose.

The greatest benefits, though, accrue to those affected by change. Geodesign provides a method and set of tools that allow people to participate in and understand the consequences of decisions in ways that many do not have available to them now, empowering the public and potentially altering the nature of professional practice.
The practice of geodesign

Both geography and design have long remained within the purview of experts, professionals who, through their extensive training and sometimes-esoteric knowledge, have largely served the needs of those in power or those who have the means to pay for the services of these disciplines. Geodesign promises to disrupt the relationship between professionals and power.

The move of GIS online and to the cloud will, alone, give many more people access to geographical information once inaccessible to the general population. Geodesign promises to provide a means by which the public as well as those in power can assess the pros and cons of particular proposals and arrive at a consensus that involves those most affected by a decision as well as those with the most to gain from it. This democratization of geographical information and the design-review process will potentially mark a shift in the role of GIS and design professionals, moving from an expert model to more of a facilitation model of practice.

Geodesign also brings together the complementary skills of designers and geographers. Steinitz recognizes that most design professionals get “educated as generalists … know(ing) a little about a lot,” in contrast to most geographic scientists, whose “education produces specialists … (who) know a lot about a little” (Steinitz 2012, 5). That complementarity also applies to the way in which both geography and design see situations. Designers, as Steinitz puts it, tend to see “every design … (as) a unique experience for a unique place,” while geographic scientists tend to think that “geography is universal” or see “regional geographical and cultural differences” (Steinitz 2012, 6).

Those differences can make geodesign challenging if either geographers or designers see theirs as the privileged approach to problems. But “collaboration and cooperation among these groups,” writes Steinitz, “is not new or unknown, and there is a long history of successes” (Steinitz 2012, 5). The activity of geodesign, in other words, predates the idea of it.

Geodesign education

One indication of geodesign’s usefulness and potential lies in the number of education programs that have emerged. Since the first Geodesign Summit, geodesign education has remained a central topic, with faculty gathering to share information and ideas about coursework and curriculum. And over the course of a few years, several universities have started programs.

They range greatly in size and type. Just in the United States at the time of writing: the University of Southern California offers an undergraduate BS degree; Penn State a graduate certificate; Philadelphia University an MS degree; Northern Arizona University an undergraduate BS track; the University of Wisconsin, a multicampus post-baccalaureate program; the University of Arizona a graduate concentration; and the University of Georgia an undergraduate or graduate certificate in geodesign.

At the same time, a number of universities have faculty who offer geodesign courses. The rapid expansion of educational opportunities in geodesign shows how much this emerging area of inquiry resonates with faculty and students, capturing the growing interest among so many “millennials” (people born sometime between the early 1980s and the early 2000s) in fields that lead to jobs while also having the potential to do good and to change the world for the better.
Applications of geodesign

The Geodesign Summits have also demonstrated the variety of applications of geodesign. Captured in Shannon McElvaney’s (2012) book, Geodesign: Case Studies in Regional and Urban Planning, the examples of geodesign range from regional responses to climate change to urban designs for sustainable development to state-wide plans for growth to neighborhood-scale urban agriculture.

A similar diversity has occurred in the case studies and lightning talks at the various Geodesign Summits. Speakers have shown how geodesign has proven useful in improving the lives of people in informal settlements in Latin America and small-town Georgia, in preserving habitat corridors around Tucson, in assessing the impact of fracking in Pennsylvania, in engaging communities in development alternatives near the Twin Cities, in creating a new campus in Kuwait, in imagining a more sustainable future for Detroit, in promoting stewardship of the Great Lakes, in using chaos theory to reshape cities, and in inventing new uses for public land in San Francisco. Those examples convey not just the range of geodesign’s applications, but its usefulness in addressing some of our most pressing social, environmental, and economic challenges.

Limitations of geodesign

Geodesign has critics coming from both geography and design. Some geographers, for example, see geodesign as overly simplistic. After a recent talk about geodesign, one geographer in the audience reacted negatively to the focus of geodesign on problem solving, an idea common among the design fields. He argued that most human situations do not lend themselves to “a solution” and that most human activities and geographical ways of knowing involve dilemmas that resist resolution and that lead to unintended consequences if not rightly understood and if viewed too simplistically as a problem to solve. More broadly, geodesign is as open to critique as GIS, including practices such as public participation GIS, and therefore is subject to standard concerns of critical GIS and science and technology studies, such as questions pertaining to positionality and power, the politics of data, and so on (see the entry on Critical GIS).

At the same time, some designers see geodesign as overly constraining. At the same geodesign talk, a designer conveyed a similar skepticism about it, asking if basing every decision to data can inhibit new ideas and limit the ability of people to imagine something new and create something we have not seen before. She saw the potential of geodesign to reduce design to a set of computational tools or to drive decision making in particular directions because of the nature of GIS tools.

Such reactions represent invaluable feedback because they reveal the potential blind spots of those so close to the development of geodesign that they no long see its limitations. Those comments also reflect the inherent tensions that occur in an interdisciplinary activity like geodesign, which combines two established fields and yet does not fit comfortably in either.

Geodesign, though, also suggests a possible response to such challenges: the answer to this criticism depends upon the scale at which we look at the question. At the scale at which geographers typically work, issues rarely lend themselves to a solution, but at the scale at which landscape architects and urban designers work – the site, neighborhood, or regional scale – there do exist solutions that can help make a situation better.
The same applies to the criticism of the designer who saw geodesign as a limitation on a designer’s freedom. At the scale of a specific site, geodesign may represent too blunt a method or tool for decisions about where to place certain elements or what details to use in a particular location. But at the scale of the site and its relationship to larger flows, networks, or systems, geodesign enhances, rather than limits, a designer’s ability to make the right decision.

The future of geodesign

The future of geodesign looks promising, in part because we know that we can no longer afford or sustain many of the development patterns, resource allocations, and public-policy decisions of the past. Geodesign provides a means of allowing us to envision a better future for people and for places, based on what we know about their past and present. Geodesign not only helps us create our future but also helps us ensure that, as one of the most vulnerable species on the planet, we will have a future at all. Embedding in geodesign the ways in both human and natural ecosystems work could make it not just a powerful design tool but also a transformative one.

At the same time, geodesign can also empower us to change our behavior in ways that benefit us as well as our environments. After several centuries of disaggregating the world, chopping up its study into discrete disciplines and isolating us from the full consequences of our actions, geodesign offers us a way of re-aggregating things, revealing the interactions of complex flows and phenomena and helping us see the possible effects, in real time, of doing one thing or another. That suggests that geodesign, in the future, might include the creation of an easily downloadable application for mobile devices that every individual can use in daily decision making.

This, in turn, implies a role for geodesign as a new way of organizing our knowledge about the world. We damage both human and natural communities by acting as if they mirrored the disciplinary way in which we study them rather than as highly interrelated sets of ecosystems that evolved in each place. Geodesign offers a way of re-aligning how we know the world with how we know it actually exists by providing a tool that arranges knowledge according to the cultures and phenomena of a place rather than according to disciplinary categories. Geodesign will not just draw from database libraries; it may become the basis for how we organize the libraries of the future.

Geodesy is the field of knowledge that studies the size and shape of the Earth and its gravitational field, and their changes over time. It covers the precise measurement of the Earth and its rotations, the abstraction of these measurements into models that can be operationalized for mapping, navigation and engineering, and gravimetry, or the measurement of the force and directional geometry of the local gravity vector. From the point of view of geography, geodesy is critical in providing accurate and updated Earth models known as datums from which positions can be found and heights measured – the foundation for cartography and geographic information systems. These Earth models are termed “ellipsoids” or “spheroids,” with their size and shape being determined by the lengths of their semiaxes, or the degree of flattening (Li and Götze 2001). Commonly used in contemporary mapping and positioning are the World Geodetic System of 1984 (WGS84) and the International Terrestrial Reference Frame (ITRF). In the United States, the major mapping agencies use the North American equivalent of WGS84 based on the Geodetic Reference System of 1980 (GRS80), termed the North American Datum of 1983 (NAD83), and its vertical equivalent for heights, the North American Vertical Datum of 1988 (NAVD88). In addition to ellipsoids, geodesy is also concerned with more precise Earth models called geoids. A geoid is the equipotential surface that would be created if Earth was completely covered with water. Differences in gravity direction locally are called deflections of the vertical. The deflections are caused by mountains, oceanic crust, and by differences in Earth’s shape. Geoid models are under continuous revision, and are sufficiently sensitive to reflect tectonic activity and changes in Earth’s rotation. A recent geoid is the GEOID12A, known as a hybrid geoid as its purpose it to tie together with a datum. Other geoids are related to precise gravimetry and to an effort to redefine the American Vertical Datum (GRAV-D) by 2022.

Earth size

The first recorded attempt to measure the size of the circumference of the Earth was by Eratosthenes of Cyrene (ca. 276 BC to ca. 195/194 BC), the Chief Librarian of Alexandria and “Father of Geography” (Rawlins 1985). Around the year 240 BC, he used the knowledge that at a well in Syene, Egypt (now Aswan), the sun was directly reflected from the water at the time of the June solstice. To Eratosthenes, this was evidence that Syene lay on the Tropic of Cancer. Using an obelisk as a gnomon at Alexandria, he measured the shadow length and gnomon height to compute the shadow angle as 1/50 of a circle (7.12′).
on the solstice. The distance from Alexandria to Syene was 5000 stades, confirmed by travel times for camel trains. This yielded 700 stades per degree, for an Earth circumference of 252,000 stades. While Pliny noted that the stade was 157.2 m, others give lengths up to 166.7 m. This translates to an Earth circumference of between 39,300 km and 41,675 km, or between 98.15 and 104.08% of the average of today’s estimate of the polar and equatorial circumferences.

Eratosthenes’s measurement was neglected in further writings, and Claudius Ptolemy changed the 252,000 stades in his *Almagest* to 180,000 stades in the later *Geography*. This led to Columbus’s much discussed underestimate of the distance for sailing west from Europe to reach India. The medieval Persian Abu Rayhan Biruni (973–1048) measured the Earth and distances on it using triangulation and calculated an Earth radius of 6339.6 km. However, it was not until the survey conducted in 1669–1670 by French astronomer Jean-Félix Picard (1620–1682) that a more accurate figure was computed. Picard measured a degree of latitude along the Paris Meridian using triangulation involving 13 triangles going from Paris to a clock tower near Amiens. His survey gave a result of 110.46 km for one degree of latitude, with a corresponding Earth radius of 6328.9 km.

During the French revolution, in 1791, the French Academy of Sciences selected a meridional definition of the meter because the force of gravity had been found to vary over the surface of the Earth, which changes the period of a pendulum of a standard length. The meter was originally to be defined as 1/10 000 000 of the distance between the North Pole and the equator, on the Paris meridian. The Academy commissioned an expedition led by Jean Baptiste Joseph Delambre and Pierre Méchain, lasting from 1792 to 1799, which measured the distance between a tower in Dunkirk and a castle in Barcelona to estimate the length of the meridional arc passing through Dunkirk, assumed equal to the length along the Paris meridian. Based on initial results from this expedition, France adopted the meter as the official unit of length in 1793. The first official meter rod, however, neglected the true shape of the Earth and so was short by one-fifth of a millimeter, making the actual Earth circumference on this meridian 40 007 863 m. Further accurate measures of the size of the Earth have necessitated having a model of Earth’s shape as either an ellipsoid or a geoid.

Earth shape

The shape of the Earth had long been assumed a sphere, based on evidence provided by Aristotle (384–322 BC). Other cultures assumed a flat disk and other forms, but the spherical shape seems to have dominated until an experiment conducted by Giovanni Domenico Cassini (1625–1712) while Director of the Paris observatory. Cassini noted that Isaac Newton’s theory of universal gravitation predicted that the Earth’s rotation would lead to its bulging out at the equator, flattening the poles. This implied that the equatorial radius would be larger than the polar, making the Earth an oblate spheroid. Isaac Newton’s theory of gravitation predicted the Earth to be an oblate spheroid with a flattening of 1 part in 230. A consequence would be that a degree of latitude measured near the pole along a meridian would be longer than the same degree at the equator. Cassini re-examined the measurements along the Paris meridian and concluded the opposite, that the length of a degree became longer as the meridian progressed south, implying an Earth model of a prolate ellipsoid. The ensuing intellectual debate over this issue became vigorous, and led to an
ambitious attempt to measure meridional arcs at high and low latitudes.

The dispute was settled by two measurements made by independent expeditions (Hoare 2004). Pierre Louis Maupertuis led an expedition to Finland in 1736–1737 to measure a degree of latitude by triangulation from a baseline on Lake Tornio, reporting back to the French Academy in 1737. According to Maupertuis, a degree at 66.23°N was 111,948.76 m, compared to Cassini's measurement at Paris of 111,212.22 m. Newton had been proven right, and the Earth was indeed shaped like an oblate spheroid, a special case ellipsoid. Maupertuis's result gives an equatorial radius of 6,397,300 m, and a polar radius of 6,363,806.28 m, for a first measure of the flattening of 1/191.

The second expedition (1735–1744) was sent to the equator in Peru, in what is now Ecuador. In May 1735, Louis Godin, Pierre Bouguer, and Charles Marie de la Condamine started near Quito. After 10 years, they had completed a meridional triangulation arc of 3°7′3″ giving a length of a degree as 110,624.82 m, again confirming the oblate ellipsoid model.

The lengths of arcs of both meridians and parallels became better known as triangulations expanded to cover the world, with major contributions in Africa (Clarke), India (Everest), Russia (Krassovsky), and North America (Hayford). Table 1 shows the steady improvement in the values for the standard measures. Starting in the 1920s there was an effort to standardize the ellipsoids globally, rather than have each nation use its own best ellipsoid. The Hayford ellipsoid, introduced in 1910, was renamed the International ellipsoid of 1924 after it had been adopted by the International Union of Geodesy and Geophysics in 1924. Another significant change was the creation of the first Earth-centered datum by the US Department of Defense as the World Geodetic System 1972 (WGS72). Over three years, data from Doppler satellites, surface gravity measurements, and astronomy worldwide were subjected to a large-scale least squares adjustment. In addition, a surface gravity field consisting of 410 10′ × 10′ equal area gravity anomalies were determined from ground measurements. The value of WGS72 ellipsoidal flattening of 1/298.26 is that still in use today.

A geodetic system is used in geodesy, navigation, cartography, and navigation systems to translate positions on a map to their actual positions on the ellipsoid or other Earth model or vice versa. A datum is a set of parameters and their values used to define a specific geodetic system. Among the most commonly used datums is WGS84, a standard for use in cartography, geodesy, and navigation and the preferred system for use with the Global Positioning System (GPS). It defines a standard coordinate system for the Earth, a standard reference ellipsoidal surface for height data, and a gravitational equipotential geoid that defines the nominal sea level. WGS84 was established in 1984 and last revised in 2004. The origin of WGS84 is located at the Earth's center of mass with a computed error of less than 20 mm. The WGS84 prime or zero meridian is the IERS Reference Meridian, which is 5.31 arc seconds or 102.5 m east of the Greenwich meridian at the latitude of London's Royal Observatory. The WGS84 datum surface is an oblate spheroid with an exact major semi-axis radius of 6,378,137 m at the equator and a flattening \( f = 1/298.257223563 \). The polar semi-minor axis is 6,356,752.3142 m. Until recently, the WGS84 Earth model used the EGM96 (Earth Gravitational Model 1996) geoid, revised in 2004, with deviations from the WGS84 reference ellipsoid ranging from about −105 m to about +85 m. The EGM96

The International Earth Rotation and Reference Service (IERS) was established in Paris in 1987 by the International Astronomical Union and the International Union of Geodesy and Geophysics. The primary objectives of the IERS are to “serve the astronomical, geodetic and geophysical communities by providing data and standards related to Earth rotation and reference frames.” Most important, the continued integration of geodetic measurements worldwide has led to complex models that link the geoid to ellipsoids and to nationally supported datums such as NAD83. This is especially important because today’s geodetic models
and geoids are time-sensitive. Due to changes in the location of the Earth's rotational axis (Chandler wobbles), and in the distribution of mass on Earth due to tectonics, land subsidence, constructions, dams, water flow, ice masses, and so on, there is a need to continuously update both geoid and ellipsoidal models. IERS has created the International Terrestrial Reference Frame (ITRF) for this purpose. It distinguished between the fluid models of the geoid and reference systems that are Earth-centered, Earth-fixed (ECEF). These are systems that tie to a particular ellipsoid and datum, which is why the date is included in the datum name. ECEF positions, such as GPS data, must record the GPS epoch in which coordinates were recorded, since over time the positions relative to fixed systems will change.

**Earth gravity**

Earth gravity can be defined as the force exerted on a mass due to the combination of both the gravitational attraction of the planet on the mass in accordance with Newton's universal law of gravitation, plus the rotational force of the planet, which has both a centrifugal acceleration and a force due to the equatorial bulge. The force of gravity is weakest at the equator due to the centrifugal force and increases with latitude toward the poles because the poles are closer to the center of mass. A standard acceleration due to gravity of 9.80665 Newtons (m/s²) was adopted by the International Committee on Weights and Measures in 1901 at 45° latitude. Nevertheless, at any specific position on Earth, this value is not uniform but follows a complex spatial pattern that reflects tectonics and material density as well as Earth’s shape and topography. The net force exerted on an object due to the Earth is termed the “effective gravity” or “apparent gravity.”

During the 1735–1744 French Academy of Sciences expedition to Peru, Bouguer noticed that the down vector, or astronomical vertical, was pulled in the direction of large mountain ranges, due to their higher gravitational attraction. This was demonstrated by Nevil Maskelyne and mathematician Charles Hutton in a classic experiment in Scotland in 1774 on a symmetrical mountain called Schiehallion. The experiment measured the deflection of a pendulum by the mass of the mountain, giving estimates of the mean density of Earth, its mass, and a value for Newton’s gravitational constant. The study of the “undulation of the geoid” and the “deflection of the vertical” became the focus of geodesy during the nineteenth and twentieth centuries. Early geodesists discovered and explained some of the differences as the result of isostatic uplift following the last ice ages.

From the 1950s onward, it became possible to measure the acceleration force due to gravity directly using a gravimeter, essentially an accelerometer that measures forces on a spring. First developed in the 1950s–1960s as a navigation aid for nuclear submarines, by the 1980s, transportable gravimeters were available for use on ships, in the air, and on satellite gravity surveys. These devices were accurate to units of gals (cm/s²), and even milligals, the more commonly used (but non-SI standard) units of acceleration. Gravimeters are of two types. Absolute gravimeters measure local gravity in absolute units, while relative gravimeters compare the value of gravity at a point to another known point.

Apparent gravity on the Earth’s surface varies by around 0.7%, from 976.39 gals in Peru to 983.37 gals in the Arctic Ocean. High-resolution airborne and satellite gravimetry show that the
The gravitation field is highly complex (Figure 1). A highly successful spaceborne gravimetry satellite, the Gravity Recovery And Climate Experiment (GRACE), a joint mission of NASA (National Aeronautics and Space Administration) and the German Aerospace Center, has been making high-resolution measurements of Earth’s gravity field since March 2002 (Tapley et al. 2005). GRACE has conducted worldwide comprehensive mapping at high spatial resolution (Figure 2).

### Geodetic mapping

As the various national mapping programs were launched during the nineteenth and twentieth
centuries, each country chose fixed points at which to conduct triangulations. These triangles were further subdivided into two more depths in a hierarchy of triangles and the main networks of triangles were extended in a mesh pattern (Figure 3). The networks included historical triangulations, such as the United States’ Mason–Dixon line, and the great arcs of the Survey of India. In most cases, the network of triangulation triangles had to be tied to the ground at a single reference point. In the United States, a position at Meades Ranch in Kansas (Figure 4) at 39°13′26.71218″N 98°32′31.74604″W (NAD83) was chosen as the single point for reference for the North American Datum of 1927 (NAD27). Most of the first generation of US topographic mapping used this datum, both horizontally and vertically. The placement of ground markers or benchmarks (Figure 5) by the United States Geological Survey (USGS) and the National Geodetic Survey extended this control system nationwide. Benchmarks and temporary geodetic tie points are shown on US and other topographic maps at detailed scale, and their reference information is usually available through public websites.

Vertical versus horizontal control

The adoption of a particular datum involves assuming the lengths of the ellipsoid semiaxes, but it also assumes an orientation or “fit” of the ECEF coordinates. Once established, this surface will be the model onto which the positions of Earth’s features are projected. This involves elevations both below and above the datum, with mountains above and oceans below. This
mapping means that different datums place features in different locations and at different heights. For this reason it is essential that maps and geographic information system (GIS) data layers carry metadata about which datum they reflect. This becomes problematic when data from different datums need to be converted to a common reference frame for overlay. In general, it is best to convert from a particular coordinate system back to geographic coordinates (latitude and longitude) and then to convert the datum. While this impacts assembling maps across tiling systems (such as the division of topographic maps by equal ranges of latitude and longitude) and for overlay, it most noticeably means changes in elevations. Map spot heights, contours, and elevations within digital elevation and surface models may change significantly.

Early vertical heights were mapped using mean sea level, and the heights were carried across land masses by using horizontal level surveying along transects. This method obviously continuously adjusts to changes in the down vector, but was inaccurate because sea level was arbitrarily set and errors were multiplicative along the transect. Similarly, positions surveyed by astronomical observation and chronometer, then corrected to sea level by altimeters using air pressure, were also inaccurate. It has only been since the advent of Global Navigation Satellite Systems, including the US Department of Defense Global
Positioning System (GPS), that the height above a datum at a point has been accurately measurable. As more global navigation satellite systems (GNSS) come into service, including the Russian GLONASS and European Galileo systems, multisystem GNSS receivers can measure latitude, longitude, and height with precisions in the millimeters. The use of the Continuously Operating Reference Station network (CORS) administered by the National Geodetic Survey, and the ability of advanced GNSS users to contribute public data to geodetic models via the Online Positioning User Service (OPUS), means that maps and GIS data can be corrected to any datum and their accuracy greatly increased. Collectively, these systems form the National Spatial Reference System (NSRS) for the United States, and align with the International Terrestrial Reference Frame globally (Altamimi et al. 2001).

There has been a recent and rapid growth of interest within the scientific and policy community in exploring a range of techniques, collectively termed “geoengineering” (or alternatively “climate engineering”), for deliberatively intervening in the climate to counteract global warming (see, for example, Royal Society 2009). Within the space of a few years, and with the endorsement of learned societies and governance institutions, geoengineering has become a topic of mainstream respectable scientific and policy debate.

One class of geoengineering techniques, termed solar radiation management (SRM), is intended to counteract the warming effects of climate change by reflecting some of the inbound sunlight back into space and hence reducing global average temperature. Methods include increasing the reflectivity of the Earth by brightening human settlements or deserts to make them more reflective, enhancing marine cloud reflectivity through for example the spraying of salt-rich sea water into the sky, injecting aerosols such as sulfates into the stratosphere to mimic the dimming effects of large volcanoes, or placing space mirrors or sunshades in space to reduce the amount of solar radiation entering the atmosphere. These techniques, particularly stratospheric aerosols, have received particular attention because of the perception that they could be fast acting and relatively cheap, but have also prompted concerns about unintended and potentially harmful side effects. The other main class of techniques comprises carbon dioxide removal (CDR) methods, which seek to slow down or halt anthropogenic climate change by removing and sequestering greenhouse gases from the atmosphere. These include land management practices to enhance carbon sinks such as through large-scale afforestation and peatland restoration, the use of biomass for carbon sequestration such as biochar and dark earths, the direct air capture of ambient carbon dioxide through innovations such as artificial trees, and the increase in the oceanic uptake of carbon dioxide including through iron fertilization to stimulate phytoplankton blooms. These techniques are for the most part seen as safer, but slower and more expensive (Figure 1).

Although geoengineering is largely at a pre-research and development stage, it has received particular attention in recent years in the science policy community. The scientific debate was granted legitimacy following an essay in 2006 by Nobel Prize-winning atmospheric chemist Paul Crutzen, in which he discussed the disconnect between carbon dioxide emission trajectories (which continue to rise despite mitigation efforts) and stabilization requirements (which according to most official estimates require 60–80% emission reductions), leading to fears that rising greenhouse gas concentrations
may push the global climate into a new state, with potentially catastrophic consequences. This provides one explanation for the rise of geoengineering as an emergent science policy discourse: concerns that current mitigation policies may not produce the necessary reductions in emissions that are necessary to avoid dangerous climate change (the “climate emergency” argument). In the context of the lack of progress in meeting Kyoto targets, the lack of strong international agreement at United Nations conferences at Copenhagen and Durban, the rapid and ongoing growth of emerging economies such as China and India, and more general questioning on the United Nations Framework Convention on Climate Change (UNFCC)/Kyoto model as a plausible mechanism to deliver change, geoengineering is presented as at least a prudent option to explore, as a means of avoiding “potentially drastic climate heating” (Crutzen 2006, 216).

The second reason is more pragmatic: proponents of geoengineering argue that solar radiation management techniques (stratospheric aerosol injection techniques in particular) could reduce global temperatures not only relatively quickly, perhaps within a few months of deployment, but also relatively cheaply, relative to the cost of implementing greenhouse gas emissions reductions. Geoengineering is thus cast by advocates, among them fellow eminent scientists David Keith (Harvard) and Ken Caldeira (Stanford), as a potential and cost-effective means of buying time to curb emissions and promote more sustainable practices (the “buying time” argument); or, more evocatively, in the words of Keith, as perhaps “the only human response that can fend off [the] rapid and high-consequence impacts [of climate change].” For both of these reasons, geoengineering is fast emerging as a third policy route for responding to climate change, alongside mitigation and adaptation, and as a necessary option that needs to be researched and developed in case it is ever to be required. As Paul Nurse, President of the Royal Society, stated in a letter to the UK Guardian newspaper in September 2011: “A time may come when mankind will need to consider geoengineering the climate to counteract climatic effects of greenhouse gases. If that time comes, we need to have a good understanding of whether such efforts will work and, just as importantly, whether they will have any negative side effects.”

The policy debate on geoengineering governance and regulation remains in its infancy. There currently exist no international treaties that cover all geoengineering techniques, although it is widely assumed that most techniques could be covered by an extension of existing treaties. Nevertheless, there have been some early statements on geoengineering by policy bodies. In October 2010, for example, the United Nations Convention on Biodiversity declared that there should be no field tests of geoengineering projects that might affect biodiversity; in October 2011 the European Parliament expressed its opposition to proposals for large-scale geoengineering; while in October 2013 the Intergovernmental Panel on Climate Change (IPCC) highlighted the risks of a scenario of SRM termination (following a period of deployment), which could lead to abrupt and rapid increases in global surface temperatures, with significant ramifications. Such statements are not legally binding, but they nevertheless reflect political unease with the prospect of geoengineering taking place without adequate regulatory arrangements. In response, a number of small-scale initiatives have occurred in recent years, aimed at articulating the goals and possible form of geoengineering research governance. These include: the establishment of the “Oxford Principles” for the
GEOENGINEERING/CLIMATE INTERVENTION

responsible conduct of geoengineering research; the development of a framework for responsible innovation aimed at guiding assessment on whether elements of a potentially controversial SRM project should be permitted to proceed (the UK Stratospheric Particle Injection for Climate Engineering – SPICE project); and the Solar Radiation Management Governance Initiative (SRMGI) set up to examine in depth the governance issues raised by research into solar radiation management methods.

There is still considerable diversity of opinion about exactly what form geoengineering governance should take. However, there seems to be an emerging consensus that it should involve a combination of soft law and hard law, be guided by principles such as “the public interest” and transparency, and involve “upstream” engagement with wider stakeholders and the public. It is also argued that governance during the research stage might be relatively “soft” to permit or even encourage “safe,” laboratory or small-scale research (with proposed governance mechanisms ranging through laissez-faire permissiveness, self-regulation, independent national policies, to an informal consortium of countries); however, most argue that governance would have to become “harder” before any large-scale field research or deployment, probably through a multilateral, international body such as the United Nations.

Pathways for critical geographical inquiry

Despite the fact that geoengineering remains at an early stage of development, there remains considerable scope for critical and engaged geographical inquiry. In the remainder of this entry we suggest the forms that this may take. First, there is the argument from nature – that geoengineering is imagining its interaction with the natural world in novel and distinctive ways. Unlike many technoscientific issues, the distinctiveness of geoengineering does not lie in the use of novel technologies with new properties: the actual interventions themselves typically involve mundane technologies such as mirrors, iron dust, sulfate particles, or crumbled rock, albeit deployed at a very large scale. Its novelty rather lies in the intention to use these technologies in a project of bringing planetary systems under human control. In philosophical terms, this encompasses the existential argument that the deployment of geoengineering would represent a hubristic extension of human powers, in that it would establish a radically new relationship between society and nature through the “making” of new climates. This constitutes arguably a distinctly new form of geopolitical formation in which humans are self-consciously considered as geologic agents within the Anthropocene – the characterization of our current geological epoch dominated by the increasing power and effect of humanity on the Earth’s systems. Cultural geographers can help illuminate the ways in which geoengineering rhetoric deploys a highly distanced global perspective and how this can be contrasted to more local and phenomenological approaches that can be used to explore the lifeworld of a geoengineered future.

Second, there is the argument from risk governance – that geoengineering may produce unforeseen and unintended consequences, with serious implications for its governability. The prominence of geoengineering in science policy debates is based largely on the idea that it could be “cheap and effective” compared with other carbon mitigation strategies. Such assessments, however, make the crucial assumption that the impacts of geoengineering interventions on the climate will be in line with those predicted by climate models. However, this remains far from
certain. Indeed, geoengineering has a distinctive relationship with uncertainty that problematizes such assumptions. With most previous technologies that have been subject to regional and global governance and control (e.g., persistent organic pollutants and chlorofluorocarbons) it is the side effects, often after decades of use, that have been of concern. Such side effects have typically been hard to predict or attribute, but research has increased certainty to a sufficient degree as a basis for global action, often underpinned by a degree of precaution, making possible both hard and soft governance arrangements. But with geoengineering technologies the task of governance is significantly different: it is the intended effects (for example, a reduction in global temperature) that are global; that may only become apparent over long timescales; and that are probabilistic and highly mediated, since they involve affecting technological and statistical constructs such as “global average temperature” through intervening into an Earth system which is highly chaotic and always in formation. Any deployment of geoengineering techniques is thus likely to have the unfinished character of research; an important role for geographical inquiry will be to problematize the boundaries and distinctions between research and deployment.

Third, there is the argument from politics – about the likely impact of geoengineering on political systems and on our collective ability to manage such interventions. Part of this concerns the “moral hazard” dilemma: the idea that geoengineering could make emission reductions politically harder once there exists the theoretical possibility for a technological alternative solution. There remains a need for social research on geoengineering’s impact on environmental attitudes and behavioral change, both with policymakers and with the wider public. Another element concerns the uncertainties and difficulties of causal attribution mentioned above, which may lead to increased conflict and strain on international relations and institutions. But another element of this argument concerns geoengineering’s relationship with intent. Questions of intent have been central to the political processes shaping the constitution of geoengineering as a technology. The formal definition of geoengineering is tied to the goal of offsetting anthropogenic climate change. Whether or not a specific action such as releasing particles into the upper atmosphere counts as SRM geoengineering deployment, or as research, or even as mere pollution cannot be determined by a mere technical procedure, but only by reference to intent. This implies that meaningful geoengineering governance would logically require the scrutiny and regulation of the intentions, whether explicit or implicit, of a huge range of research and deployment activities. Furthermore, the intent in SRM geoengineering is likely to be unstable and open to plural interpretations. The framing of SRM as a means of counteracting anthropogenic climate change is likely to be joined or displaced by alternative frames – for example, as a means to achieve humanitarian, environmental, nationalistic, military, or commercial goals. Understanding and mapping the interpretive flexibility of intent in SRM research, its intersections with democratic governance, and its potential for generating new kinds of conflict and controversy is a rich arena for future geographical inquiry.

Fourth, there is the argument from political economy – that geoengineering is likely to be conditioned by economic relations that are in tension with the imperative for democratic control. Such issues can be expected to become significant shaping factors in geoengineering research once deployment becomes more than a theoretical possibility; yet they are currently receiving little attention. The science and politics
of geoengineering have so far developed through a particular and restricted assemblage of actors and ideas, with the result that policy and regulatory treatments of geoengineering have largely failed to acknowledge questions of political economy. There have been accusations that advocacy for geoengineering research is part of a project that aims to protect established political and economic interests by creating a rhetorical defense against more aggressive carbon reduction measures. Such arguments are perhaps overly simplistic, but it is nevertheless true that geoengineering can readily be co-opted by vested interests. Substantial economic opportunities are likely to be created by any plan to deploy geoengineering, including: the patenting of geoengineering techniques; the design of particles for release into the stratosphere; the design of delivery systems; the sourcing and transport of raw materials; the design and implementation of monitoring systems; and the establishment and running of financial schemes of funding and possible compensation. In addition, there are likely to be profound issues of justice: that a geoengineered world may simply perpetuate North–South inequalities, and intensify rather than reverse the “colonization of the sky” represented by historical anthropogenic greenhouse gases from the Global North. Exploring the possible differential spatial effects of different geoengineering interventions and the geopolitics of producing artificial climates, critical geographical scholars can draw on world systems theory and postcolonial and subaltern studies, situating geoengineering in the long view of North–South relations.

Fifth, there is the argument from public engagement – the need for robust research to clarify public attitudes to geoengineering and the conditions, if any, under which geoengineering research and deployment might secure public acceptability. Current research has to date been dominated by public opinion surveys, although there also exist a number of attempts aimed at generating more qualitative public dialogue. Methodologically, there exist a number of challenges for the delivery of public engagement research. A key consideration concerns how to design the dialogue exercise in a way that permits participants to explore ways of thinking about the debate that do not simply reproduce dominant framings. It is important too that discussions are not framed by experts, that moderators seek to ensure a diversity of voice independent of background or experience, and that techniques are devised that support participants in the process of imagining the kinds of world that geoengineering might bring into being. Geographical inquiry, especially at its interface with science and technology studies, can provide examples of good practice and guidance in using deliberative methodology to research the unfamiliar, complex, and ethically challenging issues arising out of scientific and technological innovation.

More generally, it is important that critical geographical approaches – and the interpretative social sciences more generally – move away from the logic of “subordination,” in which they are allocated the task of filling in the gaps within a dominant frame provided by the physical and natural sciences, towards a more reflexive imaginary for geoengineering, that promotes and benefits from the various ways of seeing that different disciplines offer (Barry, Born, and Weszkalnys 2008).

Geographic data mining

Chao Zhang
Jiawei Han
University of Illinois at Urbana-Champaign, USA

Geographic data mining (also known as spatial data mining) applies computational methods to massive geospatial datasets to discover novel, interesting, and useful patterns and knowledge. Typical geographic data mining and knowledge discovery tasks include spatial association and autocorrelation analysis, spatial segmentation and clustering, spatial classification and trend analysis, and spatial outlier and anomaly analysis.

Historical background

As early as in the 1960s, the emergence of computer technology nurtured the management and analysis of digitized geographic data. In the following decades, geographic information systems (GIS) and spatial database management systems (SDBMS) grew rapidly, with numerous techniques designed to provide effective management as well as basic analysis of geographic data. For example, to enable fast browsing and querying of large-scale geographic data, various spatial indexing methods have been proposed to organize geographic data into efficient data structures (Rigaux, Scholl, and Voisard 2001).

Geospatial data mining began several decades ago as a confluence of geostatistical data analysis, data mining and machine learning research (Miller and Han 2009; Longley et al. 2010). While sharing a similar spirit of manipulating geographic data, geographic data mining is quite different from SDBMS techniques. The main focus of SDBMS is on organizing, browsing, and querying geographic data, whereas geographic data mining aims at designing effective, efficient, and scalable methods to extract useful patterns and knowledge from georeferenced data. Unfortunately, classic data mining methods developed for discrete data (e.g., transactional data) cannot be directly applied to discover knowledge in geographic data, because geographic data objects usually fall in a continuous space. Therefore, various algorithms tailored for geographic data have been proposed for different mining tasks.

Interest in geographic data mining has grown further in recent years, due to the unprecedented availability of diverse and large-scale geographic data. In addition to conventional geographic data types, such as map and tracking data, new types of georeferenced data are now routinely collected. For example, when a mobile phone user makes a phone call, his or her location can be inferred based on the signals received from multiple cell towers. The location information is typically also attached with abundant metadata (e.g., text message, call duration), which can be fused with geographic data for knowledge discovery. As another example, with the enormous growth of online social networking and social media sites, georeferenced data are being generated rapidly by the users of these services. A user can either specify a GPS location or mention the name of a geographic location in his or her social media post (e.g., tweet, check-in, photo, video). Such georeferenced social media data enable the discovery of interesting georelated knowledge.
Foundations

Geographic data mining tasks can vary from one application to another. Generally, major geographic mining tasks include the following: spatial association and co-location mining, spatial clustering, spatial classification and prediction, spatial outlier detection, mining spatiotemporal data, and mining text-rich spatial data.

Spatial association and co-location pattern mining

Spatial association and co-location patterns involve sets of spatial objects (or types of objects) that are often spatially located close together. For example, cities are often located close to rivers, lakes, and oceans. Finding co-location patterns may help discover associations among spatial objects and facilitate spatial reasoning and prediction. Since there are potentially an exponential number of possible combinations of spatially co-located sets of objects, efficient algorithms have been developed to reduce computational complexity and find meaningful patterns. A useful method is to find co-location patterns in a process of successive refinement. For example, patterns that are geographically close can first be found before searching for more refined spatial relationships (such as touch, intersect, overlay), or first find semantically meaningful high-level patterns before examining more refined spatial patterns. This approach can reduce the number of candidate sets to be examined and can help to find patterns at a refined scale (Koperski and Han 1995; Zhang et al. 2014).

Spatial clustering

Spatial clustering, also called spatial segmentation, is the process of partitioning spatial objects into groups such that the objects within the same group are similar or spatially close, whereas those in different groups are further apart. Given a set of spatial objects, several kinds of clustering algorithms have been developed (Han, Kamber, and Pei 2011).

Partitioning-based methods: given a database of \( n \) spatial objects, partitioning-based methods divide the \( n \) points into \( k \) groups. The well-known partitioning methods include the \( k \)-means clustering algorithm, which iteratively assigns each object to its nearest group center and then recomputes the center of each group until the assignment becomes stable. Another influential algorithm, the expectation-maximization (EM) algorithm, adopts a soft partitioning approach, assigning objects to each group in a probabilistic way and iteratively refining assignments until stability is achieved. It has also been popularly used in spatial clustering.

Hierarchical methods: hierarchical clustering methods create a hierarchical structure for the given set of objects. The hierarchy can be constructed in either an agglomerative (bottom-up) or divisive (top-down) manner. An interesting hierarchical algorithm, called BIRCH (Zhang, Ramakrishnan, and Livny 1996), first clusters spatially close objects into microclusters at a low level and then uses various kinds of effective clustering methods over those obtained microclusters to form flexible and interesting structures.

Density-based methods: partitioning-based methods can only find sphere-shaped clusters. Density-based clustering methods are able to find arbitrarily shaped clusters. One representative density-based clustering method, called DBSCAN (Ester et al. 1996), clusters objects such that a set of spatial objects are defined as core objects if a sufficient number of spatial objects are located within a specified radius, or if they are spatially connected to those core objects. Thus a cluster can be grown into arbitrary shapes by incorporating new objects.
that are density-reachable from other objects in the cluster. Other density-based clustering algorithms are based on the notion of probabilistic data distributions.

Many other clustering methods have been developed in recent data mining research, such as grid-based clustering, constraint-based clustering, stream clustering, subspace clustering, and high-dimensional clustering. In many geographic applications, clustering should not only consider spatial proximity but also proximity on time, text, network, or semantics associated with various kinds of attributes, as well as application constraints and requirements. Further development of advanced clustering methods will benefit geospatial clustering and its broad application.

Spatial classification and prediction

Spatial classification is the process of identifying the category (or class) to which a given spatial object belongs. Compared with clustering, classification relies on training data that contain the geographic instances whose categories (or class labels) are already known. Spatial classification is also called spatial prediction if the value to be predicted is a class label (i.e., category). On the other hand, when it refers to predicting numerical values with given spatial objects, spatial prediction is also called spatial regression or spatial trend analysis if the value to be predicted changes with time.

For spatial classification, each spatial object is described by a set of features, which can contain both spatial and nonspatial attributes of the object. Typical classifiers (e.g., decision trees, Bayesian classifiers, artificial neural networks, and support vector machines) can be used to build classification models based on training data, if the spatial correlations among the objects are not essential to the determination of classification labels. Then, given a new object, the trained model can be used to predict its category according to its features. In addition, methods have also been developed to consider not only the features of target objects but also the features of the nearby neighbors and their relationships to such objects. When spatial correlation is essential in determining classification labels, feature selection should be conducted to select critical features for proper classification.

In addition to spatial classification, it is sometimes useful to predict the location of an object at a specific time. For this location prediction task, the dependencies between the geographic objects need to be modeled along with the features of individual locations. Classic regression models can be applied to fit the time-stamped location sequence for the next location prediction task. Other statistical models, such as the hidden Markov model (HMM) and conditional random field (CRF) for modeling sequence data, can also be applied to location prediction problems.

Outlier detection

An outlier is a data object whose observed value deviates significantly from the values of other data objects. The following types of outliers can be defined over a set of spatial points: (i) a global outlier is an object that deviates significantly from the other objects in the entire dataset; (ii) a contextual outlier is an object that deviates significantly with respect to a specific context of the object; and (iii) a collective outlier is a set of objects that collectively lead to significant deviation to other objects.

Methods for outlier detection can be categorized into: supervised, semi-supervised, and unsupervised. For supervised outlier detection, part of the spatial dataset is examined and labeled by domain experts. Such labeled data are used as
training data to construct a classifier. Based on the trained classification model, outlier detection can be considered as a classification problem, and any new spatial points can be classified as “normal” or “outlier.” Unsupervised outlier detection methods assume the normal data points are somewhat “clustered.” Based on this assumption, this class of techniques first extracts clusters from the given spatial points, and then detects those points that do not belong to any cluster as outliers. Semi-supervised outlier detection is used when there are only a limited number of labeled spatial points, while most of the points are unlabeled. The labeled data can be leveraged to improve outlier detection performance. For example, given some labeled normal objects, nearby unlabeled data are first found and also considered normal. Semi-supervised methods are often used together with unsupervised methods to deal with situations where the number of labeled spatial points is small.

Key applications

Owing to the popularity of various location-based services, georeferenced data are becoming ubiquitous and geographic data mining is becoming increasingly useful in many real-life applications. For example, public transportation vehicles (e.g., taxis, buses) in a city are mostly equipped with GPS modules, enabling them to constantly report their locations to a data center for tracking and scheduling purposes. With the vehicle locations as input, geographic data mining methods can extract hot spots for different time periods in a city. In urban planning, such hot spots are important for improving road network design and transportation scheduling. As another example, in online social networks (e.g., Facebook, Twitter, Flickr), millions of geotagged texts and photos are being generated every minute. The massive amount of georeferenced social content opens doors to revealing regional topics, attractions, and sentiments. Such knowledge can greatly benefit tasks like targeted advertising, trip advising, and localized content delivery.

Future directions

In the past few decades, significant progress has been made in geographic data mining and numerous commercial systems have been developed for different tasks. However, three newly emerging areas have introduced new opportunities as well as challenges to this field, making geographic data mining an increasingly active research field.

Pattern discovery from heterogeneous data: nowadays, geographic data can be collected from multiple sources, including map data, sensor data, mobile data, and social media content. As a result, the geographic data are often associated with other types of data, such as phone-call data, text, photo, and video. Such georeferenced, heterogeneous data provide great opportunities for extracting semantically meaningful and important geographic patterns. For example, research efforts have been paid to mining useful knowledge from geotagged social media content and semantic trajectory data. How to deal with data heterogeneity, and thus discover useful geographic patterns, remains an important research direction.

Interactive and exploratory geographic data mining: in many geographic data mining applications, the users’ mining intents may not be known beforehand. It is important for a geographic mining system to support interactive data mining, such that end users can understand the output patterns and adjust their mining intents accordingly. Data visualization techniques have been employed to provide an intuitive demonstration of mining
results. One critical challenge is efficiency and scalability, as exploratory analysis needs real-time analysis, despite the sheer size of georeferenced data. It is critical to design efficient and scalable algorithms so that effective mining can be conducted within limited time. Many geographic data mining applications may face the dilemma between choosing a computation-intensive model and a less effective, but fast, approach. The design of efficient, effective, and scalable geographic data mining algorithms remains a critical research direction.

**Mining spatiotemporal and moving object data in cyber-physical systems:** with rapid advances in computer and sensor technologies, it is expected that many interconnected objects in the future will produce records that are geocoded and changing dynamically. It is critical to develop sophisticated geospatial data mining technology that takes time, location, text (or other high-dimensional semantic features), and sensor-network features into consideration. Spatiotemporal data mining, moving-object or trajectory data mining, geotext analysis, and physical, information, and social network analysis should be integrated to handle emerging data-mining challenges in cyber-physical systems.

Geographic information science

Matt Duckham
RMIT University, Australia

Geographic information is information concerning the spatial location and spatial relationships of phenomena and processes at or near the Earth’s surface. Geographic information science (GIScience) refers to the scientific study of geographic information, its creation, characteristics, structure, analysis, and transformations, as well as the community of experts that specialize in those topics.

On its own, however, this definition of GIScience – as the scientific study of geographic information – is tautologous. Further explanation of the complexities of this definition, and exploration of its implications, are needed to understand more precisely what is, and perhaps equally importantly what is not, GIScience. This exploration is made more challenging because GIScience is inherently multidisciplinary, drawing on expertise from disciplines such as geography, computer science, measurement science, mathematics, statistics, psychology, and design, amongst many others. This diversity has historically made it difficult to identify a common core of knowledge that makes up GIScience, as distinct from the many related areas of inquiry.

In seeking a deeper understanding of GIScience, three complementary perspectives are explored in this entry. First, a historical perspective summarizes some of the established definitions of GIScience, and some of the longstanding debates about the status of GIScience. A second perspective looks at two distinct styles of inquiry common in GIScience: as information science and as data science. Finally, a third perspective looks in more detail at GIScience from the perspective of the shared expertise common to those connected with the field.

History

A good place to start exploring the definition of GIScience is to look at the history of the usage of the term. The term “GIScience” was first coined in 1992 by Michael Goodchild (Goodchild 1992). The term was introduced better to distinguish between the technologies associated with geographic information (primarily geographic information systems, GIS) and the science behind these technologies (i.e., geographic information science, GIScience). At the time, the intellectual validity of a science of geographic information was a matter for polarized debate. Many of the most cogent criticisms of GIS were captured in the 1995 book *Ground Truth: The Social Implications of Geographic Information Systems* (Pickles 1995). Amongst these criticisms were included: the characterization of GIS as a purely technical exercise with no intellectual content; the association of GIS with purely positivist forms of inquiry, marginalizing other forms of knowledge; and the view of GIS as a technical evolution of traditional mapping technologies, a new mechanism for the continued empowerment of military and other elites. At the other extreme, GIS had been portrayed as the savior of geography (e.g., Openshaw 1997).
Its strongest proponents argued GIS provided a mechanism for applying geographical principles to a wide range of real-world problems, at a time when geography was under considerable pressure to demonstrate its import and impact.

Today, the storm of controversy has subsided somewhat. However, the debate left an enduring legacy to the emerging field of GIScience. Even the most technically minded GIScientist would today be expected to have a keen awareness of such criticisms. For example, any GIScientist would usually have a sophisticated understanding of the importance of recognizing uncertainty in any geographic information (see the section on “Expertise”). On the other hand, even the most implacable critic of GIS would typically acknowledge that important intellectual contributions have been made by researchers in the area of GIScience over the past 20 years.

The use of the term “GIScience,” as distinct from “GIS,” grew rapidly, with several of the leading academic journals in the fields changing their names (from the *International Journal of Geographic Information Systems* to the *International Journal of Geographic Information Science* in 1997; and from *Cartography and Geographic Information Systems* to *Cartography and Geographic Information Science* in 1999) and a biennial conference called *GIScience* starting in 2000.

Various subsequent definitions have elaborated on the definition of GIScience as “the science behind the systems,” in turn emphasizing different aspects. For example, Keith Clarke defines GIScience as “the discipline that uses geographic information systems as tools to understand the world” (Clarke 1997). Another often-quoted definition is as “the development and use of theories, methods, technology, and data for understanding geographic processes, relationships, and patterns” (UCGIS bylaws, quoted in Mark 2003). An attempt at a fuller, more detailed definition was the focus of a 1999 National Science Foundation workshop, defining GIScience as “the basic research field that seeks to redefine geographic concepts and their use in the context of geographic information systems. GIScience also examines the impacts of GIS on individuals and society, and the influences of society on GIS. GIScience re-examines some of the most fundamental themes in traditional spatially oriented fields such as geography, cartography, and geodesy, while incorporating more recent developments in cognitive and information science” (Mark 2000).

Mark (2003) provides an in-depth discussion of several of these definitions, while others have considered in similar detail specific aspects of the definition, content, history, focus, and contribution of GIScience (see, for example, Goodchild 2010, 2011; Longley 2000; Schuurman 2000).

Amongst the key themes underlying all such definitions, it is possible to identify two distinct styles of inquiry, two complementary approaches to creating new scientific knowledge connected with geographic information: GIScience as information science, and GIScience as data science.

**GIScience as information science**

*Information science* is concerned with the fundamental properties and behavior of information: how information is created, communicated, transformed, and used in both artificial and natural systems (cf. Mark 2003). Correspondingly, GIScience is often regarded as “that branch of information science that deals with the geographical domain, or as the set of fundamental scientific questions raised by geographical information and the technologies that collect, manipulate, and communicate it” (Goodchild 2011).
GEOGRAPHIC INFORMATION SCIENCE

The “GIScience as information science” paradigm is best exemplified by one of the most highly cited GIScience papers of all time: “Point-Set Topological Spatial Relations” (Egenhofer and Franzosa 1991).

Intuitively, topology concerns those properties of, and relationships between, (spatial) objects that are invariant under rubber-sheet transformations. For example, whether or not a point is inside a polygon is a topological relationship, because it is unaffected by rubber-sheet transformations such as stretching. The area of a polygon is not a topological property, however, since stretching and distorting a polygon will alter its shape and so its area.

The question posed by Egenhofer and Franzosa (1991) is: What are the possible topological relations between two simple spatial regions (i.e., spatial regions in the plane that are connected – all of one piece – and contain no holes)? The answer to this question is found by looking at the set-based intersections between the boundaries and interiors of the two regions. An exhaustive search of all possibilities reveals eight possible distinct relationships, each of which is uniquely defined by the four intersections between the two region boundaries, the two region interiors, and each region boundary with the other region’s interior. Table 1 summarizes the eight possible topological relations based on these four intersections (hence, termed the “four-intersection model”).

The Egenhofer and Franzosa paper highlights several important features in the context of the “GIScience as information science” paradigm. The paper shows mathematically that these eight topological relations are jointly exhaustive: the topological relations between any pair of simple regions can be described using one of these eight possibilities. In other words, it is not possible to draw a pair of simple regions whose topological relations cannot be described by one of these eight possibilities. The relations are also pairwise disjoint: any pair of simple regions must be described by exactly one of these possibilities. Assuming we have complete information about the regions, there can be no ambiguity – only and exactly one of these relations must hold.

Thus, the four-intersection model answers a fundamental question about geographic information, and helps us know what is and is not possible in this specific case of topological relations between simple regions. The question answered is about geographic information independent of specific domains of geographic knowledge. In practice the regions in question might be land parcels in a cadaster; regions of different land cover; or political, administrative, linguistic, or religious regions. As long as the boundaries and interiors of the regions are precisely defined (but see section on “Expertise in uncertainty,” below), we can be certain that the topological relations between any pair of regions can be classified into exactly one of these eight possible relations.

Precisely because such knowledge about the structure of geographic information is application-independent, it can in turn be most valuable in building tools such as spatial databases and geographic information systems (i.e., “the science behind the systems”). Today, with few if any exceptions, every spatial database and GIS will provide functions to compute the Egenhofer and Franzosa topological relations between simple regions. These functions form part of the building blocks of many higher-level spatial analyses and underlie the practical application of geographic information to diverse problem domains.

Following the analysis pioneered by Egenhofer and Franzosa, other studies have followed similar patterns. Subsequent GIScience research has investigated, for example, the topological relations between a region and a line, between directed lines, between regions with holes,
Table 1  Four-intersection topological relations between two simple regions. Adapted from Egenhofer and Franzosa (1991) by permission of Taylor & Francis Ltd., www.informaworld.com.

between regions on the sphere, and so on. Each of these studies has revealed something new and interesting about the different possible topological relationships between different types of spatial object. However, it would not be true to say that such research could continue indefinitely. As new studies uncover fewer and fewer novel and interesting patterns, the interest of the GIScience community in further such studies diminishes accordingly. It is likely that there are today no new scientific insights to be gained from further similar studies. An investigation of the topological relations between a region with a hole and a directed line, for example, would be unlikely to yield more than a mechanical application of existing knowledge based on Egenhofer and Franzosa’s already established methodology. In other words, the body of knowledge in GIScience has grown, and research has moved on.

GIScience as data science

An alternative and complementary perspective on GIScience is as a data science. Where “information science” is concerned with creating new knowledge about the fundamental properties of information, “data science” is concerned with extracting new and generalizable patterns and knowledge from data about the world. Thus, the paradigm of “GIScience as data science” is most in accord with the definition of GIScience as “the discipline that uses geographic information systems as tools to understand the world” (Clarke 1997).

Data about our geographic world continue to grow in volume, the variety of data sources, and the speed of updates to data. It should perhaps come as no surprise, then, that there is a growing body of contemporary examples of GIScience as data science. One recent exemplar of the “GIScience as data science” paradigm is the paper “Exploring Place through User-Generated Content: Using Flickr Tags to Describe City Cores” (Hollenstein and Purves 2010).

In their paper, the authors examine a large dataset of user-generated content. Specifically, the dataset comprises 8 million images, and the associated human-generated tags for those images, voluntarily posted by human users on a social media website. The questions posed by the paper are twofold. At one level, the paper asks what generalizable knowledge we can extract from this data source about how humans use vernacular place names. At a second level, the paper also aims to increase our understanding of the fundamental nature of user-generated geographic data more broadly, what characteristics and properties one might expect other such datasets to exhibit.

At the first level, Hollenstein and Purves (2010) identify a variety of interesting patterns and regularities in human usage of vernacular place names. For example, the data allow the construction of spatial “footprints” that capture that region of London that is commonly referred to as “Camden,” or the region of Chicago that is commonly referred to as “downtown.” Such vernacular regions have rather different characteristics to the administrative regions that might even bear the same appellation. Unlike the administrative London Borough of Camden, the vernacular region (the places that people typically refer to as “Camden”) does not have a clear or crisp boundary. There tends to be a core of places that most people agree can be referred to as “Camden,” and many places that most would agree cannot be called “Camden.” But there typically exists a gradation between the two: a periphery where opinion is more or less divided, where, as we move away from the core, we encounter places that fewer and fewer people would refer to as “Camden.” Certainly, the
administrative regions appear only infrequently to coincide exactly with the corresponding vernacular region. Maps of vernacular regions are quite different from those of administrative regions of the same name.

At the second level, the paper also adds to our understanding of the nature of user-generated geographic content, such as that generated via social media. For example, the paper shows that while some tags (such as “london”) are commonly used by a broad range of users, some other tags (such as “northlondon”) are strongly biased towards the most prolific users. This phenomenon, called the *Pareto* principle (sometimes the “80:20 principle”), is widely found in user-contributed data: the majority of the content (e.g., 80%) is contributed by a minority of prolific users (e.g., 20%). Even leaving aside those sections of society that are in any event expected to be underrepresented in data generated through social media (such as elderly people who are not as used to the latest technology, rural communities that have limited access to high-speed digital networks, or poorer communities that have reduced opportunities to access the latest mobile computing technology), it is frequently the case that such data contain inherent biases towards a small number of highly prolific users.

Thus, the Hollenstein and Purves paper highlights important features of the “GIScience as data science” paradigm, just as the Egenhofer and Franzosa paper did for the “GIScience as information science” paradigm. The work reported in Hollenstein and Purves (2010) relies on GIS technology and GIScience (as information science) concepts. Kernel density estimation, a technique from spatial analysis and a basic GIS function, is used to generate the vernacular place-name “footprints” from tagged point locations; spatial databases and GIS are required to store and map the large datasets and the analysis results. These results can help generate new and generalizable knowledge about our geographic world (e.g., that vernacular place names are expected to differ systematically from for administrative place names, lacking crisp boundaries or direct coincidence), and about data about our geographic world (e.g., that social geodata is expected to contain substantial biases that need to be accounted for when analyzing and interpreting patterns in such data).

**Expertise in GIScience**

The first perspective of this entry on GIScience was historical: the genesis and existing definitions of the term. The second perspective was methodological: the different mechanisms and focuses by which new knowledge is created in GIScience. The third and final perspective is descriptive: what expertise is common to practitioners of GIScience. A description of this common expertise is itself another form of definition. The written definitions encountered previously attempt to delimit GIScience by *intension* – specifying the content and focus of the field. By contrast, a description of the expertise common to research and researchers across GIScience can be thought of as a definition by *extension* – the topics and knowledge that together make up GIScience.

With a broad and interdisciplinary field such as GIScience, the precise list of topics of expertise is necessarily a somewhat subjective choice. However, it is possible to identify with reasonable objectivity a minimal list of six areas of expertise that together are the most strongly associated with GIScience: expertise in uncertainty, in dynamism, in scale, in spatial cognition, in information design, and most importantly in the structure of spatial information. Arguably, at least one, and usually more than one, of these topics
lie at the core of any research in GIScience or application of knowledge from GIScience.

Expertise in the structure of spatial information

Ask a group of GIScientists what they regard as the most important principle that underpins their expertise and almost as one they are likely to volunteer: “Tobler’s first law.” This principle posits that near things in space are more similar than distal things. This property is manifest in all geographic information. Wherever we look, geographic information obeys this law. Information about one location immediately conditions one’s expectations about what might be observed at other, nearby locations. Indeed, this property of information is measured statistically as “spatial autocorrelation”: the degree of interdependency of observations in geographic space. Autocorrelation is ubiquitous in geographic information, so much so that it is sometimes almost forgotten, regarded as “common sense” rather than “law.”

However, looking at other domains of expertise it is clear that autocorrelation is more than simple common sense. There are innumerable examples of research in other fields that start with assumptions to the contrary: that information in space is random. Experts in computer science and distributed systems, for example, may frequently assume that computing devices (such as sensor nodes) are randomly distributed through space; experts in ecology may assume that movement of organisms through space is random; experts in social networks may assume random graphs as null models of social networks. Most GIScientists would quickly and even unconsciously avoid such assumptions in their own work and identify such assumptions in others’ work. That is not to say that these other fields lack validity; research in other areas such as computer science, ecology, and economics is founded on its own specific areas of expertise. Nor would it be true to represent GIScience as the only field with expertise in autocorrelation; other areas of specialism, including geostatistics and, of course, geography, can equally point to high levels of expertise in this topic. However, the implication is that an awareness of the unavoidable autocorrelation of geographic information is not so obvious as to be common sense; and expertise in autocorrelation is at the core of GIScience.

Indeed, autocorrelation is not the only non-random aspect to the structure of geographic information. Spatial heterogeneity (also referred to as the statistical concept of “nonstationarity”) is an inherent feature of geographic information that has been proposed as a companion to Tobler’s first law (TFL) as one of the fundamental “laws” of geographic information (e.g., Goodchild 2011). Spatial heterogeneity arises because different locations in space may exhibit arbitrarily different properties. In other words, there is no “average” place: phenomena in geographic space are inevitably unevenly distributed, and an individual location cannot reasonably be treated as a sample from a population of idealized locations. Instead, the systematic similarity of nearby places (TFL) itself varies spatially, leading to an expectation of “clumps” of things in geographic space.

Spatial heterogeneity is closely related to the modifiable areal unit problem (MAUP), another area of expertise familiar to any GIScientist. The essence of MAUP is that any observed properties of geographic information that are based on an analysis of arbitrary (i.e., “modifiable”) regions (i.e., “areal units”) are not guaranteed to be independent of those units. A practical example of MAUP can be found in any first-past-the-post democratic election. The boundaries of the electoral regions can themselves have a defining
GEOGRAPHIC INFORMATION SCIENCE

effect upon who wins the election. Indeed, deliberate manipulation of these boundaries in order to gain advantage in elections is common enough that there exists a word to describe it: “gerrymandering.” Gerrymandering works because voters are spatially heterogeneous (i.e., “clumped”). Depending on where electoral boundaries are drawn, they will either split or aggregate votes from voter clusters, to the advantage or disadvantage of one or another political party.

These and other aspects of the inherent nonrandom structure of geographic information together form a core of expertise within GIScience. While GIScientists are not alone in possessing this expertise, any GIScientist can be expected to be knowledgeable on TFL, autocorrelation, spatial heterogeneity, and MAUP, and to apply that expertise in his or her research or work. However, while expertise in the structure of geographic information is a necessary skill for a GIScientist, it is not on its own sufficient expertise to define GIScience. Rather, in GIScience, this expertise is applied in combination with five other core areas of expertise.

Expertise in uncertainty

Uncertainty is an inherent and endemic feature of geographic information. Uncertainty arises because with few, if any, exceptions geographic information can always be safely assumed to be imperfect. Imperfection in geographic information arises in three main ways: inaccuracy, imprecision, and vagueness.

Inaccuracy concerns a lack of correctness in information, where the geographic information deviates in some way from “true” reality, or what is taken to be true. Imprecision concerns a lack of detail in information, where the geographic information is not as specific as it could be.

Imprecision and inaccuracy can occur independently: the statement “London is in Europe” is at once less precise (provides less detail) and more accurate (accords more closely with the actual state of affairs) than the statement “London is in France.” Although imprecision and inaccuracy are distinct concepts that can occur independently, they are related. Generally, being less precise tends to be associated with greater accuracy; conversely being more precise often leads to lesser accuracy.

Vagueness concerns the existence of borderline cases. A vague predicate will lack a crisp boundary between instances where that predicate holds, and where it does not. For example, the vernacular region of “Camden” pictured in Figure 1 is vague: it is not possible to precisely delineate where the vernacular region of Camden begins and ends. However, the administrative London borough of Camden is not vague: it does have a precisely defined fiat boundary.

Today, a considerable body of GIScience research has been devoted to the capture, description, computation with, and communication of information about these three aspects of uncertainty. Any GIScientist would be expected to have a sophisticated understanding of the importance of uncertainty in any analysis of geographic information. To date, the field has not always been successful in embedding this understanding in GIS technology. Today, most common GIS and spatial databases will, if queried, provide the distance between two points to a great many significant figures, usually as a double-precision floating point number irrespective of the precision or accuracy of the query points. This high level of numerical precision frequently equates to a precision of millimeters, micrometers, or even finer detail in the world. This high and unnecessary level of precision gives rise to inaccuracy – a problem
termed “false precision.” The actual distance between the two points will almost certainly not be correct if represented at such an excessively high level of detail (even were such an answer to make sense).

Some practical applications of uncertainty have arisen, such as in the inclusion of metadata on uncertainty in international standards for spatial data transfer. But even though the technology of GIS lags behind, every GIScientist can be
expected to have a sophisticated awareness of
the structure and implications of the unavoid-
able uncertainty associated with geographic
information.

**Expertise in dynamism**

We live in a dynamic, ever-changing world. It
follows that information about our world is nec-
essarily time-dependent. As a result, it will be
no surprise that GIScience research has a long
history of focusing on both spatial and spatiotem-
poral information.

One of the most basic mechanisms for adding
dynamism to static spatial information relies
on the “snapshot” metaphor. In the snapshot
metaphor, dynamic geographic phenomena
are represented as collections of timestamped
states. This representation may be familiar, for
example, in the everyday tracking of moving
objects, such as people. A set of timestamped
\((x, y, t)\) coordinates can be used to represent the
movement of an object in the plane.

An alternative to storing information about
states of the world through time is to store
information about the occurrences in time. Two
frequently distinguished types of occurrence are
events and processes. Events are “countable” hap-
penings, such as a traffic jam, a landslide, or the
arrival of a driver at her destination. Processes are
not countable, and include dynamic phenomena
such as traffic flow, erosion, and wayfinding.

To an extent, it is possible to infer information
about events and processes from information
about the states through time. Conversely, informa-
tion about states of the world through time
can be used to infer information about events
and processes. For example, knowing that a
person was located at home at time \(t_1\) and at
work at time \(t_2\), it is possible to infer that person
has departed home and arrived at work at some
(unknown) time between \(t_1\) and \(t_2\).

As with uncertainty, today’s GIS technology
lags somewhat behind GIScience research and
expertise in supporting dynamism and spatiotemporal information. Many GIS and spatial
databases do offer some support for storing
and analyzing moving point objects. However,
evolving regions, such as changing land-cover
regions, are less well supported. Nevertheless,
the pursuit of better computational models
for storing and processing information about
dynamic geographic phenomena has a long
history in GIScience.

**Expertise in scale**

The term “scale” has a variety of distinct
meanings, which include “spatial and temporal
extents” (e.g., an environmental occurrence
might be said to be a “large-scale event” if
it has large spatial and/or temporal extents);
“levels of measurement” (e.g., “nominal” versus
“ordinal” measurement scales); and “map scale”
(the relationship between distances as depicted
on a map and their corresponding distances in
the world).

However, in the context of expertise in
GIScience, the term “scale” is most strongly
connected to the scale-dependence of geographic
information. Scale-dependent information
reveals different patterns depending on the level
of detail at which it is analyzed. For example,
different levels of detail in a topographic dataset
can result in diametrically opposed landforms
being derived from this data. What appears to
be a peak at one scale can easily appear to be
a pit at another scale. This kind of effect can
be observed across many other types of geo-
graphic information, including in data about the
movement of animals and people; ecological and geophysical region boundaries; and even cartographic information about the structure of maps. In short, the level of detail at which information is captured and represented can have a defining effect upon the geographic phenomena that can be identified from that information (Figure 2).

Expertise in spatial cognition and spatial thinking

GIScience is not only concerned with computational models of geographic information. Over millions of years of evolution, humans (and other animals) have evolved sophisticated mechanisms for thinking and reasoning about objects and movements in geographic space. The structure and characteristics of human spatial reasoning are in stark contrast with our automated spatial reasoning procedures. For example, in a classic experiment, Stevens and Coupe (1978) showed that human subjects tended to judge that the city of Reno, in Nevada, was to the east of San Diego, California, when in actuality it is to the west.

The explanation, supported by other subsequent studies, indicates that humans do not store and reason with the geographic locations of Reno and San Diego directly. Instead, a better explanation is the use of a simple heuristic to remember only that Reno is in Nevada, which is broadly to the east of California, which in turn contains San Diego. The resulting rule (that things in Nevada are generally to the east of things in California) is frequently — though not always — correct. These simplified hierarchical structures may assist humans with efficient memory and reasoning connected with spatial relationships. Numerous subsequent experiments have shown that human reasoning exhibits systematic distortions in connection with a range of spatial reasoning tasks. Indeed, it is argued that such distortions are not “faults”; instead they are necessary features of human spatial cognition.

In this way, human spatial cognition and geographic information systems are in stark contrast. Precise digital information systems, such as GIS, are able to rapidly and reliably compute the cardinal direction between any pair of stored locations. On the other hand, humans routinely reason with and communicate uncertain geographic information, something that, as we have seen, today’s GIS struggle to cope with. A major theme in GIScience is an understanding of the mismatches between human spatial cognition and digital spatial computation. GIScientists typically possess expertise in the structure and types of inherent distortions in human spatial cognition and spatial thinking more generally.

Expertise in cartography and geovisualization

Finally, GIScientists are expected to possess expertise in the design of interfaces to spatial information, whether static cartographic
interfaces or more interactive systems for geovisualization.

GIScience draws upon a long history of expertise in cartographic design. The fundamental principles used in the design of traditional maps (e.g., map projections; the use of color, symbols, text, and type; and the different types of map, whether topographic, thematic, or schematic) are familiar to all GIScientists, evident in every GIS textbook. The problems posed by digital mapping have also been amongst the most active and successful topics for GIScience research.

For example, many ingenious algorithms for cartographic generalization have been developed with the aim of automatically generating maps at a specific level of detail. Cartographic generalization is the process by which the graphical clarity of a map is enhanced through simplifying or otherwise distorting the shapes and geometries depicted. The problem of positioning and orienting text labels on maps has similarly received much attention. In both cases, individual solutions are often straightforward, such as the famous Douglas–Peuker algorithm for line simplification. However, such per-object solutions often lead to adverse interactions between objects (for example, where moving a label to an individually ideal position then obscures another label’s optimal position). It is at least in part due to this research that today most digital mapping systems are able to make as good a job of map generalization and labeling as ever did a moderately experienced cartographer, and in a fraction of a second.

Indeed, the so-called map metaphor is still evident in the design and structure of the interface to most of today’s GIS. Like traditional cartographic maps, GIS interfaces tend to offer primarily static, planimetric views of the world, with lesser support for user interaction and nonvisual, dynamic, or three-dimensional representations of the world. GIScientists are keenly aware of such limitations, and can be expected also to have expertise in the principles of using interactive computer interfaces to geographic information. The topic of geovisualization is concerned with using the dynamic, interactive, and multimedia capabilities of computers to help users explore and gain insight into the spatial and temporal patterns and relationships embedded in geographic information. Today, geovisualization is just as active a topic in GIScience as cartographic generalization ever was, and hopefully will generate just as much benefit in the long term.

In summary, how geographic information is presented to a person is expected to have an important effect on what knowledge that person derives from the information, and even what decisions that person makes based on that information. Knowledge of the principles of presentation of and interaction with geographic information is this entry’s sixth core area of GIScience expertise.

**Expertise summary**

GIScientists can be relied upon to possess a sophisticated understanding of each of our six core areas of GIScience expertise (structure, uncertainty, dynamism, scale, spatial cognition, and design of geographic information), and most GIScientists would consider themselves experts in the majority of these topics. There are naturally, however, many other related areas of expertise that have close connections to an interdisciplinary field such as GIScience, and which many GIScientists will possess. An understanding of the social context of GIS, for example, is an area that we have already seen GIScientists will have at least a basic awareness of. From a more technical perspective, most GIScientists will understand at least the basic principles behind
spatial algorithms and spatial databases. However, while it is true that high levels of expertise in such areas exist within GIScience, it is arguably not common across all GIScientists. Thus, these six areas of expertise represent a summary of the topics that any GIScientist would usually have expert knowledge about, and by extension the topics that make up the core of the field of GIScience.

Geographic information science and technology: educational directions

Josef Strobl
University of Salzburg, Austria

Geographic information science and technology (GIS&T) became established as a term, describing what initially used to be known as simply “GIS,” with the initial publication of the GIS&T “body of knowledge” (DiBiase et al. 2006). The original concept of geographic information systems advanced towards geographic information science, recognizing the increasing independence from the original parent disciplines and the establishment of a generic spatial sciences discipline.

In parallel, academic education embarked on a move from offering “GIS classes” in a variety of spatial disciplines towards defining the curricula and syllabi for full geospatial education programs. This move went hand in hand with recognition as a professional field and the designation of distinct professional roles and job profiles by governmental bodies and professional organizations.

Due to the multifaceted and multidisciplinary roots of GIS&T, and a variety of labels such as geoinformatics, geomatics, or spatial information management, educational programs evolved across many different academic traditions. The community of GIS&T educators has contributed to strengthening common understandings and objectives among these varied constituencies, particularly through the development of joint reference documents for curricula and qualifications.

Disciplines and traditions engaging in GIS&T education

“GIS education” initially was rooted in only a few types of departments, or more correctly, advanced by individuals from only a few disciplines. The founding institutions of the National Center for Geographic Information and Analysis (NCGIA) (www.ncgia.ucsb.edu) were strong in geography as well as surveying and this was typical of this phase. These efforts were complemented by initiatives from cartography (which in turn is frequently rooted in the above subjects), planning, and computer science.

The focus of GIS&T education (Unwin et al. 2012), of course, varies depending on the respective home discipline, with only relatively few disciplines serving as backdrops for full degree programs in GIS&T.

- Geography (as a discipline, in some academic environments sharing departmental homes with other domains): due to the “quantitative revolution” and contributions from theoretical geography, close links with cartography, and engagement of geographers with numerous other disciplines and application domains (Baerwald 2010), geography worldwide certainly is the most prolific discipline when it comes to graduating geospatial professionals, typically with an applied orientation.

- Geodesy (or surveying engineering) contributes strengths in reference frameworks, spatial data acquisition, and mathematical skills. To enhance their appeal to students and reflect changes towards digital techniques,
many programs have been rebranded as “geomatics.”

- Cartography as a professional and independent academic discipline in many places is struggling to maintain its independent existence, and widely re-establishing itself successfully within a GIS&T framework.
- Planning, with orientations towards landscape, environment, and urban planning, is considered one of the fields where GIS originated. This link currently is emphasized through the emerging field of “geodesign.”
- Computer science (CS), with its core areas of data(base) management, communication protocols, distributed systems, and, of course, software design and development, is an indispensable foundation for GIS&T. While CS plays an important role in geospatial professional qualifications, this discipline rarely leads full academic programs.

These diverse academic backgrounds, traditions, and practices soon led to the insight that academic program orientation, syllabi, and resulting qualifications varied widely depending on discipline, and even on individual department and faculty orientation. It was due to this observation that one of the initial NCGIA initiatives was directed towards establishing a common platform, or at least a joint reference framework for education through the “core curriculum in GIS.”

Curriculum development

Additional early impulses towards including geospatial methods competences in the discipline of geography were provided by initiatives such as the “Geographer’s Craft” and the “Virtual Geography Department” to develop open educational materials. Results offered important insights into constraints and motivations for integrating GIS&T into discipline-specific frameworks, and contributed to the debate of dedicated GIS&T study programs versus modular integration into traditional curricula.

The core curriculum designation turned out to be a less than fitting name for this product, even though the materials had a huge impact worldwide: the distributed documents were not really structured as a curriculum, but rather as materials that could be used in a variety of combinations by instructors. Due to the paucity of learning materials and textbooks at that time, these lesson units frequently were used as lecture handouts and even self-learning materials. Furthermore, this did not turn out to be “core” as a common denominator across disciplines and program orientations, but rather a broad collection from the authors’ different backgrounds and approaches.

One measure of the success of the core curriculum initiative is the fact that it generated several spin-off projects: a “remote sensing core curriculum” was attempted, as well as a 53-unit “GIS core curriculum for technical programs (CCTP)” as a first manifestation recognizing the need to distinguish more technically oriented education in (community) colleges.

Technical advances and a discipline evolving rapidly in its early days led to quick obsolescence of some units, and even more newly emerging themes. The unit on manual digitizing (CCTP unit 13 plus a dedicated tutorial, CC unit 31) is but one example of materials needing updating,
leading to the subsequent “core curriculum in GIScience” initiative.

With the latter not able to replicate the resounding success of the original CC, the University Consortium for Geographic Information Science (UCGIS) with its “model curricula” project now took the lead towards developing a “GIS&T body of knowledge (BoK)” (DiBiase et al. 2006). This reference document is structured as a hierarchy, built from knowledge areas containing units, which in turn are divided into 330 topics. Each topic includes a list of 5–10 educational objectives for a total of 1660 educational objectives.

The BoK is accepted as a major milestone, the critical attention received leading to the BoK-2 initiative launched in 2013. In parallel, a European Commission project provided support for “Geographic Information: Need to Know” (www.gi-n2k.eu), a multipartner network aiming “to improve the way in which future GI professionals are prepared for the labor market so that the GI sector in general can evolve in a dynamic and innovative way.”

A parallel initiative with a primary focus on two-year colleges is the geospatial technology competency model (GTCM) based on an industry competence model established by the US Department of Labor (2016). This approach is based on an analysis of current job profiles, addressing the development of entry level geospatial programs for technicians.

These curricula follow a range of objectives: providing a framework for developing academic programs, offering a baseline for accreditation, orientation for prospective students and employers alike, and a reference for credit transfer or admission into more advanced study programs.

Practical work with curricula, syllabi, and learning objectives has been explored with software tools based on hyperlinks and a strong semantic foundation. These platforms support the checking of curricular consistency, identification of learning pathways, comparison and accreditation of academic programs, and generally a top-down analysis of geoinformatics programs.

**Levels of GIS&T education programs**

GIS education is established on all levels of education. K-12 is part of a separate debate (National Research Council 2006) building on concepts of spatial awareness and spatial thinking, with links to “spatial citizenship.” Only a few curricula explicitly address GIS&T as a methodology or technical skills for primary or secondary schools (Schulze, Gryn, and Kanwischer 2014), while exposure of pupils to geospatial technology interfaces is increasingly promoted (http://connected.esri.com).

The tertiary level addressed through the above listed curricula is differentiated by established undergraduate versus graduate program categories. On an undergraduate level, GIS&T is widely present through classes in a broad range of programs across numerous disciplines, with primarily technical and junior colleges addressing the potential job market for designated undergraduate geospatial qualifications.

The broadest presence and visibility of academic programs is observed on the Master’s level (Lukinbeal and Monk 2015) with more or less recently established offerings worldwide. MSc (or MTech in some regions) is considered a key qualification for geospatial professionals leading organizational departments or major projects or those in technical development, essentially serving as a passport for establishing a career in this industry.

Geoinformatics MSc programs currently are offered worldwide in numerous different curricular flavors and academic backgrounds.
They range between 1 and (a majority) 2 years in duration, and, in combination with admission from Bachelor levels, are rapidly replacing 5-year diploma studies in European and Asian countries. Due to the transdisciplinary character of GIS&T, a majority of MSc students are admitted based on other undergraduate qualifications.

Dedicated doctoral programs in geographic information science are a much more recent development and part of the pathway from “systems” to “science.” PhDs with a GIS&T focus have graduated from the leading departments worldwide since the emergence of the discipline, but the first designated PhD programs were established only recently (see for example the National Science Foundation (NSF) Integrative Graduate Education and Research Traineeship (IGERT) initiative, or Blaschke, Strobl, Donert 2011).

Due to the broad interest in and relevance for a range of disciplines, GIS&T competences increasingly are offered as “minors” or in similar formats complementing a range of majors from a geospatial methodology perspective. Depending on curriculum frameworks, a minor typically carries approximately one semester’s worth of credits and frequently is built from introductory classes plus a range of choices from existing GIS&T classes. Efforts discussing more rigid curricular frameworks for minor programs have not yet taken off.

Much longer experience exists in the closely related field of academic certificates or postgraduate diplomas, offered under different frameworks at tertiary institutions. These add-on qualifications either are taken in parallel to main study programs, or are used as continuing education facilities. Admission to a certificate in GIS or geoinformatics can be open to anyone interested, while admission to a postgraduate certificate requires a prior academic qualification.

Different educational strategies and policies are followed regarding the sequencing of GIS&T qualifications throughout academic qualification pathways. Undergraduate full GIS&T programs primarily aim at technical qualifications; completing this kind of program requires professional embedding into a broader setting – similar to other entry level technology qualifications with little background in application domains.

Many people choose to add GIS&T qualifications after they are already established in an academic discipline, which leads to the prevalence of MSc-level and postgraduate certificate programs. The job market and ultimately career prospects for GIS&T-only graduates effectively are more limited than for mixed domain-and-methodology qualifications.

Finally, essential and recognized GIS&T education occurs outside of curriculum-controlled environments. Short intensive courses and “summer schools” are offered to motivated individuals and aim at leveraging the advantages of interdisciplinary, creative, and less structured approaches. Excellent and very different examples are the “Vespucci Institutes” (www.vespucci.org) and the “Open Source Opportunities in GIS” summer schools (e.g., http://www.sigte.udg.edu/summerschool2014).

**Focus of GIS&T education programs**

Full geospatial programs started to emerge from the early 2000s, with earlier academic offerings predominantly taught as individual classes in a variety of programs. While GIS&T classes integrated in any discipline’s curriculum depend on demand, departmental strategy, and faculty availability, dedicated programs typically are explicitly linked to an academic department. This department discipline’s traditions then
reflect onto the focus and orientation of a GIS&T program’s curriculum.

- A *spin-off* study program emerging from a geography or earth sciences department is expected to offer strong conceptual and methodology foundations, stressing insights into application domains and cartographic communication competences.

- A *converted* program, for example from traditional geodesy to geomatics or from a surveying-based cartography (mapping) focus, will retain a majority of components from the original background discipline, keeping its technical orientation and focus on skills in either data acquisition or geovisualization products.

- *Merger* programs were established at universities where critical mass of faculty could be combined from qualified teachers across different departments, for example, geography, computer science, sociology, forestry, planning, and so on. While this approach potentially could result in very strong programs it tends to have issues of leadership and of compromise by offering alternative tracks instead of a clear focus.

- *New paradigm* study programs aim at developing new qualifications rooted in traditional disciplines. One example is the emergence of “geodesign” studies on undergraduate as well as graduate levels. Core ideas have a background in the (landscape) planning and architecture disciplines, but implementation predominantly occurs in strong GIS&T environments, branching off existing GIS&T study programs. Geomarketing, geohealth, and big Earth data are other examples for establishing paradigms towards GIS&T-linked disciplines.

- *Tracked* programs offer a GIS&T specialization, for example, in computer science (CS). Graduates with this kind of skill set are among the most sought-after professionals, in particular in the software industry. Due to the small footprint of GIS&T from a CS perspective, this option mostly is followed as an individual’s specialization.

- *Technical* programs are mostly established at undergraduate technical colleges (or universities of applied sciences) within a broader portfolio of study programs with a more vocational and thus stronger “training” orientation. GIS&T is identified as a professional field with perceived demand, and, depending on the respective institutional environment curricula, emphasizes software development, data acquisition, or sensor technology skills with a lesser focus on conceptual backgrounds.

While examples for all these “type models” exist, there are obviously further and mixed foci and traditions involved. Disciplinary backgrounds, programmatic positioning, and even regional specifics translate into a variety of nomenclatures for GIS&T study programs. “Geoinformatics” has taken the lead from simple “GIS” designations, with the latter increasingly being re-interpreted as “geographic information science,” although not always in the most suitable contexts: while perfectly suitable for a PhD program, it appears to be less adequate for a “GIS minor.” “Geomatics” derives from a specific disciplinary context (see above), and some newer designations with less ballast from academic traditions, such as “spatial sciences,” are getting traction.

The latter are an indication for increasing decoupling of GIS&T study programs from original parent disciplines, sometimes combining, for example, the “spin-off” with the “new paradigm” types discussed above. Examples such as the “Spatial Sciences Institute” at the University of Southern California (http://spatial.
GEOGRAPHIC INFORMATION SCIENCE AND TECHNOLOGY: EDUCATION

usc.edu), the “Interfaculty” Department of Geoinformatics at the University of Salzburg (www.zgis.at), or the U-Spatial unit at the University of Minnesota (http://uspatial.umn.edu) demonstrate the value of a trans-disciplinary home for GIS&T services, research, and education, offering an academic reference point for the “spatial perspective” increasingly of interest across numerous disciplines.

Distance learning and continuing education online

As an emerging field within a rapidly evolving technology environment, GIS&T could not establish the required quantities and qualities of human resources by regular patterns of academic education alone. The need to address experienced professionals and provide continuing education opportunities to the current workforce was already evident in the 1990s.

This demand has not changed, even after the implementation of regular study programs, due to the rapid growth of the industry, and even more so as GIS&T reaches into numerous other disciplines and professions, where individuals are exposed to the need for an add-on qualification for geospatial methods and technologies. Due to limitations active professionals face when attending full academic graduate programs, distance learning modes of delivery are an obvious choice for many.

As a first initiative, and now sustained for the longest time of any such initiative, the worldwide UNIGIS distance learning network of universities (www.unigis.net; Strobl 2011) in 1993 began to offer postgraduate programs. Its member universities have graduated thousands of students with MSc degrees or postgraduate certificates.

Penn State University’s program is another well-established and highly regarded option for flexible distance learning (DiBiase and Rademacher, 2005), with numerous additional offerings recently emerging primarily in North America, ranging from local colleges to full universities.

Online learning started opening up to a general public and to reach far beyond previous target groups with the arrival of massive open online courses (MOOCs) in the discipline. These courses were pioneered by Penn State University’s “Geospatial Revolution” MOOC (Robinson et al. 2015) in 2003, the success of which was followed and replicated by additional technology oriented courses and has started to branch out into specific application domains (geo-intelligence, geobusiness, geohealth). Clearly, MOOCs have taken an important role as an opportunity for many for a first academically inclined exposure to the field, reaching out to a huge number of potential students who might then opt for seriously studying the discipline.

Similarly, technology-specific online options for acquiring software skills are rapidly expanding. Technology vendors having established “virtual campus,” “online academy,” or online “university” platforms providing online training opportunities, complementing academic programs sometimes even to the degree of credit transfer.

Professional organizations and certification

All major professional organizations in this field have implemented working groups or commissions fostering educational initiatives. Some examples are as follows.

• ISPRS (International Society for Photogrammetry and Remote Sensing) TC6:
Education, Technology Transfer and Capacity Development: http://www2.isprs.org/commissions/comm6.html

- FIG (Fédération Internationale des Géomètres/International Federation of Surveyors) Commission 2: https://www.fig.net/commission2
- OSGeo (Open Source Geospatial Foundation) Education and Curriculum: http://www.osgeo.org/education
- ICA/OSGeo/ISPRS: “Geo for All” www.geoforall.org

These initiatives address the respective institutional membership to promote capacity building and continuing education. A specific mission of these and other organizations such as the Geospatial Information and Technology Association (GITA) (www.gita.org) and the Urban and Regional Information Systems Association (URISA) (www.urisa.org) is the establishment of certification programs aimed at distinguishing individuals, or even providing a framework for granting the right to practice a geospatial profession.

As an initiative launched by URISA in 2004 and with several other organizations as members, the GIS Certification Institute (www.gisci.org) is offering recognition as a “certified GIS professional” (GISP). Candidates need to pass a “GISCI geospatial core technical exam” plus a portfolio-based review based on ethics agreement, education, experience, and professional contributions. Recertification is required after a three-year period, based on continuing education and service to the profession.

Certification is frequently linked to legal codes, and therefore tends to have a national focus. An international example in a related discipline is PLATO, the South African Council for Professional and Technical Surveyors (www.plato.org.za), with a legal mandate reaching far beyond the surveying trade. To qualify, for example, as a “professional GISc practitioner,” candidates need to have obtained a qualification from a program accredited by PLATO, and to maintain this through continuing professional development (CPD).

In addition to professional certification, technically oriented certification programs have been established with a focus on mostly vendor-specific software skills, documenting individuals’ proficiency and familiarity with best practice in technology application. These either build on a collection of training courses assessed by some kind of exam or performance review, or are managed through testing centers. None of these (professional and technical) certifications should be confused, though, with the above-mentioned academic certificate programs.

References

A geographic information system (GIS) is a computer system for capturing, storing, querying, analyzing, and displaying geospatial data (Chang 2014). Geospatial data describe both the location and the attributes of spatial features. For example, to describe a road, its location (i.e., where it is) and its attributes (e.g., length, name, speed limit, and direction) are referred to. A GIS allows the user to manage road data and many other geospatial data, thus distinguishing it from business management systems that deal with nonspatial data.

A GIS comprises hardware, software, people, and organization, in addition to geospatial data. GIS hardware includes computers for data processing, data storage, and input/output; printers and plotters for hard-copy maps; digitizers and scanners for digitization of spatial data; and GPS and mobile devices for fieldwork. GIS software, either commercial or open source, includes programs and applications to be executed by a computer for data management, data analysis, data display, and other tasks. Additional applications may be used in GIS for specific data analyses. Common user interfaces to these programs and applications are menus, icons, and command lines, using an operating system of Windows or Linux. GIS users define the purpose and objectives for using GIS and interpret and present the results. GIS operations exist within an organizational environment; therefore, they must be integrated into the culture and decision-making processes of the organization for such matters as the role and value of GIS, GIS training, data collection and dissemination, and data standards.

History of GIS

The origins of GIS in its present form lie in the application of rapidly developing computing tools, especially computer graphics in a variety of fields such as urban planning, land management, and geocoding in the 1960s and 1970s. The flourishing of GIS activities in the 1980s was in large part prompted by the introduction of personal computers, such as the IBM PC, and graphical user interfaces, such as Microsoft Windows. Unlike mainframes and minicomputers, PCs equipped with a graphical user interface were more user friendly, thus broadening the range of GIS applications and bringing GIS into mainstream use in the 1990s. Also in the 1980s, commercial and free GIS packages appeared in the market. Environmental Systems Research Institute, Inc. (Esri) released ARC/INFO, which combined spatial features of points, lines, and polygons with a database management system (DBMS) for linking attributes to these features. Partnered with Intergraph, Bentley Systems developed Microstation, a CAD software product. Other GIS packages developed during the 1980s include GRASS, MapInfo, TransCAD, and Smallworld.
By definition, geospatial data cover the location of spatial features. To locate spatial features on the Earth’s surface, either a geographic or a projected coordinate system can be used. A geographic coordinate system is defined by its datum (e.g., NAD83, WGS84) and expressed in longitude and latitude, whereas a projected coordinate system is defined by its parameters (e.g., standard parallel, standard meridian, scale factor) and expressed in $x,y$ coordinates. Many projected coordinate systems are available for use in GIS. An example is the universal transverse mercator (UTM) grid system, which divides the Earth’s surface between 84°N and 80°S into 60 zones. A basic principle in GIS is that map layers representing different geospatial data must align spatially; in other words, they are based on the coordinate system. A GIS has tools for projecting or re-projecting coordinate systems.

Based on the representation of spatial features, geospatial data can be grouped into vector and raster data. The vector data model uses the geometric objects of point, line, and polygon to represent spatial features with a clear spatial location and boundary. Each feature is assigned an ID so that it can be associated with its attributes. The raster data model, on the other hand, uses a grid and grid cells to represent spatial features so that points are represented by single cells, lines by sequences of neighboring cells, and polygons by collections of contiguous cells. The cell value corresponds to the attribute of the spatial feature at the cell location. Although the raster representation of spatial features is not precise, it has the distinctive advantage in having fixed cell locations. In computing algorithms, a raster can be treated as a matrix with rows and columns, and its cell values can be stored into a 2-D array. Because of their simple structure, raster data can be easily manipulated, aggregated, and analyzed. In contrast, manipulation and analysis of vector data must consider the geometry of their locations and boundaries, and, when they are overlaid, the intersections of their boundaries must be calculated.

Generally speaking, vector data are ideal for discrete features such as streams, land parcels, and vegetation stands while raster data are ideal for continuous features such as elevation and precipitation. A GIS allows vector layers to be superimposed on raster layers as long as they are based on the same coordinate system. A GIS also has the capability of converting vector to raster data (rasterization), and raster to vector data (vectorization), at a loss of some data accuracy (e.g., smooth lines changed to zigzag lines after rasterization).

**Elements of GIS**

GIS operations usually involve data acquisition, data management, data query, vector data analysis, raster data analysis, and data display. These operations do not have to be sequential; for example, data display may be conducted for exploring data at the beginning of a project and for presenting results at the end of the project.

**Data acquisition**

Data acquisition is usually the first step in conducting a GIS project. The need for geospatial data by GIS users has been linked to the development of data clearinghouses and geoportals. Since the early 1990s, government agencies at different levels in the United States as well as many other countries have set up websites for sharing public data and for directing users to various data sources. As an example, Data.gov is a US government geoportal that allows public access to datasets generated by
GEOGRAPHIC INFORMATION SYSTEM

the Executive Branch of the US Federal Government. As of December 2016, the website shows more than 132,000 geospatial datasets and provides links to various agencies. Another example is the INSPIRE geoportal, which provides the means to search for spatial datasets and services, and to view spatial datasets from the member states of the European Union, including roads, populated places, land cover/use, administrative boundaries, elevation data, and ocean floor. Nongovernmental websites also exist for the distribution of geospatial data. For example, DIVA-GIS offers country-level data and data on global climate, species occurrence, crop collection, elevation, and satellite images. Another example is OpenStreetMap, a nonprofit based in the United Kingdom, which offers free geographic data of global coverage, such as street maps, points of interest, and land use, collected through crowdsourcing.

To use public data, it is important to obtain metadata, which provide information about the data. The International Organization of Standards (ISO) has implemented ISO 19115-1:2014, which defines the standards of metadata for describing geographic information and services. According to the standards, metadata should provide information on the identification, the extent, the quality, the spatial and temporal aspects, the content, the spatial reference, the portrayal, distribution, and other properties of digital geographic data and services.

If public data are not available, new geospatial data can be digitized from paper maps or created from satellite images, GPS data, survey data, street addresses, and text files with x and y coordinates. Geospatial data can be digitized using manual digitizing, scanning, or on-screen digitizing. Satellite images can be interpreted and classified to create land-cover and other maps. GPS and survey data can be converted to point, line, or area features. Likewise, street addresses and text files with x and y coordinates can be converted to point features through geocoding, a process similar to online geocoding services provided by Google, Yahoo, MapQuest, and others.

Data management

A GIS usually employs a DBMS to handle attributes of vector data, which can be large in size. Each polygon in a soil map, for example, can be associated with dozens of attributes on the physical and chemical soil properties and soil interpretations. Data management is much less important for raster data because cell values are bound to fixed cell locations. Attributes of vector data are maintained in different tables in a DBMS. An important type of table is the feature attribute table, which represents spatial features by row and attributes by column; therefore, the intersection of a column and a row lists a particular attribute value of a particular feature.

A DBMS offers two methods for linking attribute tables, such as linking a feature attribute table to an attribute table. A join operation brings together two tables by using a common attribute field (e.g., feature ID). A relate operation connects two tables but keeps the tables physically separate. Thus, using a DBMS, attributes can be linked to spatial features and to each other.

Data query

Data query allows users to select a data subset for close examination. Because the spatial (location) and attribute components of geospatial data are synchronized, data query can be approached from either component. Attribute data query typically uses a query language that is based on SQL (structured query language) developed by IBM in the 1970s. The basic syntax of SQL has three keywords: the select keyword selects
attribute(s) from the table, the _from_ keyword selects table(s) from the database, and the _where_ keyword specifies the condition or criterion for data query. Attribute data query, which can work with vector and raster data in a GIS, is basically the same as database query using a DBMS.

In contrast, spatial data query is unique in GIS because it allows users to select features based on their spatial relationships rather than their attribute values. Spatial data query is particularly useful for vector data because spatial features in vector data are represented with clear locations and boundaries. Three basic types of spatial relationships relate _features for selection_ and _features to be selected_. Containment selects features that fall within features for selection, such as finding schools within a county; intersect selects features that intersect features for selection, such as finding land parcels that intersect a proposed pipeline; and proximity selects features that are within a specified distance of features for selection, such as finding pet shops within one mile of Main Street. Variations of these basic relationships occur. For example, containment can be further classified by whether features to be selected are entirely, or partially, within features for selection.

It is common in GIS that a query combines both attribute and spatial data. For example, “finding schools within a county that has over 500 students” involves spatial data in the first part and attributes data in the second part. In such cases, the start can be with either spatial or attribute data query and the same result obtained.

Spatial join is an extension of spatial data query. Like join in a DBMS, spatial join also joins attribute data from two tables; but, instead of using attributes in the operation, spatial join uses the spatial relationship between features. For example, a spatial join operation can join attribute data of schools to those of counties by first matching schools and counties using the containment relationship.

Figure 1 Buffering around line features (black lines). The buffer zone is shown in gray.

**Vector data analysis**

Two basic tools for vector data analysis are buffering and overlay (Chang 2014). Based on the spatial concept of proximity, buffering creates two areas: one area that is within a specified distance of select features and the other area that is beyond (Figure 1). The specified distance is the buffer distance, and the area within the buffer distance is the buffer zone. Spatial features to be buffered can be points, lines, or polygons. Other options for buffering include creating multiple buffer zones around a feature and dissolving boundaries of buffer zones around features.

Overlay combines the geometries and attributes of two input layers to create the output (Figure 2). Overlay can be point-in-polygon, line-in-polygon, or polygon-on-polygon. In this classification, the first layer contains point, line, or polygon features and the second layer contains polygon features. In a point-in-polygon operation, the same point features are included in the output but each point is assigned with additional attributes of the underlying polygon.
In a line-in-polygon operation, the line features are dissected by the polygon boundaries and each line segment on the output is assigned with additional attributes of the underlying polygon. In a polygon-on-polygon operation, the output combines the polygon boundaries from both layers to create a new set of polygons, each carrying attributes from both layers. Depending on the area extent of the output, an overlay operation can also be union, intersect, or identity (Figure 3). Union preserves all features from both layers; intersect preserves only those features falling within the area common to both layers; and identity preserves only those features falling within the area extent of the input layer.

Besides buffering and overlay, there are tools for managing map layers or spatial features. Using these tools, two or more adjacent layers can be appended to create a single layer, split a single layer into two or more layers, and clip a layer by following the area extent of another layer. It is possible to erase from a layer those features that fall within another layer, and update a layer by replacing features with those in another layer. It is also possible to eliminate or select features in a layer based on an attribute data query, and aggregate adjacent features in a layer if these features have the same attribute value or values.

Two special types of vector data analysis are network analysis and point pattern analysis. Network analysis is based on a system of line features that is properly connected and has the appropriate attributes for measuring flow. The most common type of network analysis is shortest path analysis, which finds the path with the minimum cumulative distance or cost between nodes on a road network. Shortest path analysis can be extended to solve problems of vehicle routing, finding the closest facility (e.g., fire station), analyzing the spatial distribution of public resources (e.g., hospitals), and matching the supply and demand of facilities (e.g., siting of supermarkets). Given a distribution of point features, point pattern analysis can determine if the distribution is random, dispersed, or clustered at the global level or if the distribution contains...
local clusters of high or low values. Point pattern analysis has proved to be useful for analyzing crime locations (LeBeau and Leitner 2011) and public health data (Jacquez and Greiling 2003).

**Raster data analysis**

Four basic tools for raster data analysis are local, neighborhood, zonal, and global operations depending on if the analysis is performed at the level of individual cells, or groups of cells, or cells within an entire raster. A local operation can create a new raster from either a single input raster or multiple input rasters on a cell-by-cell basis (Figure 4). The cell values of the new raster are computed by a mathematical function (arithmetic, logarithmic, trigonometric, or power) relating the input to the output. A neighborhood operation involves a focal cell and its neighborhood (e.g., a $3 \times 3$ area centered at the focal cell) in a computation and then assigns the computed value to the focal cell. A zonal operation involves an input raster and a zonal raster, and produces an output raster, which summarizes the cell values in the input raster for each group of cells with the same values or like features in the zonal raster. A physical distance measure operation is an example of a global operation in which straight-line distances are calculated from cells designated as the source cells on a raster to all other cells within the raster. These four basic tools can be combined in analysis using *map algebra*, an informal language with syntax similar to that of algebra (Tomlin 1990). In addition to these data analysis tools, there are also tools for raster data management, such as clipping or mosaicking raster layers and extracting raster data based on an attribute or spatial data query.

Several special types of data analyses are based on raster data to take advantage of the ease in data manipulation and computation. Terrain mapping and analysis use a digital elevation model, a regular array of elevation points. A GIS has tools for mapping the terrain in contours, profiles, hill shading, and 3-D views, and for analyzing the terrain with slope, aspect, and surface curvature (Wilson and Gallant 2000). Terrain analysis also includes viewshed and watershed: a viewshed analysis determines areas visible from one or more observation points, and a watershed analysis traces water-flow to delineate streams and watersheds. Spatial interpolation uses points with known values to estimate values at other points and, in the process, create continuous surface data from the sample points. For example, spatial interpolation can be used to create a precipitation raster with known precipitation...
readings at weather stations. Least-cost path analysis finds the least accumulative cost path in a raster based on costs (real or relative) and cost distance measures. It is useful for planning roads, pipelines, transmission lines, and trails. For example, least-cost path analysis has been used to locate footpaths in mountainous areas (Rees 2004).

**Data display**

Maps are an interface to GIS (Kraak and Ormel-ing 1996). Map-making can be informal or formal in GIS. It is informal when viewing and querying geospatial data on maps, and formal when producing maps for professional presentations and reports. Here the focus is on the latter case. A professional map combines the title, map body, legend, scale bar, north arrow, and other elements to convey geographic information to the map reader. These elements should be arranged so that the map is balanced, coherent, ordered, and interesting to look at. The focus of the arrangement is usually the map body, which uses map symbols to depict the mapped data. For example, graduated circles may be used to display the distribution of different-sized cities in a state. Besides the graduated circle map, other types of quantitative maps include the dot map, choropleth (area-based) map, chart map, flow map, and isarithmic (isoline) map; these map types employ different visual variables of color (hue, value, chroma), shape, size, pattern, and texture to communicate quantitative information to the map-reader (Slocum et al. 2008).

After a map is composed in a GIS, it can be printed or saved as a graphic file for presentation. A map prepared in a GIS can also be converted to a KML file, imported into Google Earth or Google Maps, and shared publicly on a web server. For time-dependent data, such as population changes by county in the United States from 1900 to 2010, a series of map frames can be prepared and displayed in temporal animation (Cinnamon et al. 2009).

**GIS applications**

Since its inception, GIS has been important in resource management, land-use planning, natural hazards assessment, wildlife habitat analysis, riparian zone monitoring, and timber management. GIS has also been used for emergency planning, crime analysis, public health, land records management, transportation applications, precision farming, and military operations. Four specific examples of GIS applications are discussed here.

**Riparian management**

Riparian buffers are strips of land along stream banks that can filter polluted runoff and provide a transition zone between water and human land use. Riparian buffers are typically defined using the buffering tool for vector data. Zimmerman, Vondracek, and Westra (2003) incorporated riparian buffers of 30 m and 100 m in their simulation study of agricultural land-use effects on suspended sediment concentrations in two watersheds. They reported decreases in sediment concentrations with the presence of riparian buffers, especially the 100 m buffer.

**Site selection**

Site selection of a ski resort, a supermarket, or a landfill must consider a large number of factors. It presents an ideal scenario for applying map overlay, a tool that can combine the locations and attributes from two or more layers in either vector or raster format. In their study of emergency
evacuation shelters, Kar and Hodgson (2008) considered the following nine factors: flood zone; proximity to highways and evacuation routes, hazard sites, and health-care facilities; and total population, total children, total elders, total minority, and total low-income in the neighborhood. They chose a raster-based model because it was more efficient than a vector-based model.

Response time to fires

Many countries have established guidelines for responding to disasters and emergencies such as fires. The response time to fires is the time it takes for the arrival of an engine company at a fire scene. Shortest path analysis is the tool for calculating the response time. A study by Murray and Tong (2009) in Massachusetts (USA) reported that 25% of fires exceeded the response standard of four-minute travel time and, to be able to respond within four minutes to at least 90% of the fires, it would need 180 additional fire stations in Massachusetts.

Visual impact of “greenhouse parks”

A “greenhouse park” refers to the clustering of large-scale greenhouses on a single site. Although this clustering can reduce production costs by sharing infrastructure, such as energy, water, and gas facilities, it can impact the aesthetics of the surrounding landscape. Rogge, Nevens, and Gulinck (2008) applied viewshed analysis to a study of the visual impact of a greenhouse park in Belgium and found that it was visible in 39% of the area within a 1200-meter radius of the greenhouse park. They then examined different scenarios in which viewsheds could be reduced through the planting of trees and hedgerows.

Integration of desktop GIS, web GIS, and mobile technology

The introduction of PCs brought GIS into mainstream use in the 1990s. But the dominance of PCs has been downgraded in recent years and now PCs must coexist, and even compete, with web and mobile technologies. Web GIS or web-mapping services lets users find data (e.g., administrative boundaries, DEMs), access services (e.g., geocoding, routing), and publish maps to share with others. Web mapping received a boost after Google Maps and Google Earth appeared in 2005, followed by “Google Maps mash-ups” in 2006. The idea of mash-ups (i.e., combining a user’s own contents such as text, photos, and videos with web-based maps) quickly found its applications in real estate, vacation rentals, quasi-taxi services, and many other location-based services. Notably, maps are the foundation of these services.

Mobile devices such as smartphones and tablets with GPS can be used to perform many GIS-related tasks. For example, it is possible to download maps from a web server, collect real-time data in the field, edit the maps, and save the maps through a cloud storage service. More sophisticated operations can also be carried out by using apps that have been developed for smartphones. These apps let users conduct attribute and spatial queries; use custom templates for collecting and editing data in the field; and geocode and upload photos, video, and text in real time to map layers on the web.

Web technology’s inherent characteristics of communication and data sharing have helped the recent development of collaborative web mapping and volunteer geographic information (VGI). A good example of such development is OpenStreetMap. Often described as the Free Wiki World Map providing free geographic data such as street maps to anyone, OpenStreetMap
GEOGRAPHIC INFORMATION SYSTEM

is a collaborative project among registered users who voluntarily collect data using GPS, aerial photographs, and other free sources. As of March 2016, OpenStreetMap claimed over one million mappers around the globe. Although VGI provides a new and important data source to GIS users, the main concern about VGI is its accuracy and reliability in cases where data other than images are needed (Haklay 2010; Sui and Goodchild 2011).

From all indications, it is quite clear that desktop GIS, web GIS, and mobile technology will continue to coexist. A number of desktop GIS functions, such as data entry, data editing, map-making, address matching, attribute query, and spatial query, overlap with those of web GIS and mobile devices. Given this condition, GIS users should try to create an integrated, complementary GIS environment in which desktop GIS can play the role of performing “heavy-duty” tasks such as projection, data management, data exploration, vector data analysis, raster data analysis, and GIS modeling.

The geographical imagination affords ways of thinking about space and place, whether conscious or unconscious, emphasizing how power shapes practices, behaviors, and social structures. Scholars attach a range of related definitions to the term, most of which can be traced back to the work of the geographers Hugh Prince, David Harvey, and Derek Gregory. The geographical imagination is also often confused or used interchangeably with other key concepts, such as “imaginative geographies,” “geographic imaginary,” and “geopolitical imagination.” Gregory recently addressed the theoretical contributions of the geographical imagination in *The Dictionary of Human Geography* (2009). Theoretical and applied uses of the term address how power and knowledge are deployed in and on space on behalf of social justice. The following threads emerge in this work: perception, cognition, and behavior; processes in the urban and in nature; tensions between the arts and sciences; trends in communications and mapping; elements of identity ranging from the individual to the structural; and imagined futures, especially as they relate to policy.

Educational theorist Maxine Greene describes the imagination as that which “makes empathy possible”:

To call for imaginative capacity is to work for the ability to look at things as if they could be otherwise. To ask for intensified realization is to see that each person’s reality must be understood to be interpreted experience – and that the mode of interpretation depends on his or her situation and location in the world. (2000, 3)

While geography appears to focus primarily on the material, the imagination then opens up questions of the abstract, creative, and possible. The geographical imagination affords the user ways to pry open the power in assumptions, stereotypes, and expectations associated with space and place, and to delve into how and why they are linked.

The term “geographical imagination” was first coined by Hugh Prince in a 1962 article of the same name in J.B. Jackson’s journal *Landscape*, which led to much of the ensuing confusion around the term’s meaning, Prince relayed the contradictions inherent within the humanistic field of geography where, at the time, a focus on spatial sciences took precedence. Responding to Carl Sauer who described geography as “a finely representational art,” Prince designated the “real problem of geography” as how to “combine the subjective view … with explanation in which the subjective view has no place” (1962, 25). Only by addressing the imagination through the project of history-making could the subjective and objective be bridged, particularly through works of art and literature.

David Harvey theorized the geographical imagination with a focus on space and place rather than landscape, nature, and the aesthetic. His approach built on C. Wright Mills’s “sociological imagination,” a conceptual tool for use by individuals to compare their personal biographies to larger social structures within their specific historical era. Harvey (1973) conceived of the geographical imagination also to
consider the role of space, place, and the political economy. Developed primarily from studies of the urban political economies, Harvey’s reading laid out the geographical imagination as a “spatial consciousness” that recognized the spaces between situations, scales, and events and their effect on relationships with the individual. He demonstrated the profound effect of space by breaking down the organic, perceptual, and symbolic spaces of everyday life.

Derek Gregory responded to the exoticization of “world-as-exhibition” that continued to permeate the era of the spatial turn, or the academy’s general cross-disciplinary interests in space and place, by elaborating on Harvey’s definition. Operating at the intersection of power–knowledge–space that allows questions of representation to become a focus of inquiry, Gregory defined the geographical imagination, in the words of Cosgrove and della Dora (2005, 388) as “the complex of culturally and historically situated geographical knowledge and understanding that characterizes a certain social group.” In Geographical Imaginations (1994), Gregory describes a feeling beyond our own world that allows us to transcend our particularities and connect to universalisms in order to realize our intertwined existences. His work pluralizes the concept, showing its situatedness and emergence as a distinctive tradition of Western intellectual inquiry. Gregory gives extra attention to the geographical imagination’s role in reproducing colonial norms in map-making, art, travel writings, and scholarly writings in philosophy, mathematics, and sciences.

The imagination’s place in geography is wide-ranging, and multiple terms and related concepts inform the geographical imagination. Studies of perception and cognition as they relate to space are essential to the geographical imagination because, as Yi-Fu Tuan wrote, they deal with the common human psychological experience of imagining. Distinct from the related term “geographical imaginary” – which denotes a more unconscious construction per Jacques Lacan – the geographical imagination can be manifest in the consciousness and therefore includes a reflective construction. The geographical imagination is of key import to the field of environmental psychology, which examines how people relate to and define their space and place, and vice versa. Environmental psychologists define place identity as an accumulation of learned cognitions related to space and developed through selective emotional attachments and meaningful experiences. These connections attach to particular places past, present, and anticipated, through memory and interpretation as well as fantasies and imagination. Gregory (1994) also describes how self-identifications on spaces and places afford processes of fabrication. As a compounded life experience, patterns of stereotyping and expectation are forged in relation to emotional geographies, material and imagined, as well as behaviors and perceptions of access, belonging, and safety.

Beyond concepts of landscape, the geographical imagination plays a key role in the processes that define the production of space, from its role in the production of nature to urbanization. The 1990s shift in studies of political ecology with a keen focus on the “production of nature” embraced a dialectical paradigm that was both social and ecological, material and conceptual. The production of nature describes the development of people’s relation to material nature through a historical context. The assumption of “man’s” dominion over “nature” has required major interventions in popular media and academic writing, such as through studies of political ecology, that is, how our environment is produced through political, economic, and social processes at a variety of scales. Today, increased discussions around climate change and
the Anthropocene indicate yet another shift in the geographical imagination around nature.

In the urban sphere, radically different schools of thought have addressed the geographical imagination, from the Chicago School of the 1930s to recent work on urban assemblages, mobilities, and network geographies. In 1973 David Harvey wrote that the “only adequate conceptual framework for understanding the city is one which encompasses and builds upon both the sociological and geographical imaginations.” The geographical imagination is advantageously deployed by critical urban and Marxist geographers who examine urban processes as they relate to capital. The geographical imagination can serve as an umbrella for ways space is rendered, including the social production of space, jumping scale, time–space compression, and time–space expansion. All of these terms afford new understandings of the city and nature and ways to imagine it.

The geographical imagination speaks to the interdisciplinary nature of geography as a humanistic social science, ranging from its role in the arts to cutting-edge technologies and new media. Researchers suggest that the geographical imagination both fuels and biases scientific research as well, ranging from the energy discourse to biogenetics. Advancements in technology relate heavily to the geographical imagination, including the geographies of traditional media (film, TV, radio) and new media (gaming, social media). Relatedly, the heavy influence code plays on our everyday lives requires a different geographical imagination to recognize that space and code are mutually produced, or what Rob Kitchin and Martin Dodge (2011) call “code/space.” The widespread use of GPS (Global Positioning System) on mobile devices has radically reduced spatial cognition and awareness as individuals become increasingly dependent on a screen map rather than remembering their paths.

The geographical imagination is often taken up as a visual practice of representing space and place. Traditional cartography and spatial images strongly affect our abilities to create and sustain spaces and places; nowhere is this more evident than with geographic information systems (GIS). Other maplike visualizations – such as photos, memories, paintings, and images – shape the mind’s spatial eye as well. Processes of map-making require that both the cartographer and map viewer possess a geographical imagination while also producing that geographical imagination of a place: the popular and erroneous Mercator projection map renders the United States larger than the continent of Africa. As Kevin Lynch’s (1960) work demonstrated, humans possess an “image of the city” that informs their experience and expectation of a space, the image being urban or otherwise. Studies around cognitive and mental mapping reveal how situated and specific the geographical imagination is to a person, and also how it is related to a person’s race, class, gender, sexuality, and sense of embodiment and privilege (Gieseking 2013). Consequently, feminist geographers have called for a re-envisioning of GIS and feminist visualization by disturbing the “God’s-eye view” that we assume to be the “proper” way to see maps and instead working from our own situated knowledges.

The geographical imagination is prominently used in regard to nationalist discourses, and profoundly helpful in critiques of colonialism and imperialism. Edward Said’s (2000) imaginative geographies demonstrate how the geographical imagination of citizens’ minds can be manipulated and exploited to portray a fashioned social political history of the state. Benedict Anderson’s (1983) imagined communities describe how the
media of a nation can create a shared social identity. Frederic Jameson (1990) suggests that the stories of the colonized reside in narratives of population rather than in the conqueror’s version of history. Similarly, the connection with the explorative and imperial means that the geographical imagination is often linked to travel writing and travelogues. Later work on philosophers of the Enlightenment, namely Hegel and Kant, reveals how present-day ideas of race and racism developed from these and other scholars’ reading of erroneous and, more often, fabricated travel accounts of the period. The seemingly self-explanatory “territorial” narratives of popular nationalist geographies override those who came before, erasing indigenity. Geographies of war, such as World War II news cartography and school maps, heavily influence and limit the geopolitical narrative of a nation and its people – what Cosgrove and della Dora (2005) refer to as the geopolitical imagination.

Scholars also examine how global processes are produced within and by more intimate scales through issues of sexism, racism, and heteronormativity. Scholarship in feminist geography is particularly essential in the work of reframing and refuting patriarchal, colonial, and heteronormative assumptions often prevalent in the geographical imagination. Gillian Rose’s (1993) use of the geographical imaginary to point out how a psychoanalytic approach to geography can reveal the masculinism inherent in geographical thinking, such as assumptions of territory as a norm. Tapping into the psyche, Gillian Rose suggests, allows for the freeing of one’s self from patriarchal geographical models by the imagination. In her book on black women’s geographies, Katherine McKittrick critiques the oft used term margins to describe all black women’s geographies because the margin is “emptied out, placeless, just theory, just language” (2006, 57).

Extending work that upends patriarchal and top-down approaches by including bodies and homes, Geraldine Pratt and Victoria Rosner (2012) call for a rejection of the false binary of the global and local, replacing it instead with the global and the intimate which are kept in tension but are actually coproducive. Feminist theoretical conceptions of space that seek to encompass and break up hard lines in binary framings of identity queer the geographical imagination by redefining what is “normal,” probable, and possible. Geographers of sexualities and queer theorists rely heavily on the geographical imagination as well. For example, Kath Weston (1995) writes of the sexual imaginary of LGBTQ people that urban neighborhoods would afford safety and solace as opposed to the seemingly heteronormative settings of rural and suburban environments. By recognizing individual, structural, and territorial geographical imaginations, as well as the intersectionality of the subjectivities that embody them, scholars and individuals alike are able to unpack the production of meaning that is assumed to define spaces and lives.

Since its core conceptualizations, the geographical imagination has broadened into a tool to describe and analyze the power within the literal and metaphorical ways people imagine and render space. The concept plays a central role in envisioning and enacting possible futures that are more just. Each person’s constant production of their geographical imaginations yields fissures which can be broken open to produce social and spatial justice. For example, the legal scholar Elizabeth Brown (2010) describes how many laws and governmental policies require attainable geographical imaginations that fit the political, economic, and cultural contexts to which they are applied. The geographical imagination is therefore a central concept of critical geography, geography that aims to develop theory, methodologies, and research that combat social
exploitation and oppression. Relatedly, Gregory (2009) writes that spaces of hope are alive in the practice of creativity. As Stephen Daniels announced to the 2010 Royal Geographic Society Annual Conference, the geographical imagination encompasses “the condition of both the known world and the horizons of possible worlds” (2011, 183), or what Greene (2000) earlier referred to as “worlds not yet imagined.”

Geographies of death

Avril Maddrell
University of the West of England, UK

Mapping death has long been an important preoccupation of epidemiologists and social scientists. Think of John Snow’s 1854 map of incidences of cholera in Soho, London, which led to the identification of the local water pump as the source of the water-borne disease. Durkheim’s study of the social factors affecting suicide might also come to mind. Thus geography and death are intimately related; however, within geography, analysis of that relationship has been largely limited to demographers’ concerns with life expectancy and mortality, for example, Dudley Stamp’s (1964) medical geography The Geography of Life and Death. More recently, others have used demographic maps, based on quantitative data, to show often powerful spatial patterns of mortality and life expectancy in order to identify causal factors and to inform public debate, policy, and service provision (see Dorling 2010).

Grounded in feminist, emotional, and affective geographies, another geographical perspective on death that has emerged and gained currency within the discipline since the 1990s is that of social and cultural understandings of death and mourning (Kong 1999). Initially focusing on roadside memorials, cemeteries and columbaria, sites of tragedy, and the politics of memorialization, the concept of “deathscapes” introduced in this work has been deployed more discursively to explore a variety of spatialities including physical, corporeal-psychological, and virtual spaces, and non- or more-than-representational practices situated in particular landscapes and social-cultural settings (Maddrell and Sidaway 2010).

Drawing on and contributing to interdisciplinary death studies and other cognate fields, recent geographical work has been attentive to the emotional and affective, including other forms of loss such as home, dementia, and missing persons. Recent work deploys concepts of relationality, the absence-presence of continuing bonds, and performativity to interrogate the embodied spatialities of death, mourning, and remembrance, the poetics and politics of care and loss being intimately intertwined in the everyday, universal, but often transformative, experience of bereavement.

Geographical scholarship is also addressing the geopolitics of death in warfare (including genocide and civilian “collateral” deaths), judicial death sentences, and life on death row as well as the politics of death through gendered violence such as domestic violence, misnamed “honor” killings, sexually motivated attacks, and femicide on the US–Mexican border. Human discourses of entitlement to kill other animals for food and other products are a growing area of engagement within geographies of death. The environmental politics of sustainability and carbon-reducing lifestyles have also prompted shifts in attitudes to burial and cremation, influencing post-life consumption and disposal choices in the West, with the growing “natural” or woodland burial movements and the disposal and mourning rites in non-European cultures drawing attention from geographers. Social changes deriving from the religious needs of migrant communities have also prompted work on the political, social, and cultural geographies associated with particular
migrant communities, for example, the growing need for Muslim cemeteries in Western Europe and the campaign for open-air Hindu cremation in the United Kingdom.

Geographies of death is a revitalized field where much-needed work on situated class, gender, cultural and ethnic experiences of death, mourning, and remembrance is emerging, as is Butler-influenced work on grievability and killability, economies of mourning, and posthuman grief.

Further reading

Emerging in the mid-1990s, the term “geographies of exclusion” refers to the subtle and not so subtle signals that some social groups are not welcome in urban and rural spaces and thus experience sociospatial exclusion. This builds on ideas around socially constructed structural differences, and in particular the sense that some forms of visible difference from mainstream society can lead to experiences of not belonging in public spaces, or an inability to participate fully in social, community, economic, and cultural institutions.

The phrase “geographies of exclusion” was coined by David Sibley in his 1995 book of the title. Sibley argues that social exclusion within Western society develops from a fear of the other and manifests itself through the social codes that determine how places such as the shopping mall, the street, countryside, and leisure sites are to be used. For instance, he describes how groups of teenagers can be viewed as rowdy by shopping mall security guards and removed from the semipublic space of the mall, and how New Age travelers are depicted as a nuisance in the English countryside because they diverge from mainstream views of how rural spaces should be used and become the focus of social and political pressure to move on. Exclusion is achieved through negative interaction and nuanced forms of social pressure that build on structural exclusions along gender, race, ethnic, or class lines, among others (rather than through physical boundaries and borders); this suggests that an unwillingness or inability to fit into dominant ways of understanding social interaction can have profound repercussions for those who are excluded. David Sibley links these anxieties about different social groups to historic fears of moral pollution and discomfort with ambiguity, and notes that the ways in which such social exclusions are put into practice create patterns (or geographies) of exclusion.

These ideas have been both taken up and challenged by geographers. Parr, Philo, and Burns (2004), for instance, have argued for a need to think about degrees of exclusion and inclusion, and outline how the same group of people can at various times be both welcomed and pushed aside. The result is a more complex pattern of exclusion which makes it difficult to conceptualize groups of people as being excluded and of certain spaces as being entirely exclusionary. This is a point also taken up by Angus Cameron (2006) who warns that, in speaking of a binary of exclusion/inclusion, we may be indirectly affirming these divisions and perpetuating the social and spatial divisions challenged by this analysis. Research around these issues has moved toward documenting not only who is excluded but also who is doing the excluding.

Overview of human–environment geography

Human–environment geography, comprised of forms of knowledge that integrate the in-depth analysis of both human–social conditions in their interactions with the environment and the dynamics of the biogeophysical world, is also referred to as environmental, nature–society, and environment and society geography (Castree, Demeritt, and Liverman 2009). By integrating across the discipline’s human–environment divide, these forms of knowledge are distinct relative to other subfields (Zimmerer 2007, 2010). Human–environment geography often combines in-depth empirical research with the synthesis of information through conceptual frameworks and models. One of the leaders of human–environment geography, B.L. Turner II, has referred to this defining characteristic as the “specialist-synthesis merger.” (Turner’s works, and those of others, establish the use of the dash in human–environment geography.) The realm of human–environment studies in geography incorporates a diverse range of actively evolving approaches and interests. Variety and depth of the new knowledge systems in this realm are expanding amid the intensifying interactions and complex new relations of human societies and environments.

The accelerated intensification and potentially novel forms of current human–environment interactions are indicative of pronounced change as well as a sign of the expanded importance of this subfield. These trends are resulting in both a further strengthening of the core nodes of topical and thematic interest and, also, the rise of new issues and approaches. The factors that influence human–environment geography’s current phase include neoliberal globalization, urbanization, global environmental changes (e.g., biodiversity loss, climate change, food security issues), industrial ecology (e.g., energy and mining), population dynamics including the size, movement, and gendering of demographic factors (e.g., migration), the politics of so-called environmental security, and the growth of environment–related citizenship and social movements.

Several of the human–environment approaches responding to current changes are termed blended studies and hybrid sciences. These knowledge systems are synthesizing information, analytics, and interpretation across multiple areas of human–environment study. Such “blended human–environment studies” are characteristic of state-of-the-art knowledge and are a response, in part, to the unprecedented social urgency and complexity of environmental issues being encountered in the Anthropocene.

The Anthropocene is a term under consideration by leading scientific institutions (such as the Geologic Society of London and the Geologic Society of America) to demarcate the new geologic epoch distinguishable through the magnitude of human impacts on the Earth’s environments. The term Anthropocene also evokes
GEOGRAPHY AND THE STUDY OF HUMAN–ENVIRONMENT RELATIONS

the graphic image of planetary environmental boundaries, in which it is estimated that three of the eight most important global environmental systems currently approximate or exceed the limits of planetary sustainability (biodiversity, climate, and the nitrogen cycle) as the result of human activities. At least a couple others, namely water and land use, are significantly nearing the planetary environmental limits. Regardless of the eventual nomenclatural decision – whether or not the term Anthropocene is officially designated to denote the current geologic epoch (i.e., to follow the Holocene epoch) – it is clear that the scope of human–environment interactions has gained importance.

As a result of the aforementioned factors, the existing elements of human–environment inquiry and understanding are varied and dynamic within contemporary geography. Taken together, these human–environment approaches are clustered into nine identifiable nodes. The contours of this expansive human–environment terrain in geography are shaped principally through research and scholarship. Other influences in the coalescence of these nine nodes include the analysis and implementation of “real-world” environmental governance at multiple scales, practical applications to resource management, and environmental activism and public awareness.

This surge of interest, ideas, debate, and practice is transforming the range of human–environment knowledge systems as they seek to respond to ongoing changes beyond geography per se. Major influences currently reshaping various parts of human–environment geography range from the pivotal reconfiguring of post-structural theory in the academy to the amassing impacts of anthropogenic environmental changes leading to major societal challenges and uncertainty. Tracing the outlines of these influences can begin with the significant expansion and diversification of the human–environment sciences and scholarship through the restructuring of the academy during the 1990s and 2000s to the present (Turner 2002; Zimmerer 2010). The academic “restructuring” in these accounts refers to the influential expansion and consolidation of powerful interdisciplinary fields, such as environmental studies, the environmental sciences (including such offshoots as sustainability science), and ecological approaches incorporating social analysis as well as concomitant changes in the structure and organization of research funding. These academic shifts are leading to both new blended approaches that have recently arisen (see below) and the nodes of specialization in human–environment geography.

The contours of current human–environment geography also have significant influences outside the boundaries of academe per se. These influences stem from the increased awareness of abrupt, socially disruptive environmental changes associated with biogeophysical systems (e.g., climate change, ocean acidification, water shortage, and storm intensity). “Biogeophysical” is an appropriate term that reflects a view of the environment made up of biogeographic, geosystem, and physical geographic factors. Powerful influences arise from the policy, politics, and social issues of human–social endeavors concerning the environment. Recent trends of human–environment geography highlight the need to situate the dynamic biogeophysical changes in interacting scales of space and time. Human–environment geography is focused on the biogeophysical elements of change from a perspective centered on the interactions and entanglements with modern human societies, political economies, environmentalism, and environmental movements. Such forces exert major direct influences on human–environment studies.
The dynamism of human–environment studies has contributed to its widespread recognition as vital in the contemporary discipline of geography. In general, two disciplinary structures predominate. First is the view of human–environment geography as a kind of overlapping connective tissue across the skeletal disciplinary structure of human geography and physical geography. This treatment of human–environment geography tends to rely on a framework in which nature serves as backdrop to the analysis of social, economic, and political dynamics (in the case of human geography) or as a kind of triggering release that produces impacts on the dynamics of environmental systems (in the case of physical geography).

In a second predominant mode of disciplinary configuration the treatment of human–environment geography – which is used synonymously with “nature–society geography” (see Zimmerer 2010) – is situated as a principal and discrete core of the four-field or five-field framework of the discipline. The four-field framework, for example, recognizes human–environment geography (or nature–society geography as it is sometimes called) in conjunction with physical geography, human geography, and GIScience, with the last mentioned encompassing cartography and visualization. A five-field approach to the discipline also implemented, spreads human geography into multiple subcategories that include economic geography and regional development.

While the abovementioned modes of disciplinary configurations are distinct, each recognizes and highlights the role of human–environment geography as crucial to the potential of far-reaching intradisciplinarity within geography. Extended also to radical intradisciplinarity, this trend recognizes the major role of human–environment interactions and nature–society relations within diverse undertakings in contemporary geography (Zimmerer 2007). Whether viewed as “borderlands” or “embeddedness” the intellectual space of human–environment studies enables synapses across many highly active areas of current geography (Table 1).

Overall, a trend toward intellectual diversification is characteristic of the current status of human–environment geography. This diversification is reflective of the general pattern of multi-strand branching and transformations in areas of thought in human–environment geography, albeit in the absence presently of a single or small number of dominant paradigms. By contrast, much of the history of human–environment geography was previously distinguished by the existence of preeminent paradigms. The delineations of cultural ecology and human ecology, which became popular in the 1960s and 1970s, have continued to evolve and diversify in the context of geography as well as other disciplines and interdisciplinary fields. “Cultural ecology” is now used to refer to human–environment studies with a significant component of cultural studies, as in the works of Doolittle, Head, Knapp, Mathewson, and others; human ecology is focused on a systems-based view of human–environment interactions. Works by Brush, Butzer, Moran, and others delineate the lineage and current usage of human ecology.

As noted below, the strengths of cultural ecology and human ecology subsequently fueled the rise of such major human–environment approaches as social-ecological, land, sustainability, and coupled natural–human system sciences as well as political ecology and environmental history. These approaches have expanded prodigiously since 1990. The approach of political ecology, also rooted in cultural ecology and human ecology, has particularly burgeoned. It includes a subgroup that is focused on

</table>
human–environment interactions. This inclusion grew from the founding text of political ecology, *Land Degradation and Society*, that was authored in 1987 by Piers Blaikie and Harold Brookfield. Subsequently, political ecology was advanced in the series of texts that were launched in the late 1990s and early 2000s by authors such as Bryant and Bailey, Forsyth, Hecht, Martínez-Alíer, McCarthy, Neumann, Robbins, Rocheleau and Thomas-Slayter, Schroeder, Sullivan and Stott, Wolford, and Zimmerer and Bassett among others. Each of these works includes an emphasis on human–environment relations.

Subsequent developments of human–environment geography (2005–2015, detailed below) have taken hold as a result of the influences of both fields outside geography as well as disciplinary particulars. Consequently, human–environment studies in geography must be viewed as closely related to state-of-the-art developments in other disciplines and interdisciplinary fields. For example,
the extensive interdisciplinary dimension of human–environment geography is key to the suggested reinvention of US geography as an “interdisciplinary discipline.” This suggestion revolves around the idea of strengthening the discipline-based integrity of geography while emphasizing its interdisciplinary connectivity. Leaving aside the specific pros and cons, as well as the general feasibility, this suggestion is important with regard to underscoring the highly interdisciplinary nature of human–environment studies.

Important parallels to the high level of interdisciplinarity of human–environment geography are also found in the related fields of ecology, economics, sociology, anthropology, archaeology, history, political science, and landscape architecture. Active authors of major works based in these other human–environment fields include Belsky, Besky, Bieling, Blesch, Brondizio, Brosius, Carey, Clark, Collins, Craib, Cronon, Curran, Dove, Durham, Escobar, Fischer, Fischer-Kowalski, Foley, Friedmann, Goldman and Schurman, Grau, Hinrichs, Ingold, Irwin, Kirch, Kloppenburg, Langston, Loos, J. Liu, McMichael, Matson, Mittman, Moran, Morrisson, Nadasdy, Nazarea, Nelson, Padoch, Peluso, Perz, Plieninger, Rhoades, T. Roberts, Rudel, A. Sachs, Saito, Scoones, Stedman, Tucker, and R. White. Some of the major interdisciplinary fields important to human–environment geography are those of ecology and society initiatives, environmental studies, environment science, development studies, food studies, global studies, urban studies and urbanization sciences, and programs focused on climate change, biodiversity conservation and conservation biology, human ecology, social ecology, political ecology, and environmental policy and management (Table 2).

Prominent instances of the successful interdisciplinary of human–environment geography involve a number of the approaches mentioned above – such as the ones focusing on sustainability, social-ecological systems, vulnerability and resilience, land systems, and coupled natural–human system sciences. Geographic authors active and influential in these interdisciplinary human–environment domains include Adger, Aspinall, Bassett, Bebbington, Brannstrom, D. Brown, K. Brown, Chowdhury, Coomes, Cutter, DeFries, Eakin, Evans, Haase, Hostert, Kasperson, Kates, Kreutzmann, Kümmerle, Liv- erman, Lambin, McSweeney, Mertz, Moseley, Munroe, Radel, Reenberg, Seto, Southworth, Tschakert, B.L. Turner II, M. Turner, Vadujenc, Walker, Walsh, Wilbanks, Young, and Zimmerer, among many others. In addition to journals in geography and other fields, these works appear in high-impact science journals such as Nature, Science, and the US Proceedings of the National Academy of Sciences (PNAS) as well as other interdisciplinary journals with central emphasis on human–environment interactions, such as Global Environmental Change, Annual Review of Environment and Resources, Society and Natural Resources, Regional Environmental Change, and Ecological Applications.

In conjunction with these previous developments new insights are now addressing the challenges and potential tradeoffs of pronounced interdisciplinarity as it relates to human–environment geography. One possible tradeoff is the attenuation of cohesiveness of human–environment geography as a center within the discipline. The discussion of such potential tradeoffs has become vital in geography as well as other disciplines, such as anthropology, where interdisciplinarity has become vital and integral to the discipline itself. Internationally the influence of interdisciplinarity on human–environment geography, along with the discipline of geography in general, can vary significantly in extent and degree. In the United
States, for example, where geography is a discipline of small to moderate size, interdisciplinary influences are prevalent in human–environment studies. The influences include the role of the National Research Council and its major reports on geography in 1997 and 2010. A lesser degree of interdisciplinarity tends to occur in Britain where the discipline of geography enjoys significantly greater size and strength, and can therefore draw to a greater degree on intradisciplinarity in human–environment studies. The relative extents of environmental interdisciplinarity and intradisciplinarity have also become varied in the diverse countries of Europe, Asia, Africa, and Latin America.

Continuities and abiding influences also remain important to the understanding of human–environment studies in the discipline of geography and other fields. This theme of continuities can be used as a guide to uncover influential legacies. Viewed historically, a pair of well-defined channels of human–environment endeavors had long shaped the characteristic landscape of geography, especially in the US context of the discipline (Zimmerer 2010). One brings together landscape approaches based upon a cultural-historical framework. The other consists of the studies of recent human and social interactions with environmental changes. It has tended to focus on floodplain and other forms of resource management along with other practical applications.

The former is often referred to as the Berkeley or Sauerian School while the latter is termed the Chicago School. The Sauerian School used ecological science in order to offer cultural and historical interpretations, and thus can be thought of as adopting a cultural-historical ecology. The Chicago School used ecology explicitly in models of human–ecological interaction. As a whole, ecology was both a cornerstone and a chimera in these human–environment approaches since its usage could range from being central, mechanistic, metaphorical, or, at the other extreme, almost entirely implicit and unacknowledged. Nonetheless, this pair of parallel channels defined much of the landscape of human–environment studies in geography, especially between the early twentieth century and the 1960s. The depth and continuity of these approaches can be traced to current major nodes, such as environmental landscape history and ideas (Sauerian School influence) and the focus areas of environmental hazards, risks, vulnerability and resilience (Chicago School influence).

This pair of predominant traditions, the Sauerian and Chicago Schools, functioned for decades as a defining intellectual landscape seemingly comprised of twin gorges incised ever more deeply in geography’s intellectual landscape, each with ample depth and continuity, into the 1980s. Subsequent recontouring occurred in a transition to multiple, diverse approaches to human–environment studies in geography that continue today. This transition evokes the image of a braided stream with multiple channels. Braided-stream topography is an apt metaphor for the combined distinctness and interconnectedness of multiple topical and thematic nodes within current human–environment geography. The braided-stream image also provides the connotations of directionality and crossing-over – anastomosing in stream geomorphology – that reflects the reality of several co-existing current trends, as well as the ample continuity that can be traced to the powerful precedence of earlier flows where upstream intellectual topography continues to exert major influences. The twin channels of the intellectual landscape serve as an important complement to another spatial metaphor of human–environment geography, namely the image of spirals, bridges, and tunnels put forth in the work of B.L. Turner II.
Topics and approaches in human–environment geography

Well-established topical and thematic nodes of research and understanding are characteristic of human–environment geography. These core areas tend to cluster around nine nodes: (i) human–environment interactions in hazards, risk, vulnerability, and resilience; (ii) land use, land systems, land change, and biodiversity; (iii) social–ecological and coupled human–environment systems; (iv) political ecology, environmental governance, and human–environment relations; (v) human–environment relations in livelihoods and agricultural landscapes; (vi) resource political economy, management, and politics; (vii) food, health, and bodies in relation to the environment; (viii) environmental landscape history and ideas; and (ix) knowledge concepts in environmental management and policy.

Each node is distinct yet related and often intersecting significantly, as described in the examples mentioned below and illustrated in Table 2. In addition, the core areas can be loosely grouped into a pair of general thematic areas within human–environment geography, namely “human–environment interactions” and “nature–society relations.” Each individual node of human–environment geography is differentially situated with respect to this pair of thematic areas, and tends to reflect distinct and differentiated intellectual locations with regard to methodological and conceptual domains in human geography, physical geography, and GIScience. As discussed below, for example, the general theme of human–environment interactions tends to ally most fully with environmental hazards, risk, vulnerability, and resilience and, also, to the area of land use, land systems, and land change. In general, it ties to physical and economic geography. On the other hand, the general theme of nature–society relations is associated most closely with political ecology, with defining connections to human geography.

Human–environment relations in hazards, risks, vulnerability, and resilience

One prominent core of human–environment geography is comprised of the studies of environmental hazards, risks, vulnerability, and resilience. Environmental hazards and risks are significant themes that have continued to evolve in the context of accelerated global biogeophysical and socioeconomic changes and their human–environment interactions manifest in response to such disruptive environmental events as drought and floods as well as price shocks and the collapse of institutions. Vulnerability and resilience have become increasingly widespread concepts incorporating human–environment interactions. For example, combined social and environmental dynamics of vulnerability have become a cornerstone recognized within human–environment geography as well as geography in general (Cutter 2003). Such works tend to establish a view of vulnerability, hazards, and risks as processes involving the behaviors and multilayered networks of social actors and institutions.

At the same time, environmental shocks, such as climate–driven effects, can lead to the utilization of adaptive capacities whereby the institutional capabilities mobilized in human–environment interactions can result in significant socioeconomic benefit, such as was the case among certain forest–dwelling smallholder land users in Central America in the wake of Hurricane Mitch in 1998 (McSweeney and Coomes 2011). Equally important, the social conditions and power dynamics underlying vulnerability lead to a prevalent use of political ecology (see critique in Mustafa 2005), with attention to
such issues as social “winners and losers” in these processes and spatial patterns. Additional prominent authors in this topical and thematic area of human–environment geography include Adger, Barnes, Birkenholtz, Cutter, Downing, Eakin, Krueger, Leichenko, Liverman, Montz and Tobin, Mertz, Mortimore, O’Brien, Polsky, Ribot, Smit, Tschakert, and B.L. Turner II. This area shows close connections to various interdisciplinary fields (Table 2).

**Land use, land systems, land change, and biodiversity**

This topical and thematic area is focused to date on human–environment dynamics involving the spatial and temporal properties of vegetative cover, principally forests and urban spaces. It is closely associated with land change science, which has been subject to influential definitions and conceptual framework-building in the interdisciplinary scientific literature by human–environment authors such as Aspinall, D. Brown, Chowdhury, Crews-Meyer, DeFries, Evans, Hostert, Kümmerle, Lambin, Manson, Moran, Munroe, Parker, Reenberg, Rindfuss, Rudel, Seto, B.L. Turner II, Verberg, and Walsh. Methodologically this focus area tends to make extensive use of the combination of remotely sensed imagery, surveys of land users, and census data. The observation of major shifts of vegetative cover is considered in the context of spatial land-use systems (sometimes referred to as “land systems”) and land-cover change. Significant attention and insight thus far has focused on the entwined spatial and socioeconomic processes of deforestation involving conversions to pastureland and agriculture, as well as the regrowth of forest through so-called secondary forest transitions. Linkages to biodiversity are sometimes inferred in these studies, while they hold considerable future promise with increased use of methods incorporating the human–environment, ecological, and taxonomic assessments of biodiversity.

The changes of vegetative cover areas are linked to models of micro- and macrolevel economic and political factors ranging from household labor availability to national and international economic policies (Coomes, Barham, and Takasaki 2004). Several important studies have been located in regions of the world’s major tropical forests (especially the tropical humid forests or “tropical rain forests”), such as the Amazon Basin of Brazil and neighboring countries (e.g., Bolivia, Peru, Ecuador, Colombia) and Mexico and Central America. Forest areas of other tropical regions in Africa and Asia as well as temperate-zone forests (e.g., Europe and the United States), have also been the subject of these studies. Global market integration and postsocialist transitions, to name only a couple, are commonly incorporated as factors on the human–social side. Influential authors that have offered significant advances to this topical and thematic area, in addition to those persons mentioned above, include Aide, Arrima, Caldas, Chowdhury, Evans, Hostert, Klepeis, Kümmerle, Kreutzmann, Millington, Müller, Munroe, Ramankutty, Redo, Southworth and R. Walker. Human decision-making, social movements, governance preferences and disputes, and the active alteration of land use (“agency”) exert feedbacks whereby these modifications and activities contribute to the subsequent reworking of human–social conditions (“structure”). Human–environment interactions are understood explicitly as bidirectional and central to this framing. Here the concept of so-called structuration is being used to understand the bidirectional linkages of land use. Authors of major works on this use of the structuration theme in human–environment
geography and the study of human–environment relations

The frameworks of social-ecological systems (SES) and coupled human–environment systems are conceptual cornerstones in interdisciplinary human–environment studies that connect a thriving interdisciplinary domain to a focus within geography. SES is focused on human–social systems and the management and governance of resources. It owes much to the contributions of Nobel Prize winner Elinor Ostrom and to the legacy of earlier works examining the “tragedy of the commons” not as a demographically and culturally driven fait accompli but rather through social institutional processes. The SES framework often focuses also on interactions across the realms of humans and nonhumans. One chief SES contribution in human–environment geography is the development of ideas and examples of resilience, vulnerability, and adaptive capacity. These are being applied, for example, to the analysis of biodiversity in agroecosystems undergoing intensification and livelihood diversification (Zimmerer 2013; see also Beymer-Farris, Bassett, and Bryceson 2012).

The framework of coupled human–environment systems, also termed coupled natural–human systems (CNHS), is built upon the defining idea of coupled drivers emanating from human–social factors and feedbacks from natural systems. The coupled system CNHS perspective was initially proposed by Liu and others in the early 2000s. In human–environment geography the CNHS framework has been applied principally to the use and management of water resources and forests. Major authors in the topical and thematic areas of SES and CNHS, who come to these frameworks from the perspective of human–environment geography, include Bury, Eakin, Evans, French, Leichenko, López-Carr, and O’Brien, B.L. Turner II, and Wrathall.

Political ecology and human–environment relations

Political ecology is a burgeoning field covering many areas that include human–environment relations and interactions. It is a significant albeit minor portion of political ecology that undertakes the integration of environmental and ecological analysis (Zimmerer 2015). At the same time, the major share of political ecology is focused on nature–society relations, especially social power relations in resource conflict and coordination, environmental representations, and the roles of multiple environmental knowledge systems.

One productive subset of political ecology centered on human–environment interactions is the analysis of global climate change in relation to policy initiatives and political issues associated with sustainability, globalization, and neoliberal management (Liverman 2004). This work combines a perspective on human–environment interactions and the biogeophysical dynamics of climate change in order to better understand multiscale governance amid dominant political economic regimes, in particular neoliberal globalization. Another noteworthy subset is concerned with the multiscale political and environmental dynamics of national and international governance along with the community- and user-based management of fisheries, marine organisms, and forest and range resources. Technological change in these resource systems is often fundamental to the issues of environmental governance and to the forms of social and political coordination and contestation that arise.
GEOGRAPHY AND THE STUDY OF HUMAN–ENVIRONMENT RELATIONS

Human–environment interactions involving fisheries, grazing, and forest resources are often explicitly territorial and thus well-suited to studies that incorporate the geographic themes of territory-making and territoriality.

Still another subset of political ecology studies is concerned with the governance of water resources though social power dynamics involving planning, climate change, agriculture and land use, and international relations. Here too spatial and territorial designs are often explicit in such initiatives as the increased privatization of water supplies occurring in neoliberal globalization. Urban political ecology is notable for its examination of the roles of social and political power of the human–environment interactions involving water resources. Gendered dimensions of social power are often influential in determining control and access to water resources. Not coincidentally, the approach of feminist political ecology (FPE) has been productive and influential in understanding the human–environment geography of water resources. It is also opening new vistas that include major connections to such resource systems as biodiversity management, forest resources, and energy systems. Major geographic authors in the topical and thematic area described thus far in this subsection – in addition to those mentioned in the general introduction – include Baka, Bakker, Bassett, Bell, Birkenholtz, C. Brown, Bridge, Campbell, Carr, Emel, L. Harris, Hecht, Heynen, Huber, Kaika, Mutersbaugh, Mansfield, McCarthy, Neumann, Nightingale, O’Reilly, Perreault, Rocheleau, St Martin, Shapiro, Sneddon, Sultana, Swynge-douw, M.D. Turner, Wolford, and others.

Biodiversity management and environmental conservation are also a focus of human–environment analysis in political ecology. This focus is often centered on environmental management in the design of protected areas (PAs) (see Environmental management). The spatial extent and number of protected areas have increased worldwide in significant ways since the widespread accounting and monitoring of these units began a few decades ago. Diversity of environmental management schemes is also much increased within protected areas. One reason for this additional complexity is that protected areas have become more commonly designated in categories associated with human use and activities (e.g., “buffer zones”), rather than being strict set-asides intended to eliminate or prevent the presence of humans. As a result of these trends, human–environment geography and the recognized role of these interactions are now increasingly important to the environmental management of protected areas globally.

Still another topical and thematic area is concerned with the mix of issues related to agriculture, food security, land tenure, policy-related land change, pesticide use and transgenics, and agrarian reform and policy institutions, including urban and peri-urban food systems and land use. This mix has become part of a significant emphasis on agri-food systems, both expanding global industrial agriculture that is based on biotechnology and that incorporates a growing corporate organic sector, as well as alternative and local systems that include efforts to conserve agricultural landscapes and biota. The topics and themes mentioned in this paragraph and that preceding are being productively investigated through the perspective of human–environment geography by such authors as W. Adams, Bassett, Braun, Bezner-Kerr, Brannstrom, Buck, Campbell, Carney, Freidberg, Galt, Guthman, Graddy, Jarosz, Jepson, B. King, Kosek, McAfee, Medley, Mosely, Naughton, Neumann, Roth, Sayre, Schroeder, Wainwright, Wolford, Young, and Zimmerer.

The topical and thematic area of political ecology, as synopsized here, is illustrative of
the cross-cutting among the nine nodes identified in this section. This particular subsection contains a major emphasis on environmental governance and its influence through the forces and dynamics of political economy. Environmental governance, as it is broadly defined by Agrawal, Bulkeley, Heynen, Lemos, Liverman, McCarthy, Perreault, Prudham, Timmons, O. Young, and others, refers to environment-related institutions, plans, knowledge, management, decision-making, and practices. Yet the focus of political ecology on environmental governance is widely shared and must be appreciated as an example of cross-cutting topical and thematic influences. This theme is addressed as a major focus in several of the other principal topical and thematic areas currently active within human–environment geography. For instance, social-ecological systems (SES), mentioned above, are also focused extensively on environmental governance.

Other topical and thematic nodes identified here also evidence the significant focus on environmental governance. These include environmental hazards, risks, vulnerability, and resilience; land-use systems, land change, and biodiversity; environmental landscape history and ideas; and scientific concepts in environmental management and policy. In sum, each of these areas addresses environmental governance in a distinct and important way that needs to be distinguished in current human–environment studies. Another cross-cutting focus is concerned with the human–environment concepts of adaptation, resilience, and vulnerability. While adopted most extensively within the area of social-ecological and coupled systems, the concepts of adaptation, resilience, and vulnerability are also part of an expanding focus in political ecology by such authors as Bassett and Fogelman (2013), Beymer-Farris, Bassett, and Bryceson (2012), Ribot (2011), M.D. Turner (2014), and Zimmerer (2013). Butzer, Cote, Eakin, Nightingale, M. Taylor, Tschakert, and Watts, among others, have also authored important contributions in this area.

Livelihoods and agricultural landscapes

This topical and thematic area has arisen partly as a result of global-scale shifts to part-time land use and the importance of diversified livelihoods among the 2.0–2.5 billion smallholders who continue to engage in food production amid major multiscale changes in socioeconomic and environmental conditions. Emphasis on agri-food landscapes and agri-food systems owes in part to the fact that these smallholders include many of the world’s most food-insecure populations. Another important focus involves the extensive empirical analysis and understanding of the increasing roles of urbanization, livelihood diversification, and development on land use. These drivers incur complex human–environment relations involving agriculture, food, and the cover of anthropogenic forests. Diversified livelihoods, including the phenomenon of vast peri-urban peripheries and the “new rurality” (defined as the predominance of livelihood diversification, urban connections, and consumptive economic values in the countryside) now impinge directly on large swaths of landscapes and involve the livelihoods of much of the world’s population.

Integration with product and labor markets under neoliberal globalization, including the formation of extensive informal sectors and urban/peri-urban areas, drives many of the human–environment dynamics of development, peri-urban places, and the impacts of the new rurality (Carney 2008; Zimmerer, Carney, and Vanek 2015). The world’s 2.0–2.5 billion smallholder land users are as equally an emphasis as large corporate industrial agriculture. At
the same time, the rise of alternative and local food networks is leading to potentially novel agri-food systems and landscapes in various kinds of places. These networks may exert a sustainability enhancing influence on agriculture and food landscapes in the management of such environmental factors as soil nutrients, food and woodland biodiversity, and farm woodlands. Such human–environment interactions are presently a major priority of new research and understandings being developed and debated in human–environment geography. Authors of major human–environment works on topics and themes covered thus far in this subsection include Baker, Bassett, Bebbington, Carney, Denevan, Doolittle, Galt, L. Gray, Hecht, Hedberg, Lerner, McMichael, Moseley, Price, Radel, Rangan, Rocheleau, Shillington, WinklerPrins, and Zimmerer.

Current human–environment research suggests that the widespread and growing use of migration remittances and other factors linked to part-time land use can exert complex and sometimes favorable influences on environments, forests, and food-growing landscapes. The complex pathways of migration can lead to either the disintensification or intensification of food-producing landscapes, along with either increase or decrease in measures of social equity and environmental quality. In other words, a priori assumptions of determinacy no longer govern the investigation and interpretation of these human–environment dynamics. Instead, research scholars, policymakers, and planners are seeking to understand the conditions under which certain relatively favorable outcomes occur with regard to both migration and the environment.

The array of diverse mechanisms producing these varied human–environment interactions, ranging from labor withdrawal to the intensification of food-producing landscapes, are found to depend on the migration-related factors of remittance and the gendering of decision-making that can impact the specific properties of forest cover and biodiversity. The biodiversity in these food-producing landscapes often incorporates the variation of the biota of food assemblages (“managed agrobiodiversity”) and agroecosystems encompassing below-ground and uncultivated elements (“associated agrobiodiversity”). The geographic range of these food-producing and consuming landscapes, which include gardens, interstitial spaces, and connections among rural, peri-urban, and urban locales, adds further to their complexity (Zimmerer, Carney, and Vanek 2015). Major geographic authors in this area—in addition to those mentioned above—include Coomes, Doolittle, Eakin, Graddy-Lovelace, C. Gray, L. Gray, Hecht, Knapp, Lerner, Momsen, Radel, Schmook, Torres, Vanek, and WinklerPrins.

Human–environment relations in resource political economies, management, and politics

The political economies and politics of many issues of resource governance and politics extend across national and global scales and frequently entail the role of combined urban–rural spaces. The resource systems and the institutions range from minerals and hydrocarbons involving major multinational corporations to urban, village-based, social justice, and industrial issues that are related to water, environmental quality, and waste. Areas of emphasis in human–environment geography include the social dynamics of resource extraction, land and resource grabs, and management as well as related resource and agrarian issues. These social dynamics often entail the role of active social movements with alternative visions of development and social justice. Studies have revealed the complex dynamics and often unanticipated outcomes
of certification programs that appear to foster environmental sustainability outcomes using such resource management as sustainable forestry certification and fair-trade coffee.

Social justice aims may sometimes be incorporated in these programs with such goals as supporting poorer neighborhoods or small-holder farmers. While in certain cases they are well-intentioned, such initiatives may, in fact, not function as hoped, for their desired environmental and social benefits may be either undermined or suffer unintended negative consequences. Contributors of major human–environment research and publications on the range of issues mentioned thus far in this section include Bebbington, Bridge, Bury, Bryant, Calvert, Castree, Emel, Hindery, Huber, Humphreys, Klooster, Labban, Le Billon, Liu, S. Moore, Mutersbaugh, Perreault, Pulido, Silva, Valdivia, Watts, and Wolford.

Trenchant critiques in this area have highlighted the powerful influence of innovative neoliberal policies in prevalent environmental management policies and approaches. Examples include the ecosystem service frameworks that are being applied to reduce deforestation and hopefully invigorate sustainable forest management, to mitigate and manage wetlands while compensating for loss resulting from real estate development, and to restore freshwater stream morphologies and ecological habitats. Market-based environmentalism has become a particularly powerful form of environmental governance under the dominance of neoliberal policies. The spatial design of this governance is one reason among several for the significant increase of human–environment study on urban locales and multiple research sites spanning the Global North and the Global South (Schroeder, St Martin, and Albert 2006). Still other findings are focused on the functioning and environmental impacts of markets as sites of complex activities that may not be distilled entirely into neoliberal logics but rather may be distinguished by embedded relations of trust and knowledge that can support environmentally friendly outcomes. Leading authors in this topical and thematic area include Bakker, Klooster, Keleman and Hellin, Hinrichs, Lave, McAfee, Robertson, and Shapiro.

Human–environment relations: food, health, and bodies

The bodies, health, and nourishment of humans and nonhuman organisms are seen increasingly as being embedded in the matrix of resources and the environment created through human societies. It is an important new topical and thematic area in human–environment geography. Much of the expanding interest in this area is designed to treat issues of health, disease, and the body related to environmental interactions. It is frequently centered on the role of agri-food and fisheries systems that integrate the consumption choices of individuals, communities, and societies together with the transportation networks and agro-ecologies of production systems. The vast majority of consumption, transformation, and production occur through the global corporate, industrial food system. At the same time, growing interest surrounds whether and how the dominant food system is contested and challenged through alternative and local food networks. For example, alternative and local food networks may demonstrate “embeddedness” in which cultural practices and links to ecological landscapes (e.g., conservation agriculture) are considered as simultaneously market-based and potentially involving dimensions that extend beyond economic transactions per se, such as social trust and ethics of care and responsibility.

Hybrid food systems, such as those of peri-urban and urban areas, are also central
to this area of human–environment study. The new direction in human–environment geography described here is also being amplified through new works on the political ecology of health and wellbeing. It includes potential new human–environment insights on bodies in health and disease dynamics linked to the multifaceted role of genetics that is subject to major increases of information and scrutiny. Technological as well as theoretical advances in genetics now highlight the powerful influence of so-called epigenetic effects that result in humans and other organisms being thoroughly embedded in environments in far more extensive and previously unanticipated ways (Guthman and Mansfield 2013). Major geographic authors active in the area covered in this subsection include Bryant, Carter, Durham, Freidberg, Galt, Guthman, Hayes-Conroy, King, Lerner, Mansfield, Morris and Kirwin, Mutersbaugh, Sage, and St Martin.

Environmental landscape history and ideas

The history of environmental landscapes is a major core of human–environment geography that is rooted in a productive past and rapidly evolving productive present state. This topical and thematic area has become transformed in recent years as the result of widespread scientific findings and interpretive shifts, such as postcolonialism. It is being re-invigorated in the light of today’s recognition of global environmental change. This recognition tends to intersect in illuminating ways with influential re-framings of the so-called end of nature and the treatment of the current geologic epoch as the Anthropocene. The history of human–environment interactions in particular landscapes is providing important new insights on the nature of these changes as combined resilience, change, transformation, and, in some cases, the collapse of human societies owing to combined human–environment factors (Butzer and Endfield 2012). The insights extend to a cascade of human–environment works in geography using historical frameworks to demonstrate and detail both the transformation and the resilience of environmental landscapes under anthropogenic change across the time spans of multiple centuries and millennia. They tend to detail chronologies that combine episodes of catastrophic change typically driven through powerful drivers on both sides of human–environment interactions.

The abovementioned findings are often presented as a contrasting and compelling counter-interpretation to purportedly cataclysmic environmental events and narratives of intrinsic marginality that accompanied the earlier interpretations of European colonialism and Euro-American domination of many of the world’s landscapes. Historical resilience of traditional-appearing land use, for example, is shown to also offer potentially innovative contributions to the design of human–environmental sustainability. Leading current authors and established leaders in this topical and thematic area include Beach, Bell, Biehler, Brannstrom, Butzer, Carney, Carter, Colten, D. Davis, Doolittle, Denevan, Dunning, Endfield, Gade, Lightfoot, Lowenthal, Luzzadder-Beach, Myers, Offen, Rangan, Sluyter, B.L. Turner II, Vale, M. Williams, Wilson, and Zimmerer.

Concepts of landscape, including those created through ideas and institutions of environmental governance, are as important as the force of biogeophysical processes on the understandings of this topic. For example, the idea of a “pristine myth,” of nature created in the arts and literature of the Romantic movement in Europe and North America during the nineteenth century, has exerted tremendous albeit misleading influence on environmental understanding. Environmental interpretations steeped in the pristine myth tended to assume the
absence of significant pre-European impacts on the biogeophysical nature of landscapes. While ironically a complete opposite-tending political message, the “empty land” interpretation, an early colonial precursor to the pristine myth (the latter become predominate in the nineteenth century) tended likewise to assume certain ideas about the absence of indigenous presence on the landscape. The legacies of the pristine myth and empty land notions persist to the present, though they are now seen as both more complex and more influential in their spatial and environmental dimensions. For example, they often imply not only the treacherous entwining of the enclosing and erasures of non-Western peoples and their presence but also the creation of relational landscapes comprised of the geographic pairing of unsettled and settled areal expanses suited to European expansions in conjunction with the subjugation of indigenous peoples.

Urban spaces are increasingly understood as having highly dynamic human–environment histories whereby changes, functioning, and morphology of built environments are forged through institutional ideas of resources and landscape. The case of colonial water management in the 1500s in the urban center of Lima, Peru, for example, depended on extensive environmental governance and institutional ideas of resource dynamics and access (Bell 2015). This topical and thematic area can overlap significantly with the approach termed historical political ecology.

The concept of hybrid knowledge systems and spaces has become particularly important to human–environment studies. It is advanced in understandings of such issues as the political ecology of water resources, the production and perception of “invasive” trees in modern forest management, and the territorial designs of networks of protected areas intended for environmental management and conservation use (Zimmerer 2000). Citizen science, based on local knowledge systems, is increasingly promoted in understanding human–environment interactions and the evolving role of the environmental and ecological sciences. Indeed, it appears that citizen science may become a characteristic approach of the Anthropocene as it becomes more widely deployed in myriad projects devoted to understanding present-day environments and human–environment interactions. Important leading authors in the aforementioned topical concepts and ideas has gained new salience amid a broad spectrum of applications in these studies. They have probed and offered insights on such topics as ecological science and concepts related to human–environment dynamics and livelihoods (e.g., the nonequilibrium models of the “new ecology”), the hydrologic cycle, biological conservation corridors, carrying capacity, the science of back-to-nature farming, and scientific forestry management and politics. Technology has also become an area of increased focus in the human–environment analysis of such topics as hydrologic dams and irrigation tube wells that have been spread across large landscape areas (Swyngedouw 1999). These works illustrate the power of scientific ideas and technological tools as deriving from both their geographic dimensions and their usefulness to environmental management as so-called boundary concepts and place-based sites of interaction, negotiation, and dispute.

Human–environment knowledge concepts in environmental management and policy

Knowledge concepts in environmental management and policy comprise an important topic of human–environment geography that spans the diverse domains of advanced science and technology and those of citizen science and local knowledge systems. The history of scientific

New trends in human–environment geography

The accelerating influx of new scientific findings, ideas, and conceptual and theoretical orientations has become a defining characteristic of human–environment geography. Most notable is the increasing rate and scope of anthropogenic environmental change and transformation that now lead human–environment geography, together with other fields, to focus at the intersections of socially vital issues. These topics include the influence and impacts of global climate change on such human–environment systems as water resources, energy, food, health, biodiversity, land systems, and the roles of neoliberal globalization, urbanization, and migration. Framing issues at scales that encompass the global level has become de rigueur in the research design and analysis of human–environment interactions.

Urbanization is also an increasingly predominant theme. For example, new human–environment geography is now focused more extensively on urbanization related to climate change (Leichenko 2011) and also global changes of land systems in a rapidly urbanizing world. Long-distance interactions, referred to as tele-coupling, are increasingly found to link global land and resource use to urbanization impacts and transformations. The powerful influence of these forces of urbanization and industrial expansion has contributed to the important role of cities as sites of much human–environment geography. Leading geographic authors on the kinds of issues mentioned in this paragraph include Braun, Chen, Chowdhury, DeFries, Heynen, Holyfield, Keil, Livermore, Meyers, Munroe, Pelling, Reenberg, Seto, and Swyngedouw.

A second nexus of new intersecting issues is concerned with agri-food systems. This expanded direction in human–environment geography stems in large part from the growing recognition and policy prioritization of the importance of food quality and ecologically sustainable intensification. Major global fora and policy initiatives are being focused on agri-food systems through such high-profile human–environment formulations as sustainable intensification (SI) and ecological intensification (EI) that seek to increase food security while not incurring damage to the environment. Human–environment geography is taking a significant role in addressing these issues through the analysis of converging concerns (Sage 2011; Zimmerer, Carney, and Vanek 2015). One example is the intersecting focus on land systems that, as described above, uses existing methodological designs, tools, and conceptual frameworks to examine land use, its spatial and social organization, and the analysis of land cover and change. Until recently much of the work on land systems dealt principally with deforestation in tropical lowland and temperature areas of tree cover with insights linked to potential biodiversity impacts and climate impacts through influences on carbon stocks and sequestration. Major geographic works addressing these kinds of human–environment issues are authored by Carney, Galt, Moseley, Radel, Sage, Schmook, B.L. Turner II, and Zimmerer, among others.

Agri-food and environmental transformations are also increasingly recognized as integral, often in complex ways, to the human–environment geographies of health and disease (Carter 2014).
Here food and environment mix with political economies and social power dynamics to provide new insights into wellbeing or the lack thereof, since disease dynamics are often wrought through a constellation of similar factors. Agri-food issues are also being expanded in human–environment studies related to the social, spatial, and biogeophysical footprints of energy development, with the emergence of multiple new “energy geographies” highlighting connections to water resources and climate change as some of the latter’s most powerful cause–effect anthropogenic pathways.

Intersections with climate change lead to the most prevalent overarching concern invoked in the current framing of human–environment geography around intersectional issues. Climate change is unleashing growing impacts on such issues as agri-food, health and disease, and energy. These connections are redefining human–environment studies in the discipline of geography as well as more broadly across interdisciplinary endeavors. Impacts of the issue of climate change are also deeply impacting other human–environment disciplines such as anthropology. Major current contributions to the kinds of issues addressed here are authored by Agrawal, Barnes, Brondizio, Calvert, Crate, Dove, Liverman, Moran, Nelson, Orlove, Redman, and Ribot.

The combination of reflexive and instrumental elements is a trend characteristic of works in human–environment geography. Reflexive here refers to the element of critique and broadly defined social analysis that draws on growing social studies of the science, with the latter broadly defined to range from ecology and toxicology to genetics and human biology (Zimmerer 2015). The meaning of instrumental in these examples refers to the practice and application of science and scholarship in human–environment analysis (e.g., identifying the causes and consequences of anthropogenic climate change). Consideration of the reflexive–instrumental integration is a topic of works authored by Forsyth, Goldman, and Turner, among others, that have helped understand and advance this important new trend. Additional significance of this trend stems from the writings of major current social analysts – such as Bruno Latour and Michael Burawoy – who have recently advocated for combined reflexive–instrumental forms of environmental and social knowledge systems.

Examples of the integrated reflexive–instrumental perspective include the studies within human–environment geography that are engaged with the rapidly evolving role and use of ecological and environmental science in political ecology. In addition, the reflexive–instrumental perspective is proving fruitful in developing, using, and critically reflecting on several of the leading current theories and concepts within human–environment geography, especially those of resilience, adaptation, and vulnerability (Bassett and Fogelman 2013; Beymer-Farris, Bassett, and Bryceson 2012; Ribot 2011; Turner 2014). Such studies are able to respond to the increasing social content of scientific concepts amid the accelerating and widening influence of global socioeconomic and environmental changes in such issues as climate change and water resources. Additional leading researchers and authors currently active in this field are Birkenholtz, Lave, McCarthy, Nightingale, Sayre, and Sultana.

Understanding the human–environment impacts and social dynamics of neoliberalism operating across multiple spatial and temporal scales is another trend that defines current human–environment geography. New studies and understandings emphasize the powerful influence on human–environment systems of the political economy, politics, and subjectivities
of constantly evolving neoliberal configurations. The human–environment implications of neoliberalism incorporate factors that range from major global commodity booms (minerals and hydrocarbon-based energy, as well as soy and oil palm) to neoliberal-inflected environmental management and science. The influence of neoliberalism extends also to the protest and social movements among worker, citizen, and peasant groups arising in response to these developments.

Even such alternative movements as those associated with Living Well, which is cast as an alternative to neoliberal development, are unfolding amid the latter's influences. Neoliberalism's vast reach in the realm of resources and the environment thus extends from explicit "market environmentalism" and sustainability payment schemes to extractive industries and far-reaching subjectivities contained in prevailing ideas of citizenship and, more generally, one's sense of community belonging and modernization. Major current contributions to the kinds of issues addressed here are authored by Bakker, Lave, McAfee, McCarthy, Prudham, and Wolford, among others.

Important insights are being revealed in the pronounced influence of neoliberalism – often evidenced through its logics of accounting, metrics, and fungibility – pronounced in such mainstream approaches to environmental management as ecosystem services and territorial designs for nature protection (such as protected areas). Agri-food systems also show the powerful effects of neoliberalism in the dynamic evolution of corporate, industrial systems that effectively utilize global supply chains and consumers' choices on a daily basis. Similar to the examples mentioned in the previous paragraph the neoliberal development of agri-food systems is also unleashing potential alternatives. The human–environment dimension of the international trade in illicit drugs can also be seen as symptomatic of the far-reaching scope of neoliberal market influences. It exerts significant influence on land systems and biodiversity impacts in extensive areas. Major current contributions to the kinds of issues addressed in this pair of paragraphs are authored by Galt, Guthman, McSweeney, and Steinberg.

An additional trend is the productive unfolding of the engagement with concepts of embodiment and perspectival frames. It stems from such diverse influences as technological transformations (e.g., cyborgs) and feminist critiques of science and human–environment studies (e.g., feminist political ecology). These insights are reshaping such foundational concepts as the dualistic assumption underlying human–environment interaction and the "chain of explanation" of interlinked scales of influence in human–environment interactions (Rocheleau and Roth 2007). The existing precepts hinge, respectively, on assumptions of the categorical distinction of humans and the environments as well as non-overlapping scalar processes. Rather than binary-based interactions and neatly nested scales, the new works build on insights resembling human–environment geography's early clarion call to examine the "inner-actions." Rocheleau and her colleagues have written leading publications in this area, which builds on important prior insights by researchers and writers such as Michael Watts.

Theories and concepts of hybridization, socionatural entanglement, and epigenetics have also become central to understanding the multifaceted, reciprocal, and relational intermingling of the natural and social (Guthman and Mansfield 2013; Zimmerer 2000). The process of intermingling among human and nonhuman elements, which is less structured than the earlier image of co-production, bears
broad-brush similarities to the interests and influence of assemblage theory, which likewise strives to incorporate human and nonhuman actors and elements. The new direction in human–environment geography described here is contributing also to rethinking issues of scale and the patterns and processes of scaling that are central to human–environment studies. Important active writers across the areas mentioned in this paragraph include Anderson and McFarlane, Braun, Heynen, McCarthy, Neumann, Rice, Sayre, Shillington, Swyngedouw, Whatmore, and Yeh, among others.

Promise and peril: beyond binaries in human–environment geography

Human–environment geography is currently being defined through a multiplicity of topics and trends. These developments hold both promise and peril for its future. They have been spurred through a remarkable growth of the productivity of research scholarship. While numerical estimates are difficult, one coarse approximation demonstrates a roughly four-fold increase in the 1990s alone with the impression of a similar rate of continued growth in these studies to the present (Zimmerer 2010). To be sure, the arena of human–environment studies was already active in much of the mid-twentieth century. Still it was decidedly thinner and less diverse, being dominated by the two-channel intellectual landscape described above. By the 1970s and 1980s the accelerating developments within human–environment geography foreshadowed a diversification of topics that nowadays ranges widely across global, national, and local levels, urban, peri-urban, and rural spaces, formally regulated and highly informal sectors, from the intensely domesticated to the mostly wild, and multiscale areas of focus from microscale effects at the genome level to the scale of planetary systems.

Mixed methods and matching designs of research methodology have become integral to human–environment geography. Corresponding to its topical and thematic diversification, a swell of research has flooded human–environment geography with an exceptionally broad suite of choices of methods. Both quantitative and qualitative techniques are widely used. Similarly a mix of positivist and varied nonpositivist theoretical orientations has become common, with this critical pluralism emerging through the rapid growth and diversification of human–environment geography. The utility of this “critical pluralism” resonates with the abiding pragmatism of human–environment geography addressed by Wescoat and others. Yet such mixing of methods and concepts does not detract from the importance of generalized distinctions and differentiating theoretical commitments. For example, the large-scale, remote sensing-based human–environment modeling of land use and vegetative cover is often undertaken through the use of knowledge systems quite distinct from that of discourse, whether the latter is global or local in scope (Turner and Robbins 2008). At the same time, there are human–environment works that can and do seek to bridge these gaps, both methodologically and conceptually (Castree, Demeritt, and Liverman 2009; Zimmerer 2015).

In sum, this study’s design has highlighted the intellectual landscape of human–environment geography. A conspicuous feature is the noticeable shift away from the earlier intellectual landscape of binary intellectual spaces. It traces the emergence of the distinctly multistrand configuration of human–environment geography that began in earnest in the 1970s and 1980s and that has flourished since the 1990s. This shift to the post-binary intellectual spaces of human–environment geography has been
entwined with the growth of this area and new efforts to locate its intellectual endeavors within the discipline. This expansion of human–environment geography (or its broad designation as nature–society geography) has helped create the growth of a distinct subfield and intellectual space in the design of so-called four-field or five-field geography. Recent debate and contestation over this distinctness reflects a continued healthy level of intellectual activity in this area of study.

One such central and vigorous debate concerns the degree of distinctness among human–environment and nature–society epistemic centers, and whether and how these knowledge domains may be overlapping in a sense that enables mutual use and possible synergism. For example, a moderate or high level distinctness is illustrated in the depiction of human–environment studies as holding the key to the larger scale of analysis (e.g., global-scale studies) while nature–society is local and based on place-specific case studies (Turner and Robbins 2008). In that research, human–environment studies are represented by sustainability science while the approach of political ecology is used to illustrate a nature–society framework.

It may also be suggested the distinction of these epistemic centers is likely to reside principally in the extensive social and discursive analysis characteristic of nature–society geography. More to the point is the potential value to works that seek to integrate elements of the human–environment epistemic center (e.g., ecological systems, land use, land systems, and remote sensing) and that of nature–society relations (e.g., political ecology). Such integration has been a central, recurring emphasis of various works (e.g., Zimmerer and Bassett 2003). Additional authors of major works that focus on this interface are Bassett, Brannstrom, Beymer-Farris, Chowdhury, B.L. Turner II, M. Turner, and Vadjunec.

Similar ongoing debate concerns the disciplinary niche and openness of human–environment studies. On one hand, this area benefits from active exchanges with interdisciplinary realms as diverse as ecological sciences, urban studies, and environmental studies and philosophy, in addition to development studies, world systems, and political economy. Intellectual borderlands are also vibrant with regard to the other geographic subfields. Related physical geography, for example, incorporates human activities as triggers of disturbance events and management activities that induce the biogeo-physical processes and pathways of vegetative, geomorphic, and climate-driven conditions and changes. Many productive interactions are similarly promised in the interconnections of human–environment studies of land and climate change to human geography in general and economic geography in particular.

A signal of concern does attach to the otherwise positive prospect of future human–environment studies in geography. It suggests the ongoing success, demonstrated through its diversification and expansion amid the recognition of the Anthropocene, may potentially entail tradeoffs. Such developments could lead to a scenario of human–environment issues becoming more widespread as topics of interest while potentially diluting points of specific, concentrated research and understanding. Strengthening coherence and intellectual rigor, while continuing to embrace a characteristic openness and critical pluralism, is both a challenge and opportunity that must be engaged. Doing so is necessary to address the rapidly evolving roles of human–environment geography. Actively engaging such challenges and opportunities must become a priority, both in the discipline of geography and in the broader realms of interdisciplinary environmental studies and sciences.

Internationally, national policies and standards in geography education span a wide range of formats, implementation procedures, and assessments. Some countries engage directly with national policies and standards to create and assess a national curriculum or course of study in geography at both primary and secondary education levels. These national curricula are integrated into the education system and may or may not include teacher training to prepare instructors to teach the required content. Other countries maintain a decentralized or non-federally controlled education system. Efforts made to compare geography education in these various systems are subject to the constraints and limitations of evaluating the different systems in which geography curricula are determined, taught, and assessed.

A comprehensive comparison of geography education curricula at the primary and secondary levels across many countries is not easily produced based on existing literature. Some international efforts provide limited descriptions and some discussion or comparisons of how geography education is included in national education policies and standards. In addition to the policies or political entities influencing geography, there are also differing philosophical approaches to how geography content is presented. Geography is sometimes taught as a natural science, social science, or an integrated study of human–environment interactions. In some cases, a specific geographic approach, such as the spatial and ecological perspectives or space and place, heavily influence the geography content in certain countries. It would be valuable for future publications to include descriptions of the national policies and standards for geography education in more countries to establish more examples to increase the understanding of geography education from an international perspective.

The place and role of geography education varies greatly from country to country. The context of the education system itself provides various settings of distributed, locally controlled systems to nationally controlled or determined curricula. Examples of the standards and national policies in selected countries are provided in this entry. While not intended to be exhaustive, the examples provide a snapshot of the wide scope of geography curricula and national policies in just a few countries with a more detailed discussion of the United States national context. The following countries are highlighted based on recent publications documenting an international effort to examine and compare geography education at the national level.

Case study: Australia

In 2008 the Australian government moved away from geography content determined locally by
GEOGRAPHY EDUCATION: NATIONAL POLICIES AND STANDARDS

states and territories to a national Australian curriculum. The national geography curriculum for primary and secondary schools was approved in 2013. The conceptual and philosophical underpinnings of the new Australian geography curriculum are explained through its definition, concepts, specification of place knowledge, embedding of skills in inquiry, and state or implied perspectives (Maude 2013). Of these concepts, the curriculum tends to differ from some other national curricula in its definition, range and choice of concepts, and specification of place knowledge. The new national curriculum document includes a definition of geography that was accepted as it was inclusive of existing definitions from the states and territories.

The document is built around key concepts that are complex ideas that could not be easily defined, but only described by the ways of thinking they produced (Maude 2013). Twenty-seven points in the curriculum document form a catalog of ways of thinking geographically that are a guide for teachers on the broad geographical understandings students should develop. Previously taught as part of studies in society and environment or human society and its environment at the primary level, the new national curriculum strengthens the position of geography in Australian schools. At the primary and lower secondary levels, there is now a separate and compulsory curriculum for geography. Geography is an elective subject for upper secondary with states or territories having the option to make it a compulsory subject (Maude 2014). The national curriculum board in Australia is called the Australian Curriculum, Assessment and Reporting Authority. This entity established the framework for the curriculum, but did not influence the content which was developed by a group of writers and advisors with oversight and reviews at many levels. The recent transition from state and territory curricula to a national geography curriculum is viewed as a positive change for geography education in Australia.

Case study: Finland

Finland’s geography content has served as a model for other countries in the process of reviewing or updating their national curricula. Finland itself is currently preparing to implement a revised curriculum. The Finnish National Board of Education is the controlling body for a specific core curriculum in Finland. The national curriculum was revised during 2012–2014 and will be implemented in classrooms starting in 2016. The role of the curriculum is highly regarded and importance is placed on the curriculum as a guide for instruction and content throughout the country. There can be some local modifications of the curriculum so long as it still adheres to the national core curriculum. A national education evaluation center was established in 2014 to monitor educational progress in the country.

The curriculum places geography as part of the national core curriculum for grades 1 through 9 or the basic education level. Traditionally, geography is more closely connected with the natural sciences rather than the social sciences. In grades 1–4, geography is taught as a natural science in environmental and natural studies. During grades 5–6, students take a required geography and biology course. And in grades 7–9, a required stand-alone geography course is included in the curriculum (Solem, Lambert, and Tani 2013). In the renewed version, geography will be integrated along with biology, chemistry, physics, and health education as a part of environmental studies for the primary level students.
Case study: Philippines

The Philippines does have a national curriculum, however, geography is not considered a discrete subject in this curriculum. The “K to 12 Basic Education Curriculum” (primary and secondary) was published in 2013 and includes curriculum guides for different subject matter of study. Closer examination of the national “K to 12 Curriculum Guide: Science” reveals an emphasis on inquiry and informed decision-making on issues that involve science, technology, and environment (Republic of the Philippines Department of Education 2013). The earth science components include some physical geography concepts but lack the spatial perspective as a part of study and analysis.

The “K to 12 Basic Education Curriculum Guide: Social Studies” contains seven broad themes that are based on the “US National Council for Social Studies” ten themes for the social studies which is cited as a source. Geography is not identified as a stand-alone discipline but is embedded within the seven themes content. Appearing most often in grades 1 to 4, geography content is very limited in the curriculum. The use of geography skills is referenced at grade 4, but is not used after that in the curriculum sequence. As is the case with most curricula focused around social studies, there is thematic content based on broad concepts or ideas, but a lack of discipline specific content. The diffusion of curriculum ideas between countries seems to be a factor influencing the content of this national curriculum.

Case study: Singapore

The Singapore national curriculum in geography is described by a national syllabus document that is reviewed and subject to change every six years. Geography is included as part of a social studies subject at the primary level and is a compulsory subject in lower secondary levels. At the upper secondary, geography is an elective subject. The national government is very influential in determining the primary and secondary school curriculum. Singapore has been described as using education as an agent for social change (Yip, Eng, and Yap 1997). Government identified issues such as climate change, environmental stewardship, and respect for all cultures are examples of governmental influences on curriculum content. Structured government and Ministry of Education influence guides changes made in the national curriculum for primary and secondary schools. The development of the national syllabus document also includes academic geographers and reflects changes in the discipline heritage as well (Chang 2014).

The geography content at the primary level is expressed through four social studies goals that include the interactions and relationships between humans and physical environment in which they live. The lower secondary school geography is organized according to human or physical geography topics around a central theme of physical–human relationship (Chang 2012). The upper secondary school geography has evolved to a more conceptual approach highlighting the human–environmental and spatial relationships with some recent evidence of changes back to a more regional studies approach (Chang 2014). The geography course at the upper secondary level is elective and results in approximately 50% of students selecting this course. Acknowledging the strong state presence in geography curriculum development and the review process, Chang (2014) describes the necessity for a continuing strong partnership between academic geographers and geography educators in future reviews and discussions of the national syllabus document for Singapore.
Case study: United Kingdom

The geography education standards are part of the national curriculum program of study in the United Kingdom. The current program of study was recently revised and published in 2013 for classroom implementation in 2014. Although it is a national curriculum, individual countries may review the curriculum independently. While England will implement the revised curriculum, Wales is scheduled to conduct a review of the curriculum. Geography is a required subject at primary school level and also in the secondary to 14 years. There is no requirement to offer geography after 14 years, but it is offered in most secondary schools in the country. Geography is not necessarily taught as a discrete subject, but rather it is most often integrated with science or history or in themes such as environmental studies (Solem, Lambert, and Tani 2013).

The geography national curriculum is articulated in three key stages. Each key stage includes a purpose of study, aims, attainment targets, and subject content. The 2014 national program of study is described as being concise and defines core knowledge that students should acquire including locational and place knowledge, human and physical processes, and some technical procedures as well as content in fieldwork, the use of maps, and written communication (Geographical Association 2014). There is also a secondary level geography course that students may take in preparation for the General Certificate for Secondary Education (GCSE) exam. This content recently underwent revision and the updated content will be implemented in classrooms in the 2016 academic year. Specific geography content is included in the national program of study at all levels of education in the United Kingdom.

Case study: United States

Geography education in the United States does have a place in national education policies and standards despite the lack of a national curriculum or a federal education system. Education systems in the United States are primarily controlled at the state or school district levels rather than the federal level. In this distributed education system environment, each state determines its own curricula, assessments, criteria for accreditation, and criteria for teacher preparation and licensure through state or local school boards or legislative mandates. Therefore, the only way to accurately describe the national context of geography education in the United States is to provide a description of standards, curriculum, assessments, and teacher licensure requirements for each of the 50 states, federal district, and territories. The description of geography in the national education context is further complicated by the fact that geography is often taught as a strand in the social studies curriculum which includes the disciplines of history, civics (political science), economics, and occasionally sociology and psychology as well.

Geography’s inclusion in the social studies is most common at the primary level. Middle school curriculum increases the chances of a stand-alone geography course in many states. At the secondary or high school level, curricula vary the most across the United States. At the secondary level, states may have a stand-alone course, an embedded approach, or no geography at all. Most recently, the National Council for Social Studies approved the College, Career, and Civic Life for Social Studies State Standards (C3 Framework), which identifies civics, economics, geography, and history as the focused four disciplines comprising the social sciences. The scope of adoption of the C3 Framework by US states is still unknown among the states.
Finally, enrollment in the Advanced Placement Human Geography course offered through the college board for college credits has increased significantly during the past 10 years. This addition to the K-12 geography curriculum most often appears at year 9 in the US system. Given the context of a distributed education system, national policies are limited and national standards are voluntary and typically serve to inform the independent development of mandatory state level social studies education standards.

United States policies and initiatives

Efforts to improve geography education at the national level included the High School Geography Project during the 1960s, but met with limited success (Association of American Geographers 1966). A second national initiative responded to the publication of a less than glowing report on the state of US education in the early 1980s. The publication of *A Nation at Risk: The Imperative for Educational Reform* issued a call to improve US education (National Commission on Excellence in Education 1983). The geography community responded with a publication, *Guidelines for Geographic Education* in 1984 by the Joint Committee on Geographic Education. Despite a collective effort by the geography education community to establish geography content in the curriculum, the first standards document, *Geography for Life* wasn’t published until 1994 (Geography Education Standards Project 1994).

Despite the lack of a national curriculum or course of study, geography was included as a subject in the National Assessment of Education Progress (NAEP) national testing in 1994. The National Assessment Governing Board (NAGB) oversees the administration of the NAEP testing and determines the test schedule for subject matter examinations. A framework for the assessment was developed as a separate effort from the National Geography Standards which were published the same year as the first NAEP test. The 1994 NAEP test set an initial benchmark for student achievement in geography at grades 4, 8, and 12. Subsequent NAEP assessments of student achievement in geography were conducted in 2001 and 2010.

United States national geography standards

While there are no nationally mandated education standards in the United States, efforts at developing discipline specific voluntary national standards are actively pursued by nonprofit professional organizations, foundations, and with some funding from the US Department of Education. The US Department of Education requirements shaped how the content was presented in the standards document. A large committee of geographers and K-12 geography educators worked to develop an outline of the content necessary to develop a “geographically informed person.” The goals of *Geography for Life: National Geography Standards* 1994 outlined the geographic perspectives, skills, and content knowledge necessary to be geographically informed.

The spatial, ecological, and subperspectives provide the context in which students formulate geographic questions. The geographic skills outline a scientific approach to asking and answering geographic questions using geographic data, content knowledge, and analysis. The geography content knowledge was organized into six “Essential Elements” that included The World in Spatial Terms; Places and Regions; Physical Systems; Human Systems; Environment and Society; and The Uses of Geography (Geography Education Standards Project 1994). Eighteen content standards were organized under the six Essential Elements. The
standards served to describe and explain physical and human geography content for the K-12 curriculum. *Geography for Life* (1994) was a highly successful document that influenced state-based authors of curriculum and state standards documents. Following its publication, standards for social studies and geography education in all US states and the District of Columbia reflected content in *Geography for Life: National Geography Standards 1994*.

In 2007, a committee of geography educators, K-12 teachers, and academic geographers were recruited to work on a revision of the 1994 standards document. This committee agreed the second edition document should follow a similar format due to the number of state standards documents that had used first edition content and maintain the goal of identifying what is needed to develop a geographically informed person. The second edition committee organized all content by standards and for each standard; all three grade levels were presented in a three column layout allowing users to view content across the grade levels. As a part of the revision, the committee focused on the three principles of alignment, scaffolding, and intellectual skills (Heffron and Downs 2012). Alignment was defined as the vertical structure of a standard’s content for each grade level. Scaffolding was defined as the horizontal structure of a standard’s content across or between the grade levels to insure students would be building knowledge and complexity of understanding in the geography content for each standard. Intellectual skills were defined as the ways in which students can think geographically and were represented by a set of verbs selected to vary the intellectual challenge of the geography content.

Published in 2012, the second edition document increasingly focuses on outlining geographic perspectives, content knowledge, and skills, all working together to engage students in geographic inquiry. Revisions to two of the 18 content standards (Standards 1 and 8) and updated content including organizing themes for each content standard were made in the document. Additionally, an expansion of the extensive glossary was deemed valuable due to the limited teacher preparation specific to the discipline. The second edition document went through numerous reviews and public comment periods to inform the revision process prior to its publication.

**Future research directions**

Future research on the nature and content of curricula from an international perspective may serve to help inform the revision and development of future national standards or curriculum efforts. International perspectives would also benefit the discussion of the philosophical underpinnings and the way geography subject matter can contribute to the value of national education systems. There is evidence of the diffusion of ideas and concepts in the curricula between countries. Future research might chart or map international exchanges of ideas that are influencing national curricula. Further analysis and research may also inform areas of collaboration that might result in the areas of teacher training and professional development, instructional materials and resources, and strategies for high-quality student assessments. There are also underlying questions about the use of emerging geospatial technologies and geolocated data in instructional settings as a part of future geography curricula. Identifying potential alignment in curriculum and content may also provide opportunities for collaboration that would develop or enhance international student perspectives about other places in the world. Future research in
the area of national policies and standards holds
great potential for informing and improving
geography education at a global scale.

Summary

These six case studies are presented to highlight
differences not only in national education con-
texts and policies, but also in how geography
content is placed, explained, and taught in both
compulsory and voluntary national standards.
Some geography content at different grade levels
is evident in all countries regardless of whether
there is a national curriculum or federally man-
dated system or not. Several of the case examples
demonstrate a strong collaboration between
academic geographers and geography educators,
while it appears to be absent in other contexts.
In one context, the national curriculum may be
politicized to address perceived national issues
through education. While a few publications
document the state of geography in each coun-
try, additional published accounts for more
countries would help to inform future analysis
and comparisons of geography education from
an international perspective.

Community colleges in the United States provide academic, vocational, and professional education for students who have typically finished their secondary education and are seeking additional training or qualifications for professional advancement or intending to transfer into a four-year bachelor’s program. Such institutions typically award associate of arts (AA) or associate of sciences (AS) degrees as well as other types of professional certificates, diplomas, and qualifications. Institutions similar to US community colleges exist in other countries, but this entry focuses on US institutions because they: (i) enroll a large number of students in introductory geography courses, and (ii) serve as a major source of students moving into four-year bachelor’s programs. In the United States, these institutions are sometimes called junior colleges, technical colleges, two-year colleges, and city colleges, although the focus of this entry is on those that award two-year associate degrees in geography.

Community colleges began a century ago as an effort to develop low-cost undergraduate education at convenient locations for a growing US white-collar labor force as well as to provide advanced technical training for those in the blue-collar workforce (Ratcliff 1994). They still serve much the same role over a hundred years later, though often encompassing a broader mission including serving an expanding demand for adult and community education. There are currently over one thousand community colleges in the United States. The majority of these are public, but approximately a hundred are independent and private and about thirty-five are tribal colleges. Approximately 750,000 associates degrees and 460,000 certificates are awarded yearly by community colleges (American Association of Community Colleges 2015a).

Today, almost half (46%) of all the undergraduates in the United States are enrolled in the community college system and of these 41% are first time students. In the fall of 2013–2014, there were a total of 12.4 million students enrolled, with 7.4 million enrolled for credit. Of this total, 4.5 million were part-time students, and 2.9 million were full time (American Association of Community Colleges 2015a). Clearly, community colleges play an integral role in the higher educational system of the United States and tend to serve a more diverse range of students than four-year colleges and universities.

Vocational, technical, and further education colleges in the United States and other countries are able to offer more specialization in certain areas, specifically, in high-demand technology fields. The mission of these institutions is much narrower than community colleges, which place greater emphasis on a traditional liberal arts curriculum, particularly bread-and-butter English and mathematics courses. The relationship between all of these institutions is becoming increasingly more complex, with the “unbundling” of certificate and degree paths (students transferring credits from multiple institutions) that create new pathways toward diplomas and credentials, but also alter traditional structured progressions that are typical of both associate’s and bachelor’s degrees. In some cases...
this relationship becomes even more complex, with community colleges subcontracting with other public and private institutions for some teaching, technological, administrative, financial, and management support.

Community colleges are localized in structure, funding, and mission and the placement of geography in the curriculum is as varied as the institutions themselves. In some cases geography is part of the science, technology, engineering and mathematics (STEM) curriculum when programs feature physical geography and geographic information systems (GIS) classes, while in others geography is part of the liberal arts and social science curriculum with programs that feature world regional geography as well as introductory classes in human and cultural geography. Many programs also offer classes such as economic and political geography, specialized courses with a regional and local focus, and other courses that fit into the liberal arts and social science curriculum. Sometimes geography courses are offered within other academic programs such as global studies, environmental science, and anthropology.

Unlike many four-year colleges and universities, few community colleges are residential and only about 25% of community colleges offer any sort of on-campus housing (American Association of Community Colleges 2015b). Most students live at home and may attend college part time while working. Community colleges are funded through tuition (often underwritten by student loans) as well as local, state, and federal support. In contrast to most four-year colleges and universities which receive little or no local or municipal funding, community colleges receive an average of about 17.8% of their funding from such sources as well as approximately 9.9% of their funding from grants and business partnerships (American Association of Community Colleges 2015a).

Roles and demographics

Community colleges play a key role as pathways to education and better jobs for immigrant communities and, in turn, are heavily influenced by the needs of these communities. Currently, one in four community college students are landed immigrants or children of immigrants (Connell 2008). “The national conversation about immigrant education has only just begun, but community colleges are well positioned to meet the needs of this growing student population. By helping our newest neighbors successfully integrate into US society, community colleges will contribute to the overall health of the economy and fortify the country’s social fabric” (Wisell 2010).

Certainly there is a challenge to be met – while immigrants’ overall educational attainment has remained the same since 1970, the educational attainment these immigrants bring with them has decreased dramatically (Haskins 2007). This would certainly seem to indicate that while immigrating to America today is more accessible than ever, the people that are emigrating from their countries of origin are not as well prepared to meet the educational requirements for employment in the US workforce. These immigrants need access to upgrade skill sets (especially technological) at local community colleges that match the local labor markets and allow them entry into the market. The education offered by community colleges can also act as a stepping stone that allows immigrant students easier access into 4-year institutions, particularly those with what are termed “Direct Transfer Agreements” with community colleges. Also, for many families that struggle after moving to America, community colleges offer the most affordable pathway to higher education.

Community colleges are particularly important for many students because they focus on helping
students succeed in classes needed for their first two years of college. Geography is often included as a “general educational requirement” in these programs and, as a consequence, can sometimes serve to attract students into further study. This is important because community colleges tend to attract a more diverse student body with greater proportions of underrepresented populations. This means that community colleges in the United States can help to promote diversity and inclusion within the discipline.

Community college students, in contrast to many in 4-year institutions, are often balancing other work, family, and personal responsibilities as they pursue their education. Of all community college students, 59% (4016789) attend on a part-time basis compared to 41% (2849203) that attend full time. This seems to reflect a divide among community college students between those seeking an associate’s degree for transfer to a 4-year institution and those in vocational/technical programs or enrolled in fewer classes as they work and balance family commitments. When looking at community college students starting out, 39% transfer to a 4-year institution, while 42% receive a vocational/technical certificate. While the students whose goal is a four-year degree may not realize what academic or vocational area they may choose to enter, students in vocational/technical programs and balancing life commitments often have very specific goals in mind, such as becoming a nurse, welder, or GIS professional.

However, the reasons students attend community college is as diverse as their personal backgrounds (Johnson and Sullivan 2010) as shown in the following list.

- High school graduates completing lower-division courses before transferring to four-year institutions.
- High school students co-enrolling in courses at community colleges or taking courses at colleges as part of homeschooling programs.
- Students pursuing Career Technical Education (vocational) degrees or certificates.
- Adults working toward General Equivalency Diplomas (GEDs) or entry-level workplace competencies (such as Welfare-to-Work2).
- Re-entry students who have been in the workforce for some time and are looking for new careers or skills.
- Students of all ages pursuing personal interests.
- Students who have already earned bachelor’s degrees or higher and want new skills or skill upgrades. The growing trend of these so-called reverse transfer students has led some to refer to community colleges as the new form of graduate school (Arnone 2001).
- Long-term unemployed students and high school graduates who hope to acquire skills needed to enter or re-enter the workforce.

Some facts that stand out are that the average community college student is 28 years of age, 36% of students are the first generation to attend college, and 17% of all students are single parents. This would certainly present a much different picture than comparable demographics at 4-year institutions and, to put it simply, many of these students are getting a chance they would not get elsewhere. With the average community college tuition at $3347, just over a third of the $9139 tuition cost at 4-year institutions (American Association of Community Colleges 2015a).

Challenges facing community colleges

Geography is part of the curriculum at many community colleges, but it is not a major discipline. This means that that 24% of geographer
faculty in 2-year institutions serve alone as the only instructors in their field or what are termed stand-alone geographers (SAGE). This can often place these faculty and part-time instructors in challenging positions in regards to synergy and interaction with colleagues in their field as well as competition for resources for teaching. 

Teaching geospatial classes can be especially challenging at the community college level, with these classes requiring more investment in computer software and hardware, and typically requiring lower faculty to student ratios and smaller class sizes. In effect, these classes require a greater investment on the part of the college and this requires support from administration especially when competing for resources with engineering and other technological fields.

One significant demographic characteristic of community college students is that 61% of all students are female and 39% male. With a higher representation of night-time and online classes than 4-year institutions, community colleges offer greater flexibility for single-parent families, and those where a female partner is attempting to re-enter the workforce after her children begin school (this would be only one example of many different arrangements that would require more flexibility in scheduling attendance in classes). Looking at ethnicity, 68% (3,981,099) of all community college students are Caucasian, 15% (1,003,795) are Hispanic, 13% (865,578) American Indian/Alaskan Native, and 6% (421,097) are Asian/Pacific Islander.

Although community colleges rely less on state funding than four-year colleges and universities, many have still not rebounded from cuts from the great recession less than 10 years ago. These institutions are also subject to localized issues that cut back funding, such as major industries relocating out of an area or shifts in allocation of local revenues.

This is causing many if not most community colleges to “do more with less.” Most community colleges have responded with a variety of efficiency measures from utilizing more part-time instructors to “lean” methods of streamlining routine campus operating costs (such as printing, classroom reservation systems, advising, how class catalogs are offered, and enrollment systems). In some cases, this has also resulted in the offering of fewer geography classes (and liberal arts classes as well) and more “bread-and-butter” math and English classes.

The most common trend is to rely heavily on more affordable part-time teaching staff and it is becoming increasingly important to make the case of why full-time faculty make a difference in the quality of higher education.

More recently, community colleges are increasingly finding their relationships with for-profit institutions becoming more complex. While for-profit institutions played a minor role in the 1990s, they are becoming more of a factor with their emphasis on customer service, degree completion rate, and support for students finding employment after they graduate. This is balanced by community colleges maintaining a greater emphasis on a broad-based curriculum with fewer constraints than for-profit institutions which often have very limited missions.

There are also many cooperative arrangements between the community and for-profit colleges with community colleges preparing students for later upper-division classes at for-profit institutions. It is still the case that community colleges have an advantage over for-profit colleges in regard to articulation agreements or direct transfer agreements with four-year colleges and universities. These agreements specify how course credits can be transferred from institution to institution. Many four-year colleges and universities do not accept credits from for-profit colleges or transfer the credits as less
specialized general study (independent) credits. Many community colleges and statewide 4-year institutions have direct transfer agreements in place, which allow priority for transferring community college students.

**Instructional and learning technologies**

The extent and quality of instructional facilities are as varied as the communities where these colleges are based and owe much to each college’s unique history and funding sources. One thing that most share is the lack of classroom space. This has meant that, for several decades, online programs and classes have provided community colleges with the opportunity to increase enrollment and add new classes and programs, even during challenging times.

Many colleges are now starting to question the efficacy and success rates of online classes: “Poor online performance rates in community colleges are not simply due to the characteristics of students who choose to enroll in those courses. Challenges related to the online format – including technical difficulties, a sense of isolation, a relative lack of structure, and a general lack of support – may contribute to poor performance, particularly among community college students” (Moore 2013).

One of the great challenges over the next several decades will be the balance that institutions will seek to provide in regards to blended learning and teaching. Learning communities, linked classes, and hybrid and flipped classrooms are some strategies being employed. These will continue to evolve as the era of the lecture classroom collides with modern technology and lifestyles. However, this evolution will be tempered by the reality of fiscal economics and providing efficient forms of classroom structures that feature quality and technology that are innovative and cost effective.

**Opportunities and challenges**

Over the next decade increasing opportunities in geographic information science (GIScience), geographic information systems (GIS), and geospatial technologies may play a role in the development of additional courses and programs in community colleges. The development of the Geospatial Technical Competency Model by the National Geospatial Technology Center of Excellence in 2013 has provided community colleges with a model and framework to provide the knowledge and skills needed by today’s geospatial technology professionals. The model framework was developed through a collaborative effort involving the Employment and Training Administration (ETA), the Geotech Center, and industry experts (GeoTech 2015).

In addition, the Geotech Center also provides a wide range of support for geospatial education from skills competitions and mentoring programs for undergraduates to model courses and syllabus repositories for faculty and instructors.

Courses and programs focusing on geospatial technologies, remote sensing, and other GIS applications are growth areas, but geography also has a vital role to play in exposing students to a wide range of important contemporary environmental and geographical topics such as global climate change, the impacts of globalization, the spatial dynamics of American cities, and many other topics. The rise of interest in spatial thinking and learning as a fundamental mode of human cognition that cuts across many domains of STEM education may also offer opportunities for curricular innovation.

In general, one of the greatest issues facing community colleges is the increasing reliance
on part-time rather than full-time faculty. Currently there are often more than twice as many part-time faculty as full-time faculty at most institutions. This means, potentially, that there are fewer full-time faculty available to advise student and to devote energy to curricular innovation and improvement. Some of the more encouraging factors are that female faculty and faculty of color are well represented and increasing in numbers. However, many faculty at community colleges, especially full-time faculty, are approaching retirement age. Addressing this generational changeover and attracting replacements for retiring faculty may prove a challenge; those qualified to teach often have more diverse employment options available (Rifkin 2015).

Community colleges do offer opportunities for successful professionals to “moonlight” and supplement their income with part-time teaching. It might be useful in the future to encourage such moonlighting by full-time educators at four-year colleges and universities to help build, strengthen, and expand community college programs. This is because one of the greatest challenges facing community colleges is the issue of staff turnover and providing some sort of financial security for faculty. While some of these factors can be ameliorated with better benefit packages for full-time faculty, this does not necessarily impact part-time faculty. All faculty – full- and part-time – can benefit from faculty development programs, early career training, support and mentoring, and programs for professional development. Such programs are, unfortunately, short-changed in efforts to cut cost.

**Conclusion: looking to the future**

In the United States, community colleges currently serve almost half the nation’s undergraduates. The forecast is for enrolment to increase by approximately five million students over the next five years. The financial and staffing strain on smaller programs may be daunting without increased support from the federal government. Currently, federal assistance accounts for about 15% of community college funding, with state revenue and tuition providing about 29% each of community college revenue. About 40% of all students work to pay tuition and living expenses (American Association of Community Colleges 2015a). The federal proposal to boost federally supported Pell Grants and to provide “no cost” tuition for the first two years of community college education could have a revolutionary effect on the number of students served by community colleges. Even if these changes do not materialize, community colleges will remain a backbone of higher education for blue-collar, working-class students, a path to accessing technological skills for others, and a point of entry into American society and the US workforce for first-generation immigrants.

In looking forward over the next few decades, it may emerge that community colleges will begin to offer both associate’s and bachelor’s degrees, thus blurring the distinction between two-year and four-year institutions. It may also transpire that consortiums will emerge between private industry and community colleges to create educational “pipelines” for students interested in specialized career opportunities as varied as aircraft manufacturing and remote sensing. The success of companies such as Google and Esri has increased a global demand for geospatial skill sets, and community colleges will continue to be centers of innovation in these and other areas of innovation.

Community colleges will continue to play an important role in debates over affordability and access to higher education in the United States and, perhaps, in other countries. Recently, for example, the community college system in the
United States has been thrust into the national spotlight with a proposal to provide education free of cost to all Americans. The ten-year, $60 billion plan, mentioned above, would pay for the first two years of community college for full-time students that maintain satisfactory grades. The impacts of this new legislation could be profound. In a recent speech, President Obama (2015) noted that jobs requiring at least an associate degree are projected to grow twice as fast as those requiring no college experience. It was suggested that by 2020, America will once again have the highest proportion of college graduates in the world, and that community colleges produce an additional five million graduates. This certainly presents a charge for community colleges in the coming years, placing considerable weight on their ability to serve these numbers.

Addressing this charge may involve changes on many fronts. One of the most important is closer coordination between community colleges and other institutions of higher education. Most articulation agreements between community colleges and universities are between public institutions within a state system or within a given geographic area. More can be done in this area. For example, one effort underway in the State of Washington has been to create “common course” numbering to eliminate a multitude of different course numbers for similar classes offered at different institutions.

A second area for improvement involves having a more meaningful dialogue between not just administrators and instructional councils, but also faculty in how courses align and match between these institutions. It is in everyone’s best interest that students have a clearer understanding of what classes they need to take for transfer from one institution to another and from one degree program to another. Given current financial pressure and growing enrollments, both two-year and four-year colleges have an interest in increasing degree completion rates and lowering the average time-to-degree. These efforts are also in the students’ best interest as the cost of education and the risk of high student loan debt rises.

Professional development is another area of concern for faculty at community colleges. Given the changes underway in higher education, as well as the pace of change in some fields like geospatial technologies, many part-time faculty find themselves too busy or simply are not aware of opportunities for professional development. Certainly organizations on and off campus can play key roles in improving these opportunities.

More geographical and educational research needs to be directed toward community colleges. Although community colleges are a very important part of US higher education, they haven’t received as much research attention as four-year colleges and graduate education, particularly doctoral programs. Most attention has focused on policy plans or on issues regarding administrative streamlining, financial cost-cutting, and topics such as class size. These last issues are important but, given the role community colleges play in US higher education, more attention might focus on the sorts of broader issues alluded to in this entry. These include the impact of community colleges in helping blue-collar and working-class students move into and advance in the workforce, developing student technological skills, and supporting the success of first-generation college students and recent immigrants. In addition to research in these areas, more attention needs to focus on the impact of part-time versus full-time faculty in these institutions as they prepare for yet another era of increased enrollments and reduced budgets (Belfield 2015).

Finally, it is worth considering the role of institutions like community colleges in other countries. This entry focuses on the United States, if only because community colleges offer
so many geography courses to so many students. But geography is an element of vocational, technical, and further education colleges elsewhere around the globe. It is this sector of higher education – positioned midway between secondary schools and four-year colleges where change and growth may occur. This is not only in the United States, but in other countries where increasing demand for students with geospatial and geographical knowledge and skills may be served by increasing numbers of innovative programs.

Geography education: digital and online trends

Michael N. DeMers
New Mexico State University, USA

Traditional lecture-style, face-to-face classrooms are still the norm in geography education, especially in colleges, but this is changing rapidly. The costs of classroom space, the varied schedules and learning styles of today’s learners, and the availability of an increasingly sophisticated set of computer software tools are resulting in a move to digital and online learning as a growing proportion of the total learning environment. Concurrently, new learning paradigms are appearing with increasing frequency. They include models of teaching based on the nature of the learner’s age, background, experience, and motivation such as pedagogy versus andragogy (Knowles, Holton, and Swanson 1998) versus heutagogy (Hase and Kenyon 2000). Some models are more structural, including problem-based learning and the flipped classroom. Still others focus on styles of learning from auditory, to reading-based, to visual, to tactile and experiential learners (Kolb 1984) and even include the concepts of multiple intelligences (Gardner 2000).

While much of this explosion in research regarding learning paradigms may be prompted by pure research stemming from educational and especially cognitive psychology, a major driving force may be found in the very nature of today’s neomillennial learner – generally those born after 1982. Ready access to the World Wide Web encourages the comparison of often incomplete and collectively inconsistent information and knowledge seeking, filtering, and synthesizing rather than relying on information from a single authoritative source (Dede 2005). Multiple sources of digital interaction (e.g., iPods, mobile phones, and Internet access) encourage multitasking which reduces focus and often results in superficial learning. The availability of multiple access points has also allowed people to demand individually structured digital products (e.g., tailored MP3 music as opposed to prepackaged albums) including individualized learning, often called personal learning environments (PLE). Today’s learner demands access to information whenever and as often as he or she wishes.

As digital environments grow and change, as digital content expands, and as accessibility grows, educators are presented with considerably more learning opportunities at the same time as learners demand greater personal relevance. There is also a growing demand for a shift from passive delivery methods to more active and collaborative learning, which involves the development of learning communities, placing the burden of learning on the learner rather than on the instructor. This is particularly important for the online learning environment, where the faculty member is not physically present as in a classroom. A major change in the delivery of online courses is the vastly improved learning management systems (LMS) available today.

Principles of online teaching

While all forms of educational delivery share principles, online delivery has some that are very specific to that domain and some of the shared
principles need to be emphasized for online courses. Pelz’s (2004) first principle derives from the constructivist school of thought in that the learner is responsible for his or her learning and, therefore, for doing most of the work of learning. Examples of such work include:

- student-led discussion;
- locating and discussing web resources (web quests);
- peer assistance, whereby students help each other;
- student-to-student assessment;
- case study analysis.

The second of Pelz’s (2004) principles is that, at the center of asynchronous learning, there are three meaningful interactions between learner, content, and instructor. These interactions should also include interactions with the Internet, with the entire class, within small groups and/or teams, and one-to-one with a learning partner. The interactions should include not just course content but also learning about the nature and parameters of assignments, problem-solving, laboratory activities, case studies, and more.

The final principle is that there must be an emphasis on presence. Pelz (2004) suggests three forms of presence for online learning: social presence, cognitive presence, and teaching presence. Social presence, the feeling of being there, allows for the creation of a community of learners, not unlike a community of practice in the professional work environment. There are three forms of social presence:

- affective (expression of emotion, feelings, and mood);
- interactive (evidence of attending, reading, understanding, and contemplating others’ responses);
- cohesive (a sense of belonging, commitment, shared goals, and objectives).

Cognitive presence is the extent to which a community of inquiry and discourse forms to construct meaning. This can be demonstrated by introducing relevant facts, concepts, and theoretical knowledge into the discussion. The value of this depends on the source, clarity, accuracy, and comprehensiveness of the knowledge acquired.

Teaching presence is defined as the facilitation and direction of the cognitive and social processes for the achievement of meaningful and educationally worthwhile learning outcomes. There are two ways in which the educator and students can add a teaching presence to a discussion. The first is direct instruction, such as presenting content and questions, focusing and summarizing discussions, confirming understanding among the learners, diagnosing misperceptions, infusing relevant content from diverse sources, and responding to technical concerns (e.g., file incompatibility). The second component of teaching presence is the facilitation of discussion by identifying areas of agreement and disagreement; seeking to achieve consensus and/or understanding; providing encouragement and reinforcement; setting a climate of learning; encouraging and prompting discussion; and assessing the effectiveness of the process.

New tools for online learning

The primary tool for managing the many components of online courses is the learning management system. The LMS is able to provide the following functions, among others:

- store and deliver content in many different forms;
- facilitate email and other digital communication between learners and educators;
- deliver assessment materials;
- track assignments, student progress, and attendance;
In its early years the LMS was often used primarily for storage and delivery of content, an approach to online education that has often been considered the norm. This approach does not take advantage of the tools variously available in existing LMS like Blackboard, Canvas, Desire2Learn, Moodle, and many others. It has also often contributed to a negative perception of online courses. A particular complaint of such unidirectional courses is that the instructor is not present and doesn’t interact with the learner.

Fortunately the use of LMS and non-LMS social media, collaboration, and multimedia software is becoming more common as a result of efforts by educational institutions to provide training in both the tools and the theoretical underpinnings of online teaching (Solem 1991). While stored course content can include text-based materials, audio files, and instructional videos (including narrated lectures and other podcasts), the material doesn’t in itself provide interaction with the instructor or the other students. Fortunately, most modern LMSs provide chat rooms for group discussions that some geography instructors use for projects, and discussion channels that enable learners to consider difficult questions posed by the instructor and to share ideas with fellow learners as well as with the instructor. The chat room, and especially the discussion channel, allow for original posts and for responses (replies) to be posted asynchronously so that learners have control over when they participate.

These tools allow the instructor to monitor conversations and to intervene when the students wander off topic or reach conclusions inconsistent with the evidence. Some instructors use wiki (e.g., PBworks) and blog (e.g., Blogger) sites outside of the LMS for convenience and because of the advanced features of these commercial tools. One tool that has been increasingly used for group discussions is VoiceThread, which provides text, voice, and recorded webcam video interactions rather than being limited to text. One advantage of this tool is that it allows learners to ask questions and add comments directly on narrated PowerPoint-style lectures. It also allows participants to actively draw on visuals for emphasis.

Some LMSs incorporate webinar tools directly, while others support external webinar systems such as Adobe Connect, GoToMeeting, BigBlueButton, and Meeting Burner. For the educators and the learners who are more comfortable with synchronous interactions, which are more like face-to-face lectures, the webinar allows for the sharing of visuals, online real-time lectures, and question-and-answer sessions during a preselected time period. Additionally, the entire webinar can be recorded both as a means of study and recall and for those who are unable to attend the scheduled event. Such webinar software is becoming increasingly sophisticated and available through educational site licenses.

Special circumstances of geography education

Impediments

Unlike some subjects, geography is both vast in its content and varied in the methods normally applied both to research and to the teaching. Conceptual material is relatively easy to deliver online via readings, either digital or analog, but laboratory and field-related courses present serious problems for delivery online. Questions arise
about how to gather weather information for a physical geography or meteorology course or how to perform rock and mineral identification in an online environment. How would field course-related interactions or a problem-based learning environment be delivered online? Or, more generally, how can almost any experiential course content be delivered online?

While the solutions to these circumstances may require some creative thinking, there are solutions, especially if one moves from a purely online to a blended course, in which some of the activities are performed offline. To use the meteorological exercise as one example, the learners may be provided with the necessary instruments, either as needed or as part of a course kit, and given a time frame in which to gather the data and record them. In a group project, the data could be shared using the Google Sheets software, which allows for multiple users to enter and delete data from a single spreadsheet. The spreadsheet can also be downloaded and converted as an Excel file if needed.

The Google spreadsheet is part of a suite of online collaborative tools that can enhance group projects. Another common tool provided by Google is Google Docs, which allows collaborative work on a single document online. This is an easy solution to the development of group reports resulting from the collection of any data, whether of weather, soil, or surveys.

Field data can also take advantage of digital technology. For example, most of today’s mobile phones have on-board Global Position System (GPS), which allows for the recording of locational information, alongside photographic evidence of a site via geotagging. This technology can be used in a field trip as part of a blended course to demonstrate tagging in a neighborhood, the condition of buildings or bridges, or the visual appearance of a soil profile or geomorphological feature. These digital data can easily be uploaded to the LMS either as part of a data repository or as an integral component of a final digital report. Beyond the LMS itself there are numerous online repositories such as Dropbox, Google Drive, OneDrive, and iCloud, which provide means of sharing content from learner to learner.

Another difficulty of many geography team projects is that they may consist of multiple tasks such as data collection, data compilation, project write-up, not to mention the need for scheduled meetings, whether they be online via a chat room or face to face in a blended environment. Coordinating these roles is difficult enough in a face-to-face environment, let alone in an online setting where many interactions are asynchronous. Fortunately, technology again comes to the aid of the educator with collaboration tools such as Trello or Bitrix24, which provide methods of scheduling tasks, managing projects, and tracking progress for each individual collaborator in the context of the larger project. These tools, like many others, have professional versions that can be prohibitively expensive for educators, but also have free or low-cost alternatives, most of which are sufficient for the online classroom.

Laboratory exercises such as the rock and mineral identification example pose problems in the purely online environment but have ready solutions in a blended environment. One online approach would involve the use of video-conferencing tools such as Skype, which would allow a laboratory instructor to monitor the work of several learners working with their samples and testing equipment. This can be done in real time and would allow for the student-to-student interaction necessary for a robust online learning experience.

Digital laboratory exercises such as those encountered in geographic information system (GIS) classes can be managed in one of
two ways. Step-by-step laboratory exercises, designed for personal training by the software vendors themselves, can be used in a completely online environment. The assignment due dates are scheduled and the learner returns the content within the LMS for grading and feedback. Alternatively, in a blended environment, the laboratory portion of the course can be delivered through a traditional face-to-face component of the course, while lecture, discussion, and other substantive content can be completely online. For learners who cannot attend the face-to-face laboratory sessions because of scheduling or geographic separation, the laboratory instructor can set aside time for the use of Skype or another video-conferencing tool as a consulting period for the learner. In some cases part of the consulting period takes place during the laboratory time slot itself. This allows learners who are separated by distance but who are otherwise free during that time to work on their laboratories with the lab instructor present. When difficulties arise, the learner is able to share his or her screen with the instructor, thus allowing the instructor to spot mistakes or procedural problems much as they would in a classroom.

Field excursions in which the instructor shows the learners what features look like are invaluable experiences for sensitizing the learner to visualize the landscape. While the face-to-face version of this is preferable, the experience can be simulated through the use of video. A good example is to actually take either teaching assistants or students on a site visit that would normally be visited by the class. The characteristics of the site can easily be recorded using relatively inexpensive digital video recorders, and the assistants and/or student aides can be given appropriate scripted questions to pose to the instructor.

Another approach to such field excursions is the use of live-feed video, which is also quite inexpensive. Action cameras can be set to live-feed mode so that learners can visit the site via an Internet connection. This approach could also include real-time audio connectivity, allowing learners to ask their own questions as if they were actually in the field. The live excursions could also be recorded so that learners have access to the experience at any time. This is an enhancement of the face-to-face field experience, which is often a one-time event and is usually recorded via pictures and notes.

Opportunities

The combination of advances in learning technology, social media, multimedia, and geospatial tools provides not only an opportunity to teach geography effectively online but also experiences that are otherwise not available. One example employs digital globe technology provided by Google Maps and Google Earth. Google has both a normal and an enhanced, professional version of Google Earth product (Patterson 2007). This tool allows educators to develop learning modules based on a bird’s-eye view of anywhere on the Earth. For example, an instructor in geomorphology in an online course offered by a school in California can create an exercise on glacial finger lake processes by using Google Earth to transport the learner to New York. Instructors can develop urban field trips by using Google Street View to take learners along the streets of Chicago, for example. These trips can be recorded, placed in moviemaking software for learners to edit, narrate, and annotate. Not only does this provide a unique opportunity to explore other places, but it also provides an alternative approach for the learner to demonstrate his or her mastery of the material beyond the traditional paper reports.
Another tool developed by Google for educators is Lit Trips. This tool leverages the power of Google Earth to provide a more complete geographical context for a wide variety of literature. Characters’ travels are linked to positions on Google Earth, and the actual terrain they traverse is displayed in planimetric view or as street view, if available. This approach is currently popular among educators of young children. Some educators require their students to create the story maps themselves, giving them an opportunity to use geospatial tools in both geography and nongeography courses.

A similar but more robust tool for linking geographic position to experiences, landforms, and conditions around the Earth is the story map recently developed by Esri as an outgrowth of its ArcGIS Online environment. Using prefabricated templates, users can develop stories based on portions of the Earth in which they are interested. Story maps allow learners and/or educators to leverage real GIS data and combine it with text descriptions, pictures (with or without annotations), movies, and other media to create maps with advanced functionality. The templates themselves provide a wide variety of display types such as tours, journals, shortlists, countdowns, playlists, tabs, side accordion, swipes (sliders), and spyglass. In addition to some minor programming, custom designs for story maps can also be created. Such a wide variety of options provides for creativity both in presentation and in assignment creation.

Today’s handheld devices provide opportunities for more creativity, whether in online, blended, or face-to-face environments. Tools such as Google Goggles provide some amazing opportunities for experiencing enhanced reality of observed landscapes. Ritter (2012) pointed out how the use of this enhanced virtual reality too can be effectively employed in online physical geography courses. Google has already released glasses with this technology, bypassing the need for a mobile phone app to perform such tasks. As these and newer technologies develop, innovative geographic educators will find unique ways to employ them in their classes.

Challenges and research needs

As with any new technology applied to learning, it is important to recognize that the technology can become compelling in and of itself and may not be the best, or even a viable, approach to learning. Little research has addressed whether proof-of-concept studies for the use of online learning environments in education are more a function of the nature of the learners or of the instructor. The educators who attempt to develop virtual learning environments are often either digital natives with gaming experience or digital adaptives, those who have taken the time to adapt to the world to which their learners will be exposed during such educational experiences.

Even more so than in education in general, studies linking the sciences of cognitive psychology and neurophysiology to learning in online and blended classes are lacking. Literature identifying how learners begin to identify with their avatars and how they develop social presence is required to provide the hard evidence needed to make bold statements about the relationship between social presence and learning outcomes. User interfaces for virtual worlds need to be simplified, particularly in the area of in-game building tools which, while useful, are difficult to learn and detract from the focused learning objectives.

There is very little research quantifying the degree to which established learning objectives are obtained via online or blended learning.
experiences. Controlled experiments comparing learners using online and blended versus face-to-face learning environments are needed to establish its ultimate utility. Case studies using different control groups would also be invaluable to the literature. Such studies may prove to be the needed impetus for a renewed focus on the scholarship of geography learning.

Geography education: primary and secondary

Joseph P. Stoltman
*Western Michigan University, USA*

Geography in primary, and later in secondary, education became established in many countries and regions of the world during the eighteenth century. Colonists migrating to new places sometimes viewed the study of geography as a means of maintaining an attachment to the home country as well as preparing for the challenges of living in unfamiliar places and environments. Information about distant places was presented as geography lessons in school. Vivid geographic descriptions of new settlements in distant places such as Asia, Africa, and Australia beckoned potential immigrants to land, sunshine, and prosperity. The extension of geography in primary and secondary education coincided with the era of exploration and globalization as distant places became linked by migration, trade, and politics. Immigrant populations were on the move, and the geography of the destination and its environmental conditions often attracted potential settlers. The study of geography continues in the twenty-first century with the exploration of contemporary conditions and issues on Earth. Just as earlier generations learned about the Earth through storytelling, print materials, photographs, and film, the current generation has the opportunity to study geography using the Internet, the World Wide Web, and virtual field trips to learn about the Earth, its people, and its environments.

Geography education and its importance to society

Geography is an academic discipline and a school subject based on established traditions and emerging opportunities to study the Earth and its people. Geographic education includes the perspectives, concepts, and skills that professional geographers use in a form adapted for people studying geography in both formal and informal settings.

Geographic education is both studied and applied by all twenty-first-century societies. For example, when a farmer in West Africa uses a mobile phone to research the market price for the groundnuts that will be sold to a local commodity broker at harvest time, he or she is acquiring geographic information. Geography may also be used to predict the effects of a desert locust outbreak on groundnut production in a nearby country, which may consequently influence groundnut pricing. In each case, the farmer is either using geography to make decisions regarding pricing or collecting geographic information regarding supply and demand. In both cases, geography education is being applied to make personal decisions locally, while using global information about conditions in other places. Geography education also serves to mitigate disasters, such as the deadly outbreak of ebola in West Africa in 2014. Medical treatment and fatality data were converted to spatial information and mapped. The maps enabled health workers and local community leaders to alert people in the affected region regarding the geographical spread of the disease. Procedures were taken...
to establish geographical zones where travel and personal contact were greatly limited, thus stemming the spread of the disease. Geography education is applied each day by every one of us, whether it relates to a local journey to the market or an air journey halfway around the world. Geography education provides the information and skills that individuals and societies must know and apply in a dynamic world. Geography education has played that role for a very long time.

Geography education: the early years

The early years of primary and secondary geography education were similar in many countries during the period of colonial influence. There were mainly two types of colonization that affected education. The first is the one most readily recognized as a colonizing country taking economic and political control of a place and introducing social norms and values. This included the introduction of an educational system. Colonial America was a good example of this process. The second form of colonization was the diffusion of ideas about geography in primary and secondary education but without the exercise of colonial control; this is often described as cultural colonialism. Examples of cultural colonialism include the educational philosophies of Jean-Jacques Rousseau (1712–1778) in Europe, and later John Dewey (1859–1952) in the United States, which were diffused internationally through writing and research. Both philosophers influenced educational practices relative to the view of nature and the role of the environment in education. In his analysis of American geography and how it was influenced by its European roots, William Warntz (1964) reflects on the role of educational colonialism. The writing of textbooks and atlases for school and home became a major educational influence in colonial and later post-colonial countries. Published materials further signaled the diffusion of geography through schools. Geography was viewed by educators as a good preparation for the development of reasoning and for the study of natural and moral philosophy.

The memorization of geographic names and locations has often dominated the study of geography. While the memorization of geographical names may be less demanding intellectually, place names are considered important for students to develop a worldview. Developing a proficiency in geography requires some memorization, map work, and cumulative experiences in the study of regions of the world at different scales. Developing a worldview has become a standard goal of geography in primary and secondary education, which persists globally in the twenty-first century. The discipline serves as a spatial platform for the study of economic, social, and political changes that affect places and regions. Those changes in spatial patterns of trade, population, and territorial claims introduce students to the dynamics of a twenty-first-century worldview.

Early teaching of geography

In its early years geography instruction consisted mainly of the study of maps, agricultural and industrial production, and physical geography, including weather and climate. It was reported to be bland and not very motivating. Methodologies incorporating the educational theories and philosophies of Johann Pestalozzi, a Swiss educator, and Arnold Guyot, a Swiss geographer, found ready acceptance in the teaching of geography. Both became influential and affected
the teaching of geography in Europe and North America. Pestalozzi promoted the philosophy that direct observation and sense perception are essential for meaningful learning by children. What better subject than geography in which to implement that pedagogical approach? Maps and line drawings became essential components of textbooks and other instructional materials within educational systems in many countries. Drawing maps of their home region and completing field studies became widely accepted ways to teach geography (Dahmann 2011). Geography proved to be an ideal subject for using information from photographs, black line graphics, and other visuals to enhance student learning. Graphics in early textbooks were the initial version of geospatial technology used in teaching.

Arnold Guyot was educated as a geographer in Switzerland and arrived in the United States at a time when state-supported secondary schools were being established. In Europe, Guyot had become familiar with the pedagogical practices of Pestalozzi. He had considerable success using field studies to build observational skills among his students and as a means to collect geographical information. He achieved considerable fame in American geography as an author of secondary school and college textbooks. Secondary school physical geography prospered under his influence.

By the start of the twentieth century, primary and secondary geography education had matured in content, scope and topics, teaching methodologies, and philosophical underpinnings. The technology of the time permitted the reproduction of diagrams, maps, textbooks, and wall maps, which were combined with direct observation to engage students in geographic content. Teacher-led recitations of content were enhanced by visuals and increased information about the world, which led to the development among students of a more comprehensive worldview. Physical geography was widely accepted as an important scientific study of the Earth and assumed a prominent position within the curriculum.

The philosophy of education that was to dominate the early part of the twentieth century, the progressive education movement, looked favorably on geography education. Local study, developing a sense of geographic place and space, and discovery learning complemented geographic study. Moreover, Rousseau and Pestalozzi became the dominant influences as, in many parts of the world, the curriculum engaged students in local study in the primary grades, gradually extending to the geography of the world in secondary school. This was the initial indication of a curriculum movement that later became known as the expanding environment.

Academic and professional societies and geography education

The twentieth century was a period when professional and academic organizations assumed a greater role in geography education in the United States and elsewhere. In the United States, the National Education Association (founded in 1857) completed major reviews of school geography in the 1890s. Reviews also took place in other countries, where they were usually sponsored by academic or professional societies. Scholarly societies addressed the role of geography education, the content most suitable for primary and secondary students, and what should be taught to students of different ages and grades. Among the most influential of the professional societies of geographers were Société de Géographie (Geographical Society, 1821), the Royal Geographical Society (1859), the American Geographical Society (1851),
and the National Geographical Society (1888). While the societies were academic in their charters, they were broadly interested in promoting geography and in applying developing technologies in cartography, photography, and publishing in their mission to educate the public. Those missions, however, strongly influenced primary and secondary education, since students represented inquiring minds about the world and were potential future supporters of geography, exploration, and education.

The interest of scientific societies in promoting geography education prompted teachers to become interested in establishing organizations specifically devoted to geography in primary and secondary education. For example, the Association of American Geographers (1904) had among its members geographers who had written textbooks, served on national committees, and greatly influenced the teaching of geography. Educational geographers moved forward to establish the National Council for Geographic Education (1915). The initial mission of the council continues today to support geography teaching through the publication of articles and reports on content, teaching methodologies, and research. Similar organizations of geography teachers began in other countries: Geographical Association (United Kingdom), Associazione Italiana Insegnanti Geografia, Turkish Geography Teachers Association, Korean Association for Geographic and Environmental Education, Australian Geography Teachers Association, Geography Teachers’ Association of Singapore, and the Verband Deutscher Schulgeographen (Association of German Geography Teachers), to name just few. Nearly every country has either a formally or informally organized group of geography teachers in primary and secondary education who represent the voice of geography education.

The International Geographical Union (IGU) is the largest international organization of geographers, representing the discipline in more than 150 countries. Membership in the IGU is largely by national units, with the provision for membership by individuals if membership is not held by a national research organization that represents a country. The IGU sponsors a Commission on Geography Education (IGU-CGE) which communicates information and provides expert advice to national organizations of geography teachers. The commission holds regular conferences in different countries, hosted by a local university or geography teachers’ association. The conferences include research paper presentations devoted to classroom teaching, curriculum development, geographic literacy, assessment in geography, and theoretical treatises on the subject. The commission distributes an electronic newsletter and has regional representatives in many countries responsible for coordinating national participation.

Research, curriculum reform movements, and global impacts

Curriculum is the driving force in determining the importance of and position of geography within a country. The curriculum prescribes the content and skills that are taught and when they are taught in primary and secondary schools. It is perhaps the most important element in the preparation of teachers. Teachers are expected to align the content they learn in their academic preparation as professionals with the curriculum they are expected to teach.

Research in geography education for primary and secondary education has not regularly addressed curriculum questions, which have often been left to educational researchers.
Initially, educational researchers were not specifically interested in geography content, but rather in questions such as: How do children learn? What materials attract the attention of children and promote thinking in specific ways? Is there a sequence of learning that advantages students as they progress from early to later years in school? Those questions remain familiar, for they have persisted into the twenty-first century and continue to be addressed by contemporary researchers. However, the difference is that, while some of the early twentieth-century research was completed while observing students in learning environments, much of the research was philosophical in nature, based on conventional wisdom regarding primary and secondary students. The research was often in the quest for grand ideas about learning. Those philosophical treatises were then transformed into curricula and the learning progressions that were most appropriate in elementary and secondary schools. It was the development of curriculum and sequencing the curriculum for optimum learning that engaged geography education.

Curriculum development and curriculum change have been important topics within educational research for the past half century. Curriculum change is the product of dynamic societal expectations or demands on the educational system. Discussions regarding reforms in geography education and the implementation of reforms began in earnest in the latter part of the twentieth century. There was little research on the need for, or the type of reform that would provide, geography education with a proactive position within the curriculum. The result was that geography education has been a product of reform rather than an advocate with the potential to shape its role within the curriculum through reform.

Curriculum decisions are made at either state or national level, depending on the country being reviewed. For example, England has a national curriculum, whereas in the United States and Germany state and lander authority, respectively, determine the curriculum. In all instances, the curriculum is expected to meet the demands of a country’s state or national ministry, department of education, or another national legislative or governmental body.

Numerous national curriculum reform movements have impacted geography education. Perhaps the most monumental was the transition in the national curriculum that occurred in African countries following independence for Ghana in 1957. The primary and secondary educational systems during the colonial period were replicas of the curriculum in the colonizing country. This was the case not only with European countries but also with Japan’s colonial rule of Korea and with US colonial rule in the Philippines. In the former British colonies, students who were fortunate to complete primary and secondary school were administered either the Cambridge or Oxford Sixth Form Examination. That practice continued well into the late twentieth century, when new African-based examinations were introduced, for example the West African Senior School Certificate Examination (WASSCE), which initiated a transition from a Eurocentric to an African curriculum. Today students across much of Africa take examinations based on their own postcolonial curriculum models. The Kenya National Examinations Council provides countrywide assessments as a means to ensure conformity to Kenya’s national goals and governmental policies relating to the curriculum and examinations. Attention is focused on a national or regional curriculum and examinations are aligned with the curriculum. In the twenty-first century African students examine the urban structure of not just London, as they had done for the Oxford and Cambridge examinations, but also
Lagos, Nairobi, and other African cities. In both West Africa and the Kenyan examples, the examination drives the curriculum. Research on the success of the geography curricula and the adjustments needed for changes in the discipline are continually being pursued by African geography educators in the twenty-first century.

In the United States, earlier in the twentieth century, a major reform in education began that would eventually have considerable influence on the role of geography education, both nationally and internationally. This was the social studies movement, whose influence continues into the twenty-first century. The basis for the movement began in the late nineteenth century in the United States and gained considerable attention from educators in the early years of the twentieth century (James 1969). Those far-reaching effects began with educational policy recommendations by the US National Education Association (NEA) regarding geography in the curriculum. NEA recommendations favored a curriculum organized as social studies. The social studies provided a new structure for adding subjects to what had been principally a geography and history curriculum. Social studies was intended to include geography, history, government, economics, and other subjects that were concerned with the social development of citizens and with content that had societal applications. Social studies represented a major curriculum reform. The geography curriculum that was taught as a stand-alone series of courses beginning in primary school and extending through secondary school would, in time, become integrated within the social studies curriculum.

Two additional circumstances at the time weakened the role of primary and secondary school geography. First, there was disagreement between geographers regarding the roles for physical, human, or regional geography as the curricular focus. Second, geographers did not participate in the committee discussions that formulated the social studies curriculum (James 1969) because physical geographers did not regard geography as a study of social issues. The lack of participation in the policy recommendations disengaged geographers from the subsequent educational decisions that established social studies permanently. Geography education had a place in the social studies curriculum design, but few geographers were willing to help transition the subject into the new curriculum. However, changes were underway and over the six decades following the NEA policy recommendations, geography education gradually became integrated into the social studies curriculum in the United States. In the twenty-first century, students may study geography, but the discipline is a component of social studies. This diminished role of geography in education continued during the remainder of the twentieth century. The discipline assumed a less prominent role in the curriculum, in terms of both disciplinary name and content.

The social studies reform movement of the twentieth century has had international implications for geography education. In many countries geography was initially taught as a stand-alone course in primary and secondary education. However, as the social studies curriculum diffused to other countries, the preference for an integrated series of topics that drew on the disciplines became the norm. Social studies’ major objectives included curricular concepts such as civic development and citizenship. In practice, social studies served a purpose that neither geography nor history provided for newly independent countries. It was the development of citizens through school, with the eventual outcome being an informed, responsible citizenry.
Attention to social studies varied between democratic and totalitarian systems of government, and reflected different priorities between different countries within each category of governmental structure. Over time, social studies has become the preferred curriculum choice among educators and in both primary and secondary schools. Internationally, the curriculum is called social studies in primary school, but in secondary school geography sometimes remains clearly defined as a subject. The 2014 curriculum change in Australia is a case in point. Formerly social studies had been designated for all grades, but the national government reinstated a specialized geography course in the high school.

Internationally, the social studies expanding environment curriculum model, or contextual derivations of it, has achieved widespread acceptance. Few countries depart significantly from its basic structure (Box 1), although the terminology used for the topics studied in the curricular sequence may vary. The expanding horizons model has been the curriculum most consistently applied to primary education. It dominates social studies curricular frameworks in textbooks, national content standards frameworks, and national examination formats.

While the expanding environment has been prominent in primary schools internationally, it has not in secondary schools. In most countries, geographic content is taught in courses referred to as “geography” in the curriculum. When asked, students say that they are studying geography. In the United States, courses with substantial geographic content are often titled “global studies,” “world studies,” “cultural studies,” or “contemporary issues.” The major exception in the twenty-first century is Advanced Placement Human Geography (APHG) and the International Baccalaureate (IB) in geography, both of which are rigorous and content- and skills-intense courses in high schools.

The expanding environment, while widely used, is not without critics. A major criticism is based on the greater opportunities for primary and secondary students to extend their interests to more distant geographic locations and prior historical eras by using twenty-first-century technology. The globalized world is often cited as another reason the expanding environments model is outmoded. These criticisms are difficult to support because the geographical study of nearby spaces precedes and links to that of more distant and abstract spatial topics. While the expanding environment curriculum appeared to offer little flexibility, there was considerable opportunity to link the local environment to national and global topics in the early years of schooling, and to link national and international topics to the local environment in the later years. There is still little research on the alignment of the expanding environments curriculum with child development or the manner in which social studies and geography learning occurs. Within primary education, research is needed on learning progression, concept development, and the understanding of basic and complex content. Such research will provide important information for the design, structure, and content of the curriculum in both geography and social studies.

The curriculum remains a critical component in determining how much time is allocated to geography education during the school year, and what content from the discipline is emphasized. Curriculum provides the access for including geography within the educational experiences of students. For example, there was little attention to curriculum structure as it was applied to geography education in the second half of the twentieth century. In 1994 the United States published the National Geography Standards in response to a national educational reform.
Box 1 The expanding environment/horizons curriculum model.

Topics in the curriculum are quite consistent for grades 1 to 5 in many countries, but they vary in secondary schools. High school courses generally follow social science disciplines, often embedded in the social studies curriculum. Political science content is often labeled “government” or “civics.”

in many subjects. The intent was to make the subjects studied by students more rigorous (the popular term used was “raising the bar for content proficiency,” comparable to raising the bar for a high jumper in track and field). However, there was little corresponding research-based curriculum information available to inform the standards-building process. Research in curriculum development is necessary in sequencing topics in geography and in social studies, in the learning progressions that students respond to in sequencing content, and in identifying the ways a student should demonstrate proficiency in knowing and applying knowledge. The curriculum must be a well-developed plan for presenting the study of geography for students.

Curriculum research and planning is a complex matter. A continuing issue that faces geography education in the twenty-first century is the discipline’s future role and placement within the curriculum in different countries. For many decades, geography education filled two major functions in the education of primary and secondary students. First, the discipline’s content is diverse, and includes both human and physical study of the Earth. The discipline is dynamic and changes with new technologies, new ways of thinking about the world, and new ways of researching the Earth and its inhabitants from a geographic perspective. Second, different societies have different expectations for geography education, although one seems to dominate. The societal view of geography by policymakers and teachers is largely that of developing a worldview that enables students to become informed about the countries of the world and the ways in which
they are either linked or separated by contemporary issues. In part, that expectation is tied to the geography education of the past, when knowledge of the world was the main concern of geography. At present, modern geography education is dependent on the availability of geospatial information and the tools of mapping and graphing those data to solve problems and make decisions. In the twenty-first century teachers, students, policymakers, and the public regard geography as providing the content, skills, and perspectives essential to make sense of the world. What is needed is a widely recognized research basis for how an understanding of the world develops progressively in primary and secondary students (Lambert and Jones 2013; Butt 2015).

International initiatives in geography education

The United Nations, founded in 1945, took an early interest in geography education. While there were international conferences of geographers prior to 1945, the United Nations claimed the role of geography education was to enhance international understanding. This was partly as a result of the important role geography played in establishing peacetime territorial agreements at the end of World War II. The United Nations also took the view that, if young children learned about the world and its human and physical geography, there would be greater international understanding. The educational task of the United Nations was delegated to the United Nations Educational, Scientific and Cultural Organization (UNESCO) in 1945. UNESCO assumed responsibility for nearly all educational programs on behalf of the United Nations. From the very beginning, geography education was viewed by UNESCO leaders as a necessary subject in primary and secondary education. Collaboration between the International Geographical Union Commission on Geography Education (IGU-CGE) and UNESCO led to the publication of two major international handbooks on the teaching of geography in the 1960s and 1970s. The books were designed to inform teachers in developing countries regarding the most recent and effective practices in geography education.

The interest of UNESCO in the growing international popularity of the social studies curriculum movement had spread from the United States to other countries by the 1990s. The international focus on social studies gained traction with a newly published handbook on the teaching of social studies in primary and secondary schools (Mehlenger 1981). Each chapter of the book was devoted to a subject or method that applied to the social studies. A single chapter was devoted to geography. The sourcebook was intended to provide a menu for interdisciplinary or multidisciplinary contributions to curriculum and teaching. It was widely distributed to developing countries through UNESCO. In developing countries, this often marked a transition from geography as a stand-alone subject to its inclusion as part of the social sciences and humanities content that constituted the social studies curriculum. A central focus of the sourcebook for social studies was the importance of preparing students for citizenship in their countries and the essential content and skills to meet the demands of twentieth- and twenty-first-century societies.

An additional handbook on geography was published in the early 2000s. It was sponsored not by UNESCO but by the IGU-CGE, and distributed mainly through the network of the Commission on Geography Education and direct sales by the publisher. Entitled the International Handbook on Geographical Education (Gerber
2003), it was organized in much the same way as each of the prior handbooks were composed. Geography experts in different regions of the world were invited to contribute to a planned table of contents that represented critical issues in the teaching of geography at the time. While topics such as geographical skills persisted through each of the handbooks, the applications of classroom methodologies changed. For example, the classroom technology made the transition from the use of wall maps and chalkboard visuals in the first sourcebook to the use of computer-based and Internet graphics in the final handbook. These three books represent an important extension of geography education information to teachers primarily in developing countries from the 1960s to the beginning of the twenty-first century.

Similar to handbooks have been the specialized methods books devoted to the teaching of geography that have been published, but they are not common. In the United States there is just one current teaching methods book devoted specifically to geography education (Gersmehl 2014). In the United Kingdom the major geography methods book is published by the Geographical Association, the professional society for geography educators (Balderstone 2006). Similar geography teaching methods are published within the contexts of specific countries, such as India, Australia, Germany, France, and Singapore.

Geospatial technology, World Wide Web, and teaching geography

During the twentieth century, perhaps the most important source for practical classroom suggestions regarding teaching was a printed geography instructional methods book that demonstrated ways to teach content and skills. Methods publications in print form have largely been replaced by materials that may be accessed on the World Wide Web, either as electronic books or as suggestions for teaching that are contributed by other teachers to websites. Both professional societies and commercial publishers have engaged in providing methods materials for preservice geography education students and classroom teachers engaged in professional development. The Annenberg Learner project entitled “Teaching Geography” (www.learner.org/workshops/geography) provides professional development for teachers as well as curriculum materials that can be used in the classroom. National Geographic Education provides classroom materials in human and physical geography for download from its website (http://education.nationalgeographic.com/education/?ar_a=1).

The advantage of the World Wide Web for professional materials in geography education is its global accessibility to teachers and students in primary and secondary schools. Search engines list many hundreds of lessons, reference materials, and scholarly articles for keywords such as “geography methods,” “teaching geography,” “geography skills,” and “teaching with geographic information.” The materials available on the web must be evaluated carefully prior to use, since they vary greatly in content accuracy and teaching methodology. Websites often include basic suggestions for teachers and materials for students, as well as lessons that advance particular methodologies such as inquiry, problem-solving, and decision-making as a component of geography instruction.

The introduction of computers in the latter decades of the twentieth century to geography education marked a major transition in the availability of reference materials and resources for students in primary and secondary schools. Geography through virtual field trips and collections of photographs, and access to data about
the world in electronic format, were early advantages. An early use of computers in primary and secondary geography education was to search and view maps that would normally be available only in specialized map collections. Basic maps could also be printed. Initially printed maps were used mainly for labeling countries, cities, and topographical features. As geography instruction began to rely on statistics that reflected climatic, population, and economic data, the nature of map study as a teaching method changed. Students were able to use electronic maps to show the spatial patterns of population change, soils, climate, and the economic conditions of local communities as well as to compare their country or region with other places. Most of the early maps were reproductions of printed maps in electronic form. In electronic format, the spatial patterns on several different maps could be compared visually to search for similarities and differences that helped explain the geography of the place.

Since maps are the geographer’s most widely used means to display geographic information, the capacity of computers to produce and deliver maps continued to evolve. With the advent of the World Wide Web, high-resolution electronic maps of both historical and contemporary topics became available. They could be viewed electronically and saved as electronic files to use for future work on projects. Lessons were developed to teach students how to use electronic maps. Many of these lessons are available on geography education websites to new generations of teachers and students. Electronic maps provided greater opportunities to interpret and explain the spatial patterns relating to numerous topics in physical and human geography.

In the twenty-first century, geographic information science (GIScience) is one of the most rapidly growing applications of academic geographic research. GIScience has also stimulated an important transition in the teaching of geography, perhaps the most important invention since the printing of the first geography textbook. It permits mapping, the use of photographs, the streaming of video from handheld devices, and the use of geographic data to address geographic issues and problems from the local to the global scales. The availability of web-based GIScience has made it possible for primary and secondary students to access geographic information and mapping software with only an Internet connection and a computer or handheld device. GIScience information may be shared with similarly aged students or academic experts to prepare research reports and data collected in the field. During the twenty-first century, students use web-based mapping in their research and class projects in local schools, as well as participate in research challenges and contests with international groups of students to focus on topics or issues of significance. The continuing potential applications of GIScience for use in primary and secondary education increase with improvements in the software. Whereas considerable expertise in GIScience was once required to produce a map, the web-based mapping programs of the twenty-first century have become available to the general public, including schools, at little or no cost for the right to use the software.

The early twenty-first century also saw initiatives to encourage the use of GIScience in primary and secondary education. The first, Esri, is the internationally recognized leader in the development of GIScience. The Esri leadership viewed the wider use of web-based mapping in schools and by the general public as a corporate responsibility. Esri has developed web-based mapping software for education that does not require a large amount of computing power but, rather, relies on the capacity of the web to process data that can be used by students.
The result is its continued support and provision of software for educational purposes, and its licensing of software use to many thousands of schools. Its web-based mapping software and operations are less complex, are menu-driven, and include datasets that can be selected as mapped layers for the overlaying and analysis of spatial patterns.

The second initiative came from the National Geographic Society (NGS), a major provider of geography teaching materials and teacher professional development. NGS software was developed to introduce students to the use of the web in mapping. Called MapMaker, it applies basic mapping skills, using scale, geographic patterns, and drop-down menus, to place symbols on maps (http://mapmaker.education.nationalgeographic.com/?ar_a=1&b=1&ls=000000000000). The maps can be viewed on screen and printed, and several types of information can be compared and analyzed at a very basic level of complexity. It is web-based mapping specifically designed for use in primary and secondary geography education.

GIScience is one example of how geospatial technology is reshaping primary and secondary geography and social studies teaching in the twenty-first century (Milson, Demirci, and Kerski 2012). While more sophisticated applications are used in secondary schools, there are instances where younger students are using GIScience, mapping, and satellite images on websites. They may use geospatial devices such as computers, tablets, smartphones, and so on to display geographic information: for example, for a bird’s-eye view of the school and nearby street patterns. In secondary schools, such devices are used to analyze data and compare and contrast conditions, and to explain why a change in one geographic pattern, such as land use, can result in a change in a second pattern, such as vehicular, pedestrian, and bicycle traffic. Geography and social studies teachers in the twenty-first century must have a good grasp of geospatial technology to address local and global issues. Students should learn the benefits and advantages of using geospatial technology both inside and outside of school.

Geospatial technologies are common components of modern devices used for communications between individuals. When they are used to address geographic problems and aid decision-making, these devices have considerable relevance to geographic education. Geography educators consider geospatial technology as a means to enhance learning in geography. Students often demonstrate an interest in using technology in many different and creative ways. The challenge for the future is to make the use of geospatial technology and the content of geography as seamless and engaging as possible. Geospatial technology may be applied widely across societies to address problems and to formulate solutions relating to the world in which these students live (Sinton et al. 2014).

Geography education research in the twenty-first century

The major investigation topics in geography education prior to the twenty-first century were on the effectiveness of teaching methodologies and student learning of geography, with some attention to curriculum development (Lambert 2015). Geography education research related to thinking and learning received less attention during the same period. However, it became increasingly apparent that ways of learning and thinking about the world were an important item on the research agenda (Lambert 2010). Prior research in geography education was based largely on research in education and on the educational aspects of geography. What was needed,
and which steadily materialized during the final decade of the twentieth century, was an initiative that would integrate geography education and educational research with theoretical positions supported by both geography and education (Seo and Kim 2012; Segall and Helfenbein 2008).

The research topic that gained prominence among geography educators was spatial thinking. The spatial tradition of geographical science served as the gateway to spatial thinking research and the development of geospatial perspectives by students in primary and secondary education. It also served as the logical extension to the spatial thinking research being pursued in other disciplines. For example, spatial thinking had a long research tradition in psychology, especially among developmental psychologists. Spatial thinking and its application to learning were also of interest to educators in mathematics, science, and cognitive studies. Those researchers had demonstrated that spatial thinking was related to perspective-taking, to hierarchies of inclusion whereby students understand that different geographic features fit within larger categories and that linear and area measurements required spatial transformations. Those topics were deeply embedded in the spatial nature of geography as a discipline but had not been highlighted for research in geography education. By the 1990s, research reports began to address spatial thinking in geography, written by both geographers and psychologists. The publication of *Learning to Think Spatially* (Geographical Sciences Committee 2006) was a milestone that built a case for the relationship between geography and spatial thinking, as well as highlighting the research potential for geography education. By the 1990s, research reports began to address spatial thinking in geography, written by both geographers and psychologists. The publication of *Learning to Think Spatially* (Geographical Sciences Committee 2006) was a milestone that built a case for the relationship between geography and spatial thinking, as well as highlighting the research potential for geography education. The opportunity to pursue spatial thinking and the development of a geographic perspective gained considerable attention as a research topic. This was due, in part, to the concurrent attention to geospatial technology in the curriculum. While geography education had traditionally viewed spatial learning as a goal, there had never been compelling developments that promoted it as a research topic. GIScience, global positioning systems (GPS), and the use of handheld geospatial devices, such as smartphones and tablets, provided the opportunity to connect spatial thinking and geography education research. Using such devices, students both in primary and secondary classrooms and outside of school were immersed in spatial data and spatial thinking. The connections between the geospatial devices and the spatial attributes of geographical thinking were not readily known. This provided a research opportunity.

The transformations resulting from the geospatial revolution that was underway in geography, and the use of GIS in other subjects, became an inviting research agenda. While there had been reviews of research in geographical education, there had not been a projective discussion of what was needed to advance the research. The four major scholarly and professional societies in geography in the United States joined forces to address the future of geographic education. The project produced *A Road Map for 21st Century Geography Education*, which devoted most of its pages to projecting the directions for the future of geography education (Bednarz, Heffron, and Huynh 2013).

The project concentrated on three topics in geography education that were high priority: (i) research; (ii) instructional materials and professional development; (iii) and assessment (Bednarz, Heffron, and Huynh 2013). While the *Road Map* project initially focused on researchers and future research in the United
States, attention was given to international views on geography education. What the Road Map aimed to accomplish for the United States also resonated with geography educators in other countries. The three priority recommendations of the Road Map project are attracting interest in other countries. The Road Map project presents a big picture, leaving individual researchers and their institutions to develop the capabilities to engage in the research.

As a result of the Road Map, projects are being planned and initiated that involve international collaborative research. The GeoCapabilities project is researching two questions about geography education’s role in society. The first asks how geography education can contribute to the development of human capabilities. The goal is to explore the significance of geography education in preparing students for a successful lifetime career and civic engagement. The second question is the obverse of the first: What are the consequences for young people, in terms of their future potential and wellbeing, of not having access to geography education? The project seeks to identify the disadvantages for individuals and societies if young people are deprived of a geography education. The long-term negative effects on each person’s capacity to play a participatory role as a citizen through a career and civic life have particular relevance in countries where geography education has a low profile in the curriculum. These are big questions that arise from the societal belief that education benefits everyone. Does a geographic education benefit societies in ways that other disciplines cannot? The research may identify the particular role that geography education plays in the attainment of those goals, and the negative consequences of not providing geography education. Among the partners and affiliates of the project are Belgium, England, Finland, Greece, the United States, China, the Czech Republic, Germany, the Netherlands, Portugal, Serbia, Singapore, Sweden, and Turkey. While each country will research GeoCapabilities within its particular national context, the research results will be shared and analyzed to provide a research-based global rationale for teaching geography in primary and secondary schools.

The second project recommended by the Road Map project encompassed international research collaboration as a natural outcome. Learning progressions in geography education have long been a research interest. To date, most beliefs about learning progression are based on conventional wisdom, such as the expanding environments curriculum that is dominant in social studies education. The intent of the research is to determine the progress students make in studying geography compared to the desired standards for information acquisition, conceptual understanding, and geospatial skills applications. The theoretical and practical interests in learning progressions in geography education emerged in the first decade of the twenty-first century (Bennetts 2008). Reports on the progress students make in learning various subjects are reported in the research literature, and Bennetts (2008) used a critical analysis methodology to examine progressions and understanding in geography specifically. He made the case that learning progression research is necessary to align the curriculum to national geography standards by way of students in the classroom who are engaged with the subject. Learning progression is a universal concern in geography education and lends itself well to international collaborative research. Initial research on GeoProgressions as a topic within learning was initiated in the United Kingdom (England and Wales) with the support of the Geographical Association, and was later recommended as a main research topic by the
**Road Map** project in the United States. The major emphasis of the most recent learning progressions research initiative is on teaching early career scholars and researchers about the theoretical and practical attributes of learning progressions. The project to achieve capacity building is sponsored by the American Association of Geographers. Its goal is to develop the critical capacity necessary to design and complete sustained investigations about learning progressions in geography content, understanding, and skills.

### Journals in geography education

Geography education research has been widely diffuse. Much research is the result of doctoral dissertations completed at universities. Dissertation research that is synthesized, rewritten to journal publishing standards, and submitted for publication in research journals becomes accessible to other researchers. The first journal devoted specifically to geography education research was sponsored by the Commission on Geography Education of the International Geographical Union (IGU–CGE). Entitled *International Research in Geographical and Environmental Education* (IRGEE), it has been the main source for publishing research articles on geography education since it was started in 1992. The journal features research articles that employ both qualitative and quantitative methodologies, and accepts for peer review all research topics that are representative of geography and/or environmental education.

A second research-oriented journal is *Research in Geography Education* (RGE), published by the Grosvenor Center for Geographic Education. First published in 1999, RGE has research as its principal focus. It also publishes opinion, philosophical, and historical reflections on the state of geography education. The journal’s wide interpretation of research in geography education results in a broad range of topics.

There are general journals that represent a broader cross-section of geographic education than the research journals. They include suggested teaching methods for elementary and secondary classrooms, examples of online satellite images and photographs that can be printed, and lessons designed to address a particular topic or issue. The journals are sponsored by geography teachers’ organizations in different countries, but may be printed by a major publisher and marketed as printed copies and/or as electronic journals or articles.

The following is a list of print and electronic-access journals for geography education: *Geography* (UK), *Journal of Geography* (USA), *Geographical Education* (Australia), *New Zealand Journal of Geography*, *Journal of Korean Association of Geographic and Environmental Education*, *Geography Teacher* (USA). The following are online journals for geography education: *European Journal of Geography* (international), *J-Reading – Journal of Research and Didactics in Geography* (international), and *RIGEO: Review of International Geographical Education Online*.

### Summary

In the United States, geography in primary and secondary education is a component of the social studies curriculum. In other countries the placement of geography varies, but a common pattern is for geography to be included in elementary social studies, and then taught as a geography content course in the secondary school curriculum. In some countries physical geography is an important component of the science curriculum. Within the social studies curriculum, the
challenge for geography is to attain, and then maintain, an equitable role among the other content subjects, namely history, government, economics, and, in some cases, the humanities. The introduction of geospatial technology in the twenty-first century has provided an opportunity for geography to assume a larger role within the growing technology component of education, both in the United States and internationally. In the United States the science, technology, engineering, and mathematics (STEM) initiatives represent an opportunity for geography and geospatial technology to join the privileged curricular components that are given priority. STEM subjects have increasingly become priorities in many countries, since they are viewed as essential for sustained national economic growth.

In order for students to meet STEM content and skills expectations, a major adjustment in primary and secondary geography education began early in the twenty-first century. First, new cohorts of geography teachers are being prepared, either in their initial teacher education or through professional development, to gain proficiency in using geospatial technology. Second, a scientific basis for geography through STEM will need to draw from the earth science tradition of the discipline. Geospatial technology has opened up numerous opportunities for student engagement, advanced education, and careers. Geographic content and geospatial technology are powerful academic and applied components for primary and secondary students to pursue as they prepare for college, careers, and civic life within their communities. Geography education can play a leading role, with skills and technologies that provide access to spatial information. Spatial information is essential for solving problems, making decisions, and thinking critically about the world in which students live.

Gersmehl, Phil. 2014. Teaching Geography. New York: Guilford Press.

Lambert, David. 2015. “Research in Geography Education.” In MasterClass in Geography Education:
Diversity is a multifaceted issue within geographic education, one that brings together social, cultural, political, and ethical questions and concerns. How is diversity conceptualized? How do perspectives and initiatives change over time and place? Who teaches and studies geography? Do curricula and pedagogy reflect commitments to social inclusion, justice, and equity? This entry emphasizes American geography, primarily since the 1960s, but also introduces examples from other settings to illustrate some ways in which concepts, priorities, and approaches may cross boundaries but also differ.

Conceptualizing and measuring diversity

How diversity is understood has varied over time and across different constituencies within geography, reflecting national and local contexts. Much, though not all, attention in the literature has focused on higher education. The range of interpretations is diverse, most commonly dealing with “race,” ethnicity, and gender, but also with national and immigrant origins and status, (dis)abilities, sexualities, indigeneity, and social class. Major attention emerged in the United States during the 1960s as the Civil Rights Movement and federal government policies prompted concerns about the low representation or exclusion of “Blacks” or “African Americans” within higher education. By the 1970s, with growing feminist activism, attention to the situation of women also became an issue in the literature and within professional organizations. In subsequent decades, interpretations have widened to incorporate additional categories and to recognize their “intersectionality.” The initial ones remain those most often addressed, however, and accordingly will be discussed in the most detail here.

The first significant organizational endeavor by the Association of American Geographers (AAG) to increase diversity was the establishment of the Commission on Geography and Afro-America in 1964–1965. Its primary goals were to recruit and support African American undergraduate students in graduate studies, emphasizing those from Historically Black Colleges and Universities in the Southern states (AAG Diversity Task Force 2006). Beginning in 1972, additional categories were included in summary statistical profiles of composition of the overall membership of the AAG (published in its Newsletter): “Blacks,” “Spanish Americans,” “Oriental Americans,” and “Native Americans.” Difficulties of making estimates were noted. By 1981 the categories “Not Classified,” “American Indian,” “Asian,” “Black,” “Hispanic, “Native Alaskan,” and “Pacific Islander” were adopted, though for the next 20 years more than 90% of members were reported as “Not Classified.” Longitudinal membership data since 1972 are available from the “Disciplinary Data” section of the AAG website. These should be interpreted with caution, however, since not all geographers are AAG members and not all members reside in
GEOGRAPHY EDUCATION: DIVERSITY AND PARTICIPATION

the United States. Increasingly, with the use of online applications for membership, individuals do not provide these data. What are available do indicate some small growth over time of those identifying as (Black) African American (1.17% in 1972 and 3.15% in 2012), and Hispanic (0.13% in 1972 and 4.38% in 2012), but the other minority categories remained below 1% except for the noticeable increase in “Asian” representation, from 4.02% to 11.53%. Going beyond AAG membership, a 2004 survey of 74 departments (Estaville, Akiwumi, and Montalvo 2009) revealed that two-thirds of them had no minority faculty, that only 1.1% of the faculty was Hispanic and 3.6% Black. Asians accounted for 7.1%, more than their representation in the national population, likely including those who had come as international students and remained as faculty. That survey also sought information on undergraduates. Responses from 66 departments showed Blacks accounting for only 2.2% of geography students, and Asians 4.6%. The changes have been slow and limited and are not confined to geography programs, however.

National scale data present only part of the picture. As a recent theme issue of The Professional Geographer (66(2), 2014) highlighted, the location of institutions has implications for the potential and actual recruitment of students of diverse backgrounds. Large metropolitan areas like New York and those in the Middle Atlantic and Pacific Coast states offer more potential than central and southeastern states. Those community colleges in which geography is taught appear to have a greater likelihood than four-year institutions of enrolling minority students. Also documented is that sustained initiatives at the departmental level make a difference in increasing the representation of minority students on geography programs. Examples from two universities in Illinois illustrate ways in which setting and missions are relevant. Southern Illinois University Carbondale (SIUC) is distant from major metropolitan centers that have substantial minority populations. Normally, its incoming students have little prior knowledge of geography as a discipline. To foster diversity, the geography department adopted several strategies, among them collaboration with other units in a summer program to help underrepresented students make transitions from high school to university studies. Faculty also engaged in outreach to schools to reach potential students of minority or of the first generation in their families to participate in higher education. The faculty also established personal ties with geographers at the nearest Historically Black College and University with whom they shared interests in geographic information systems, resulting in recruitment of its students into SIUC’s geography graduate program. Different strategies were pursued at Southern Illinois University Edwardsville, located close to urban St Louis, Missouri. The institution has an advantage in that it offers the lower in-state tuition rates to students from across the state border. Faculty engaged in outreach to schools in St Louis. The department also used its undergraduate qualitative methods course to interview nonmajor women and minority students to investigate what would make geography attractive to them as a major. Drawing on those findings, a new information brochure was designed for undergraduates which included information on careers of alumni. Additionally, urban studies were reinvigorated within the department’s course offerings. The department has continued to monitor how these approaches impact on the makeup of their student body.

As with the initiatives about racial representation, international feminist activism in the 1970s fostered attention to the position of women in geography, a theme highlighted...
by AAG president Wilbur Zelinsky (1973). As women increasingly entered graduate programs and early-career faculty positions they became increasingly politically active. Through the newly created Committee on the Status of Women in Geography, they devoted themselves to supporting research and teaching on women and promoting the election of women to positions in AAG governance. Research also examined the representation of women across types of institutions and by specialties. Supplementing and challenging mainstream feminist perspectives were the voices of women of color, highlighting their distinctive experiences and priorities for social justice that reflected their personal and communal experiences (e.g., Pulido 2002; Sanders 2006).

The growing representation of women in geography reveals how cultural, political, and economic contexts both in academia and in the larger society have been implicated in the changing gender representations and position of women in the discipline. Historical research has revealed that women had been significant in geographic education from the late nineteenth to the mid-twentieth century in the United States both in the schools and in the institutions designed to prepare teachers for elementary and secondary teaching, though they were barely present on the faculties of universities. In 1917, for example, shortly after its founding, 645 women were members of the National Council on Geography Teachers (later the National Council on Geographic Education) and held leadership positions. This contrasted markedly with the elitist male-dominant membership of the Association of American Geographers that, over many decades was oriented to university faculty. Only 10 women were elected to its membership between its founding in 1904 and 1945, and several of those worked outside educational institutions, for example in federal government agencies (Monk 2004).

Since the 1970s, the increasing enrollment of women in graduate education has been sustained, though unevenly, intersecting with other political and economic changes. Data compiled by the National Center for Educational Statistics of degrees awarded in geography indicate that both the number and percentage of PhD degrees awarded to women have increased markedly over the succeeding decades from 6.0% in 1960–1961 to 46% in 2010–2011, a period in which the total number of doctorates increased almost fivefold. Awards of master’s degrees to women similarly increased from 14% to almost 43%. Gains have been slower at the bachelor’s level, with women earning only about one-third of those awarded in recent years at a time when they make up about 60% of undergraduate students nationally. The latter situation has been largely unexplored, but trajectories of change in gender representation at the graduate level appear connected to aspects of academic labor markets and public policies, as well as to women’s changing aspirations. The number of graduate degrees earned by men peaked relatively and absolutely around 1970, dropping or growing slowly thereafter, whereas increases in graduate degrees earned by women continued. Changes in representation in doctoral awards may be interpreted not only in relation to women’s aspirations or departmental cultures, however, but also as a result of men’s engagement with graduate education having decreased rapidly in the 1970s. The ratios of male to female student memberships in the AAG declined precipitously from 7.2:1 in 1967 to 1.7:1 in 1988. That change likely reflected not only expansion in the numbers of women but also men’s responses to a tight academic labor market as the expansion of undergraduate enrollments due to the baby boom passed, with related decreases in the creation of new faculty
positions. It may also have reflected the cessation of government fellowships offered under the National Defense Education Act (most of which had gone to men), and the end of the Vietnam War during which some men had gained military draft deferments through their status as graduate students. Government policies on affirmative action may also have shaped increasing employment opportunities for women (and minorities), though the extent and patterns of their influence are not clearly evident.

The location of women has, however, been institutionally uneven. Analysis shows that in departments that granted a total of 30 or more PhDs between 1990 and 2000, half or more of the recipients were women whereas in others they received only about 15% of PhDs granted (Monk 2004). Women’s representation also increased more on the faculties of doctoral departments than in institutions in which the highest degrees awarded were the masters or bachelors. This pattern may have reflected the smaller total size of the latter and perhaps also greater responsiveness to federal government affirmative action policies in the former which were more sensitive to external research funding. Still, it was noted that women took longer to achieve promotion in rank than their male peers.

Several studies of the representation of women in geography outside the United States also reveal the effects of geographic, political, and cultural contexts. In the 1970s research by Linda McDowell revealed that 43% of British geography departments lacked women faculty, but they were much less well represented in most English university departments than they were in Scotland and in the London colleges. The proportions of women declined rapidly with the progression from undergraduate to master’s and doctoral studies, and even more at the faculty level. In Spain changing demographics, legal contexts (including policies relating to practices of academic hiring), and shifts in labor markets saw low representation of women faculty in the 1970s, with increases in their hiring from the 1980s when government policies afforded greater local autonomy to universities and when academic curricula in geography were especially associated with preparation for teaching. More recently, the increased masculinization of academic geography departments has been evident as academic labor markets have shrunk while curricula geared to professional and technical work outside education have expanded in Spain (Garcia-Ramon and Pujol 2004).

Widening interpretations: beyond dichotomies

As critical studies have developed on the theme of diversity, it has been recognized that categories related to race and gender do not reflect the varied and layered social and educational experiences of students or faculty. The notion of intersectionality has become recognized, with calls to avoid essentialism. Research with American master’s and doctoral students, for example (Schlemper and Monk 2011), found that they spoke of themselves and their peers in relation to citizenship, country of birth, marital status, social class, language fluency, life stage, and sub-discipline. Less often did they mention physical disabilities or sexual orientation. Compared to students, however, faculty tended to refer to their students in the dichotomous categories of “men” and “women” or sometimes also to “minorities.” The location of institutions played a role in the perspectives expressed – those in large metropolitan areas reported different experiences and daily practices from those in smaller college towns. Married students and faculty also brought up the particular situation of dual career couples in relation to finding employment.
In the United States, foreign-born faculty and students are significant among those teaching and studying geography. They represent a variety of cultural backgrounds, national origins, and choice of specialties. Articles in the Journal of Geography in Higher Education (32(1) and 32(2)(2), 2008) explore a range of issues related to foreign-born faculty and teaching. Some commonly expressed (or assumed) views include students who are native speakers of English reporting problems understanding the accents of those from abroad, and students differing from teachers in their expectations of assumed knowledge or of grading scales, and in the choice of an appropriate language for interpersonal interactions. Yet research has also revealed positive comments by students, for example, that their perspectives have been widened and that they appreciate engagement with teachers who have firsthand experience of another culture or of employment outside academia. In addition to their academic work, international faculty may also simultaneously face legal problems relating to residency and challenges in balancing family and other personal responsibilities that differ from those of their native-born colleagues. Their concerns may include not only pedagogical matters but also aspects of marginalization by colleagues, and expectations that they are identified with technical and quantitative specialties. Beyond these aspects of internationalization in higher education at the individual level, however, are the longer-term implications of increasing internationalization in multiple national settings for the reshaping of knowledge, as recently proposed by Madge, Raghuram, and Noxolo (2015).

Placing diversity in the curriculum

An important issue in geographic education is how to approach teaching about diversity and to diverse groups of students. Attention to these matters is uneven in terms of contexts and approaches. The literature tends to focus on higher education rather than elementary and secondary levels. While it is not possible to make a global assessment, it is evident that initiatives to instigate change have varied over time and place, as explored, for example, in a series of articles on “Feminist Geographies Around the World” in the journal Belgeo (2007/3) and also in International Research in Geographical and Environmental Education (20(3), 2011). Gender themes, for example, emerged in geography teaching in an array of Western countries in the 1970s and 1980s, but have been more recent in Central and Eastern Europe, and continue to be largely absent in geography in some parts of the region. Research and teaching on gender and sexualities have recently expanded in some institutions of higher education in Brazil. In Asia, there is a strong program in Singapore, sustained teaching in Taiwan, and growth of participation in some institutions in India and Japan but apparently not in China. Most articles in International Research in Geographical and Environmental Education address elementary and secondary education but attention to diversity as a curriculum theme or of students is relatively rare within them other than by disaggregation of the quantitative data of male and female student responses on surveys or test scores. These tend not to be interpreted, however. An exception is a study of why British boys do not achieve as well as girls in secondary school examinations in geography, with differences connected to gendered cultural norms and preferences for different styles of teaching and classroom interaction.

Resources for teaching about gender in geography, especially in undergraduate courses, were developed in the United States as early as the 1970s, for example, when a federal government–funded project within the AAG
generated a set of teaching modules under the title “Women and Spatial Change.” An early introductory text by Mazey and Lee followed in 1983. In Britain, the Women and Geography Study Group of the Institute of British Geographers (IBG) published a widely used text, *Geography and Gender*, in 1984 (WGSG 1984), while a group of Spanish geographers published the text *Mujeres, espacio y sociedad* in 1995 (SabateMartínez, Rodríguez Moya, and Díaz Muñoz 1998). The research journal, *Gender, Place & Culture*, initiated in 1994, has periodically included articles related to educational themes and experiences, while the text *Space, Place and Sex* by New Zealanders Johnston and Longhurst (2010) widens the scope of attention to include sexuality, as have other subsequent texts aimed at university level, especially to advanced students and researchers. Joni Seager’s multiple editions of an atlas of women in the world, published between 1986 and 2009 under slightly different titles, some with co-authors, have also been a widely disseminated resource for students in other disciplines as well as geography (e.g., Seager 2009). Introductory undergraduate texts in the United States in human geography and world geography also integrate attention to gender situated in a variety of contexts.

Although a significant research literature in diversity has developed in geography, somewhat less attention has addressed experiences of teaching about race and ethnicity than gender. Two focused issues of *Journal of Geography* (98(4), 1999 and 107(6), 2009) included descriptions of courses, including one taking a historical approach in an introductory-level undergraduate course on the experiences of multiple racial/ethnic groups and another on developing student-led field explorations in multiple types of urban neighborhoods. Other articles reflected on the challenges of dealing with racism in the classroom, noting that approaches that may be well received in one setting may raise problems in another, reflecting the race/ethnicity of the teacher and those of the student body, and who is identified as “other.” A significant project entitled “Finding a Way,” led by Rickie Sanders, sponsored two summer institutes for teachers in 1996 and 1997 (Monk et al. 2000). These took up both content and pedagogy, particularly in relation to women and gender, while also considering multiple forms of diversity and incorporating pedagogies that are responsive to aspects of classroom climate and alert to local school and community contexts. At the secondary level, a workshop of the Australian Geography Teachers Association was followed by the book *Teaching Geography for a Better World*, which incorporated attention to gender (Fien and Gerber 1988). However, publications reporting sustained initiatives focusing on diversity themes in elementary and secondary geographic education appear to be relatively rare, though they may be cast within wider goals as in inclusion in a New Zealand mandate to foster critical thinking in secondary teaching.

Attention to forms of diversity other than gender and race are not as well represented in the geographic education literature, especially in relation to elementary and secondary education, but articles relating to higher education recur. A review of two decades of articles addressing the “other” in the *Journal of Geography in Higher Education* (Monk 2000) revealed articles on fostering sensitivity by the able-bodied to those who have various physical limitations, on dealing with diverse sexual orientations of students on field courses, or ways in which majority-culture students might be brought to appreciate the values and perspectives of indigenous or “other” communities. How students might gain insights into othering presents another pedagogical challenge that some geographers have addressed via exercises that involve experiential approaches to
simulate being in positions of the other or ones that involve tasks framed in terms of analogies. Recently, interest appears to have increased in online communications about the availability of resources to enhance teaching geography to students with impaired vision as, for example, they participate in online courses.

**Place, politics, and traditions**

Addressing multiple forms of diversity within education is a political endeavor. In a valuable examination of the dimensions of diversity and higher education, Sylvia Hurtado and colleagues (2008) argued that, in order to create and support an inclusive climate, it is important to consider community members’ attitudes, perceptions, behaviors, and expectations. She saw these as involving the historical legacy of campus cultures, traditions, and policies, structural diversity in relation to inclusion of previously underrepresented groups, the psychological dimensions of how people perceive diversity, the behavioral dimension of intergroup relations, and the degree to which individuals actively engage with diversity on campus. How these are enacted emerges in various ways across time, space, and place. The complexities are well illustrated in a study of postapartheid experiences in South African universities, in which Higham (2012) presents interpretations of students’ voices in the historically white University of Cape Town and the historically “colored” University of the Western Cape. Higham found that, though the desegregation of schools and universities aimed to promote inclusion, new class cleavages and other social differences emerged, based on group and institutional heritage and practices, complicating students’ experiences and perceptions. Black students at these institutions, for example, were drawn largely from emerging black elites, likely coming from schools that had already been privileged, not from the critically underresourced Bantu schools. Among students in the formerly “colored” university were feelings of loss of their previous solidarity and cultural heritage. Other issues across the campuses related to differential availability of financial support, the persistence of culturally distinctive classroom and recreational traditions and of gendered representations, and the difficulties some women saw of achieving access and status in the face of male stereotypes. Yet, Higham observed, not all students shared the same perspectives.

At another political level, Torres and Wicks-Ashbun (2014) identified the dilemmas and challenges of undocumented youth in North Carolina who had been brought as children to the United States. While state laws enabled them to enroll in elementary and secondary education, they were not subsequently eligible for in-state tuition rates or scholarships in public universities. Such policies place obstacles in the way of youth’s educational aspirations, possibilities, and/or on performance in high school. Other research has also shown that the way students of diverse racial ethnic backgrounds interact in school settings may generate yet other tensions, such as in the creation of spatial territorialities that are expressed in students’ sense of racial and ethnic subjectivity.

Overall, then, although geographers have become more alert to diversity within the profession, interpretations and practices are uneven across temporal and spatial contexts. Challenges remain in structures, in professional participation and engagement, and in the creation and implementation of pedagogies that strive to be inclusive of opportunity and learning. The current scene is that, though geographers are more cognizant of diversity issues within the discipline – as in who participates, what content is taught, and pedagogical approaches – interpretations and practices vary across temporal and spatial contexts.
and between individuals. Initiatives appear to be more extensive and sustained, or at least better documented, within higher education than in elementary and secondary levels. That they have been slow and limited is not confined to geography programs, however. As Patricia Price (2014) has noted, contemporary higher education espouses policy goals that articulate diversity as positive, ethical, and just, but the pressures of neoliberal economies that emphasize individualism, increasing budgetary pressures, and, in some contexts, legal challenges to affirmative action in student admissions and faculty hiring contribute to making the attainment of diversity elusive.

Informal education is a term applied to learning outside of organized or “formal” school settings. It takes a range of forms including visits to museums, libraries, zoos, and exhibitions; field experiences, tours, and travel; civic engagement projects; as well as festivals, public lectures, community events, and many other types of activities. Informal education also encompasses learning that occurs through the mass media, including movies, newspapers, television, the web, social media, magazines, and even video games.

Informal education is generally contrasted with its formal and nonformal counterparts. Formal learning occurs within educational or training institutions, usually accredited schools and universities, where courses are intentionally designed and structured in terms of learning objectives, learning time, or learning support, whether in-person, in-class or online. Nonformal education can include community or noncredit adult education courses or activities (such as sports, fitness, or health programs), participation in noncredit MOOCs (Massive Open Online Courses), professional conferences, and continuing professional development. These are “organized” in a technical sense but no credential, degree, or certificate is awarded for participation or completion. Learners participate to increase skills and knowledge, or simply for enjoyment.

Informal learning tends to be even less structured and more spontaneous, also with no intention that the activities lead toward any particular certification or degree. Informal education may or may not be organized around specific learning outcomes, but these objectives may be in the background. Learners typically participate because the activities themselves are fun, interesting, and engaging. Informal education may also be embedded in programs of formal programs, such as in community engagement projects, forming a pedagogical link between formal and informal education. In recent years, there is an increasing trend to engage students, even starting in preschool, in various nonformal and informal activities, especially in developed countries (Salmi, Kallunki, and Kaasinen 2012).

Informal education in geography takes many forms and occurs in many different contexts depending upon targeted educational goals. Formal geography education in which students learn about people, place, and environments often involves teacher-centered, school-based, whole-group instruction. Informal learning contexts stand in marked contrast to this. Informal education is generally community based, individual or small-group-focused, and learner-centered (Gerber 2002). Geography education that takes place outside of the classroom – in local communities, field settings, or through the offerings...
of other cultural institutions – allows students to understand how geographic work contributes toward the solution of problems and improvement of society. Geography educators have explored and used these alternative learning methods and contexts to advantage for a variety of purposes.

Informal education has long been an essential part of geographic work, given its tradition as a field-based discipline. The discipline’s central tenet is that location matters for understanding the relationships and interdependencies that shape varied local communities. This spatial perspective provides a cross-cutting way of looking at processes and phenomena that other disciplines tend to treat in isolation. Sensitivity to the ways peoples, places, and environments are connected can help communities address the social and environmental concerns they face. Geography education in informal settings or through public or community engagement can help students connect the classroom subject to the ways in which this knowledge can contribute to society. Informal education that is unconnected to formal purposes may also help people understand their own communities better, although ascertaining whether this occurs is a challenge, given the very nature of informal learning.

With increased globalization, public issues and social problems stretch across spatial scales, affecting large numbers of people and offering potential for individuals and communities to learn together. The concept of engaged learning is based on partnerships between educational institutions and local communities. These opportunities incorporate the advantages of informal learning within the structured, formal setting. The concepts of civic, community, and public are three interchangeable terms that reflect the notion of participatory citizenship. The term “community” is a notion with varying definitions, uses, scales of inclusions, and significances to different constituencies and stakeholders. The “public” comprises an infinite range of potential audiences for whom targeted activities/events are appropriate: families, adults, special-interest groups, the elderly, community groups, schools, teachers, and so on. Indeed the term public is now being more generally used (Nicholson and Wheater 2012). By whatever name, community engagement may be undertaken at a range of geographic scales – from the immediate or local community, to inter-, cross-, multi-, or transnational communities – to communities founded on other diverse characteristics, such as education, occupation, age, ethnicity, or social, sporting, political or environmental affiliations. It can be applicable in local, national, or international settings. Hanson (2004) noted how important it is for geographers to convey to others, particularly students, what we do and why it is important. This can be achieved through the diversity of the questions we ask to show relevance of geography to a variety of problem areas (access to clean water, responses to climate change, sustaining biodiversity), in a range of settings and scales (urban neighborhoods, smallholder farms, national parks), and to an array of audiences (community groups, NGOs, government agencies). Examples are discussed later.

Types of informal education in geography

A wide range of informal learning in geography can be observed outside the classroom and typically outside of academic settings. Important examples include community engagement projects, field trips, museum visits, public lecture, and geography festivals. Many of these
informal opportunities may be a component of a formal education, organized as supplementary learning opportunities for classes. Along with educational institutions, most of these forms of informal education have been organized by different geographic organizations and professional associations like Royal Geographical Society (London), National Geographic Society, Geographic Society of Chicago, American Geographical Society, Geographic Alliance Network, Esri, and various government agencies and community groups.

Community engagement

Generally, community engagement can be defined as “the collaboration between institutions of higher education and their larger communities for the mutually beneficial exchange of knowledge and resources in a context of partnership and reciprocity” (Holland and Ramaley 2008). Community based learning is a process by which people from the community engage with students and faculty to bring about changes that enhance local life. In terms of learning, community engagement is a complex, multifaceted process that involves activity in, for, with, and/or through communities, with potential benefits and challenges for all parties involved (Bednarz et al. 2008).

Engaged learning represents a blend of formal and informal settings and is part of a broader effort in higher education to incorporate community engagement in teaching and research. For faculty members, engaged scholarship incorporates teaching, research, and service responsibilities with the goal of partnering with community groups for mutually beneficial outcomes. Students work informally (within their formal educational experience) with community groups on a variety of projects. For students, engaged learning is a journey through “knowing that” to “knowing how.” Student learning through community engagement is rooted in problem-based, reflective, “deep learning” pedagogies of empowerment, transformation, critical thinking, and social participation. Such engagements can involve learning settings that take the student “outside” to work, research, and learn in partnership with communities – on a variety of civil, social, environmental, economic, and moral issues with local resonance (McEwen 2013). Geography education through community engagement is more evident in the United States, Australasia, and Western Europe than in other parts of the world, but such partnerships are now also being tried in the developing world, such as in Pakistan.

Table 1 presents summaries of the benefits received from geography–community partnerships in informal settings. The engagement benefits vary with the level of involvement and the stakeholders involved.

Community engagement can be used to attain various goals. For example, project goals include reaching cognitive outcomes (community based learning through fieldwork, Liverpool, UK); promoting participatory citizenship (understanding flood histories – understanding risk, UK); and improving student employability in the field of geography (supporting emergency planning using the geographic information system (GIS), USA). Similarly, student volunteers from the geography program at the University of Gloucestershire worked with community members to develop an informed community understanding of flood risk. Together, they examined flood probabilities and the issues associated with living with uncertainty, through development of local knowledge of historic floods and extended awareness of local flood impacts. Students had the opportunity to develop their skills by engaging with environmental and social

aspects of sustainable flood-risk management and flood-risk science. Similarly, geography students were involved in the Plymouth East End Urban Regeneration project, which offered various community benefits including housing renovation, improvements of local parks, commercial improvements, and development of community villages (Klein et al. 2011; McEwen 2013). Learning through community engagement offers many benefits to all stakeholders, particularly to students and the community. It helps students to develop interpersonal communication skills and improve their understanding of geographic contents. It may also increase student’s motivation, add to their work experience and career development, and heighten their moral and civic responsibility.

Community engagement can also help foster a culture of interaction and mutual respect among community leaders and students. Proponents of community engagement argue that it helps produce a better-skilled and educated workforce that is self-motivated, flexible, and adaptive to change. For institutions of higher education, community engagement can reduce barriers and create strong links between them and the public. It also increases students’ awareness about civic and social issues and promotes active citizenship. The most prominent benefit to the community is that it helps find solutions to problems. For faculty members, the main reward is to develop and improve their personal pedagogy skills. Key barriers for faculty are workload issues, a lack of incentives, confidentiality issues, inexperience with engaged pedagogy, and insufficient financial resources. On the other hand, engaged scholarship can provide a meaningful structure for course content and improve a variety of learning outcomes. Engaged teaching and learning can transform instructors into reflective practitioners as well as provide them with future research opportunities.

Field trips, tours, travel, and field experiences

Fieldwork is at the heart of geography, arguably one of its signature pedagogies. Fieldwork often plays an important role in formal geography education and research. In the informal domain, field experiences, field trips, and travel can also serve to promote geography education. The UK Quality Assurance Agency (QAA) benchmark statement provides a definition of fieldwork as being, “active engagement with the external world.” Defined “fieldwork” may include field teaching, field trips, field research, or field camps or indeed “any arena or zone within a subject where, outside the constraints of the four walls classroom setting, supervised learning can take place via firsthand experience.” Field experiences are recognized as a vital part of the teaching of geography at all levels. Not only is it considered essential, but it is considered by both academics and students to be an extremely effective and enjoyable learning and teaching method (Fuller et al. 2006). Michael Palin, former president of the Royal Geographical Society, said that field trips were a vital component of geography, insisting that students’ interest in the subject was fired by good teaching combined with opportunities to “get out of the school building.” Exposure to television, advertising, and modern travel has extended learners’ awareness of other places and environments, but nevertheless they often remain unobservant, uncritical, and unchallenged. Many learners make little use of their experiences in their local area to really understand why things are as they are. UK universities with an overseas fieldwork component always find places on such trips easy to fill, no matter how far the destination (e.g., University of Plymouth to Australia; University of Wales, Aberystwyth, to New Zealand). Massey University and Victoria University, Wellington, also offers field trips to the South Island of New Zealand, although the
GEOGRAPHY EDUCATION, INFORMAL AND FOR PUBLIC ENGAGEMENT

geographic isolation of New Zealand generally precludes overseas field trips.

Field trips can also be done at the local scale. In formal educational settings at any grade level, geography courses often include local trips to better understand and interact with the community. Students of urban geography at the Department of Geography, The Islamia University Bahawalpur, Pakistan, were assigned a field study task to visit the core city to know and understand the urban morphological character as well as the issues and challenges of the area. This activity facilitated interactions between students with the local community and highlighted the issues faced, such as environmental degradation in these communities. Research students in medical geography from the same department were sent to the urban slums to identify the socioeconomic and environmental issues affecting public health, particularly sanitation, water quality, and housing. After appropriate research findings, they voluntarily communicated with local dwellers about water purification methods, hand-washing and maintaining domestic sanitation utilizing local resources to avoid health problems, such as diarrhea. Involved students and faculty also communicated their findings and suggestions to the Tehsil Municipal Authority Bahawalpur for environmental upgrading in slums.

Research on the outcomes of field trips has pointed not just to the social benefits of spending time working together, but also to the added benefits of the development of cognitive and effective learning. It aids motivation and self-development of students and provides them an opportunity to be creative and to have personalized outcomes which give them a sense of ownership of the learning process. In addition, it enhances students’ understanding of geographical features and concepts and allows them to develop specific as well as general skills. However, significant amount of planning and resources are required to carry out successful field trips. Liability issues relating to field risks and lack of local knowledge can also undermine effective outcomes.

Similarly, variously themed guided tours have been organized by the American Geographical Society, National Geographical Society, New York Times, the Royal Geographical Society, and various other organizations. One example is Discovering Britain, which is an exciting series of geographically themed walks created by the Royal Geographical Society (with the Institute of British Geographers) that aim to bring these stories alive and inspire everyone to explore and learn more about Britain. Similarly, but more informally, guided tourist trips are organized by private travel agents, sometimes working with local musicians or others who want to show fans their home country (e.g., Albannach, a Scottish band, leads tours annually to remote corners of Scotland). This does not even mention the travel options available to tourists at any resort where features of local interest can be explored. Again, by definition, there are no learning objectives specified or assessed, but it is likely that these kinds of experiences broaden people’s geographic awareness.

Museums and exhibitions

Many museums can be used in geography education. School field trips to local museums to study the local history and geography, or to natural history museums, zoos, and other museums, are common in the United States and Western Europe. Museums offer a variety of possible learning experiences for different age groups and learning styles. In the specific context of geography, the National Geographic Museum, Washington DC, is great for all ages and features a wide range of changing exhibitions, from interactive experiences to stunning photography
exhibitions featuring the work of National Geographic explorers, photographers, and scientists. Similarly, The National Museum of Natural History (NMNH) Smithsonian Institution, Washington DC, is dedicated to inspiring curiosity, discovery, and learning about the natural world through its unparalleled research, collections, exhibitions, and education outreach programs. In the past, the exhibition called “The Power of Maps” by Denis Wood, author and a cartographer, at the Cooper-Hewitt National Museum of Design in New York in 1992 was considered as a great exhibition in the context of geography. That show was remounted at the Smithsonian Institution in Washington in 1994.

Many academic institutions also arrange exhibitions on various geographical issues. For example, the Department of Geography and Environmental Management at the University of Western England in Bristol designed an interactive sediment-core exhibit, which helped visitors understand how climate and environmental changes are recorded in fossil sediments spanning 15,000 years. This activity benefited academic staff as they communicated complex science and unfamiliar subjects to a nonacademic visitor audience, enhancing the profile of the department.

Therefore, in terms of strengths, this informal setting offers an extremely effective, interactive and enjoyable learning form. It is an easy way of elaborating knowledge which enhances intellectual curiosity of visitors. Moreover, exhibitions are the most effective way of disseminating geographic research works to the public. Lack of money, accessibility, and mobility are the key barriers for this form of informal education.

Community events and festivals

Informal geography education also occurs in varied community, nationwide, or even international events that are devoted to familiarizing the general public with the content, methods, and relevance of geography. National Geographic Education Programs (NGEP) created Geography Awareness Week more than 25 years ago. This annual event, during the third week in November, focuses on a specific geographic theme; for example, in 2014 the topic was food and nutrition. In most US states, the geographic alliance sponsors a variety of events and resources related to the topic. Students, families, and community members celebrate the importance of geography by using lessons, games, and challenges in schools and the community, often meeting with policymakers and business leaders as part of that year’s activities. The main objective is to raise awareness among young Americans about geographic issues, recognize their impacts as global citizens, and excite people about geography as a discipline, as a career, and as a part of everyday life. This annual public awareness program also encourages citizens, young and old, to think and learn about the significance of place and how they affect and are affected by it. Each year more than 100,000 Americans actively participate in Geography Awareness Week (GeoWeek).

GIS Day has been celebrated every year since 1999. This is an international forum for users of geographic information systems (GIS) technology to demonstrate real-world applications that are making a difference in our society. Esri president and co-founder Jack Dangermond credits Ralph Nader with being the person who inspired the creation of GIS Day. He considered GIS Day a good initiative for people to learn about geography and the uses of GIS. He wanted GIS Day to be a grassroots effort and open to everyone to participate (www.gisday.com).

The International Geography Festival is also one of the important geographic events organized by ADFIG (Association for the Development of FIG (International Federation of Surveyors)) in Saint-Dié-des-Vosges in France.
since 1990. The festival is under the patronage of the International Geographical Union. In the United States, local festivals held in conjunction with Earth Day in April also may include presentations and community resources related to environmental and sustainability issues that tie to geographic content.

Social media and “popular geographics”

There are many other informal settings and a wide range of activities that offer geographic learning opportunities to the public community, for example, online games and simulations, social media, mass media, and community clubs, among others. Sometimes these kinds of informal opportunities are sponsored by institutions of higher education. One of the examples is that the University of Gloucestershire established a cafe society in Cheltenham to share and explore the latest ideas in “science and technology” and “geography and environmental sciences” (i.e., climate change). This informal setting facilitates interaction among members of the public with academic staff and students at a neutral and public venue. Geocaching is an interesting outdoor recreational activity in which participants use a global positioning system (GPS) receiver or mobile device and other navigational techniques to hide and seek containers, called “geocaches” or “caches,” anywhere in the world.

The proliferation of GPS-based mobile apps and widely available mobile mapping technologies has created a revolution of public interest in maps and spatial representations. This is a growing part of informal geography education. Geospatially referenced posts on Twitter and other social media have led to an explosion of interesting maps and other creative ways of visualizing spatial information that now circulate across the Internet. Beyond that, there is an ever-larger array of emerging location-aware technologies, which allow people to connect to local spaces by coordinating and communicating with others without depending on physical proximity to each other. Lacking any official structure or leadership, and manifested in many different types of technologies, this revolution reflects the democratization of spatial information; Jerry Dobson of the American Geographical Society has called this phenomenon “popular geographics” (Dobson 2011/2012). Individuals of all stripes, who are not mapping professionals and may have little formal geography education, are generating an enormous amount of new spatial data. While some of this is perhaps unwitting – the spontaneous and hidden creation of big geodatabases used in marketing research, based on browser searches or other uses of GPS-equipped apps – there is also an intentional side. Basically, people are suddenly mapping for fun. Examples range from widely used desktop and mobile apps such as Google Earth and Google Maps (and its competitors) to open-source GIS software for people seeking to analyze publicly available spatial data.

The public has also itself become, collectively, an agent of spatial data-gathering (“crowdsourcing”). Tens of thousands of individuals voluntarily collect georeferenced information for sharing and creation of crowdsourced maps, such as Open Street Map. These allow users to read and write locations. Social networks and some location-based services enable users to read tips and comments that previous users left attached to that location. This information, now with geographic coordinates, becomes an intrinsic part of the location. All of these (and more, both in existence and yet to be invented) comprise a new form of informal geography education. Popular geographics are built on the foundation of applying local knowledge. Going forward, it is likely that these informal
activities will be incorporated into formal educational experiences, overlapping with community engagement efforts, for example, when students and community groups work together to map issues of local concern. Murmur is an example of such a project. Launched by the Canadian Film Centre’s New Media Lab, it integrates audio interviews into cell phone-based tours. Similarly, the Center for Digital Storytelling created storymapping.org in 2006, with projects in Mendocino (California), Houston, New Orleans, and Tuscaloosa (Alabama) to promote the connection between storytelling and issues of local memory and civic planning. Popular geographics is an emerging area of research in geography education and to what extent these public activities will improve people’s understanding of their own local conditions and spatial connections with others remains to be seen.

Informal education and future of geography

Geography as a discipline has a long history of developing learning settings beyond the traditional parameters of the classroom and for engaging with diverse communities as part of its fieldwork. Effective geographic practice is at its best when engaging across a variety of places, spaces, and scales. In recent years, geography educators have sought to make their pedagogy relevant to pressing social and environmental issues, integrating the approaches of place-based education to make geography education more relevant. Community based research, teaching, and learning provide significant potential for geography’s and geographers’ engagement in societally relevant research and learning. Placing the academic curriculum into a “real-world” context helps students realize geography’s applications. Through informal learning opportunities, geography students can engage more fully with their local communities, “not just as passive observers but as active participants and contributors” (Mohan 1995).

Geography education, workforce trends, twenty-first-century skills, and geographical capabilities

Michael Solem  
*American Association of Geographers, USA*

This entry focuses on the role of geography in professional and personal life, framing the discussion on international examples from the research literature and broad-scale projects and programs led by geography’s professional associations. The discussion will illustrate the complexity of workforce development issues in geography, touching on the uneven opportunities for students to study geography in schools and universities, the variety of contexts in which geographers find employment in the public and private sectors, and how different countries view what it means to be geographically “literate,” “competent,” and “capable.”

Geography education varies strikingly when considered from an international perspective. There is tremendous diversity in the scope and sequence of geography in schools, both within and between different national jurisdictions. In some countries, geography in schools is affiliated with the natural sciences (Finland, for instance, aligns geography with biology in the curriculum). In other places, such as the United States, school geography is considered to be primarily a social science, albeit one with an increasingly high technological profile in the form of geographic information systems (GIS). Travel to schools in Japan, and geography assumes a greater curricular role as the study of human–environment relationships. The reasons for this variety are political, cultural, and historical. This rich tableau also extends to undergraduate and graduate (postgraduate) settings across the globe.

Unsurprisingly, all of this disciplinary complexity means students leave schools and universities with quite different educational experiences in geography (if they are fortunate enough to have received any at all). And yet, recent work on comparative education in geography finds some commonality in vision as to the discipline’s purposes and values in the education of young people and adult learners. When thinking about what it means to be a professional geographer in a global context, a broader view of the discipline and the significance of its body of knowledge for life and work – a philosophical issue – can reveal insights that may not be evident through a finer-grained analysis of the skills students acquire through their geography classes – a workforce development issue. This dualism is explored further in the following passages, beginning with a discussion of the trends shaping skills-led curricula for workforce development.

**Trends in the twenty-first-century world of work**

One of the benefits of geography’s high degree of interdisciplinarity and cross-cutting analytical technologies is the wider range of potential industries where students might find employment. In the United States, the US Department of Labor projects “faster than average” or “much
faster than average” growth in openings for geographers, geoscientists, cartographers, urban and regional planners, and other geographic professionals, with projected needs of upwards of 15,000 additional employees in each of these career fields between 2008 and 2018 (Solem, Foote, and Monk 2013). Many of these opportunities are in new areas of employment for geographers, and employers often seek novel combinations of geographical and general skills.

Nonetheless, many secondary and undergraduate students are unfamiliar with the extent to which geography is practiced in public and private sector organizations (the same might also be said for their faculty advisors and career counselors). Because few vacancies explicitly call for a “geographer” per se, one of the main challenges that students have in finding work is convincing a potential employer that a geography degree qualifies individuals with a unique set of skills and abilities. In practical terms, preparing students to enter the geography workforce requires consideration of a very broad range of occupations, few of which carry the job title of “geographer” but all of which stand to gain from the geographer’s spatial perspective and repertoire of applied and analytical skills.

At the graduate level, a master’s is now considered by many employers as the entry-level degree in many countries. Employers are increasingly seeking graduates with advanced credentials and prior working experiences that reduce the need for additional training. The emergence of degree models such as the professional science master’s, which blends scientific training with coursework in management and administration, warrants attention from geographers. Constructive relationships can be built through the establishment of internship programs, which are often major recruitment mechanisms. All varieties of internship program can lead to applied experience that students frequently cite as a reason for having entered the profession in the first place. Internships also have value for helping departments understand industry needs and challenges in order to prepare graduates for future careers.

Geographers pursuing a PhD in preparation for faculty careers also face significant challenges. The modern university is undergoing considerable change with the advent of sophisticated learning technologies, rapidly changing demographics, new business models affecting everything from tuition to tenure decisions, and increasing expectations for excellence in teaching and research. Against this backdrop, the importance of faculty development, in the form of mentoring and professional support in areas such as writing, grant proposals, curriculum and assessment, and publishing, will likely continue to grow as new faculty make the transition from doctoral study to academic posts.

As the role of the PhD in society continues to evolve, students with advanced degrees will likely see more opportunities to participate and contribute through nonacademic careers, especially given the demands for a highly skilled, analytical workforce in a knowledge economy. The question remains, however, of whether the “Plan B” stigma (i.e., the belief that a nonacademic career is a “fallback” plan) often associated with PhDs working outside of academia can be overcome. The issue concerns the extent to which postsecondary faculty, whose career experiences are largely shaped by academic culture and contexts, can better prepare PhD students who prefer a different career path.

**Modeling competencies in geography**

A common thread across these varying international contexts and levels of education is a sense of the need to ensure geography students obtain the education and master the skill sets that will prepare them for careers in both core areas where
Geographers have traditionally found employment (such as secondary education, government agencies, and urban and regional planning) and in emerging and nontraditional areas – including geospatial intelligence, medical geography, sustainability management, and operations and logistics analysis. In Eastern Europe, for instance, researchers have documented a disconnect in Poland between academic preparation, career advising, and employer expectations, a situation that has resulted in difficulties with job placements for many geography graduates (Piróg 2014). Hungarian geography has a centuries-old tradition of preparing students for careers in elementary and secondary education, but has only since the early 1990s attended to workforce development and the education of geographers at the undergraduate and postgraduate levels (Mezősi, Mucsi, and Garamhegyi 2001).

Geographers have led multiple studies for the purpose of identifying the ways geography education prepares students for work and life in the twenty-first century. International attention to workforce issues in geography has increasingly focused on connections between employment sectors and academia. In Europe, there is widespread activity attempting to define and measure competencies – that is, collective sets of knowledge, skills, and perspectives required for effective work in different industries. Competency models are now available for a large number of industries, and have become popular tools for preparing future workforces and assessing the abilities of current employees.

Debates over competence-based curricula across Europe are mainly influenced by the competency-based design of educational processes in the wake of the Bologna Process. Within this process the major goal is to connect subject-related knowledge and generic competences among students in order to achieve basic competences to foster multiple problem- and application-oriented solutions. This competence-led approach, with its concrete description of knowledge, skills, and perspectives as educational outputs, has been implemented on the European level in the form of the European Qualifications Framework for Lifelong Learning and on the national level in the form of the German Qualifications Framework for Lifelong Learning. Devised on the basis of the Tuning Project (Donert 2007) and the Dublin Descriptors of the Joint Quality Initiative, a model has been developed by German researchers with the goal of identifying core competences such as spatial thinking, technical skills and problem-solving, and modeling and measurement of spatial data in the geospatial technology sector (Schulze, Kanwischer, and Reudenbach 2011).

In the United States, research with employer organizations and professional geographers led by the Association of American Geographers’ Enhancing Departments and Graduate Education (EDGE) project (http://www.aag.org/edge) found that employers value training in both geographic and more general “soft” skills (Solem, Cheung, and Schlemper 2008; Schlemper, Adams, and Solem 2014) (Figure 1). Employers across the public and private sectors reported that they are especially interested in hiring people with strong skills in areas such as time management, writing, problem-solving, technology, and communication. Employers want employees who are systems thinkers, who are interdisciplinary, and who can locate and integrate information from varied sources, but specialized skills and disciplinary knowledge are also highly valued. Professional geographers are also often expected to collaborate in team settings and, as they progress in an organization, must exercise a number of interpersonal skills to supervise and manage subordinates. Transferable skills such as these are important for practice, irrespective of scientific specialization. The
Figure 1  Skill areas noted by geography alumni (N = 280) as ones they “always or very often” need to perform. Numbers in brackets signify the overall ranking based on the percentage responding.
full range of geographic and general skill areas expected to be performed in professional geography is available in a competency model produced by the EDGE project (Boxes 1 and 2). A competency model has also been developed specially for the geospatial technology industry (DiBiase et al. 2010).

Geography’s graduate programs generally provide students with a diverse and highly valuable set of transferable skills (Solem, Kollasch, and Lee 2013). Graduate students in all types of programs received the most extensive skill preparation in writing, critical thinking, and research planning and design. There are some differences
in skill preparation, depending on the type of department offering a master’s degree. For instance, PhD-granting departments appear to provide master’s students with more preparation in ethical practice and time management. Doctoral training, meanwhile, tends to concentrate more on academic publishing, grant proposals, and professional and organizational culture.

There are many similarities across graduate programs in terms of skill areas that are relatively underdeveloped. Graduate students in all types of programs receive the least training in fiscal management, entrepreneurial skills, and foreign languages. They also tend not to acquire much experience in developing skills that are especially valued outside of academia, such as supervising, relationship-building, project management, visioning, and adaptability.

Improved professional development and career preparation can help support the participation of women and underrepresented ethnic and racial groups in geography. This is an issue that has long been of international concern within the discipline (McEwen et al. 2008; Adams, Solís, and McKendry 2014). Professional development can help enhance the discipline’s diversity through recruitment and retention because there is often a mismatch between the implicit knowledge and skills needed to succeed in professional careers and the topics covered explicitly in curricula, advising, and mentoring. While many teachers and advisors are well equipped to prepare students for careers, they are often unprepared to advise students about the specific ways geography can address the needs and demands of employers in the business, government, and nonprofit sectors where the majority of students will seek careers. For students from economically disadvantaged backgrounds, having a clear understanding of what a discipline such as geography offers them is perhaps the steering criterion when making decisions about future career paths.

**Geography education for human capabilities**

As schools and universities seek better ways of preparing students for the twenty-first-century world of work, students also need help with understanding the broader purposes and values of the geographical knowledge they acquire through their academic studies (Solem, Lambert, and Tani 2013). Although being knowledgeable and proficient in geography opens pathways leading toward careers in a broad array of industries, many students find it difficult to express what their geography education affords them in terms of their future potential and well-being beyond employment. This is largely a consequence of educational systems that often uncritically promote a skills-driven agenda to make curricula more “relevant,” without giving due consideration to the broader purposes and values of education in life.

At the same time, career preparation is increasingly emphasizing considerations of lifelong learning, professional ethics, and the significance of disciplinary knowledge for thinking and reasoning about life in the broadest sense. This perspective on life, education, and careers attempts to strike a balance between education for human capital development, such as the competency approach described in the preceding section, and education for human welfare development, known as the capability approach. In addition to the challenges of addressing workforce development, researchers in several countries have begun to consider questions of how education contributes to human potential and wellbeing. Whereas much of the current reforms shaping curricula internationally in
schools and universities can be traced to neoliberal economic pressures for producing human capital (skills and competencies), capabilities offer a different (yet complementary) view of the role of education in human life. Rooted in the early writings of economist Amartya Sen and philosopher Martha Nussbaum (Nussbaum and Sen 1993), capabilities refer to sets of “functionings” that, once attained, provide people with real opportunities to reach their potential and wellbeing.

The capabilities movement is not intended to discredit efforts to prepare students for the modern global economy; rather, it is simply meant to broaden the dialogue over the role of schools and universities in ways that capture more holistically the benefits of disciplinary knowledge for lifelong learning, citizenship, and social relations. As such, the concept of capability is distinct from that of competency. Capabilities represent more clearly our educational goals and are more broadly related to human welfare development. Graduate attributes are often used by educators in synonymous terms with capabilities. They are difficult to assess as they are more subjective, holistic, and values-based.

In geography, the GeoCapabilities project is exploring these issues in partnership with several universities and scientific organizations in different countries (www.geocapabilities.org). Using comparative methods, researchers are analyzing the ways geography is considered by nations to be a form of knowledge that enables the development of human capabilities. A challenge for geographers is to identify the specific ways that geographical knowledge, skills, and perspectives contribute to the development of graduate attributes, or “geocapabilities,” which enable us as humans to think creatively and critically about ourselves, our communities, and our world. This challenge might be summarized by the question: What unique ways of understanding, thinking, and explaining do geographers introduce to students in schools and universities?

A capabilities study comparing the national geography curricula and standards in the United States, England, and Finland found that, despite the considerable variation in geography content and sequencing across grade levels, all three nations share a view that the role of geography in schools is to prepare students for life in three specific ways (Solem, Lambert, and Tani 2013). First, geography education is seen to promote individual autonomy and freedom by cultivating the ability to use the imagination and to be able to think and reason using geographic information and concepts. A second capability of geography is being able to identify and exercise choices in how to live, based on worthwhile distinctions with regard to citizenship and sustainability. A third contribution of geography human capability development is the way the subject helps people see their potential as a creative and productive citizen in the context of the global economy and culture. Collectively, these are the ways that three countries share a view of how geography education provides students with opportunities to achieve their life’s potential and wellbeing; without it, they are restricted and deprived in ways that have a real impact on their lives and those of others.

Work on the capabilities approach in geography has extended beyond Europe to include educational systems in Singapore, Japan, India, and China, as well as in Australia and New Zealand. In all of these settings, educators are debating how to best design curricula that fulfill societal expectations for the future workforce while not subjugating geography education only to vocational training and an over-reliance on a skills-defined experience. This means geography teachers, whether at the school or university level, must become re-engaged with some of the
most enduring and fundamental questions about educational purpose and practice in their discipline. A capabilities approach asks teachers to consider the specific curricular role of geography in helping young people think about their life in relation to the world, and what may become of their communities as well as people, places, and environments around the world.

Conclusion

It is important to contemplate what the trends and demands discussed in this entry mean for the role of geography in schools and universities worldwide. On the one hand, it is clear that geographers are wrestling with how curricula can be engineered to produce graduates with the skills needed for achieving the workforce goals of different nations. Opportunities abound for international dialogue and collaboration aimed at expressing the many ways geography can be deployed to enhance the operations, efficiency, and effectiveness of businesses and governmental agencies. Given the globalized and highly interdependent nature of the contemporary world economy, geography’s status in education seems tied, at least in part, to its perceived value in building an internationally competitive workforce.

There are, however, other values of a geography education that can help to solidify and expand its presence in school and university curricula. The capability approach to education is meant to orient a discussion about educational aims more toward how subjects such as geography provide knowledge that is needed for attaining one’s full potential and wellbeing in life. The opportunities for geography scholarship and geography careers are exhilarating, and the connection between higher education and workforce needs will remain critically important in the coming years. At the same time, schools and higher education institutions will be challenged to consider how curricula can be shaped to ensure a place for geography in the education and preparation of young people for life and citizenship in the modern world. This is different from a narrow focus on a skills-led curriculum that tends to emphasize learning outputs (competencies) over considerations of why subject knowledge (such as geography) is important for the fulfillment of particular educational goals; a capabilities approach asserts that both are important.

**Further reading**

The magnificent diversity of Earth’s cultures and environments is fully evident in the many expressions of geography in school curricula around the world. Although the fundamental concepts and principles that make geography a spatial and ecological science are generally shared across borders, the world’s nation-states have set their own priorities as to what, when, and how the subject is taught to school children. Consequently, geography is a school subject that shows little conformity from place to place in terms of expectations of what students should know and be able to do as an outcome of their primary and secondary education.

In the United States, for example, geography is strongly aligned with the social sciences (history, economics, civics, and philosophy), whereas students in countries such as Japan and Finland study geography more as a natural and environmental science. In other parts of the world, such as in England, geography has a curricular association with the humanities. Much of this variation can be attributed to the fact that, like other subject areas (and especially in the social sciences), the content and status of geography in the curriculum is susceptible to external influences and vicissitudes in public opinion, economic conditions, political governance, and environmental change. This influence is most often felt in the content of the subject’s national curriculum standards.

In the following sections, selected countries are profiled to illustrate the range of curricular traditions that geography has experienced internationally as a school subject.

**United States**

Since 1994, the United States has had voluntary national standards for geography that set benchmarks for geographic learning at the 4th, 8th and 12th grades. Published in the volume *Geography for Life* and most recently updated in 2012, the 18 US national geography standards specify expectations for student learning in six domains of knowledge: the world in spatial terms, places and regions, human systems, physical systems, environment and society, and the uses of geography. In a nutshell, the purpose of school geography in the United States is to develop a geographically informed person – “someone who sees meaning in the arrangement of things on the earth’s surface, who sees relations between people, places, and environments, who uses geographic skills, and who applies spatial and ecological perspectives to life situations” (Heffron and Downs 2012, 7).

Because of the voluntary nature of national curriculum standards in the United States, states...
determine the goals of the curriculum, the instructional materials used to support implementation of those goals, and the assessments designed to measure student attainment. Forces ranging from economic globalization and global environmental change, to political calls for national educational reform and accountability, and an utter lack of federal funding appropriations for geography, have all contributed to the waxing and waning of the subject in US schools (Bednarz, Heffron, and Solem 2014).

As of 2015, at either the middle school (grades 6–8) or high school (grades 9–12) level, geography may be present as a strand within social studies standards or as a separate set of standards (sometimes paired with history), often linked to a course (McClure and Zadrozny 2015). In the elementary grades (K–5), geography is mostly integrated with the social studies. At the middle school level, nine states require a stand-alone geography course, and four states offer a combined geography/social studies course. At the high school level, four states require a stand-alone geography course, six states offer a combined geography/social studies course, and geography is an optional course for graduation in four states.

Europe

There is tremendous diversity in school geography requirements across Europe. Some of the significant differences and experiences are highlighted here. In England, geography is compulsory in years 5–14 with optional courses of study in subsequent years. As stated in a report to the International Geographical Union (Brooks and Catling 2014), the aim of the national curriculum for geography in primary education carries an affective component (to inspire curiosity and fascination about the world) as well as a content dimension, which calls for students to become knowledgeable about people, places, and resources, as well as physical and human environments and processes. Through their learning of geography and applications of map skills and field methods, students are expected to develop locational knowledge, including the human and physical features and characteristics of places, as well as the spatial interactions and interdependence of places and how these can change over time. In secondary schools the emphasis shifts to the study of where places are, how places and landscapes are formed, how people and their environment interact, and how a diverse range of economies, societies, and environments are interconnected.

Nordic countries offer an interesting comparison with England and the United States, but even there the differences can be remarkable. As in the United States, school geography in Sweden is classified as a social science. In grades 1–3, geography is a subject integrated with the social studies. At the middle school level, nine states require a stand-alone geography course, and four states offer a combined geography/social studies course. At the high school level, four states require a stand-alone geography course, six states offer a combined geography/social studies course, and geography is an optional course for graduation in four states.
two mandatory courses in geography (one in physical geography, one in human geography). In addition to these two courses, every school in Finland offers two extra courses, one on hazards and another on regional studies. The Finnish national curriculum will also be updated and implemented in 2016 in upper secondary schools. It has been decided that geography will have only one mandatory and three voluntary courses in the future.

Continental Europe exhibits even more variation in geography education. Primary geography education in the Netherlands (4–12 years old) is taught alongside history and biology under the guise of a “world orientation” curriculum. In lower secondary education (12–15 years old), geography is taught as a separate subject on par with the hours dedicated for science education (but less than given to languages, arts, and mathematics). The content focuses heavily on human–environmental relationships. In neighboring Germany, geography education bears a resemblance to the situation in the United States, with geography’s position in the curriculum varying significantly between different federal states. Some states within Germany promote a regional geography (most commonly environmental and physical geography), while thematic issues and topics are the focus in others. In Germany’s upper secondary schools, geography is affiliated with the social sciences in all of the federal states.

Asia

The status of geography education in Asia is also highly variable. In some Asian countries, requirements for school geography are on par or exceed those in Western societies. Elsewhere, it is difficult to find even cursory attention given to geography education. Formal geography education in India is generally neglected in schools. Where it is taught, geography is characterized by a highly didactic pedagogy, with little, if any, exploratory learning. In all but the most prestigious international schools and private schools, students are tasked with rote learning and memorizing disparate facts; little emphasis is given to teaching critical thinking and application skills. The state does not provide for teachers to deliver geography education that develops practices of analysis, application, and communication. For these reasons, an informal education sector has emerged to provide alternative educational experiences for youth and professional development opportunities for teachers across India (Solem and Balanchandran 2013).

The geography content in Japan’s primary and secondary schools is influenced by the government’s interest in promoting safety and awareness of natural hazards (Ohnishi and Mitsuhashi 2013). In high school geography, on the topic of natural environment, students learn about the geomorphological features of Japan and the ways Japanese cities and towns have worked to engineer the built environment to reduce the adverse impacts of earthquakes, tsunamis, landslides, and other natural disasters. Students learn the geographic features of the natural environment of Japan and their relationships to natural disasters and human responses to disasters. Students also study how human–environment interactions with regard to natural disasters vary across different regions in Japan, often by completing activities that make use of data, maps, and other geographic representations.

In Singapore, the national curriculum in geography from primary to pre-university level is described by a national syllabus document (Chang 2014). Geography is taught as part of an integrated social studies course at the primary level. At the lower secondary level, geography
is a compulsory subject, while it is an elective subject at the upper secondary and pre-university levels. One distinctive element of Singapore’s national syllabus document is the inclusion of desired outcomes of education (DOE), which are a broad set of attributes that define the aims of school education. Subject teachers are expected to correlate syllabus content and instructional methods with the four-part DOE, which are: (i) a confident person who has a strong sense of right and wrong, is adaptable and resilient, knows himself, is discerning in judgement, thinks independently and critically, and communicates effectively; (ii) a self-directed learner who takes responsibility for his own learning, who questions, reflects, perseveres in the pursuit of learning; (iii) an active contributor who is able to work effectively in teams, exercises initiative, takes calculated risks, is innovative and strives for excellence; and (iv) a concerned citizen who is rooted to Singapore, has a strong civic consciousness, is informed, and takes an active role in bettering the lives of others around him.

At grades 9 and 10, students in Singapore take the Singapore – Cambridge General Certificate of Education (Ordinary Level) Examination. During these grades students take a mandatory combined humanities syllabus, which is organized around two core ideas – “being rooted” and “living global.” The twin core ideas are delivered through six themes reflecting the topics from disciplines such as history, geography, political science, sociology and economics. The O-level geography elective syllabus is structured around three major themes: “our dynamic planet”, “our changing world” and “geographical skills and investigations.” The physical geography topics span plate tectonics, geomorphology, weather and climate, natural vegetation, and rivers and coasts. The human geography topics include agriculture, industry, tourism, and economic development.

Teacher education in geography

United States

Just as the fifty US states set their own school geography standards, so, too, do teacher certification requirements vary from state to state (Heffron 2013). Most colleges and universities offer an accredited teacher education program. At some institutions, pre-service teachers enroll in an academic degree program (subject major) at the same time they complete instructional methods coursework in the teacher education program. Other institutions require students to complete a traditional four-year undergraduate major followed by a fifth-year or master’s teacher preparation course of study. In either format, pre-service teachers are usually expected to complete a teaching practicum in a local school. Only a handful of US teacher education programs offer pedagogy courses specifically for geography.

Chronic teacher shortages and high rates of teacher attrition have led to so-called alternative teacher certification programs. These programs are aimed at practicing professionals who are interested in a career change to K-12 teaching. Alternative certification options are now available in nearly every state.

Europe

In Europe, the Bologna Declaration signed by the ministers of education in 29 countries in 1999 was designed to reform higher education systems in significant ways. Foremost among the changes was the adoption of systems of “easily readable and comparable degrees” at both the undergraduate and graduate levels, with the undergraduate (bachelor) level lasting normally three years and the graduate (master’s) level for two years. In addition, the comparable system of credits (the ECTS system) was established. These
changes resulted in enhancing mobility for students, teachers, researchers, and administrative staff of higher education institutions.

Implementation of the Bologna Declaration has proven especially challenging for teacher education because of the great variation regarding its structure, length, and required qualifications. Major reasons for this can be found from the fact that teachers are employed in national education systems, which can vary not only between the countries but also nationally. Bauer and Prenzel (2012) have shown, however, that despite this variation most of the countries that have signed the Bologna Declaration now have teacher education delivered in tertiary institutions, most often in universities. Some countries (e.g., Denmark, Hungary, Italy, and Luxembourg) have shifted their teacher education systems to the university level during the Bologna process and 38% of all the Bologna countries now require a master’s degree for at least all secondary teachers. Moreover, 20 countries have established new national standards and guidelines for teacher education (Bauer and Prenzel 2012, 1642).

The following examples, adapted from a report prepared for the GeoCapabilities initiative (Tani 2015), illustrate these diverse trends and patterns in European teacher education.

In the Flemish region of Belgium, teacher education for primary and lower secondary school is provided by professional bachelor institutions. At the lower secondary school level, students are required to select two subjects (e.g., geography and mathematics) and study a program that includes general courses on pedagogy, specific courses on subject education (subject didactics), and a third-year internship. For qualification at the upper secondary education level, students generally concentrate in a major subject and enroll in courses and internships leading to a master’s degree.

In England, becoming a qualified teacher once only required a course of study consisting of a three-year bachelor’s degree followed by a one-year postgraduate certificate of education (PGCE). That model has been criticized on grounds that the separation of subject content and pedagogical instruction made it too difficult for teachers to link theory, knowledge, and practice. This led to the introduction of alternative pathways to teacher preparation. As of 2014 in England, there are four major routes toward qualification.

1. The PGCE is one-year postgraduate certificate normally carrying 60 master’s level credits. The program is university-led and organized in partnership with local schools, in which trainee teachers spend around 60% of their time – usually in two blocks of teaching practice in two different schools.

2. “Teach First” is a one-year program starting with an intensive “summer school” before participants are allocated to often very challenging schools where they teach a heavy timetable from the start. Teach First, run by the independent body in partnership with universities, is designed to attract high performing and often very ambitious young graduates who are encouraged to see themselves from the start as “leaders.”

3. “School Direct” was introduced by the coalition government of 2010. From the trainees’ point of view it is almost identical to the PGCE, except he or she applies and is given a training place directly by a school. This is seen as a measure to wrest control from the universities, but it has had a slow start and is seen as a threat to standards.

4. “School Direct” (salaried route) is a variation that diminishes even further the role of the university element in training: the trainee is employed by the school from the start. This
route is an attractive option for those considering a change of career to become a school teacher.

Finland’s teacher education system for primary as well as lower and upper secondary schools is organized by universities. Students seeking to become qualified for these schools need to earn a master’s degree. In primary school teacher education, the students study educational sciences as their major discipline, while in subject education (to be qualified for teaching in lower and upper secondary schools) the students will most often have two subjects. For example, almost all the geography student teachers have a combination of geography and biology in their degree; one of these is studied as a major and another one as a minor subject. Unlike in many parts of the world, the teaching profession carries a good amount of social prestige and respect in Finland. This can be seen for example in the popularity of the studies: the intake in primary teacher education is only 10% of all applicants.

Teacher education for secondary schools in Germany is organized by the federal states; thus, there are a number of different approaches. Notwithstanding the differences, students are usually required to study two school subjects. In some federal states and universities one of these subjects has to be German, mathematics or a foreign language. In other federal states students can combine practically all subjects. This often leads to combined courses of study (e.g., physical education and geography). With the Bologna process teacher education became extremely diversified, making it a lot harder to move from one federal state to another. The reason for this is that some federal states did not change their teacher education system at all, but kept the Staatsexamen (wishing to keep state control over examinations). Others changed completely over to the Bologna system, but introduced different undergraduate and postgraduate degree systems. Still others kept the old system, but introduced modularized studies so as to better combine teacher education courses with courses for academic geographers. Independent of the Bologna process, there is a move to integrate more pedagogy and more practical studies into the first phase of teacher training. This has led to an influx of non-academic educators at universities (thereby lowering the costs of teacher education) and a marked reduction in subject studies. At the moment there is also a major move towards integrating modules on inclusion into all teacher-training courses, which further reduces the time for subject studies.

In the Netherlands, pre-service teacher training programs for the various types of school are part of higher education, some being provided at institutions of higher professional education (HPO), and some at universities. There are full-time, part-time and dual (i.e., work–study) HPO teacher training courses. There are also full-time, part-time and dual university-based training courses leading to a grade one secondary school teaching qualification for all levels of secondary education, including pre-higher education. These courses are open to university students and graduates only. The HPO institutions provide teacher training at both bachelor’s and master’s level. Universities provide training at master’s level only.

All teacher education in Sweden was integrated within the university/university college system in 1977. Two important changes on the structural level have affected the Swedish school system from the early 1990s. In 1991 there was reform which increased local autonomy for the municipalities and, secondly, a very open policy towards independent schools was introduced (1992). The first change meant that all teachers are employed by the municipalities or by independent schools. Government grants are given
but the system gives the municipalities or the independent school owners the right to decide on local priorities.

Since the social democratic government was replaced in 2006 by a center-right alliance, a massive reform program has been launched in the educational sector. Several new changes have been introduced to the school system, for example, a new education act (2011), new curricula (2011), new grading system (2011), and introduction of teacher certification (2013). Grading has been reintroduced in year 6 (2012), and national tests have been introduced in natural and social science subjects in years 6 and 9 (2013). In 2011, a new reformed system of teacher education was launched in Sweden. The previous common degree of Bachelor/Master of Education was replaced by four new professional degrees: pre-school education, primary school education, subject education, and vocational education.

Asia

India’s teacher education system pays only cursory attention to geography, if any at all (Solem and Balanchandran 2013). With the teaching of geography being left to the discretion of teachers, it is becoming more and more an ancillary topic in many schools. Teachers have long felt unprepared to teach the subject due to inadequate training. In recent years, informal approaches to teacher education have emerged in an attempt to promote geography in schools and support schools that wish to include the subject in their curriculum. This work has largely been led by The Indian Institute of Geographical Studies through a regional network of GeoVidyaa Centres located at the Army Public School in Bangalore, Nirmala College in Coimbatore, and the Cascade Montessori Resource Centre in Chennai.

In Japan, certification for primary school teachers is relatively simple: the “primary education license” allows anyone to qualify for teaching practice at the primary level (Ida et al. 2015). In the teacher education curriculum in Japanese universities, almost all students select some specialty subject, such as mathematics, social studies, or comprehensive studies. Student teachers who wish to acquire a social studies teacher’s certification must major in a social studies-related discipline, such as geography, history, and civics. This means that teachers who elect a discipline other than geography may require additional training and preparation to teach the geographical content of the curriculum (a situation which mirrors that of the United States).

The National Institute of Education at Nanyang Technological University in Singapore is that country’s sole provider of a geography teacher education program. Initial teacher preparation in Singapore consists of three possible pathways: primary, secondary, and junior college. Each provides a foundation in pedagogy and specialized subject knowledge in at least one discipline. Programs offered include a two-year diploma in education (for primary education), a four-year bachelor of arts or science in education, and a 1–2 year postgraduate diploma in education. Components of the degrees include coursework in subject areas, education, language and communication, character development, and field experience (school practicum).

Research, curriculum and professional development resources

There are many international examples of resources, curriculum materials, conferences, and professional development programs for geography educators and researchers (Table 1).
Table 1  Selected international programs and resources for primary and secondary geography.

One of the leading world organizations for primary and secondary geography education is the International Geographical Union’s Commission on Geographical Education. The IGU-CGE sponsors conferences and symposia in different parts of the world, often in conjunction with the IGU Congress. The Commission is also pursuing a broad range of initiatives aimed at improving research capability and capacity, supporting international curriculum projects, an international geography Olympiad, and charters for geography education and sustainable development and cultural diversity.

National organizations such as the Geographical Association in the United Kingdom, the National Council for Geographic Education in the United States, and the Geographical Education Society of Japan offer professional memberships for primary and secondary teachers, teacher educators, and geography education researchers. Through their annual conferences, publications, and special projects, geography teacher associations such as these provide important opportunities for continuing education and professional development. Similarly, many of the professional associations listed in this Encyclopedia’s appendix have internal specialty groups and task forces that focus on issues of primary and secondary education.

There is also growing international cooperation in the area of geography education research. One influential US report originated in 2013 called for broad-scale improvements in geography education research, including international collaborative research. That report, issued by National Geographic’s Road Map for 21st Century Geography Education project (Bednarz, Heffron, and Huynh 2013), presented a research agenda framed by four key questions.

1. How do geographic knowledge, skills, and practices develop across individuals, settings, and time?
2. How do geographic knowledge, skills, and practices develop across the different elements of geography?
3. What supports or promotes the development of geographic knowledge, skills, and practices?
4. What is necessary to support the effective and broad implementation of the development of geographic knowledge, skills, and practices?

The road map project spawned subsequent research projects in the United States and also had an influence internationally. A National Center for Research in Geography Education, established in 2013 by the Association of American Geographers and Texas State University, is coordinating research activities of networks of geography and STEM education researchers affiliated with over 50 universities in the United States and several international institutions. Some of these initiatives involve research collaborations with universities abroad as well as with the state Geographic Alliances: GeoProgressions, a capacity-building project for learning progressions research, and GeoSTEM (GeoSpatial Teaching Enrichment Modules), a pilot project that is supporting the Esri-ConnectED initiative by creating ArcGIS online-based resources, materials, and tools for STEM teacher education programs.

The IGU Commission on Geographic Education is using the road map project report as a reference for designing an International Declaration on Research in Geography Education. This declaration, which was released in 2016, assesses the international need for more and better quality research in geography education. One multiyear research project, GeoCapabilities, is active in several countries across Europe, Asia, and North America. The project’s research component is gathering evidence of how teachers in different countries understand the value of
geographic knowledge and thinking in terms of its capacity for human development over the lifespan. As a leading example of an international comparative research project in geography education, GeoCapabilities may well offer a model for other disciplines to follow in researching the purposes and values of their subject in the context of primary and secondary education.

The fact that everywhere on Earth is different makes geography both a fascinating and challenging field of study for students. The description and analysis of spatial variation in Earth processes and human activities underpinned the lectures and publications of Alexander von Humboldt (1769–1859) and Karl Ritter (1779–1859) in Germany, and laid the foundation for the work of innovative educators such as Arnold Guyot (1807–1884) and William Morris Davis (1854–1935) in the United States.

Geography has been among the disciplines at the forefront of innovation in teaching and learning since the early twentieth century. The first discipline-based academic journal devoted to teaching and learning was the *Journal of Geography*, first published in 1902. Geographers were early adopters of objective assessment in the 1920s, and also of well-defined learning objectives and active learning in the 1990s.

Contemporary teaching and learning in geography is informed by a significant body of research on the ways that people learn and the most effective ways for students to achieve their learning objectives. The scholarship of teaching and learning geography has gained considerable traction in recent years; many instructors now research not only their discipline area but also their classroom practice (Day 2012). The result is a much better understanding of how to design teaching activities to encourage engagement by students. Research findings have become influential through blogs, academic conferences, and postgraduate teaching qualifications. Journals such as the *Journal of Geography*, the *Journal of Geography in Higher Education*, and *International Research in Geographical and Environmental Education* are respected outlets for peer-reviewed research on geographical education. Some mainstream geography journals, such as *Area*, the *New Zealand Geographer*, and *Progress in Physical Geography*, also occasionally publish papers on geography education and/or have a section on it.

Teaching and learning is increasingly recognized as an important activity in its own right, not just an adjunct to discipline-based research. Geographical societies around the world have prizes, awards, and honors that recognize excellence in teaching, such as the AAG Gilbert Grosvenor Geographic Education Honors, and Distinguished Teaching Honors.

Learning and doing geography is an important way for people to interact with the world, to see the world differently, and to structure and think about that information. Thus, education is not just the acquisition of skills and information but, as John Biggs (2003) said, it is about conceptual change. The aim of geography education is to produce graduates who can think, act, and practice as geographers. To develop such graduates it is necessary to have good alignment between the intended learning outcomes, the teaching methods, and the assessment regime using a framework called “constructive alignment”
(Biggs 2003) in which course design begins by considering what students should be able to do by the end of the course. This determines the assessment regime and the teaching and learning methods (so-called outcomes based or backwards design). Ideally, curriculum mapping occurs, with desired outcomes mapped across all courses in the degree program to ensure that key outcomes or attributes are developed and assessed.

A range of teaching approaches can be used, providing there is good alignment with the intended learning outcomes and the assessment regime. However, it is known that some teaching approaches can be particularly powerful in terms of promoting engagement and developing ways of thinking and practicing. Signature pedagogies in geography include fieldwork, visualization, map-making, and map interpretation (Komoto 2009), and integrative learning, learning through inquiry, and service learning (Spronken-Smith 2013). Ten other high-impact education practices identified by George Kuh and colleagues (Kuh 2008) include service learning and undergraduate research, first-year seminars and experiences, common intellectual experiences with required core course, learning communities, writing-intensive courses, collaborative assignments and projects, diversity/global learning, internships, and capstone courses and projects. Many of these practices are commonly used in geography curricula to prepare students for citizenship, work, and life (Spronken-Smith 2013). Increasingly, there has been realignment of the curriculum to focus more on skill development and the needs of employers (see entry Geography education, workforce trends, twenty-first-century skills, and geographical capabilities).

Good geography instructors encourage students to take a deep approach to learning, promote active learning and engagement, use an outcomes-based or backwards-design approach, and incorporate research experiences into the curriculum. Although there are many possible routes to attaining learning outcomes, many demonstrably successful pedagogies and teaching approaches are constrained by infrastructure, institutional norms, and union-management negotiated labor agreements. In practice this means that new approaches commonly have to be incorporated into traditional frameworks of lectures, laboratory/practical work, and fieldwork. Fortunately, good practical advice is available (Solem and Foote 2009) and new pedagogies are supported by new technologies.

### Lectures: technological and pedagogic change

The traditional lecture is rapidly changing in universities and colleges. Mick Healey, Alan Jenkins, Sue Vajoczki, L. Dee Fink, and other geographers have led the way in a refocus of the lecture on active learning, with an influence that has extended beyond the discipline. It is now widely recognized that students cannot focus on a lecturer speaking for long periods. Activities such as group discussions and think–pair–share exercises are widespread. In-class tests can be undertaken as group work, an approach that most students find engaging and effective.

Technology plays a major role in the modern lecture. “Clickers” or “personal response systems” (PRS) are now used in many lectures. Originating from game shows, the clickers (or smartphones) allow students to anonymously key in responses to questions with responses captured and displayed instantaneously on a screen. Clickers can be used to gauge background knowledge on a topic, to immediately test understanding of the lecture, and to gauge viewpoints on polarizing issues. Students enjoy
using them and are more engaged. Some lecturers also have live-streaming of twitter feeds (or other social media) and use digital whiteboards to promote participation and generate questions and comments.

Technology is usually a key tool in the “flipped” or “inverted” classroom. Typically, the lecturer generates a video or audio recording of lecture material, or other digital resources on a learning management system or other digital platform. The expectation is that students will access this material online in advance of their “lecture” session. The lecturer then facilitates discussion of key concepts and skips over easy material that the students have already mastered before the lecture. Some lecturers use a “just-in-time” method, whereby the students’ grasp of the background material is tested by an online quiz or questioned by asking the student to volunteer their uncertainties and connections to the topic. The testing and questioning is usually based on reading of a textbook or paper and is undertaken just prior to the lecture. By uncovering common misconceptions, misunderstandings, and topics of particular interest, the lecturer uses the lecture to address relevant points.

Lectures are also increasingly taking place in an exclusively online environment. Massive open online courses with lectures developed by geographers such as Anthony Robinson and Todd Bacastow (Pennsylvania State University), and Brent Hecht (University of Minnesota) have attracted tens of thousands of participants. Online lectures and webinars have also become important teaching tools in the teaching of geographic information system (GIS) software (see entries on Geographic information science and technology: educational directions and Geography education: digital and online trends).

Many lecturers are now wedded to a constructivist theory of learning. This means that they see their role as a guide on the side – rather than the sage on the stage – or even a doc on the laptop. Instead of just talking, lecturers work to get students engaged in their learning. Although the form of the lecture is changing, the lecture itself is likely to continue its importance for the foreseeable future.

Laboratory/practical work: new technologies for more complex problems

Although understanding geography is valuable for intellectual development, doing geography is the difference between knowing about geography and being a geographer. Geographic skills are taught in the context of laboratory and practical classes, and involve map analysis; statistical methods; calculation of the rates and quantities of environmental, social, and economic properties; and spatial modeling.

Maps have long been synonymous with geography and are still an essential component of all geographers’ education. However, paper maps, protractors, rulers, compasses, and dividers are now virtually obsolescent, and along with that obsolescence there has been a decline in the importance of learning tedious calculations of map scale, area, gradient, and magnetic declination. At the same time, the widespread use of GIS and the availability of global navigation satellite systems, such as GPS on smartphones, has meant that there has been a rise in the importance of geodesy, coordinate systems, map projections, and spatial modeling in student practical work.

Descriptive and inferential statistical methods have been important since the 1960s. First taught with logarithmic and statistical tables and small hypothetical datasets, most statistical exercises now rely on larger, more relevant real-world datasets analyzed with user-friendly software. Spatial statistics are now much more accessible to students in the context of GIS.
Current or even real-time data are now readily accessible on the Internet and are used in laboratory exercises. These datasets include extensive meteorological, hydrologic, and oceanographic data. Other data, such as digital elevation models and socioeconomic data, are also freely available. Students are also able to obtain their own data, which they can quickly download for analysis, for example from a GPS receiver or smartphone. The use of digital data has now largely supplanted air photo interpretation based on stereoscopes. Remote sensing imagery, such as Landsat and European Space Agency data, may be freely downloaded, and many jurisdictions provide GIS and remote sensing data and imagery that are available online. Images can be processed with free software such as Multispec and LEOWorks. Students also generate their own remote sensing imagery with balloon kits and inexpensive cameras.

Fieldwork: opportunity and challenges

In an educational context, fieldwork is any organized teaching and learning activity that takes students out of the lecture hall into the environment that is being studied. The value of geography fieldwork has long been self-evident to participants (Boyle et al. 2007). Practical skills developed and practiced in fieldwork include the ability to work safely and efficiently as part of a team in pursuit of a defined goal. Technical skills, such as sampling, the use and care of scientific instruments, socioeconomic surveys and other methods of data collection, and the accurate recording of results, are developed, along with associated skills such as report writing, the application of statistical techniques and analysis, and the preparation of maps and diagrams. Fieldwork enables students to make sense of the world and to better understand and critically evaluate theories that explain it.

Contact with the field environment promotes more than just a cognitive function; it also provides a sensory experience that associates an environment with long-term learning. Fieldwork promotes positive attitudes and values toward the environment and, therefore, enhances both cognitive and affective learning. Social relations between students and instructors developed during fieldwork enable instructors to better appreciate the challenges faced by students and to mutually develop teaching approaches that enhance learning. Conversations with individual students in the context of fieldwork also enable an instructor to promote and develop higher-level learning by the student.

Fieldwork has traditionally been more important in Europe and countries of the British Commonwealth, than in the United States. Many European, UK, and Australasian universities require one or two residential field trips for all their undergraduate students. In the United States many universities offer residential field courses but they are not always mandatory and may be unattractive to students because of scheduling conflicts with summer employment opportunities. In the United States and elsewhere many faculty members also have concerns about the legal liabilities arising from the risks of fieldwork and, as a consequence, the importance of fieldwork in the geography curriculum has declined in many institutions in the United Kingdom, Australia, and Canada. However, this reduction in fieldwork is not universal and some geography departments have expanded fieldwork within the curriculum.

Concerns about the risks of fieldwork are legitimate but the risks can be mitigated. Safety concerns require that expectations and responsibilities be made clear to everyone, preferably through a code of conduct that is discussed prior
to departure. In some cases, students participate in the development of safety and conduct guidelines. Site-specific issues may be discussed at or adjacent to a site. Every field trip needs a qualified person to deal with major or minor accidents, and appropriate first aid equipment to be carried. The extent of the training and available equipment depends on a prior risk assessment that takes into account the environment, physical abilities of the students, and access to medical assistance. Access to medical assistance in areas of poor telephone coverage may involve the use of radios.

Safety issues may be different for students with disabilities of various types. Issues of hearing, sight, mobility, heart and lung diseases, allergies, agoraphobia, and other conditions all pose different challenges for both the student and instructor. In some cases an initial fieldwork plan that assumed a site was accessible may need to be modified to ensure that the work is accessible to all students. In some cases a student with a disability cannot be accommodated and an alternative program may be required. Arrangements of this type are usually made through the college or university office that specializes in dealing with the learning challenges of students with disabilities.

Although cost and health and safety considerations are considered to be barriers to the implementation of fieldwork, one of the biggest barriers is the way that curricula have been designed. In many cases the curriculum is so content-rich that there is little room for even short local excursions.

Despite the barriers there have also been issues with overuse of certain areas for fieldwork. Some areas of the United Kingdom, such as Dartmoor and Malham in the Yorkshire Dales, have been subject to intense environmental pressure by field classes. However, there is a risk of damage to field sites anywhere. This has included indiscriminate hammering of outcrops, unauthorized collection of samples, damage to fences, and impacts on livestock through disturbance and escape of livestock onto roads. The Geographical Association and Field Studies Council in the United Kingdom have developed a code of conduct for fieldwork, and many universities and colleges have their own guidelines.

Concerns about the risks of fieldwork have inspired interest in self-guided audio tours and have also resulted in some interest in virtual fieldwork, that is, the development of investigative case studies based on virtual worlds. In some cases this virtual fieldwork is a complement to a visit in the real world, but it can also function as a substitute. However, even with immersive technologies, the virtual world fails to provide students with connectedness to nature. In fact, there are broader concerns that students are increasingly alienated from nature. This has been framed as “nature deficit disorder” (a term used by Richard Louv in his 2005 book, *Last Child in the Woods*). Although the term is more of a metaphor than a medical diagnosis, Louv draws attention to numerous health benefits associated with time spent in nature. Edward O. Wilson’s biophilia hypothesis is also a framework for attachment to nature, the place that is truly “home” for people. These societal contexts and the fact that fieldwork is usually a social group-based activity means there are good sustainability arguments for an enhanced role for fieldwork in the geography curriculum. Combined with the role that fieldwork plays in discipline-based learning, the position of fieldwork in the curriculum should be unassailable.

Experiential and service learning: making geography relevant

Experiential learning can include the assignment of students to employers for internships
or cooperative education work terms during their degree. In the United Kingdom, the term “sandwich course” is more or less synonymous with “cooperative education.” The student is given academic credit, a salary, and an opportunity to apply what they have learned in their education to the “real” world of employment. In this experiential learning process the student connects their life as a student to their subsequent work life. Sometimes students succeed admirably and obtain long-term employment from the employer. In other cases there is a mismatch between the student’s abilities and interests, and the needs of the employer. This too is learning.

Student experience of cooperative education and internships is generally positive. Areas of student concern include dissatisfaction with a lack of constructive performance feedback, the need for more time on the job, and a need for better training (Jackson and Jackson 2009); particular attention should be paid to these issues to implement a successful program.

The desire to produce graduates who are relevant to society has also given rise to service learning, where students may assist a community group or project. In contrast to cooperative education, the student is not paid for their work, and the work assignment is always to a not-for-profit organization for some social good. Service learning often involves groups of students, rather than single students. Student service learning benefits the community, assists the student in generic skill development, and also has the aim of producing graduates who are global citizens and agents of social justice. Involvement in service learning not only helps the student develop a host of desirable generic skills and insights into social problems but also has been recognized as a high-impact educational experience leading to higher retention rates (Kuh 2008). The community partner should also benefit, but in some cases the community benefits are apparently modest and have not been investigated as closely as the benefits to students. Oldfield (2008) advocates for service-learning projects that are built around community skill, knowledge, and experience.

Issues to consider with the implementation of service learning include whether it is a compulsory part of the curriculum, whether it involves the entire class or small groups working with agencies or organizations, how best to assess it, evaluation of the impacts of the program, and the nature of the relationship between the university and the wider community.

In general, geography curricula have embraced service learning more than cooperative education. Within many geography departments there may be a quiet tension between those who support a notion of geographic education as a process of intellectual development and those who see geography as a route to career opportunities. Service learning supports both perspectives, but cooperative education has been seen by some as leaning too far toward career development as a fundamental goal of a geographical education (Zhou, Smith, and Spinelli 1999). In contrast, geographers were among the pioneers of service learning in the academic community from the early 1990s.

Undergraduate research and inquiry: moving the subject forward

Undergraduate research reinforces linkages between geographic research and the teaching of geography (Healey 2005). Undergraduate research has been particularly important since the Boyer Commission in the late 1990s noted that many undergraduates complete their degrees unaware of the research culture of the institutions in which they studied. Undergraduate research equips students with transferable skills, better preparing them for future postgraduate study.

and/or the workplace. Undergraduate research shifts the student from audience to participant in the teaching–learning process. Healey and Jenkins (2009) presented a framework showing the link between curriculum design and the research–teaching nexus (Figure 1) and argued that more emphasis should be placed on research-tutored and research-based pedagogies, as these models have the most benefit for student learning.

The discipline of geography has been well known for innovation and engaging pedagogies, and for many years has embraced the idea of students doing research (Figure 2). It is commonplace for geography undergraduates to undertake a range of research and inquiry activities during their degree. Activities may range from a major project in an honors degree program to smaller, shorter activities. For example, Spronken-Smith et al. (2008) describe in-class activities with questions such as “Where might sand-dunes be on Mars?” or fieldwork in groups to assess the impact of hazards on local communities, or international student collaborations working on geographic problems based around topics such as population, the global economy, and nationalism in order to promote understanding of geographic concepts and international perspectives. Paid employment as student research assistants also provides opportunities to participate in research.

Some programs have courses designed around inquiry, with students working in groups over an entire semester or longer on one problem, while others design their whole program to progressively develop inquiry skills in their students. Thus the term “inquiry” can encompass a range of activities but, importantly, all are student-centered, with the students active in their learning and the instructor acting as a facilitator. Students benefit from greater exposure to learning through inquiry (e.g., progressive development of inquiry skills throughout a degree).
and open, discovery-oriented inquiry offers the greatest benefit for developing higher-order learning outcomes and a host of other generic skills.

Textbooks: going online

Although advanced courses in geography are typically based around readings from the research literature, most lower-level undergraduate courses are built on, or are supported by, textbooks. Modern textbooks have their origins in works such as the *Geographia Generalis of Varenius*. The 1672 edition of *Varenius* (edited by Isaac Newton) was particularly influential and was translated into several European languages. Textbooks expanded rapidly in the nineteenth century with the *Kosmos* of Alexander von Humboldt (1845–1862), the *Physical Geography* of Mary Somervell (1848), and works on physiography by Eugene Cortambert (1836) and Thomas Huxley (1877). Human geography textbooks developed in the twentieth century with the *Principles of Human Geography* by Huntington and Cushing (1921) and by Paul Vidal de la Blache (1923). Later textbooks such as Arthur Strahler’s *Physical Geography* (1951), *Spatial Organization* by Abler, Adams, and Gould (1971), and *Geography: A Modern Synthesis* by Peter Haggett (1972) both reflected and supported later developments in the discipline. By the end of the twentieth century the revision cycle for textbooks had shortened, regional editions became more common, chapter structures were increasingly nonlinear as publishers demanded “features” in boxes within the chapters, and instructor support materials, student manuals, and online support material became ubiquitous. Some recent textbooks emphasize the role of learning theory in textbook organization.

Textbooks are increasingly free of the constraints of print formats, with electronic versions of traditional textbooks produced by commercial publishers, together with free online textbooks self-published by several authors, for example the introductory physical geography texts by Michael Pidwirny (http://www.physicalgeography.net/fundamentals/contents.html) and the interactive text of Michael Ritter (http://www.earthonlinemedia.com/ebooks/tpe_3e/title_page.html). The Saylor Foundation free online courses include an introductory undergraduate course in world regional geography with a free textbook available under an attribution-noncommercial-share alike license (http://www.saylor.org/site/textbooks/World%20Regional%20Geography.pdf).

Although the move toward electronic textbooks has been a slow one, the trajectory is clearly moving in that direction. Commercial publishers, such as Pearson Prentice Hall,
McGraw-Hill, and W.H. Freeman/Macmillan offer learning management systems in support of textbook content. The development of new digital content, including videos, animations, interactive components, and the ability of instructors to choose content, means that there has been an inevitable blurring of pedagogy and textbook materials.

Conclusions

The last decade of the twentieth century saw a massive shift in geographic pedagogy. The advent of active learning approaches and technology in the classroom, a greater interest in applied aspects of the subject, and enhanced focus on undergraduate research and experiential learning all took place in a broader context of the growth of social networking and increased government demands for accountability in terms of graduate employability and system efficiency. These changes have impacted the relationship between teaching and research in universities, as well as the relationship between universities and their communities.

The next few decades will likely continue to see innovative, technology-driven pedagogies that will evolve in a way that cannot be predicted with any great degree of confidence. However, there will probably also be consolidation of advances made in the past two decades. A wide variety of research questions need to be answered (Day 2012). Among the more pressing topics are: Do students learn particular knowledge and skills better by inductive or deductive approaches? How can virtual field trips be improved? How can the fieldwork experience of students with disabilities be enhanced? What is the effect of class size on the effectiveness of different teaching methods? Does subject research by faculty enhance student learning, and, if so, in what way?

One likely trend in the coming decade is the development of more rigorous testing of innovative approaches. Broader student diversity means that it is almost impossible to provide universally applicable and definitive conclusions on any intervention; therefore, studies will probably become more focused and less likely to purport to be the final word on any particular pedagogy. The more studies that are undertaken, the more confidence there will be in the results, which may increase the rate at which innovation is diffused. In order to accommodate an increase in the number of research studies, there will be a need to either increase the frequency or size of existing journals and/or introduce new journals.

The current position of geography in higher education

Geography is part of the higher education landscape in most countries. Growth in the discipline has taken place through a rich mix of structures including dedicated departments, multidisciplinary units, and combined programs. Geography is also encountered in a variety of institutions. For example, it might be encountered in traditional universities, dedicated geoscience institutions, modern universities (former polytechnics and colleges in the United Kingdom) and in further education colleges/community colleges where selected courses are taught at higher education level or where foundation or associate degrees are taught. Some higher education providers are state run or funded whereas others are private (fee paying).

There has been a rise in the number of universities developing overseas campuses, particularly in Asia. These are universities where English is not the first language of the country but in which courses are taught in English. Additionally, geography is sometimes part of international educational consortia and reciprocal mobility agreements. All these are responses to increased marketization of higher education. It is no wonder then that the study of geography is characterized by a diversity of provision, state and commercial drivers, content and perspectives, and methods and conceptual frameworks.

Within this rich tapestry it is possible to specialize in either human geography or physical geography within subdisciplines of these or to take an integrated degree course.

The breadth of content in physical and human geography has had impacts upon higher education provision: first, in some countries an increasing specialization and separation of the disciplines has taken place over time, although this has been tempered where an integrated geography is still taught; second the breadth of the discipline has created a demand for taught MA courses that allow for more specialist or vocational skills to be developed. However, the evolution of different geographical traditions has a pattern of its own and the content and scope of the discipline remains contested and open to productive dialogue as well as dynamism. For example, standard geography departments in universities in the Soviet Union (USSR) include specializations in physical geography, economic geography, and cartography. Areas such as cultural geography are largely confined to the United States, Europe, Australia, and New Zealand. Entire institutions dedicated to the geosciences have developed in China.

The relationship between geographic research and teaching in institutions providing geography are also varied; some specialist teaching institutions exist and research intensive universities usually also have some teaching activity, although some have limited undergraduate places; however, the majority of providers offer a blend of teaching and scholarly and research activity. Unsurprisingly, topics, theories, and methods vary in both research and teaching
GEOGRAPHY IN HIGHER EDUCATION

internationally as well as the degree to which each informs the other.

During the 1950s to 1970s the number of geography departments around the world grew significantly and in North America GIS provision grew rapidly. In the United States geography developed in close connection with cartography, the links to GIS still being apparent to a greater extent in, for example, the United States than in Europe.

From 2000 onwards there has been a global diversification of geography provision in universities with a huge variety of courses, combinations, interdisciplinary projects, and collaborations. There has been a clear trend toward managing geography within larger multidisciplinary units as seen currently in many British and Australian universities, so although the name geography persists as a “unit,” “division,” “subject area,” or “department,” there has been a merging of units for cost saving purposes or attempts to encourage cross-disciplinary collaboration. One reason for this may be the “spatial turn” in the humanities and social sciences which has allowed other disciplines often closely allied to geography to view space as an essential element in their own research and teaching agendas. Geographical patterns and processes and the significance of space and place have been highlighted by geographers such as Doreen Massey and space–time ideas have been widely adopted in other disciplines, particularly in the social sciences. The question of whether geography’s relationship with other fields of study will become further subsumed within interdisciplinary departmental structures as a result remains to be seen, but this process is taking place in some countries where the imperative to research in interdisciplinary teams in order to address global problems is paramount.

The overall political and economic context of higher education continues to evolve with cuts in some areas and expansion in others, but a positive growth trend for the discipline is currently in evidence and a wide range of courses available.

The range and diversity of geographical courses

The study of geography has moved from traditional single subject departments and schools (generally geography remains a distinct department or school in the universities where it has been established the longest) to departments of environment/earth sciences/society, enterprise, and environmental studies. The move to modular courses in the late twentieth and early twenty-first centuries across many universities has further encouraged the interdisciplinary connection of geography with other subjects (Johnston 2004).

Geography draws from and contributes to a wide variety of other subjects from the natural sciences, social sciences, and humanities. As a result students may choose to combine geography with other subjects and vary the weighting of this combination either as a major/minor or an equal combination. The length of degree courses varies significantly as does the degree of specialization and choice of content. Degrees in geography can be awarded as a Bachelor of Arts (BA) or Bachelor of Science (BSc). The demand for postgraduate degrees has created a diverse market for specialist masters courses. Differing amounts of independent research are integrated into masters and doctoral courses in different institutions. Two-year community (or technical or junior) colleges in the United States offer associate’s degrees, an alternative to the traditional four-year bachelor’s degree programs. These institutions offer geography, among a wide range of subjects, to postsecondary students of all ages and academic levels. Students studying at a community college
may either receive a standalone two-year qualification, the associate’s degree, or transfer to a four-year institution to complete the final two years of the bachelor’s degree. In the United States just over a third of students who completed a degree at a four-year university in the academic year 2012–2013 had previously been enrolled at a two-year institution, however, only selected universities and colleges share articulation agreements allowing these credit transfers to take place. In the United Kingdom foundation degrees in partner colleges are completed as “honors” degrees in universities reflecting an outsourcing of foundation level work which is completed at a lower cost for students. In the United Kingdom most students are working toward an honors degree, completed typically over three or four years, whereas in the rest of Europe degrees can take much longer as students finance themselves part time and students tend to start degrees later. Certificates are also awarded in specific programs that typically require less than two years of study.

At the graduate or postgraduate level, degrees also vary. There is the MA/MS, the PhD/DPhil and a host of advanced degrees and attainments (such as the habilitation in some countries). Many of these advanced degrees are unique to their national setting. In recent years there have been efforts to standardize these qualifications (see discussion of neoliberal trends below), often employing the US model of a two-year taught MA/MS including a research thesis or professional report and 3–5 year PhD degree. It is the MA/MS degree where much growth is occurring at this time. Standardization at this level has been initiated in the European Union via the Bologna process. In the United States institutions offering master’s courses but not doctoral study are termed “master’s only” which has become a defined Carnegie category. The growing number of master’s courses represents a highly dynamic part of higher education (HE). However, this growth and development has not gone on unquestioned. Several articles have proposed the “rethinking” of postgraduate education (e.g., Monk, Foote, and Solem 2012).

Postgraduate provision

As the proportion of people with undergraduate degrees increases, the demand for master’s courses is rising in response to the need to distinguish oneself in the graduate labor market and master’s degrees provision is expanding rapidly. International mobility has made the taught master’s degree (usually one year, sometimes two) a globally competitive marketplace and the degree can serve multiple functions: as a stepping stone to doctoral research; as a vocational course; for interest from lifelong learners; a means to change career track; allowing students to specialize beyond a broad degree; and an opportunity to apply a geographical background to an interdisciplinary research area. Master’s courses are more closely aligned to career opportunities than the degree or PhD. The pedagogic challenge associated with this is the requirement to bring a diverse group of learners together to cover the same material when their backgrounds and previous experience may be significantly different. As master’s courses increasingly become a gateway to doctoral study the increased diversity of learners may help to address concerns with a lack of diversity at doctoral level. Fairly traditional models are still being adopted in master’s courses although some include projects, placements, online and blended elements, and use practitioner teaching staff. The traditional research-based master’s degree is being replaced with a mixture of taught modules that cover soft skills as well as disciplinary content, however, a research project is usually the culminating experience.
Boyle, Foote, and Gilmartin introduced a special issue of GeoJournal in 2014 on “Rethinking the PhD in Geography.” It outlines current challenges and new models for a changed trajectory for this degree type. The key challenges are the lack of diversity of PhD candidates, the narrow training that the degree provides, poor retention and completion rates, extended deadlines, and the dangers of corporate sponsorship reorienting the degree. Most PhD students come from a privileged group and this situation is worsening with the growth of self-funding. One reason for this may be the narrowness of training provided during a PhD, which is often aimed at an academic career for which the supply of doctoral students far outstrips demand. Indeed the casualization of the labor force has created many “teaching only” contracts for which a PhD is a requirement but does not provide time for ongoing research, resulting in a skills mismatch. Many PhD students experience difficulty in gaining teaching experience, although in some institutions it is embedded in their training. There is a general lack of consistency across institutions in this respect. A careful balance needs to be struck between overloading and exploiting PhD students with teaching related work and providing carefully scaffolded opportunities for them to build a portfolio of experiences, for example, in marking student work, being a fieldwork assistant, laboratory demonstrating, leading tutorials, and lecturing. While corporate sponsorship of PhDs may be seen as an opportunity to diversify training and shift it toward more vocational and skills oriented objectives, this could be at the expense of critical reflection. The authors suggest that the “market model” may create more teaching opportunities in the future but this could further contribute to the precariousness of a casualized labor force in HE.

Alongside the supervisory relationship, complementary classes and training opportunities are being provided to enhance doctoral education and student-led activities, such as postgraduate conferences, provide opportunities to present work in a supportive environment as well as to develop skills in event organization and committee work – the RGS postgraduate mid-term conference is one example. Another discipline specific initiative is the inclusion of doctoral students in the writing groups of the INLT so that PhD students in geography get to meet international colleagues and co-author journal articles. The EDGE project has produced research articles and books, conference mentoring, and career planning resources among other support initiatives for graduate students. Other multidiscipline research training initiatives come from foundations such as the US National Science foundation’s research traineeship program and German research foundation’s graduate research training groups as well as foundations encouraging underrepresented groups into science. The United Kingdom’s Higher Education Academy accredits university teaching certificates for graduate students and awards associate fellow status for those who successfully complete this.

Geography, like all disciplines in higher education, is being shaped by a number of broad-based economic, political, social, and technological
changes at the national and international levels. Online education, interdisciplinary imperatives, competition, marketing, and rebranding have all impacted on the nature of courses being provided at undergraduate and postgraduate level.

There is a desire for more students to receive college degrees more rapidly at less cost and online education seems to provide a possible solution (Erickson 2012). MOOCs (Massive Open Online Courses) are one way in which institutions are testing the appetite for online learning, although completion rates are low in some cases.

Movement toward modular teaching and assessment with clearly stated learning outcomes in the late twentieth and early twenty-first century in many institutions enabled the blending of geography with many different subjects at the outset of degree courses (combined degrees) or during a period of study so that students can incorporate geography modules with almost any subject. This has led to geography being branded and rebranded. It can be marketed with geospatial technologies and environmental science, which are seen as more entrepreneurial and more clearly linked to graduate labor markets. Geography in most Nigerian universities is now found within environmental science or environment and regional planning faculties, resulting from national level changes in education. In Australia, there are now no standalone geography programs; all are combined with other disciplines. This blending of geography with subjects including geology, biology, earth sciences, social sciences, history, and economics for an undergraduate degree reflects the integrated nature of twenty-first-century geography departments.

There is clearly a danger of a loss of identity in blending geography with other disciplines just because it has permeable boundaries and can quickly respond to interdisciplinary agendas. In such a situation the gap between human and physical geography is likely to widen further and potentially weaken the discipline. The future of geography would seem to hinge on clear links to employability for geography graduates and to the supply of geography students from schools.

Geography as a discipline of synthesis has generated many innovative pedagogic approaches and is well known at higher education level for providing pedagogic guidance that other disciplines seek to emulate. This reflects epistemic diversity and gives rise to the broad portfolio of geographical courses on offer. The development of geography as a discipline shows how geographical ideas have been established, challenged, and consolidated, shaped by diverse scholarly traditions and manipulated to fit the ideological needs of the time.

Development of the discipline

The rise of geography in higher education was inextricably linked to changes in economy and society in the nineteenth and early twentieth century. Geography had discipline status before, but the need for territorial security, exploration and empire, industry, agricultural development, and developing military interests led to the organization of both professional associations and the development of new programs of study.

The state, in terms of territorial security and empire, coupled with private commercial interests helped launch geography as a discipline through learned societies and universities in late nineteenth and early twentieth-century Europe (Maddrell 2009) and since then geographical education has been used internationally as a strategic tool to acquire applied knowledge for military, urban, industrial, and agricultural development. In France in the early nineteenth century it was recognized that scientific and
engineering research could help the military, followed by the rise of the German research university as a model for education in the service of empire and capitalism. Prior to 1900 geography at higher education level was initiated by the activities of a small number of individuals forming learned societies, established during an era of European and global exploration and by the publication of landmark texts such as Alexander von Humboldt’s *Cosmos: A Sketch of a Physical Description of the Universe* published in 1845, Carl Ritter’s *Die Erdkunde* in 1817, and *Physiography* (1877) by Thomas. H. Huxley (Martin 2005), which had a significant influence on the discipline. The rise of associations such as the Royal Geographical Society, American Geographical Society, Berlin Geographical Society, and Russian Geographical Society helped to lead, and was concurrent with, the transformation of higher education (on the German model) beginning in the late nineteenth century. The combination of texts and society backing led to the eventual recognition of geography as a subject in universities. Relatively soon after, organized graduate programs were established.

The period between 1900 and 1950 was characterized by growth in the number of universities offering geography, particularly in the United Kingdom, the United States, Belgium, Canada, and New Zealand as well as growth in the number of national societies supporting the discipline. With the growth of geography in universities, the discipline gradually attained a higher status. Although geography grew steadily throughout the first half of the twentieth century the growing prestige of “hard” sciences and the division between “physical” and “social” sciences led to geography becoming marginalized in some places.

The concerns of individual states have been central to the development of the discipline over time. Several countries, including Canada, recognized the need for geographers in collating an inventory of resources for development. Booms and slumps in the number of departments offering geography have characterized the development of the discipline in the United Kingdom and United States and by the end of the 1950s geography was a popular subject choice for undergraduates in the United Kingdom, with an intellectually vibrant atmosphere (Johnston 2004). Johnston suggests that human geography was not identified as part of social sciences until the end of the 1960s and did not fit contemporary perceptions of the frontiers of knowledge and that without advocates in the British Academy and Royal Society at that time, geographers had no influence on the structure and future of the academy. Indeed the academy of sciences structures around the world differ greatly, particularly in socialist and postsocialist countries, leading to differences in the way that the subject is organized.

There was further expansion of higher education provision in the United States but geography was dropped as a subject by several high ranking universities in the 1950s and 1960s, a trend that continued on a more dramatic scale into the 1970s with 32 geography departments closed in the United States in the period between 1970 and 1976.

The Open University, founded in 1968 and admitting students from 1971 included geography from the outset. Allowing access to geography courses at a distance via technology meant that students who did not have the opportunity to attend traditional campus universities to access degree courses, could now through distance courses. Through Future Learn, an international university collaboration, online learning now has a global audience.

The “traditions” within human geography have seen prominence at different times during the evolution of the discipline in the twentieth
century. These include a regional approach to geography, the quantitative revolution, spatial turn, and cultural turn, that have impacted on different countries at different rates and in some cases have spawned subdisciplines as geography has evolved.

In the late 1950s in North America the quantitative and theoretical revolutions started a change that had effects across the geographical community demanding a rigorous scientific approach. Emphasis on quantitative data collection and computation soon became embedded in geographical degree programs. Research teams and groups were needed to gather sufficient data to solve large-scale problems. For example, international research collaborations like the Metropolis Project, a multidisciplinary, multisite inquiry into migration and the integration of ethnic and religious minorities in the world’s urban areas. Funding became much more important to sustain multi-institutional teams and research councils, foundations, charities, and societies became crucial to supporting this work. Gradual fragmentation and modularization in some institutions has led to student choice from a range of specialist modules, rather than being able to cover the entire scope of the discipline.

The role of the nation-state

Higher education is often closely tied to national political and economic agendas, particularly in those nations in which the higher education system is funded, for the most part, centrally. A set of articles in a 2007 issue of the Journal of Geography in Higher Education examined the role that national contexts and the state can have on intellectual and educational agendas in geography with examples from China, South Africa, Australia, Canada, Singapore, and the United Kingdom. The Canadian geographical project has been inextricably linked to the nation-state with the government understanding the strategic importance of an inventory of the nation’s resources for planning and management in rural and urban areas. This led to rapid growth of geography departments with significant expertise in quantitative and statistical expertise as well as GIS growing from the government need for maps for land management. In China the state has even more significant, direct influence on the higher education system by allocating student quotas for HE institutions, recommending textbooks and controlling the classification of undergraduate and postgraduate programs. The government also decides whether geography forms part of admission tests for HE which has driven decline and more recent expansion in HE geography in this way. Greater global outreach by Chinese institutions, the use of non-Chinese textbooks, publications in international journals, and collaboration with overseas scholars and partnerships with overseas institutions all reflect greater openness in China today. Despite less direct intervention by the state in Singapore, the national context is evident in the research questions that Singaporean geography considers, for example, national identity, transnational corporations, multiculturalism, migrant workers, and water resources.

Beyond the influence of the state an increased awareness of the subject by prospective students has led to a proliferation of courses (for instance, there are more than 200 undergraduate geography courses in US universities today). Alexander Murphy, writing about the United States in his article for the 2007 collection, suggests that the main reasons for growth include: geography being seen as relevant to issues of the day such as increased public interest in what geographers do as geography is in the news and the geo-technology revolution and forensics are popularized through TV shows; geography being increasingly appreciated among scholars.
in other disciplines; huge growth in the use of GIS; an expanded job market for those with geographic training; and, finally, the emergence of more analytical and sophisticated geography in school curricula. The relationship between school and university geography is strong with schools creating a demand for and feeding undergraduate courses.

While the role of the state is still highly significant, more recently the marketization of higher education provision, created by the neoliberal agenda, has internationalized the availability of access to higher education degrees in geography and this is leading to new developments in terms of competition and divisions of labor.

The neoliberal agenda

In recent decades, many universities’ systems have had to confront neoliberal policies on several fronts. One of the most significant is that students are being asked to cover more and more of the costs of higher education as government funding declines, creating a consumerist culture. Second, universities are under increasing pressure to publish outcomes. World rankings of geography departments now exist and several departments from the United Kingdom as well as those in the United States, Singapore, and Canada feature in the top ten. These are created through a variety of teaching and research metrics. In 1986 the Research Assessment Exercise (RAE) was carried out across UK higher education and this was linked to funding allocations for research based on assessments of measures of quality. The RAE led to a growth of a management and accountability culture in universities. New measures of research quality and impact have become embedded in the more recent incarnation in the United Kingdom, called the Research Excellence Framework (REF), and metrics are likely to continue to be used to make distinctions between types of research output and activity, particularly in the area of demonstrating research impact beyond higher education. Similar research quality assessments are carried out in other countries such as the Research Quality Framework (R.Q.F) in Australia.

A teaching excellence framework (TEF) to measure teaching quality, learning environment and student outcomes, and learning gain is being implemented in England. Teaching quality has also been measured through student survey data (student satisfaction in the United Kingdom and student engagement surveys in the United States and Australia) that have differentiated geography courses. Key information sets such as the number of faculty who are trained teachers and the number of contact hours on courses, are becoming public information indicators that students can use to make choices between courses. In addition, metrics such as retention rates, graduation rates, the proportion of students graduating with “good” degrees (as defined by grade point average scores in the United States or by degree class in the United Kingdom), graduate employment (particularly whether graduates are in employment within six months of graduation and whether graduates have successfully secured graduate level jobs) are also made known. The success of particular groups is also monitored, including gender, non-traditional learners, such as those from families with no previous higher education experience, minority ethnic groups, and people of differing generational status. In some cases metrics show that particular pedagogic practices benefit nontraditional students much more, for example, engaging in undergraduate research with a faculty mentor.

The segmentation of academic labor into research only and teaching only roles has created a contingent labor force of nontenure-track faculty (or those on fixed term and temporary
contracts). For those focused on teaching there is no provision for research or writing time as part of their employment, and both postdoctoral researchers and teaching fellows share precarious employment terms.

Competition between universities as part of this marketization of HE has had benefits in terms of fore-facing learning outcomes and the unique academic offering of particular courses. In addition it is ensuring that universities communicate academic research more widely and with public groups to market their research activity and clearly demonstrate the impact it is having.

**Learning, teaching, and assessment**

**Content, standards, and quality markers**

The wealth of potential subject content at higher education level is vast and an appreciation of the multiple ways in which geographical phenomena can be interpreted and studied is part of the disciplinary perspective. The range of techniques and methods used by geographers in HE courses allows students to gain familiarity with a number of technologies and approaches, for example, cartography, fieldwork, GIS and remote sensing, modeling, and quantitative and qualitative methodologies for gathering and interpreting data. Fieldwork provides an engagement with real places allowing concrete understanding of the complexity and dynamism of geography.

Drivers for curriculum content come in a variety of forms. In the United Kingdom, the Quality Assurance Agency created a first geography subject benchmark statement in 2000, drawn together through consultation with academics from a number of institutions as well as the Royal Geographical Society (with the Institute of British Geographers), hereafter RGS (IBG). The subject benchmark statement is revised through consultation with academics, learned societies, and employer representatives. It describes the nature and characteristics of geography degree programs in the United Kingdom and creates an agreed expectation of the standards students should achieve. The statement contains the aims, subject knowledge, skills/attributes, and the types of learning, teaching, and assessment which are likely to be encountered, recognizing the diversity of educational providers. Further quality assurance is provided by external examining which is used to demonstrate comparability of awards (a practice largely confined to the United Kingdom and Ireland).

**Contemporary pedagogy**

The country in which geography is being studied makes a large difference to the type of material being taught, the variety of assessments being made of student work, and the freedom which students experience in choosing the elements they study as well as the extent to which the discipline mirrors school geography. For example, the idea from geographers Healey and Jenkins that students learn *through* as well as *about* research (Healey and Jenkins 2009) has not reached all institutions, in policy or practice, despite a wealth of inspiring case studies where it is taking place.

The regional approach developed a commitment to fieldwork as a pedagogy and this has been adopted in a range of places including local and exotic field classes. The benefits of fieldwork in terms of participation in communities and experiential learning have created concerns about “othering,” particularly in human geography in some countries. A range of active learning approaches that promote dialogue and reflection has been adopted where there has been significant consideration of the values
communicated through choice of discipline content and geographical pedagogy. These include simulations, such as role play, debates, authentic decision-making exercises, and research-based learning, in order to synthesize reason and factual content with emotion and moral values. This synthesis could be considered a signature pedagogy for the discipline and has given rise to a range of creative forms of assessed work. Students are encouraged to reflect on their learning through assignments, such as reflective diaries, briefing papers, critical reviews, and creative ways of conveying the combination of affect and discipline content, such as exhibitions and video. Greater diversity of assessment types may result from universities as they seek to develop creativity and employability skills in their students and to show how their curriculum is transformational. More information about contemporary pedagogy and trends can be found under Geography education: fieldwork and contemporary pedagogy.

The graduate attributes agenda, to which David Nicol in Scotland and Simon Barrie in Australia have made significant contributions, has been influential recently with universities nominating the graduate capabilities that their students will leave with and geographers are increasingly being asked to demonstrate links to these generic capabilities (such as communication, information literacy, research literacy). This agenda has emphasized self-regulation and development through self and peer learning that is social and reflective. It will become increasingly important for geographers to identify discipline-specific graduate and postgraduate capabilities.

The student experience

The student experience of learning geography in universities can be described on a continuum. At one end there is a high degree of choice in content via specialist modules with emphasis on being rewarded for wide reading, originality, and demonstrating critical thinking and often this is coupled with an individual research project as the culmination of the course. At the other extreme is a heavily prescribed curriculum with low levels of choice and autonomy where core knowledge is tested particularly through examinations. In order to develop transferable skills for employment, students may be expected to engage in a wide variety of assessed tasks beyond just essays and examinations; for example, work placement reports, press releases, briefing documents, podcasts, blog entries, reflective diaries, journal articles, and posters.

Employability and transferable skills

Learning outcomes became a feature of module specifications in the early twenty-first century and the vast majority of university courses are modular. The importance of “employability” is evident from university webpages and the transferable skills that graduates can hope to obtain during a period of study with the particular university feature strongly in the introductory literature that advertises degree courses. Further specialization as a result of the wide choice of modules on degrees plus the need for graduates to differentiate themselves in a competitive job market has led to the development of specialist and vocational master’s degree courses (see also Geography education, workforce trends, twenty-first-century skills, and geographical capabilities).

Learning technologies

There has been a proliferation of learning technologies to support higher education and student expectations are growing in terms of accessibility to online material, online communication, and the use of technology in learning
and teaching. Distance education courses have a long history in some institutions and are now providing access to learners from around the world. Some face-to-face taught courses have transitioned to online provision, whereas others have a blended approach allowing technology to enhance face-to-face contact such as through online submission of assignments, online feedback, institutional virtual learning environments that store course materials, and online links to resources. University academics have also adopted technology as a means of coping with larger numbers of students, such as through the development of multiple choice questions for assessment with automated feedback, and online marking allowing students to receive feedback more quickly. Technology has also had a major transformative effect on geography pedagogy as noted in Geography education, workforce trends, twenty-first-century skills, and geographical capabilities and Geographic information science and technology: educational directions.

**Key challenges**

**Debates on the purpose and value of geography**

There is an ongoing debate about the balance between and importance of providing training for a future workforce with educating students with a passion for the discipline and due consideration of the values of studying geography in terms of developing global citizenship and ethical thinking that extend beyond graduate employability. This is echoed to some extent for academics in relevancy debates about the need to carry out applied research that informs policy. The value of geographers, in contrast to those from other disciplines, suffers from a lack of public visibility demonstrating the impact of geographers in the wider context and on public policy, evidenced by repeated calls in presidential addresses from geographical societies in the 1970s and early 2000s. Very few geographers have entered the public’s consciousness through media interventions, in contrast to archaeologists, historians, and geologists, and as such have had little impact on policy direction.

Engaging with students in the neoliberal university is more challenging than in the past. Students can be highly strategic in their engagement with the discipline if they are only seeking a qualification that results in employment, prioritizing assessments over a deeper engagement with the geographical perspective. One response to this is the new concept of “GeoCapabilities,” the discipline-specific capabilities that a geographical education engenders, allowing graduates and postgraduates to contribute to their own welfare development as humans, that of their community, and the wider world through a lifelong geographical perspective. The approach is informed by the work of Amartya Sen and Martha Nussbaum whose human capability development advocates a capabilities approach to education, resulting from a reaction to the neoliberal conception of the modern university. The capabilities approach is a resource for the lifelong development of human potential and wellbeing. Solem, Lambert, and Tani (2013) have started the process of defining internationally recognized GeoCapabilities. This is a very different educational agenda from the managerialist approaches that characterize neoliberal universities with students being seen as consumers and faculty (teaching and research staff) as “human resources.” Decreased government funding has meant that universities have to find alternative finance, competing to attract income from overseas students, taught postgraduate courses, consultancy, refresher courses, and continuing professional development provision. This
is monitored and evaluated to ensure value for money in a culture of audit and accountability. A recent development in the university sector is the senior manager roles being taken by people with a nonacademic business background. State funding of universities shows great variability globally, giving rise to differing outcomes as a result of diverse funding models. An example of the impact of economics is noted by Xiaojian Li, Yunfeng Kong and Baovu Peng writing about education in China since 1980 in the *Journal of Geography in Higher Education*. China is one of the largest countries in terms of geography student enrolment in higher education and the subject has shared favorably in the country’s recent expansion in higher education. The regional patterns by number of geography programs correlate to the size of population while the quality of geography programs shows a close relationship with regional economic development.

Marketization and growth in HE provision has served to increase access to HE geography, allowing a greater number of students to take degree courses. This has led to a challenge in terms of ensuring participation is accessible to all groups of prospective students and universities are often provided with targets for “widening participation” (nontraditional) students as well as international students who pay significantly higher fees. In order to achieve targets HE providers often create bursaries and scholarships to ensure that support is created for recruitment and retention of particular sectors of the student population.

The transition challenge

Students experience three key transition challenges as they engage in higher education. First is the transition into university from school (or alternative prior experience), second is the transition they go through as they become an autonomous learner and “becoming a geographer,” and, finally, the transition into further study, employment, or other setting beyond the university. These are dealt with in turn.

Translating the critical, often experimental, and tentative material which forms part of university level research in geography into teaching occurs in many departments where the development of critical skills is a central objective. However, this does not easily translate into the school curriculum where subject content needs to be more enduring, certain, and stable. This has led to a declining influence of university geographers on the geographical content of the school curriculum and therefore to a key challenge to transition into higher education. Students arriving have different expectations about the geography they will be learning from the academics involved in teaching and grading their work. In the United Kingdom previously strong links between geography in schools and universities have weakened, creating a transition challenge for staff and students (e.g., Sidaway and Johnston 2007). The motivation to integrate cutting edge university research in the school curriculum has weakened as a result of the national curriculum dictating content and student performance being used to create school league tables, reducing teacher autonomy. The syllabus at advanced level (the level students achieve to gain entry to university) allows school teachers to omit skill and content areas they are less confident to teach, such as statistical techniques and some of the content of physical geography.

In developing autonomous learners, universities often adopt a “students as researchers” pedagogy where students are encouraged to formulate research questions, to collect or use existing data sources, and to present their findings. This approach requires support from the
faculty and with the growing numbers of students on courses the challenge is to provide this support to all students. Where this is not possible on a one-to-one mentoring basis, supervision and group work is used to provide peer mentoring. Embedding research-based learning early in the curriculum is seen as a good way to support this transition (Walkington et al. 2011).

Links to employability for geography graduates

The preconditions for growth in geography as a discipline in higher education relate strongly to the ability of students to perceive a direct future benefit in terms of employment from a qualification in the subject. In South Africa’s post-apartheid era, teaching and research has been local or applied with geography courses being cross-disciplinary and vocational, providing marketable skills. Clear links to employment have been crucial to the growth of the discipline in many other countries too. In Spain a dichotomy is evident between an inability to attract undergraduate geographers and greater visibility of geographers in the public eye, particularly in GIS, remote sensing, and planning. Geography is on the political agenda of the EU through the Infrastructure for Spatial Information in Europe (INSPIRE) project. This aims to build a common geographical space through ensuring that the infrastructure which holds spatial data is compatible across all member states, the objective being to allow sharing of data to solve transboundary sustainability challenges a development that may attract more undergraduates to geography in Spain, particularly through technical approaches like GIS. Geography recruitment is healthy in Singapore, but the subject is not oversubscribed as it is not seen as effective as subjects such as economics in securing employment and social mobility. There is clearly a challenge for geography faculty in making clear to students the links between their academic study, lifelong learning, and employment.

Fragmentation of geography as a discipline

In some countries there has been a tendency over the past twenty years to reduce the link between geography and area studies. Fragmentation of the discipline for marketing purposes has led to new labels for geographical courses. In Australia Chris Gibson reported in a 2007 paper in the Journal of Geography in Higher Education a recent decline in many undergraduate geography programs, a commensurate reduction in faculty numbers, and a reduction in independent departments named “geography.” Department names have been replaced with titles such as “environmental management” and “urban studies.” Reduced government funding and increasing staff/student ratios, the decreasing popularity of high school geography and the strong emphasis of the Australian RQF on interdisciplinarity have all contributed to the need for geography as a discipline to be adaptable. Fragmentation can be conceptualized as adaptability, resilience, and resourcefulness of the discipline, particularly at a time when interdisciplinary research is seen as an approach to solving complex large-scale problems, however, it could lead to marginalization and a loss of what “geography” means as a discipline (Holmes 2002).

Tensions between teaching and research

The teaching–research nexus is an ideal state where mutual benefits are derived from a combination of teaching and research. The relationship between teaching and research varies across institutions and countries, with some institutions
focused primarily on research with teaching being a relatively smaller enterprise, whereas increased participation in higher education in some places has led to larger cohorts in the universities that focus on teaching. In Russia there is a split between largely teaching-focused universities and government research institutes.

Le Heron, Baker, and McEwen (2006) suggest that institutional rules and government strategies, funding, and assessment have divided teaching and research and harmfully continue to suggest that they are unrelated whereas a culture of co-learning should be developed where synergetic relationships between research and teaching contribute to the development of both and the quality of teaching and research are enhanced. Most universities have the philosophy of a department that is “research led” with “research-led innovative teaching,” but what this means is different in different places. The number of students who participate and produce research, rather than simply learning about it, varies significantly from one institution to another. Two national journals of geography dedicated purely to publishing the results of undergraduate research – GEOview in Australia (www.iag.org.au/publications/geoview) and Geoverse in the United Kingdom (http://geoverse.brookes.ac.uk) – demonstrate what is achievable.

Sidaway and Johnston (2007) highlight the positive outcomes of research assessment arguing it has improved productivity and quality of UK research and that dynamic, strategic goals have been incorporated into a previously static system and it has created opportunities for innovative academics. However, they note that it can be to the detriment of teaching quality. Precedence is now given to particular formats of publications such as single-authored journal articles in high ranking journals. Sidaway and Johnston (2007) suggest that part of the reaction to the RAE has been a renewal of focus upon teaching and learning, described by Healey (2003) as “the scholarship of teaching.”

Inclusion

Higher education continues to be a site of privilege and exclusion and this continues to be the case despite years of effort to create a more inclusive discipline. Gender, ethnicity, citizenship, class, disability, life stage, age, sexuality, and international origins are all aspects of the diversity and inclusion agenda in higher education. These challenge the discipline on a number of levels. The content of the curriculum, the nature of the pedagogic approaches employed, the composition of the student body and that of faculty, and whether they are tenured and promoted all highlight huge challenges in undoing sexist, racist, ablest, heteronormative pasts. The challenge is to teach about diversity issues in an inclusive way regardless of the makeup of the student population. Globalization has made higher education much more international in terms of students, faculty, and outlook and in some places a third of geography departments comprise of overseas students and faculty personnel. In other institutions diversity issues may be more hidden. Recognizing students as individuals who intersect with all these diversity variables is essential. Schlemper and Monk (2010) have acknowledged that multiple approaches are needed for an inclusive approach, including a proactive and sustained approach to the recruitment and selection of students and staff, by integrating inclusive perspectives across the curriculum through proactive planning, fostering participation in events that address inclusivity, reflecting on inclusive perspectives at departmental level so that the climate is one that welcomes diversity, raising staff consciousness of
websites, noticeboards, use of space, and so on as the face of its culture and embedded behaviors.

In summary the discipline of geography has been challenged in terms of identity by its interface with other disciplines and inherent tensions between synthesizing or fragmenting into a human–physical divide or more specialist areas. Academics have to balance their time between teaching and research and many are faced with rapidly growing student numbers. Students who might not have previously accessed HE are now attending university and staff have to respond by supporting learners to make three significant transitions, that is, into, through, and out of HE. The integration of an academic’s own research into their teaching and adopting a “students as researchers” pedagogy are positive responses to these challenges.

Opportunities

There are many opportunities within geography for contributing to research and teaching in higher education generally as the discipline lends itself well to connecting with other subjects, being an integral part of international collaborations and addressing global research problems. The pedagogic practices which are distinctive are also of interest to other disciplines and there are a wealth of sharing mechanisms in place through networks, journals, learned societies, and online resources.

There is a wealth of opportunity to address global challenges through higher education research and teaching in geography. The discipline is composed of a range of diverse perspectives as geographers have an ability to combine reason and emotion in decision-making that has resulted in a “signature pedagogy.” Geography can provide students with a discursive environment to scaffold and advance learning and to maintain a reflection on values and opinions as they are developing, all within a global perspective. Field-based learning uses a spatial framework and this can serve to broker dialogue with science, social science, and humanities researchers due to the ability of geography to speak to and through many different disciplines. The language of the discipline is one which values scientific, social science, and humanistic perspectives allowing geographers to coordinate multidisciplinary teams and work on interdisciplinary problems. Furthermore, the public can engage with geographical data in new ways through volunteered geographic information, allowing them to engage in geographical knowledge production and dissemination.

International mobility and collaborations

The European Higher Education Area has specifications for academic qualifications as part of the Bologna declaration, an agreement made by 29 countries in 1999 to ensure comparability of standards and quality of higher education qualifications. It describes European credit transfers for degrees at bachelor’s, master’s, and doctoral level with 60 European credit transfers equivalent to a year of study. This system allows greater ease of movement between countries for both study and employment and is complemented by international exchange schemes such as Socrates/Erasmus, as well as multiple institutional links that are developing rapidly. In the United States, statewide articulation agreements and transfer practices are developing for general education which can include six credit hours for geography. Students are therefore more mobile than ever.

Specialist staff deliver intensive courses in different parts of the world as “flying faculty” and universities with multiple campuses create the opportunity for students in several countries
to share the same curriculum. This type of development has led to new laboratories being set up and laboratory practices being shared, for example, UK universities with campuses in Asia have been developed through staff partnership. The norms and practices of different countries can be challenged and reflected upon as a result of these collaborations. The growing movement of students and faculty internationally, for example, through the Erasmus program and Fulbright Fellowships, allows new practices to be shared as does the growing popularity of online courses which allow ideas to be shared without the need for travel.

UNIGIS is a worldwide network of universities collaborating on the creation and delivery of geographical information science and systems through distance learning. Currently postgraduate courses are offered in six European languages and partner institutions are present in over 40 countries. The initiative acts like a large multi-institution department. UNIGIS also hosts residential workshops and summer schools. This style of learning has provided enhanced accessibility to leading-edge teaching for students in countries all over the world.

Open educational resources (OER)

Making educational resources openly available for use and reuse worldwide is the basis of the open movement. Each university has adapted this in their own particular way with some favoring lecture capture which can be accessed as downloadable online resources, others developing institutional repositories for research and teaching materials with varying levels of public access, and others engaging greater participation through online courses. In the United Kingdom, OpenLearn labspace has collated many geography open resources and JISC (a UK charity which champions digital technologies in research and education) uses a repository called JORUM to make these searchable and available. Some institutions have developed MOOCs allowing the public and prospective students to access teaching materials freely, such as videos of lectures, and to join in interactive exercises and discussions online. A project called C-Change, developed through multi-institutions working in association with learned societies from geography, earth, and environmental sciences on climate change, attempted to create a pedagogic shift to support colleagues to open up their own resources for sharing by creating examples of practice and clarifying copyright law and policies. The American Association of Geographers (AAG) has also created modules to support the teaching of geographical issues based on country specific case studies developed through partnerships negotiated through the Center for Global Geography Education.

The interest in a self-sustaining community of practice through OERs is growing, especially where academics view greater exposure of their work as a positive action and institutions recognize that branding and sharing their intellectual property is a valuable marketing tool.

Networks

Learned societies provide excellent networking opportunities through research groups, teaching groups, support materials, training, journals, and conferences. The International Network for Learning and Teaching (INLT) is a collaboration among geography academics to facilitate collaborative writing on themes of international interest to develop teaching and learning practice. Many of these writing events result in symposia for the Journal of Geography in Higher Education. Other journals include the Journal of Geography and International Research in
Globalization could soon mean that the dominance of English as the medium for educational debate in geography could be diversified or replaced as agendas for the internationalization of committee memberships of journals and conferences are implemented.

**Frontiers in research and practice**

**Technology**

In the last decade social media has become a significant vehicle for engaging with the public and disseminating research, but also for enhancing face-to-face teaching and attracting students. Technology has the power to transform learning and people have envisioned a future without formal classrooms at place-based campuses while still providing directed learning. Students can be taught while in the field by a faculty member who remains within the university, for example, by carrying out field research methods, but gaining feedback on observations they relay via social media to peers and faculty elsewhere. Academic material can be sourced, packaged, and marketed for online consumption and products can be accessed on the move in the field or at a desk through a wide range of electronic devices. In the search for cheaper education “flying faculty” are already delivering intensive short courses around the world, though these are currently only complementing place-based courses rather than replacing them. New technological developments already allow students to engage in the remote control of laboratory equipment, the use of virtual microscopes, and involvement in whole class virtual fieldwork through the use of avatars and even virtual graduation alongside students at a real ceremony.

**Measuring learning gains**

Despite technology assisting with some transactional aspects of the student experience there remains a strong desire for face-to-face “contact time” with faculty, particularly in individual or small group settings. In addition, increased demand for work placements and overseas experiences (as part of a course through reciprocal mobility arrangements or exotic overseas fieldwork and expeditions) have cost and equality of access implications. The learning gains from these types of added-value experience are challenging to measure. Methodologies for doing so need to be developed across different types of institution as contextual factors can be highly influential. There is a strong ethos of collaboration among the learning and teaching community in geography, but pedagogic research and the scholarship of teaching and learning are often poorly funded and as a result the status of this form of inquiry suffers or remains unpublished. If we are to adopt an evidence-based practice approach then further research is essential to explore the most effective strategies for: creating learning communities online; maximizing the impact of overseas experiences on learners’ geographical understanding of the world; inclusive assessment; rapid but effective feedback; internationalizing curricula (Haigh 2010); fieldwork with larger classes; and the development of attributes, such as global citizenship, through discipline teaching.

**Conclusion**

There is clearly potential for radical change if informal learning technologies prove able to successfully create a sense of learning community online and allow authentic engagement in dialogue and decision-making without face-to-face
contact. Chism (2006) suggests that social learning can take place in virtual spaces that transcend the social and academic divide. Yet, significant differences exist around the world in access to computing hardware and software, the Internet, educational resources, and funding within and between countries. In addition, national or commercial monitoring of the web has the potential to widen existing inequalities further.

The trend toward international, national, and regional university consortia is likely to continue as universities seek to stratify and differentiate themselves. Opening a formerly elite HE system to mass educational access does not necessarily reduce inequalities. Michael Young has argued that we have the potential to provide epistemic access to all students through formal study and the transmission of powerful knowledge. What constitutes powerful knowledge in geography will be an interesting area of future debate. The impact of technology in opening up apparently endless opportunities for learning “any time, any place” needs to be clearly differentiated from the unique offering of a university or college experience in gaining epistemic access where a new way of thinking can become the basis for suggesting and practicing realistic alternatives.

Geography in higher education has been characterized by changing fortunes. The strength of the discipline lies in its ability to synthesize a range of perspectives and generate problem-solving and decision-making research areas as well as to create innovative pedagogies to teach a variety of forms of geographical thinking. Signature pedagogies (Schulman 2005) in geography that develop applied skills, ethical thinking, spatial understanding, as well as engagement with more generic graduate attributes through the powerful knowledge of a geographical education can develop students’ geocapabilities to prepare them for living responsibly in a supercomplex world (Barnett 2000).

**Further reading**

At first glance it may not be advisable to divorce the terms “knowledge,” “education,” and “science.” They are all based on learning processes and are strongly interrelated. However, the rapid expansion and specialization of research has sundered the wide field of the geography of knowledge and education as it was defined until the late 1990s (Meusburger 1998) into geographies of education, geographies of knowledge, and geographies of science. The boundaries between these three fields of inquiry may occasionally blur, but scholars working in them have different research interests, use different theoretical approaches and methodologies, and build different citation networks.

The geography of education in the narrow sense – the topic of this entry – deals with the causes and consequences of spatial variations in the provision and consumption of education; the impact of local milieus and social environments on educational attainment; spatial variations of the sociodemographic structure of the teaching profession; the influence that political systems, educational policies, and demographic change have on location patterns of schools and universities; the spatial mobility of scholars, students, and ideas; and other issues where places, spatial relations, and social environments have an impact on educational processes. So far, the vast majority of publications in this field have centered on formal education, but nonformal education and various forms of preschool education and child care also figure as research issues of geographies of education.

“Knowledge” is a much broader term than “education.” It encompasses not only the results of learning processes within the educational system but also professional expertise, abilities, capacities, experience-based intuition, and values. It is represented in individuals, organizations, technologies, research results, and material products. Geographies of knowledge study the places and spaces of knowledge generation, the diffusion and application of various categories of knowledge, and the reasons and consequences of spatial disparities of knowledge. Many interests pursued by geographers of knowledge lie beyond the educational system. Because knowledge constitutes a capacity for action, a knowledge-oriented approach lends itself to the study of many different topics of human geography. Scholars in this field study the relations between knowledge and power, knowledge and economic performance, and knowledge and various societal processes.

Geographies of science (Livingstone 2003) examine the spatiality and situatedness of science and research. They inquire into the sites at which scientific knowledge has been produced, assessed, and consumed; study the travel of explorers, scientific ideas, theories, and methodologies over physical and cultural space; and examine the geography of reading by analyzing why scientific works or authors are interpreted very differently in varying cultural and political contexts.

At first glance, geographies of education seem to have some research topics in common with comparative education. But the theoretical
approaches and methodologies of these two disciplines diverge greatly. Geographers are not as interested in comparing educational systems, policies, and practices of various states as they are in exploring the profound impact that places, local milieus, regional structures, social environments, and cultural contexts have on processes and institutions of education. In their view, organizational and cultural contexts of learning are not abstract concepts, but become manifest in sites, places, and regions.

Early roots and development of the geography of education

Empirical research on the spatial structures and disparities of education harks back to the first half of the nineteenth century. Many social reformers in the 1800s believed that social problems associated with early industrialization, such as poverty, child labor, crime, alcoholism, and a lack of decent housing resulted from ignorance and a lack of moral education. They therefore started investigating the social and spatial variations of illiteracy and educational attainment, spatial inequalities in the provision and quality of various types of schools, the skills and salaries of teachers, the availability of books in households, and other issues to describe the social, cultural, and economic settings of neighborhoods (Marsden 1987).

France was the first country to engage in the comprehensive, nationwide study of regional differences in illiteracy. This work drew primarily on examinations of military recruits and the inspection of marriage registers, both sources yielding data on the ability to read, write, or both. In 1826 Charles Dupin published the “Carte figurative de l'instruction populaire de la France” (Thematic Map of Popular Education in France). This map (reprinted in Meusburger 1998, 193) revealed remarkable regional disparities in educational attainment between northern and southern France. The map’s accompanying tables compared educational attainment, the number of patents for inventions, and membership in the Académie Française with various economic indicators, suggesting a high correlation between the population’s educational achievement and regional economic performance.

In the United Kingdom, a number of statistical societies emerged in the 1830s and 1840s to study the living conditions and social situation of the poor, and to foster social reform, with literacy again being a main focus. One result was a map entitled “Ignorance in England and Wales,” published by Fletcher in the Journal of the Statistical Society of London (1849). When C. Booth, R. W. Rawstron, J. Fletcher, and others analyzed poverty in London, Manchester, and other cities, they, too, used various indicators pertaining to schools, teachers, and educational attainment. A number of studies in different disciplines described inequalities between states with regard to literacy, the introduction of compulsory education, educational attainment, enrollment in universities, the distribution of leading scientists, and the level of technology. But few studies focused on inner urban disparities. One of the exceptions was C.R. Shaw, a member of the Chicago School of social ecology, who in the 1920s investigated spatial disparities of the relationship between truancy and juvenile delinquency in Chicago.

However, these traditions were not taken up in the mainstream human geography of those days. Apart from occasional early studies, education attracted little attention among human geographers until the 1960s. Early exceptions were W. Christaller and H. Bobek, the pioneers of central place studies, who used the hierarchical structure of the educational system (from
elementary school to university) as one of various indicators to construct their system for ranking central places. After World War II, E. Parker and C. Colby in the department of geography at the University of Chicago supervised four doctoral dissertations on educational land use. Three of them were published as research papers of the department of geography at the University of Chicago between 1948 and 1949.

The interest that geographers showed in education grew in the 1960s and 1970s, when many countries strove for unprecedented expansion of their educational systems, including the establishment of many new secondary schools and universities, a steep increase in university enrollment, and the needed reorganization of elementary school location patterns. It was necessary in that period to plan and negotiate locations for new schools and universities, justify the closure of small elementary schools, reorganize catchment areas and student transport, and explore the reasons for intolerable spatial disparities in educational attainment in order to counteract them. These tasks required competence in geography; experience in urban and regional planning; sensitivity to the importance of local identities and social environments; and detailed knowledge of the history, culture, and economy of the towns and regions in question. Geographers soon became involved in applied educational research and regional educational planning. This boom in reforming educational systems was also nourished by emerging discourses about the economic importance of human resources and about brain drain, the knowledge society, and the legitimacy of social and spatial inequalities.

One of the first and internationally most influential pioneers of the geography of education was the German geographer Robert Geipel (b. 1929; Figure 1), whose research focused predominantly on this field from the early 1960s to the late 1990s. He was professor of social geography at Goethe University in Frankfurt am Main, Germany (1961–1969), then held a chair for applied geography at the Technical University in Munich (1969–1994), and served as director of the Bavarian State Institute for Higher Education Research and Planning in Munich (1982–1994).

In 1967 Geipel and scholars from other disciplines founded the working group on spatial educational research at the Academy for Spatial Research and Planning in Hanover, Germany, which until the late 1970s was an important platform of inter- and transdisciplinary research about spatial disparities of education. In these
functions he had close scientific relations to the pioneers of this research field in other countries (particularly the United Kingdom) and disciplines (sociology, psychology, and economics).

In 1983 the Association of German Geographers founded the Geography of Education Study Group, which is still highly active today. Members of this study group produced the sixth volume of the *National Atlas of the Federal Republic of Germany on Education and Culture* (Mayr and Nutz 2002).

In the United Kingdom the early pioneers of the geography of education in the 1970s and 1980s were G. Hones, W. Marsden, R. Ryba, W.T.S. Gould, L. Bondi, and M.H. Matthews. However, the number of education-related publications by geographers did not begin to soar in the United Kingdom until the 1990s. The great majority of the authors restricted their citations to English-language publications and were not aware of the research in other countries (see review articles of Hamnett, Ramsden, and Butler 2007; Hanson Thiem 2009). Sporadic publications about the geography of education also appeared in other countries.

**Main research topics**

In the early period between the 1960s and late 1990s, geographers of education and educational systems investigated a wide sweep of topics, including: the spatial organization of educational systems (size, location criteria, and catchment areas of schools and universities); the reasons and consequences of spatial disparities in educational attainment; relations between towns and their universities; the economic and cultural impacts of universities; the social composition of schools (measured by the educational achievement and occupations of both parents); school segregation and student transport; spatial disparities of vertical social intergenerational mobility (comparison between the educational achievement of parents and of their children); spatial variations of professional skills, sociodemographic structures (age, social origin) and the feminization of the teaching profession; the impact that geographic structures (e.g., population density, size and distribution of settlements, road and rail communications, and local employment structures) have on location patterns of various types of educational institutions; spatial variations of expenditure on education; spatial impacts of various political ideologies on educational policies and school-planning concepts; relations between communities and schools, especially the social, cultural, and economic effects of school closures on communities; the impact of educational achievement on professional careers and migration; the mobility of academics and students; the role of schools in ethnic conflicts and processes of nation building; illiteracy as an obstacle to economic development and societal modernization; the spatial distribution of jobs for high- and low-skilled employees; career mobility and networks of scientists and highly skilled professionals; and the correlation of different levels of educational achievement with unemployment, women’s employment rates, housing quality, and reproduction rates. In this early period, many geographers situated educational systems and educational attainment in a very broad economic, social, cultural, and political context (for details see Freytag 2003; Geipel 1966; Kramer 1993; Mayr and Nutz 2002; Meusburger 1998; Schmude 1988).

Since the late 1990s, new research questions and theoretical approaches have been added. Some of the latter deal with normative understandings of childhood, treat young people as subjects rather than objects of education, deepen the understanding of children’s spaces of learning, attend to gendered identity construction in schools, and focus on various facets of
nonparental childcare provision, to name just a few of the aspects addressed (for details see Holloway et al. 2010; Holloway and Jöns 2012; Matthews and Limb 1999). Other new research activities focus on the neoliberal international education industry. The intention of establishing schools and universities overseas is to attract fee-paying (revenue-generating) students, but it also creates new geographies of social exclusion within societies that send the students (Brooks and Waters 2011; Koch 2014).

Other research focuses on the spatiality of learning processes, alluding to the fact that learning and problem-solving do not take place in a social, political, or economic vacuum but rather are influenced by a multitude of factors whose local interaction results in a spatial context, learning environment, or knowledge milieu.

Because the educational system is an important sounding board of political, societal, and economic structures and processes, various indicators of educational attainment and educational achievement have been used in other fields of human geography as well to study spatial variations of societal structures, to uncover social and economic inequalities, and to display unequal power relations.

History shows that educational systems have an important political and economic function. In the nineteenth century the processes of nation building and democratization were intimately connected with the spread of literacy and the introduction of compulsory schooling. A high degree of literacy is regarded as a precondition for the evolution of large and complex organizations and bureaucratic administration and for the successful adoption of many innovations. In many new nation-states the primary functions of the educational system were not only to eliminate illiteracy and create a well-educated labor force prepared for various innovations but also to consolidate administrative power, support national identity and cultural memories, create heroic national historiography, shape stable interpretations of the world, promote an official language of instruction, construct an ideological and cultural homogeneity, and assimilate ethnic minorities.

The administrative control of schools, the language of instruction, the selection of teachers, the spatial organization of elementary schools, and the location of new universities have been of paramount political importance. In communist and other totalitarian systems basic education is a decisive instrument for controlling the minds of the population. In multiethnic or bilingual areas the language of instruction is a salient political issue. When territories are annexed, one of the first measures taken is to replace teachers and schoolbooks of the former system and to change the language of instruction.

The educational system has functioned as the key component of nationalization and denationalization policy. In order to Italianize the northern and northeastern regions of Italy, where the vast majority of the inhabitants spoke German, Slovenian, or Croatian, the so-called Gentile Reform of Fascist Italy in 1924 forbade the use of non-Italian languages in schools and kindergartens. A decree issued by the prefect of Trent on November 27, 1925, prohibited even private tutoring in German within families if it was given to more than three children at the same time. Police watched diligently for any form of private or clandestine instruction, and intervened frequently. In the United States the Bureau of Indian Affairs strictly forbade the use of Indian languages in schools it controlled, and enforced the rule until the end of World War II.

Varying priority of research questions

The priority of research issues examined by geographers varies not only over time but also
from one country to another. Priorities depend on the answer to a number of questions: What kind of governance does elementary education have – centralized or decentralized? Which administrative authority (local community, district, province, state, nation, or church) establishes, finances, and controls various types of schools or selects and pays teachers? Are elementary school catchment areas defined by school administrations or by parental decisions? What are the mechanisms for distributing pupils of different ability levels across different types of schools? Is the selectivity of schools based on the children’s cognitive abilities or on the financial resources of parents? Is school attendance free of charge? What is the degree of social inequality, ethnic diversity, and vertical social mobility in the society of a given region? Is competition for students between schools open or not? To what extent is the ethnic composition of a population a source of social strife? Are the problematic or socially deprived areas of education located in urban or rather in rural regions? What data sources are available to scholars?

Major recent topics of geographers of education in the United States and the United Kingdom have been school segregation, desegregation busing, the competition between private and public schooling, educational inequalities that arise from residential sorting, the flight from working-class schools, repositioning of inner-city schooling, relations between family income and educational attainment, the neoliberal education market, and the studentification of urban areas. In states that have no tuition fees, a less hierarchic class society, less segregation, or high-quality public schooling, the focus has been on other topics. Accordingly, different research cultures and citation networks have developed within the geography of education. To avoid such national specialties, the following sections of this entry discuss three research topics of general relevance.

**Organization, size, and location patterns of elementary schools**

Siting primary schools in sparsely inhabited rural areas is highly controversial in many countries. It requires more geographical, historical, and cultural expertise than siting institutions of secondary or tertiary education in urban agglomerations. Discord between communities and school administrations frequently arises when educational planners or school administrators show little sensitivity to regional and cultural diversity, the importance of local identities, social cohesion within villages and small towns, and the symbolic meaning of places. Some politicians and administrators have been unaware that planning principles and guidelines concerning the location and organizational structure of schools (e.g., minimum size of schools) should be flexible and adaptable in order to account for regional diversity and local requirements. Sparsely inhabited rural areas suffering from depopulation have had to respond much earlier to declining school enrollment, fiscal constraints, and the difficulty of attracting skilled teachers than more densely populated urban agglomerations. They have therefore had to experiment with specially designed classes, new organizational forms of schools, and new teaching methods in small schools, where children from several grade levels are taught in one classroom.

In rural areas of many states, two different concepts of regional educational planning compete (for details see Kramer 1993). That of large centralized elementary schools to which students are transported over long distances by school buses or parents is claimed to increase financial efficiency, enhance the flexible assignment of teachers, augment the variety of study courses,
broaden social equality, improve the quality of education, and exemplify modernity. Proponents of this concept usually overlook its attendant negative implications, such as transporting 6- to 10-year-old children over large distances into social settings unfamiliar to them, confronting the children with values contrary to those of their family environment, exposing them to emotional stress, and unduly reducing their leisure time.

The alternative concept of regional educational planning promotes small decentralized elementary schools located in or near the villages and towns where the 6- to 10-year-old pupils live. Designed for small classes and schools, this approach requires more teachers, and thus greater financial resources, per 100 students than large urban schools. It is less flexible in the assignment of teachers. However, supporters of this concept assert that its pedagogical advantages and many positive extracurricular effects outweigh the higher financial costs. Its adherents have a different view of childhood, are more sensitive to spatial disparities and local needs than advocates of centralized elementary schooling, acknowledge the negative experience many children have with long-distance busing, and are primarily interested in the needs of communities. They maintain that elementary school teachers in peripheral rural villages play an important extracurricular role and have a greater long-term impact on the community than their counterparts in large cities. If sparsely inhabited rural areas are successful in attracting skilled teachers, their schools will be indispensable elements of the community’s infrastructure. They will be places that form and strengthen local identity, social networks, and social cohesion, and that nurture cultural activities and sensitivity to regional environmental problems. In social milieus of that kind, skilled teachers are still key people in the community and have many functions to perform beyond the school (e.g., church choir director, head of the amateur theater, or leader of the volunteer fire department). In urban areas the professionalization of these functions greatly reduces the need for the extracurricular roles of teachers. The closure of the only elementary school in a sparsely inhabited rural area, and the disruption of children’s living and learning spaces, have far more negative social, cultural, and economic effects than in a large metropolitan area.

Clashes between these two concepts become particularly explosive in multiethnic or multilingual areas. Since the advent of compulsory schooling in the late eighteenth and early nineteenth centuries, administrative control of school systems and the language of instruction in elementary schools have emerged as flash points in bilingual areas. During the nation-building process in Europe and North America, one of the primary functions of public elementary schools was to foster national unity and assimilate ethnic minorities. The language of instruction in the early grades of elementary school was of paramount instrumental value in suppressing or emancipating ethnic minorities. School authorities could easily disadvantage autochthonous ethnic minorities by raising official standards for the minimum school and class size, by forbidding the use of minority languages for instruction, and by assigning teachers who did not speak the language of the school’s minority students and were not familiar with their culture.

Cost-efficiency and “rationalization” of educational infrastructure are powerful arguments in favor of centralizing basic education. They are often used as pretexts for the pursuit of political goals. In Hungary the communist system in the 1950s considered all settlements with fewer than 3000 inhabitants as “uneconomical” to maintain, and planned to close thousands of small schools. This decision was also shaped
by the regime’s negative attitude toward rural society, which it considered a feudal vestige that had no place in the new socialist society it wanted to create. In the 1970s the country’s authorities brought about another historically unprecedented decline of scattered farms, small villages, and their educational infrastructures, a demise much more severe than similar trends in capitalist countries (Gyuris 2014, 538–545).

In alpine regions of western Austria, it was reasoned by educational planners that cost–benefit analysis should not be focused on education alone, that it should also include the unintended consequences that school closures have in other areas of society and the economy, and that educational policies and concepts of educational planning should be coordinated with other spheres of regional planning. The same logic applies to urban areas. Without improvement in the housing quality and the reputation of a given urban area, educational policies will not be able to raise low levels of educational attainment there (Bondi 1987; Gordon and Monastiriotis 2007).

When analyzing the political significance of basic education in bilingual areas, researchers find it revealing to compare the size of elementary schools shortly before they were closed. An instructive example is South Tyrol, which Italy annexed after World War I. From 1971 through 1981, a large number of small elementary schools in the Alpine regions were closed, whereas numerous one-class Italian schools in South Tyrol were maintained as long as possible. Of the 66 elementary schools with Italian as the language of instruction, 71.2% had no more than one to three pupils before they were shut down, and not a single one of the schools had more than 10 pupils. By comparison, only 5.1% of the 78 schools with German as the language of instruction were allowed to continue until they shrank to that size. Indeed, 42.3% of the German schools in South Tyrol had more than 10 students in the year preceding closure, but not a single Italian school did (Höfle and Meusburger 1983, 247).

Spatial disparities of educational achievement and attainment

Indicators of educational achievement describe the final result of an educational process. Indicators of educational attainment are used to describe a current status in an ongoing (unfinished) process of education.

The educational achievement of an adult population is measured by indicators such as the percentage of that group that is illiterate, the percentage of its adult members who have completed a certain level of education (e.g., elementary school, vocational school, college, or university), or the median number of school years completed. Indicators of educational attainment illustrate both the flow of students through the hierarchical structure of an educational system and the students’ performance in various types of schools. Spatial disparities in the educational attainment of students can be measured by indicators such as the percentage of a given age group attending a certain type of school, the transition (enrollment) rates of an age cohort to various institutions of higher education, the school survival expectancy or persistence of school attendance (i.e., how many years children remain in the school system), performance on general certificates or achievement tests (e.g., the United States’ National Assessment of Educational Progress; the United Kingdom’s Pupil Level Annual School Census and General Certificate of Secondary Education (GCSE)), the share of dropouts and truants (rates
of unexcused absences at school), and rates of suspensions from school.

Vast ethnic disparities of educational achievement within a state can mirror existing inequalities and potential political conflicts. An ethnic group with a high proportion of adults who are illiterate or have a very low educational achievement is caught in a vicious circle (Gamerith 2004). Autochthonous minorities who are not allowed to have elementary schools teach in their mother tongue, who are offered underequipped schools and poorly qualified teachers, and whose cultural heritage is devalued in or omitted from schoolbooks may demonstrate low performance, low commitment, low aspirations, and high resentment. If the value system of an ethnic minority (e.g., First Nations in Canada, Native Americans in the United States, and Aborigines in Australia) does not meet the expectations and attitudes of a modern society, many students in this group will develop strategies for resisting the rules and goals of the school. This response will create an antischool culture marked by truancy, refusal to study, and academic failure. This behavior then becomes justification for further discrimination, and reduces minority people’s power to compete on equal terms for jobs in the labor market.

Table 1 ranks the ethnic groups in the former Yugoslavia according to their degree of illiteracy shortly after World War II. At that time the illiteracy rates of ethnic groups such as the Gypsies (the term “Roma” was not used then), Albanians, Turks, and autonomous Muslims were still extreme, ranging between 54% and 74%, compared to less than 10% among the Slovenes, Czechs, Slovaks, Germans, Italians, and Hungarians in Yugoslavia. In other words, the ethnic groups at the bottom of the ranking had illiteracy rates that had been surpassed by those at the top 150 to 200 years earlier. Such large disparities of literacy within a nation almost inevitably result in large social and economic inequalities, social distance, cultural prejudice, and political tensions, especially if the social disparities are coupled with religion or the mother tongue, or if the politically dominant group has a higher percentage of illiterate adults than the groups that feel politically disadvantaged.

It goes without saying that the so-called collective status of an ethnic group is just a rough concept. Within each ethnic group, too, there are major regional and social disparities. As shown by Table 2, the educational achievement of the cigány (Gypsies) in Hungary varies with the size of their place of residence: the larger the size of their villages or town, the lower the percentage of Gypsies without a basic education.

The usefulness or explanatory power of indicators of educational attainment and achievement is not stable over time and space. First, it is influenced by the differentiation and selectivity of the school system. A highly differentiated and selective school system provides indicators of educational attainment that are of greater significance than those from a less differentiated and less selective one, where almost all children achieve high levels of education.

One of the greatest challenges in this research field is to explain spatial and social disparities of educational attainment. They are influenced by at least eight groups of factors, and explaining them requires knowledge of a broad range of theoretical concepts from various disciplines.

The foremost factor of influence is the sociocultural milieu in the family. The family background includes the social status of the parents, their educational achievements and professions, their cultural values and attitudes toward education, the time they spend with their children, and the encouragement they give their children. Families as educational settings
The impact of teachers – for example, their qualification and interaction with the community – on the educational performance of children can hardly be overestimated. However, not all teachers have the same training and skills, not all teachers will provide the same inducement to students, not all teachers are willing to commit themselves to meeting the needs of the local community, and not all teachers are socially accepted by the community. High turnover rates among teachers usually indicate that they are not satisfied with the situation at their school. High rates of extracurricular activities that teachers

contribute to the development of the cognitive abilities, motivations, and aspirations of children. However, the sociocultural milieu of a family should not be equated with its financial circumstances. True, in many cases – especially where high school fees are charged – there is a close positive correlation between the affluence of parents and the educational attainment of their children. But affluence is only a proxy variable for other factors, and there are many examples of rich communities whose students have low enrollment rates in institutions of higher education.

*The Hungarian Census of 1990 used the category “Cigány” for both “nationality” and “mother tongue.” The Census of 2001 offered three alternatives, “Cigány (Roma)” (plural cigányok, romák), “Beás” (plural beások), and “Romani” (plural romanik). The Census of 2011 used one category, “Cigány (Roma),” for nationality, and one, “Cigány (Romani, Beás),” for mother tongue. In the 1990 Census, 142 683 Hungarians declared their nationality as “Cigány.” The total number of Gypsies in that year was estimated to be about 600 000. This terminological muddle reflects the change in political discourse. Until the early 1990s the word “cigány” was used in both scientific and political discourse. It thereafter became politically incorrect and was largely replaced by the term “Roma,” especially in official debates. Since about 2006, people have been using “cigány” as the designation, for Hungary is host to several groups of Gypsies who vehemently reject being called Roma. Because the data are based on self-declaration as cigány, it is scientifically unacceptable to call these people Roma or Sinti.

offer their students or community signal a high degree of commitment. In some countries the impact of teachers on educational attainment is especially strong because teachers are entitled to recommend the type of school a child should attend after completing the fourth grade of elementary school.

The third factor of influence is the school composition. Schools differ strongly with regard to the social background and abilities of their students. Because high achievers and low achievers are sorted into different schools after they pass elementary school, the composition of the student body shapes the values and attitudes prevailing among peer groups. Student culture and peer approval may establish positive or negative stereotypes for ambitious students.

The fourth group of influences can be labeled neighborhood effect. The type of neighborhood in which a child grows up is another very effective predictor of her or his educational performance (Webber and Butler 2007). The neighborhood effect is partly based on the social composition of the resident population. However, it also consists of close social or cultural relations, shared values, a sense of belonging to a local community, and social control within the community. Emotional attachment to a place, the feeling of safety among
their “own” people, the support of strong social networks, and the fear of becoming an outsider in schools located in other areas seem to be strong motives for parents from ethnic minorities and working-class families to keep their children in low-performing schools in their own neighborhood even if they are free to opt for a school in another area (Bunar 2010, 142).

Some authors mention a fifth group of factors of influence, namely organizational structure (e.g., comprehensive school vs grammar school, pupil–teacher ratio, and size of schools). However, the importance that the size of a school has for educational attainment is overestimated in many publications. A large school is not necessarily a better one. Wide curricular and extracurricular choice does not automatically imply that the quality of education or student performance improves. Combined with other factors such as the professional skills and motivation of teachers, or the governance of a school, however, organizational structures and size of classes may have an influence.

The sixth group of factors of influence is the spatial allocation of educational opportunities, the locally offered density and variety of secondary schools and institutions of higher education. Urban agglomerations provide a greater density and variety of schools than peripheral rural areas. In rural areas the distance to secondary schools on average is larger than in urban areas. Among upper-class parents long distances to school have little or no impact on the choice of secondary schools and institutions of higher education, but long distances may deter parents from lower social strata from sending their children to these schools, especially in ethnically segregated areas and areas where free school transport is not available.

It has been shown that the quality of the regional labor market also has a certain influence on educational attainment. A highly differentiated economy, the availability of many highly skilled jobs, and high vertical social mobility influence the occupational and educational aspirations of children by offering them more attractive role models and more economic prospects than a lower-skilled and less differentiated labor market does. Children from working-class and peasant families seem to be more influenced in their educational aspirations by the diversity and qualification structure of jobs offered in a region than children of academics.

Some countries influence educational attainment by harsh political intervention. Highly feudal European territories, where the abolition of serfdom was delayed in the nineteenth century, experienced much lower rates of school attendance and became literate much later than areas with an early introduction of democratic elements and prospects of vertical social mobility. Between 1740 (South Carolina) and 1838 (Ohio), a number of US states adopted compulsory ignorance laws, which excluded “Negro” children from public schools or even declared that anyone who taught slaves to write or employed slaves as scribes would be fined or imprisoned for up to 12 months. Under some communist regimes (e.g., the German Democratic Republic), children from ideologically “unreliable” families were prohibited from attending grammar schools or studying at universities, and states governed by a fascist regime openly restricted the proportion of Jewish students at their universities.

The relations between the various factors influencing educational attainment are so complex that it would be naive or presumptuous to attempt to formulate explanatory models that are equally applicable to all societies, cultures, and spaces. Regression models using individual variables lead to equivocal and inconsistent results. It is the local combination of multiple
deprivations or multiple privileges – represented by a local milieu, knowledge environment, or context – that entails low or high educational attainment. Because high or low educational attainment tends to occur in many different contexts and for quite different reasons (Webber and Butler 2007, 1241), an investigator interpreting causal relationships needs deep knowledge of the society, culture, economy, and value systems of the neighborhoods, places, or regions in question.

Institutions of higher education

Some of the research issues discussed so far are also relevant to universities and other institutions of tertiary education. However, universities pose additional challenges for the geography of education by raising a number of other interesting questions: What factors influence the catchment areas of universities and the spatial mobility of scholars and students? What factors are responsible for the intellectual ups and downs of universities? Why do Nobel Prize winners or other outstanding scholars tend to cluster at such a small number of universities? What impact does a university have on the economy, society, and culture of its town or wider region? How do transnational knowledge networks of scientists evolve, and what long-term consequences do they have? These questions indicate that talent, motivation, and wealth of ideas are not the only characteristics determining how successfully a scholar’s research and academic career develop. A number of external factors come to bear as well. The interaction of these external components yields a spatially localizable societal macrophenomenon called a knowledge environment. A university’s knowledge environment is definable as the result of systematic interdependencies and causal interactions relevant for the generation and diffusion of scientific knowledge. Knowledge environments have an impact not only on the generation, evaluation, and legitimation of new scientific knowledge but also on the reading and interpretation of texts. Universities are not simply locations but social spaces, epistemic venues, and knots of scientific networks. Studying local knowledge environments and worldwide communication spaces of academics opens up additional horizons for explaining academic careers and scientific achievements.

What does a scientific milieu or knowledge environment consist of and how can one explain its impact on the research processes and careers of scholars and students in a nondeterministic way? Academics depend on financial resources and research infrastructure (e.g., libraries, laboratories). They are affected by formal and informal organizational structures, institutional regulations, and expectations of their social environment. A university’s knowledge environment can have a bearing on whether and how soon new scientific concepts, practices, or technical innovations are accepted and acted upon. It also plays a part in determining the possibility of conducting expensive experiments, becoming part of important international networks, hearing promptly about crucial new developments, and meeting with agreement (or criticism) when new ideas are aired. The research interests and fields of interaction of young scholars are influenced by the experiences, scientific stimuli, and critique of other scholars active at the same site, and by the encouragement received from key people and critical audiences at various places. Spatial proximity is pivotal because it facilitates spontaneous face-to-face contact, but it does not guarantee interaction. Yet, for all the importance of clustering and proximity, the key words are actually communicative interaction and ways to transcend the silo principle.
A knowledge environment should not be thought of as an independent variable that directly influences all actors in the same way. It is a locally available potential or local range of resources. It stands for challenges, stimulation, opportunities, and support networks that can be used, overlooked, or ignored. A knowledge environment also consists of resistance and obstacles. Some scholars will be paralyzed by local restrictions and opposition to their ideas; others will overcome them. The local potential of a knowledge environment should be clearly distinguished from the scientific results arrived at within it. No one can reliably predict whether and how someone will make use of a milieu’s potential. Knowledge environments vary from place to place. The discrete elements of a knowledge environment are never stable or immutable; they are constantly changing. Nevertheless, the scientific reputation of a knowledge environment may be remarkably consistent because of a university’s high recruitment standards and scientific attractiveness.

The stronger the scientific reputation of a university and the greater its resources, the more it acts as a magnet for talent and brains, the more it can draw scholars from prominent other universities, the more international its catchment area of students is, the more it disseminates ideas and scholars throughout the world, the more professorships other universities offer its young researchers, and the more impressive its global networks are. However, the spatial expanse of scientific relations and the areas from which a university gains its professors and students can also be drastically affected by political and religious conflicts, language barriers, and the economic and political situation in the home countries of scholars and students.

Figure 2 illustrates the regional provenance of Heidelberg’s students in the Faculty of Theology between 1560 and 1620, a period when Heidelberg University stood as a European center of Calvinism and enjoyed its first golden age, which was abruptly ended by the outbreak of the Thirty Years War.

Since medieval times, scholars and students have been expected to be geographically mobile for various reasons. First, mobility can inspire new ways of thinking and bring about new networks and cooperation in the world of academia. Second, in order to remain creative and competitive, a university’s knowledge environment must continually be replenished by the best available candidates bringing in new research questions, scientific methods, and networks. Faculties that systematically favor their own former students for professorships run the risk of narrowing their scientific perspectives and eventually diminishing the quality of their scientific performance.

Third, the career mobility of a scholar can serve as one of many indicators of his or her scientific potential. If two or more faculties confirm that the scientific achievements, competence, and other merits of an academic warrant that individual’s appointment to a position as a lecturer or professor, then the uncertainty about the person’s scientific potential is much lower than if confirmation comes only from the faculty where the candidate studied and graduated. An academic who has worked successfully at various universities generally has a greater range of experience, more extensive personal networks, and a better academic reputation than one who has worked in only one institutional setting.

Fourth, revolutionary scientific concepts and findings that contradict common paradigms of mainstream science are not immediately accepted elsewhere. Despite the Internet, it can take years or even decades before new theories or methods are recognized within one’s discipline or in adjacent ones. The surest way to transmit contested
epochal scientific findings and methods from place A to place B is the geographic mobility of scholars who possess the relevant knowledge.

Other variables describing scientific relations and the migration of ideas are networks of correspondence, collaboration in joint research projects, co-authorships in joint publications, the destinations of sabbatical leaves, the distribution of fieldwork sites, and the distribution of honorary doctorates.
Further perspectives

Further perspectives include the impact of political ideologies on educational systems and educational priorities; the varying role of the meritocratic principle in different societies; the relevance of educational inequalities in political discourses; the increasing internationalization and marketization of higher education and the attendant consequences thereof; the development of international student flows and the impact that alumni networks in foreign countries have on cultural and economic policy; the schooling of underprivileged ethnic minorities and of children with special needs; and spatial differences in the philanthropic support of education.

A highly challenging research issue is the description and analysis of knowledge environments and their impact on learning and research processes. Various indicators help describe and analyze a university’s staffing, financial resources, research equipment, intellectual attractiveness, scientific achievements, and reputation. It is more difficult to reconstruct interactions, networks, and knowledge exchange retrospectively by conducting interviews and analyzing documents, biographies, and protocols. The impact a knowledge environment has on the learning and research processes and scientific achievements of scholars becomes apparent only after years or even decades.

Structuration theory, actor-network theory, environmental psychology, environmental phenomenology, gestalt psychology, interaction analysis, and communicative constructivism are able to help explain the interactions between knowledge environments and the learning processes of individuals to a certain extent. But further research and theoretical concepts dealing with social macrophenomena such as knowledge environments are needed. Students of knowledge environments are less concerned with the discovery of causalities in the sense of universal laws than with the causal reconstruction of the network of interactions. In their empirical analysis of social macrophenomena, they do not seek abstraction and maximal simplification as much as specification and an adequate explanatory complexity.

Geography of evolution

Amanda J. Chunco
Elon University, USA

Geography has been central to the study of evolution since the idea of natural selection was formalized by Charles Darwin and Alfred Russel Wallace in the 1850s. Observations of patterns of species distributions provided critical evidence underlying early work in the field of evolution. Today, the availability of modern genetic and geospatial techniques is furthering our understanding of the myriad ways in which the environment shapes the organisms that live there.

For both Darwin and Wallace, the idea of gradual change in a population or species over time was heavily influenced by their observations of spatial patterns in the distribution of current and fossil species. In particular, both men observed: (i) differences in biological communities in different geographic regions which suggested that the local environment shaped the species that lived there, and (ii) similarities between fossil and extant species in the same region which suggested that species had changed over time. Both men also began to speculate on the importance of geographic isolation to divergence and speciation — a theme that is still critical to the study of evolution. Darwin noted that island fauna were morphologically similar to, yet distinct from, fauna from the nearest continent, while Wallace observed that geographic barriers, such as large rivers, frequently separated morphologically similar species. Many of the ideas raised by Darwin and Wallace are still important in modern evolutionary biogeography.

Following the foundation laid by Darwin and Wallace, a second era of advancements in the study of evolution occurred during the first half of the twentieth century when ecologists began tackling the question of how similar species coexist. This was a difficult theoretical issue given Darwin’s arguments for the importance of competition (which would likely be greatest between similar species) and Geory Guase’s experiments in the 1930s that demonstrated extinction of one of the competing species. Work by Joseph Grinell, Charles Elton, and G. Evelyn Hutchinson led to the formalization of the concept of the niche as a way of describing how species partition time, space, and resources to minimize competition. Although the meaning of niche continues to be debated, Hutchinson’s definition of the niche as the multidimensional set of environmental parameters that allow the long-term existence of a species remains commonly used (Hutchinson 1957). This work furthered our understanding of how the abiotic and biotic environments shape the distribution of individual species and entire biological communities. This era also saw the advent of the modern synthesis, a flurry of research activity aimed at integrating new advances in genetics with natural selection during which the field of speciation developed in earnest. Ernst Mayr (1942) extended earlier work by Darwin, Wallace, and Grinell in identifying a fundamental role for geography in the formation of new species. In Mayr’s paradigm, speciation could occur only with geographic isolation between two populations. Whether speciation could occur in the absence of isolation remained highly controversial and was a leading area of theoretical and experimental research throughout the twentieth century (Coyne and Orr 2004).
The study of geographic patterns in population divergence and speciation remains an important focus of research. When describing the geographic relationship between different populations or species, biologists typically recognize three specific distribution patterns categorized by the relative ease of migration and gene flow between the populations: allopatry, sympatry, and parapatry. At one extreme, allopatric populations are physically isolated from one another via a physical barrier or a long distance resulting in no (or very low) gene flow between the populations. This physical and genetic isolation leads to the accumulation of genetic differences as a result of local adaptation and random genetic drift. Over time, sufficient genetic divergence can result in speciation.

In contrast, sympatric populations co-occur within the same geographic area. Because the potential for gene flow is high without physical barriers to prevent interbreeding, sympatric speciation was considered a theoretical impossibility, or at least exceedingly rare, by many evolutionary biologists for much of the twentieth century. This view was not, however, universal, and several theorists (including John Maynard Smith) outlined conditions that could potentially result in speciation, even in the absence of physical barriers (Coyne and Orr 2004). Recent work has shown that sympatric divergence and speciation is theoretically plausible under specific circumstances, and several empirical cases of sympatric speciation have now been documented (Coyne and Orr 2004). Outlining the environmental and genetic conditions that can promote sympatric speciation and documenting empirical examples remains an active area of research.

Whether two populations are allopatric or sympatric can have profound implications for the evolutionary trajectory for both groups. If two sympatric populations compete for the same resources, competition may lead to the extinction of one population. For example, competition with invasive species can result in declines in population size and even local extinction for native species, which is a major current conservation concern. Alternatively, both populations may persist, but diverge in terms of morphology, resource use, and behavior. This will result in heightened differences between the two populations in areas where they are sympatric, but not in areas where they are allopatric, a pattern (and process) referred to as character displacement. Allopatric populations, however, will diverge as a result of geographic separation (i.e., isolation by distance) and adaptation to local conditions. Even populations that are widely separated environmentally and geographically, however, may retain similarities in their basic requirements. The degree to which populations retain similar niche requirements (i.e., niche conservatism) versus adapting to new environments (i.e., niche evolution) remains a critical topic in evolution.

Allopatry and sympatry have been the most commonly studied geographic patterns of distribution and represent the extreme ends of the spectrum of physical isolation, from complete isolation (i.e., allopatry) to complete contact (i.e., sympatry). In between these extremes lie parapatric distributions. Parapatric populations are not isolated by any physical barrier, but populations occupy different geographic space and only overlap at a relatively narrow contact zone. Typically, the distribution of parapatric populations spans a gradient of environmental conditions resulting in divergence as populations adapt to local conditions. Because gene flow is hindered both by environmental divergence (due to local adaptation), and by distance, a parapatric distribution can result in speciation. Several other geographic patterns of speciation have been studied, although less prominently than the three mentioned above (for a review, see Coyne and Orr 2004).
Identifying a species’ distribution as allopatric, sympatric, or parapatric depends heavily on the likelihood of contact and gene flow between populations. In practice, it can be very challenging to classify a given population into a single discrete geographic category (i.e., allopatric, sympatric, or parapatric) for several reasons. First, the relationship between distribution and degree of gene flow is scale-dependent and relative to particular organisms. Populations of poorly dispersing organisms will be considered allopatric at distances much closer than well-dispersing organisms. Thus, even two populations that appear to co-occur at a coarse geographic resolution, and would therefore be considered sympatric, may actually show isolation at a finer geographic scale (i.e., microallopatry). Second, populations may be isolated by habitat in a way that limits the potential for gene flow even in the absence of any physical barrier. For example, parasites that reproduce in different host species may have very low potential for gene flow, while still being in relatively close physical proximity. Finally, it has been argued that the very use of terms that demarcate discrete physical categories to describe phenomena that, in reality, span a continuum from complete isolation to complete overlap should be abandoned in favor of specific measures of genetic isolation (Butlin, Galindo, and Grahame 2008). Given the heterogeneous nature of both habitats and species’ distributions, a single species may exhibit the entire spectrum of conditions, from complete sympathy to complete allopatry across its range, making it difficult to place any given set of species or populations into one discrete category.

Determining whether a speciation event occurred under a specific geographic pattern is further complicated by the fact that species distributions are not static, but shift in space over time. Two populations may move repeatedly from sympathy to allopatry and back repeatedly over geological time frames. Because current species result from speciation events in the distant past, the current distribution of a species cannot definitively represent its distribution when speciation occurred. If two related species are currently isolated, speciation in allopatry is supported. This observation cannot, however, eliminate the possibility that divergence occurred during a period of sympathy, followed by a period of geographic isolation. This shift between allopatry and sympathy may actually occur during the speciation process. For example, two populations may start to diverge in allopatry, but come back into secondary contact before the speciation process is complete. If relatively little genetic divergence has occurred, the two populations may merge back into a single interbreeding population. If divergence has occurred to an extent that interbreeding is deleterious (e.g., because it produces less fertile offspring), then there will be strong selection pressure on individuals to mate only within their population. This process can strengthen the degree of isolation between the now sympatric populations through a process termed reinforcement (Coyne and Orr 2004).

Although research on patterns of distribution remains important in evolution, the rapid advances in GIS (geographic information systems) technologies, genetic tools, and widely available high resolution environmental data have led to intense research activity at the interaction of geography and evolution over the last decade. Three areas of research in particular are worth noting.

First, the field of phylogeography, which was launched in the late 1980s (reviewed in Hickerson et al. 2010), has provided significant insights into the historical origins of a growing diversity of taxa. Phylogeography uses genetic tools and models to elucidate the spatial and temporal patterns of genetic lineages. This work can provide insight into the ecological
GEOGRAPHY OF EVOLUTION

and evolutionary forces shaping current distributions. Currently, phylogeography is used in conservation by highlighting geographic areas with high phylogenetic diversity and by elucidating how past periods of climate change influenced biodiversity in order to predict future responses to current anthropogenic climate change (Hickerson et al. 2010). In addition, advances in computer software have resulted in phylogeographic information systems that can visualize geographically rooted phylogenies thereby increasing the ability to explicitly link genetic changes to a physical space.

Second, ecological niche models that integrate geographic and environmental data to predict the distribution of species are increasingly being used to study evolutionary processes. New software packages (including DIVA-GIS, Maxent, and GARP) along with an increasing availability of free, high resolution, geographically referenced environmental (including temperature, rainfall, and land use) and species locality data has greatly simplified the process of creating niche models. The increasing interest in niche models has led to a resurgence of interest in the theoretical definitions of the niche initially defined decades ago. Ecological niche models have shown great potential for investigating how the abiotic and biotic environment contributes to selection, divergence, and speciation (Hickerson et al. 2010). Improvements in paleo-climate models are allowing niche models to explicitly test hypotheses about both past distributions and the environmental and evolutionary drivers of current species distributions. This work can provide insight into patterns of niche conservatism. Finally, the combination of phylogeographic tools and ecological niche models can provide a particularly powerful approach for testing how species respond over evolutionary timescales to changing environments and for predicting how species will respond to ongoing anthropogenic global change.

Third, the field of landscape genetics is providing insight into how current human modification of the landscape alters the genetic makeup of resident populations. By geographically linking land use with genetic diversity, landscape genetics can address questions related to demography, gene flow, and local adaptation in human altered environments. This approach can be used to prioritize conservation efforts for habitats and populations that will maximize genetic diversity and evolutionary potential.

While the two parts of the term “geohumanities” – “geo” and “humanities” – have a long and diverse history in and of themselves, their merging is a very recent phenomenon. In 2011 the edited book GeoHumanities: Art, History, Text at the Edge of Place (Dear et al. 2011) was a key product of a series of events designed to explore the intersection of geography (mostly cultural and historical geography but including elements of geographic information science (GIScience)) and other humanities disciplines. These included a Geography and Humanities Symposium at the University of Virginia in 2007 organized by the Association of American Geographers (AAG). Subsequent meetings of the AAG included highlighted sessions on “Geography and the Humanities” that, in turn, led to the edited volume GeoHumanities (Dear et al. 2011), as well as the edited collection Envisioning Landscapes, Making Worlds: Geography and the Humanities (Daniels et al. 2011). In 2015 a new AAG journal, GeoHumanities, was launched. In a parallel development, in 2013 the Alliance of Digital Humanities Organizations (ADHO) recognized a GeoHumanities Special Interest Group, intended to address the spatial, spatial-temporal, and place-related aspects of the digital humanities.

These two formalized articulations of geohumanities indicate not only a growing interest in and commitment to cross-disciplinary thought and practice, but also something of the differing aims and objectives, emphases, and expertise brought to bear in the making of this loosely contained field. The involvement of the AAG, for example, speaks to the continuing evolution of a modern-day discipline thoroughly engaged with the broad range of humanist thought, manifest, for example, in an emphasis on the “geo” as a human making of worlds, but also, and more recently, of a more-than-human worlding that both draws on and shapes the Earth. By contrast, the input of the digital humanities is more targeted; it indicates a desire within humanities disciplines such as English literature and history to bring to light the role of increasingly everyday geolocation technologies (such as Global Positioning System, or GPS) in shaping people’s spatial imaginaries, but also to use technologies such as geographic information systems (GIS) in turn to visualize imaginaries that are otherwise glossed in cultural texts, from diaries to poetry. The “geo” here thus refers to the location and distribution of phenomena over Cartesian space, but also to relational accounts of people and place.

Clearly, there are many moments when these two articulations of a geohumanities overlap: GIS, for example, is very much indebted to the spatial science turn in the discipline of geography, while an emphasis on cultural texts as “readable” has helped shape a cultural geography concerned with understanding landscape as just such a text. What is also clear, however, is that this twofold emergence of a geohumanities undercuts any easy notion of shared objectives, concerns, approaches, and methodological
apparatus. Their moments of intersection and difference owe much to the development of disciplinary specialisms, but also to the particular framings of the “geo” that are brought to bear. This highlighting of “geo” is important precisely because it is such a complex, and fecund, term that has been afforded meaning and import from the classics through to the (European) Reformation, the Renaissance, and the Enlightenment. According to the Oxford English Dictionary, it derives from the ancient Greek γεω (Earth) that appeared in a number of words including γεωγραφία (geography). The career of “geo” really took off in the fourteenth century with the arrival of familiar terms such as “geometry” and (now) less familiar ones such as “geomancy.” “Geography” as an English word did not appear until the fifteenth century, while entirely English inventions that utilize the meanings that “geo” brings with it did not appear until the early nineteenth century when adjectives such as “geohistorical” and “geomorphic” began to appear.

“Geo,” then, brings with it a dense association of meanings related to the Earth, while also having the capacity to add to and transform the meanings of other words, usually working in symbiotic combination with those that are of Greek or Latin origin. “Earth” itself is a remarkably complicated term that brings to mind both the planet we inhabit and some of the stuff it is made of – particularly the earthiness of soil. Somewhere between these two, “Earth” also refers to the ground in general, the lowest, basest and dullest of the four elements (earth, air, water, fire) in classical philosophy, and the world as a dwelling place for humans (contrasted with heaven and hell). Adding “geo” to a word clearly brings a lot of baggage, and a lot of possibilities.

To bring “geo” into proximity with the term “humanities” is to set in train a number of possibilities. The term “humanities” itself has its origin in European scholastic traditions of the fifteenth century, and referred to a branch of learning that was opposed to theology. Its focus was on ancient Latin and Greek, and the various associated traditions of philosophy, rhetoric, history, and grammar. By the early seventeenth century, in the work of Francis Bacon, the universe of knowledge had been divided up into three fields – divinity (theology), natural philosophy, and the humanities. Today, the humanities are generally thought of as those disciplines that engage with human culture and meaning, and that utilize interpretive, qualitative methods rather than scientific, quantitative ones. These typically include literature, history, philosophy, art, and music as well as modern languages. The discipline of geography has historically been included in the humanities but less so in recent years when it has been demarcated more as a combination of social and physical sciences.

At a very broad level, then, geohumanities indicates an interest in the human condition, certainly, but a condition that is somehow connected with the materiality and processes of the Earth itself. It also indicates an interest in how proximities and distances, whether absolute or relational, and the spatial imaginaries that underpin these, such as Cartesian, topographic, and topological, are fundamental to such a condition. The full richness of the term, however, only emerges with further archaeological digging.

Geography/humanism/the humanities

Importantly for us, the use of the prefix “geo” became widespread at about the same time as the term “humanities” became meaningful. Both arose in the European Renaissance, and both had their origins in classical Greek and Latin literatures and thought. Indeed, the sundering of humanities as a distinct sphere of learning, apart
from divinity, was an outcome of the broader emergence of Renaissance humanism, with its insistence on a human-centered view of the world wherein “Man” became “the measure of all things.” Centering of the human brought with it a whole new range of learning – both the humanities, as we now understand them, and natural philosophy (later to become natural history, and then the natural sciences). Central to Renaissance humanism was a strong belief in the very human power of reason and rationality, a belief that, of course, also underpinned a natural philosophy that was capable of investigating and understanding the Earth and the cosmos, despite our more modern tendency to worry at a humanities/sciences epistemic divide (Cosgrove 1984). As the notion of humanness became centered in learning, so too did attention turn from the heavens to the Earth and the human relationship to it. Geography, geology, geometry, and other “geo” subjects all experienced a revival thanks in part to the translations of classical texts by Strabo, Ptolemy, and others that began to appear in centers of learning (Glacken 1967). It is this turn toward the Earth – toward the “geo” – that arguably enabled the flourishing of humanistic thought. Importantly, it also set in train a way of thinking about phenomena – a geological perspective, one might say – that organized social as well as physical phenomena. That is, the visualization techniques developed by natural scientists, such as the geological cross-section and its delineation of formations and boundaries, produced a stratified ontology wherein layer built on layer. In turn, these were to indicate “deep time” – a historicism necessary for such sedimentation processes to occur. This idea of a stratification was to percolate through the Romantic literature of the eighteenth century, and its presentation of social groups.

To be sure, the reorganization of geography in the late Enlightenment as a synthesizing discipline that sought to uncover general Earth processes did much to sunder such a utilitarian endeavor from what became regarded as an unscientific, aesthetic preoccupation with articulating a distinct sense of place; indeed, the current institutional organizing of geography into either physical or human shows the force of such a division. Despite intermittent efforts through the nineteenth and twentieth centuries to work across such a divide, it was not until the 1970s that a concerted effort emerged that sought to ground philosophical concerns with “a life worth living” in an inquiry into how we live with, as well as on, the Earth. With the rise of “humanistic geography,” geographers such as David Lowenthal (also a historian), Yi-Fu Tuan, Edward Relph, and Anne Buttimer combined a knowledge of the field’s older tradition as a humanities discipline with newer interests in philosophies of meaning (such as transcendentalism, existentialism, and interactionism) to create a mode of inquiry that challenged the then hegemonic versions of geography as a spatial science. This new humanistic geography centered the formally marginalized questions of what it was to inhabit the Earth, and how individual and shared meanings arise from human–environment interactions. Traditional humanities values were very much part of this scholarship, including: centering the human as the basis for experience, knowledge, and understanding; looking to interpretive rather than scientific modes of inquiry; and pioneering the use of texts and images as evidence for the human relationship with the Earth. The notion of “geo” as of the “Earth” (with all its attendant meanings) was thus at the center of this field of inquiry. Indeed, Tuan (1991) attempted to provide a humanistic definition of the whole discipline by focusing on what he considered to be a key intellectual
problematic but also an everyday preoccupation for people, that is, how humans make the Earth into home. For Tuan, spatial science risked a reductionist view of humanity, but also of the Earth itself. Geography, he wrote, for all the technical sophistication of its specialized subfields, is not remote or esoteric knowledge but rather a basic human concern. Humans everywhere seek to understand the nature of their home ... if in every instance geographers insist on precision and quantifiability at the expense of a roundedness of view and resonance, they can never hope to understand the earth as home. (Tuan 1991, 99, 106)

The strong sense of a humanistic geography informed by philosophies of meaning and opposed to more quantitative and scientific forms of inquiry gradually percolated across the general field of human geography and became less distinct as an approach, despite several rounds of reinvigoration. Nevertheless, a deeper sense of geography as a discipline rooted in the humanities continues to exert its influence and it is this sense of “humanistic” inquiry that helps shape the emergent field of geohumanities.

One aspect of this deeper and broader version of humanistic scholarship is its interdisciplinarity, or even transdisciplinarity. Geohumanities is not a disciplinary project, despite the immediate efforts of the AAG to bring both the concept and the journal with that name into being. The subtitle of the journal GeoHumanities is Space, Place, and the Humanities. This collection of key words points toward a serious effort to have what might be thought of as disciplinary concerns with space and place become the subject of both conversations between disciplines (interdisciplinarity) and emergent themes in the spaces between disciplines (transdisciplinarity). This conversation, in turn, recognizes a wider interest in space and place across humanistic disciplines such as literary studies, history, and philosophy.

In literary studies, perhaps emerging with the groundbreaking work of Raymond Williams and Edward Said, geographical imaginations have become active components of the ways literature and other representational forms are interpreted. Space and place are no longer regarded as settings or backdrops for literary action, but are themselves actors in the construction of literature (Harding 2014). Similarly, history has seen an enthusiastic embrace of what has been called an “environmental history,” exemplified by William Cronon’s Changes in the Land: Indians, Colonists, and the Ecology of New England (1983). More recently, a “spatial history” has been identified, with a landmark contribution from Paul Carter, The Road to Botany Bay (1987), followed by initiatives such as the “digital history” emerging from Stanford’s Spatial History Project.

Philosophy, meanwhile, has seen something of a rebirth of interest in space and, particularly, place, as key elements of what it is to be a human on the Earth. There is no doubt that Deleuze and Guattari’s “geophilosophy” has had a profound impact on academia, insofar as it poses questions not as to what the Earth and its inhabitants are, but how they work. It is a Deleuzian-inflected feminist philosophy, however, that has perhaps delved most deeply into the nature of the “geo” as a means of getting to grips with the human condition as an embodied one. A key preoccupation here is the notion of an “earthly body,” that is, one that is no longer constrained by the model of a sovereign corporeal subject, but is immersed within, draws sustenance from, engages, and negotiates a material realm that cannot always be reduced to or even connected with an imaginative and discursive realm. Such bodies are certainly open to cultural intervention – they can be inscribed on as a text, one might say – but this does not thereby negate their earthy dimensions, which provide for a body’s form and capacities (Grosz 2008). Importantly
for this reconfiguration of the “geo,” such an approach provides a sense not only of the complex material proximities and distantiations that continually rework the corporeal geographies of the body but also of other temporalities, such as the evolutionary tempo of species and the deep history, or “Earth history,” within which all life, as well as the materials that enable and aver this combination, is embedded. It can reference the capacity of corporeal bodies to undertake work, a capacity enabled and limited by their interaction with other bodies, some human, most not. And it can prompt explorations of the plurivitality of the body, taking into account, for example, the work of microbial viruses and bacteria, as well as the earthly components of air, water, earth, and fire, all of which not only subvert the idea of a sovereign subject in a fleshy container, but prompt an ethics of responsibility to the these “nonhuman” presences. Such a feminist philosophy has permeated numerous academic spaces, particularly in the arts, where notions of a “dark ecology,” for example, and “becoming animal” have taken hold.

These kinds of developments have sometimes been referred to as a “spatial turn” in the humanities, reflecting the belief that space and place were previously neglected or reduced to passive roles. Certainly, the importance of space and place as analytics has become lauded across academia, helped in large part by the translation into English of key texts by prominent social theorists such as Henri Lefebvre and Michel Foucault. These developments have also been prompted by what has been termed a “material turn,” wherein emphasis is placed on interrogating and moving beyond the art/science divide in writings by Deleuze and Guattari, Elizabeth Grosz, Rosi Braidotti, Isabelle Stengers, and Karen Barad. Taken together, what these turns make clear is that space, place, and earthliness – all of which have become associated with

the term “geo” – are no longer seen as the property of the discipline of geography; there is a distributed sense of the importance of these terms, enabling in turn more creative forms of transdisciplinary conversation.

Geohumanities/spatial humanities/digital humanities

Bearing in mind the broad and long-term pervasiveness of the influences noted, the more immediate cause of the increased “visibility” of geohumanities is, undoubtedly, rooted in the widespread and relatively sudden uptake of geographically coded data across humanities disciplines thanks to a combination of GIS, GPS, and various forms of locative media attached to GPS-enabled mobile devices. For this reason the prefix “geo” has had something of a second renaissance since the turn of the twenty-first century. In addition to the long-standing uses of “geo” in terms such as “geostationary” and “geochemistry,” we now have “geo” entering popular culture thanks to the idea of being “geolocated,” of data being “geocoded,” and of the ability to partake in “geotagging.”

What is not immediately apparent is what these terms have to do with the older idea of “geo” as referring to the Earth and all of the humanistic implications that come with that association. Rather, underpinning all of these technologies is a framing of the Earth as Cartesian – that is, composed of four dimensions – such that an absolute location can be discerned. This mode of understanding and engaging with the Earth has its own historical trajectory, being implicated in classic and Renaissance cartographic efforts, the rendering of the Earth and its inhabitants as machine-like entities in the Enlightenment, and especially the emergence of a military science that relied on a universal cartographic language
to render territories knowable, and a precise mathematical knowledge of how projectiles moved through the air (Gregory 1994). Small wonder, then, that geotagging, which refers to the addition of locational metadata to almost any form of media, has been facilitated by a twentieth-century network of military satellites that provide precise locations. These systems were only completely freed from military use in 2000, since which date the prefix “geo” has exploded as a way of denoting that something is precisely locatable.

The term “spatial humanities” tends to refer to a particularly close partnering of GIS and the geospatial web with traditional humanities scholarship, and is perhaps best illustrated by work undertaken by historians and historical geographers who use GIS alongside other modes of visualization. According to Bodenhamer, Corrigan, and Harris, there are pitfalls as well as promises here in that

Spatial humanities, especially with a humanities-friendly GIS at its center, can be a tool with revolutionary potential for scholarship, but as such, it faces significant obstacles to knowledge that, at first glance, rest on different epistemological footings. Humanities scholars speak often of conceptual and cognitive mapping, but view geographic mapping, the stock in trade of GIS, as an elementary or primitive approach to complexity at best or environmental determinism at worst. Experts in spatial technologies, conversely, have found it difficult to wrestle slippery humanities notions into software that demands precise locations and closed polygons. At times, applying GIS to the humanities appears only to prove C.P. Snow’s now-classic formulation of science and the humanities as two separate worlds. (Bodenhamer, Corrigan, and Harris 2010, viii)

Bodenhamer, Corrigan, and Harris correctly identify a deep humanist distrust of GIS as a tool that arose out of the sciences, with all its privileging of certainty and authority. To be sure, GIScience practitioners have themselves acknowledged such a disciplinary lineage and its epistemic implications. And yet, some have also pointed to the need to interrogate such presumptions critically and, in practice, to augment the visualizations of GIS with other forms of knowledge-making, such that its conceptual thresholds are demarcated.

Perhaps a key moment in the negotiation of how GIS was to be brought into alignment with the notion of a geohumanities came with the 2011 publication of GeoHumanities: Art, History, Text at the Edge of Place (Dear et al. 2011). GeoHumanities represents a broader interdisciplinary and transdisciplinary convergence of geography and the humanities that centers the concepts of space and place rather than the techniques and epistemologies of GIS. Indeed, the book privileges creativity, with contributions from architecture, the arts, English, history, and curatorial practice as well as geography; and it is in the midst of these discussions that the potential of GIS for creative and historical research is situated. What is more, GIS is augmented by other forms of digital geovisualization, including the kinds of virtual reality environments most often associated with the world of gaming. If we extend our technological imaginations, Harris, Rouse, and Bergeron argue in this collection, we might “contribute to a Humanities GIS that is sensuous, reflexive, and sensitive to issues of humanities place as well as geographical space” (2011, 238). Such a call resonates with other discussions within the collection of the place of media within geohumanities, including a photographic essay on Broadway in Los Angeles by Robbert Flick (2011), and a critical essay on the Sophie Ristelhueber’s artistic installation, Fait, by Caren Kaplan (2011).

It has become apparent in the early years of the twenty-first century that framings, media, and interfaces provided by GIS alongside GPS,
mobile digital devices, locative media, and so on have produced new ways of thinking about classically humanistic problems. One of the most prominent of these is the practice of "distanced reading" proposed by Franco Moretti and the Stanford Literary Lab. Moretti and his colleagues have used the resources of the web to analyze published literature as a source of "big data." That is, rather than reading one or two books in depth (for a close reading), Moretti argues for the analysis of thousands of texts at once. Large patterns over long periods of time are often presented digitally, hence the title of his book *Graphs, Maps, Trees: Abstract Models for a Literary History* (Moretti 2007). One of the pamphlets produced by the Stanford Literary Lab, for example, analyzes the texts of 2958 British novels. It finds that, for instance, the spaces of the novel over time expand from relatively small domestic and rural spaces, through the spaces of the city, to the expansive realms of adventure and science fiction novels. In a century that featured the invention and triumph of the railway as well as the emergence of Britain as the world’s first urban nation, this is hardly surprising (Hueser and Le-Khac 2012).

This kind of banal outcome, articulated by an often visually stunning image, is not unique to the Moretti et al.’s distant reading projects. Mike Crang has noted similar outcomes across the digital humanities, suggesting that

Our banal social lives become digitally mediated and can be subject to quantitative encapsulation through lexical analysis. For instance, Alan Mislove and colleagues applied a word-rating system — scoring positive and negative connotations — to US-based geolocated tweets to produce stunning time lapse maps of the "mood of the nation." Similar approaches have correlated postings with stock market movements, and yet so far the conclusions have been banal. The poetics and affective power of the visualisation have often been more powerful than the supposed “result.” (2015, 354)

Despite these analytic shortcomings of the still young digital humanities, it is clear that aspects of the new field are key to the even younger field of geohumanities. Geohumanities would not exist as a word or interdisciplinary field without the emergence of a spatial web of technologies that produces massive amounts of located data, some of which can be broadly “humanistic.”

**Geo/geo/geo**

Geohumanities, then, can be traced through a number of genealogies including forms of classical scholarship, the long history of humanism, the specific history of “humanistic geography,” the spatial and material turns across academia, and the more recent embrace of the digital by humanistic disciplines.

In regard to the future, consider the many meanings of “geo” and the contrast between the older “geo” of the Earth as dwelling place and the newer “geo” of location. Understanding something of the polysemous nature of “geo” helps us to fabricate a future for the only just born, yet very old, project of the geohumanities. The ancient Greek origins of “geo” take us back to a time of radical predisciplinarity. Scholars, explorers, and others such as Strabo, Ptolemy, and Herodotus engaged with the Earth as both a planet (Earth) and the site of human dwelling separate from the heavens. Well before the specialist landscape of the disciplines, there was a general attempt to understand the Earth, and concerns with space, place, and location were at the center of this endeavor. Greek philosophers and historians were also geographers (insofar as these labels were meaningful). Herodotus, claimed as the father of both anthropology and history, spent much of his time trying to find the source of
the Nile and might reasonably be claimed as the father of geography too. His project was one of constant accounting for, and description of, the heterogeneity of the inhabited Earth. Meanwhile, the librarian of Alexandria, Eratosthenes, was busy measuring the Earth and developing the system we now know as latitude and longitude, and which locates our every thought and move through our mobile phones. He was a mathematician, geographer, poet, astronomer, and music theorist. Eratosthenes (and later Ptolemy) thus provided a geometry within which the position of humanity could be assessed.

These are all examples of a radical predisciplinarity that reveals entwined goals and desires: these exceed the expertise of what now constitute scientific and humanistic approaches as to what it is to live on and with the Earth. As such, they present an alternative form of knowledge-making to that which now dominates academia, one that can move laterally across conceptualizations and mediums, as well as dig down into specific problematics. What they also help bring into clarity, however, is a tension that haunts the birth of the interdisciplinary or transdisciplinary project of the geohumanities. On the one hand, we can see a desire to root the project in a critical conception of the roles of space and place in what it is to be more than human in the twenty-first century; on the other hand, we can discern a desire to harness the analytical potential of the digital geospatial web. This tension is itself a fecund one that needs be acknowledged but does not require a “bridging.” To congeal geohumanities as a distinct field of inquiry – a field with common concerns, goals, and an all-purpose methodological toolkit – would be to bring a halt to this lateral movement. As geohumanities continues to unfold, it is its transdisciplinarity that emerges as key.

The other “geo” is the “geo” of earth as soil/ground – the “geo” in a term such as “geophagy,” which is the act of eating soil. To be sure, over the course of the nineteenth and twentieth centuries the humanities, including human geography, addressed themselves in large part to the rapid course of urbanization and “city life.” A direct contemplation of the physical world was left to the physical scientists such as geologists and geochemists. This distinction has also, however, become blurred, particularly with the rise of the term “Anthropocene” and its enthusiastic take-up across academia. Environmental concerns have become increasingly visible across the humanities as evidenced by environmental history, eco-poetics and eco-philosophy – all dealing with forms of meaning-making in relation to the Earth. There has even been a “geological turn” as humanistic scholars have turned toward the very matter of earthly inhabitation (Yusoff 2015). A robust geohumanities project, then, will take this notion of “geo” as soil/earth seriously, and become a venue for transdisciplinary explorations that incorporate the work and aspirations of physical scientists.

Geolocation services

Chin-Te Jung
San Diego State University, USA

Geolocation is the identification of the geographic location of an object. Every object that exists in the physical world, even Internet-connected computer devices (e.g., computers, notebooks, and mobile phones) has a geolocation to describe its position. The most common and precise way to represent the geolocation of an object is by using geographic coordinates (i.e., a set of latitude and longitude coordinates). For example, San Diego, California, is located at 32.73°N and 117.17°E. Several locating engines and technologies can be used to retrieve geolocations in coordinates, such as the global position system (GPS), assisted GPS (A-GPS), or the Wi-Fi positioning system. More details about these geolocation technologies can be found in Djuknic and Richton (2001).

However, a physical address, ZIP code, or place name is often used as a meaningful way to express geolocation. For instance, the geolocation of San Diego State University (SDSU) is 5500 Campanile Drive, San Diego, CA, 92182 (a physical address); or a basketball game will be held at SDSU (a place name). In addition, for network-connected computer devices, an Internet protocol (IP) or a media access control (MAC) address is used to identify the geolocation of the devices on the Internet. These alternative ways to describe a geolocation can eventually be converted to a set of geographic coordinates by a mapping database or a web service. For example, someone can look up an IP address on a WHOIS (http://tools.whois.net/whoisbyip/) service to retrieve the registrant’s physical address and its coordinates can be mapped using MapQuest’s open geocoding web service (http://developer.mapquest.com).

This entry mainly focuses on geolocation web services (geolocation services) which (i) can reveal the geolocation information of an object using geolocation technologies, such as GPS, A-GPS, or the Wi-Fi locating system, and (ii) can geocode an address, a ZIP code, a place name, or an IP address into geographic coordinates. A geolocation can be simply retrieved by sending a request to a geolocation service in a web browser (e.g., Internet Explorer), rather than by installing any professional GIS software. Additionally, a geolocation service can be a mashup (i.e., integrated with other web services, e.g., searching points of interest) to provide a location-based service (LBS), such as finding points of interest near a user’s location or automatically pushing relevant location-based information to a user’s mobile device (Schiller and Voisard 2004).

This entry lists several common geolocation services, as shown in Table 1. For a more complete list of geolocation services refer to Santos (2012). Geolocation services are classified by type (i.e., revealing geolocation information or geocoding), input (i.e., what geographic data can be geocoded), and output (i.e., geographic coordinates) with their data type format, such as Extensible Markup Language (XML) or JavaScript Object Notation (JSON).

The development of GIS has been greatly influenced by information technology (IT) and the Internet, which stimulated the evolution of GIS from desktop-based systems to web-based GIS services. The geolocation service belongs

GEOLOCATION SERVICES

to one of the GIS services that allow groups of GIS users and organizations to access clients’ geographic coordinates more easily. Additionally, the geolocation service can be integrated with various standards of GIS services defined by the Open Geospatial Consortium (OGC), such as a web map service (WMS) (OGC 2006), a web feature service (WFS) (OGC 2005), or a web processing service (WPS) (OGC 2007).

By integrating GIS services, geolocation services lower the difficulties of learning and manipulating GIS software, and increase the usability of GIS with various domains and purposes (e.g., to mashup Google Maps with real estate data). Moreover, they have emerged as the service-oriented approach that allows users to access, assemble, and process geospatial content and functionality distributed across a network via a standard Internet browser (Tao 2001).

Geomancy, or fengshui (meaning “wind and water” in Chinese), has played a key role in the site selection and landscape design of cities and rural settlements, temples, monuments, graves and houses in East Asia. It has been a difficult and confusing subject to grasp for those in the West, as there is no equivalent concept in Europe to geomancy in China. A contemporary Western scholar declared, “if there is a subject which should have captivated Western Sinologists, it is Chinese geomancy” (Lemoine 1974, 1), and nineteenth-century Western scholars labeled fengshui the rudiments of natural science in China (Eitel 1873, title p.) or a quasi-religious and pseudoscientific system (de Groot 1897, 935). Geomancy cannot be simply classified as a superstition, religion, or science, but combines elements of all three into a “unique and highly systemised ancient Chinese art of selecting auspicious sites and arranging harmonious structures on them by evaluating the surrounding landscape and cosmological directions” (Yoon 2006, 4). The idea of fengshui is also known as dili (the principles of land), which also means “geography,” or Kanyu (the carriage loaded with a myriad of things, meaning “heaven and earth”). Historically, geomancy influenced East Asian culture so significantly that a proper understanding of East Asian landscapes requires some knowledge of the art.

Traditionally in China and Korea, people were more interested in locating auspicious gravesites than house sites, which led some scholars to argue that geomancy originated from the art of finding auspicious gravesites. A careful analysis of the fact that geomantic principles regarding gravesites are essentially the same as those of house sites contradicts this earlier view and suggests that ancient geomancy seemingly first developed as an art for choosing ideal house sites, especially for the preparation of a comfortable cave dwelling in Loess Plateau, North China (Yoon 2006, 15–32). Geomancy later developed into two schools from the time of the Han dynasty (206 BCE–220 CE) through to the Song dynasty (960–1279): (i) The Jangxi School that emphasized the methods of landform observation in site selection, and (ii) the Fujian School that emphasized the methods of divining cosmological directions by compass. The ancient Chinese art of geomancy diffused into Korea, Japan, and other neighboring regions along with an early wave of Chinese cultural diffusion and influenced East Asian cartography through its distinctive method of portraying the relief of landforms in maps for documenting auspicious places.

The principal criteria for examining an auspicious site are the conditions of the landform, availability of water, and whether the site faces a sunny auspicious direction. An ideal landform condition is a location surrounded by hills on three sides, like a horseshoe or an armchair shape with an open front (Yoon 2006, 76). Thus, a basin is often accepted as an auspicious site and its surrounding hills are named; the one behind, the main mountain (or black warrior); on the left, the azure dragon; and on the right, the white tiger. If a place with these background hills also faced southward, it would enjoy maximum sunlight, while being protected from the cold wind blowing from the northwest during winter.
Thus, a southward direction is considered auspicious and its quality is examined with a geomantic compass that reflects the complicated Chinese cosmology based on the combination of the Yin-Yang and the Five Element Theory, the 12 zodiac animals, and the Eight Trigrams from the *I-Ching* (Book of Changes). To be an auspicious place, a site with an appropriate landform and an auspicious direction also requires a watercourse in front of it. If such a site (basin) is formed on a big scale, it can become a site for a major city, while smaller scale sites are suitable places for smaller towns or villages.

Geomancers believe that a place that meets such geomantic requirements is auspicious and blesses the people who occupy it, because such a site can conserve vital energy (shengqi) which is mysteriously developed from Yin-Yang energy. An ancient classic on geomancy elaborates the function and mechanism of the energy cycle: the energy of Yin-Yang belches and becomes wind; ascends and becomes cloud; descends and becomes rain; flows underground and becomes vital energy (Guo 1875, 1). This is a crude but ancient Chinese concept of the environmental energy cycle. This vital energy mysteriously ingenerates and supports a myriad of things and flows only through underground veins dispatched like blood vessels. It is accumulated in an auspicious site and blesses the occupier of the place. That is why the believers of geomancy spent much energy and resources in finding and occupying an auspicious site. This attitude toward geomancy helps explain why the rulers of China, Japan, and Korea attempted to shift capitals so eagerly.

Traditional East Asian capital cities such as Nanjing in China, Seoul in Korea, and Kyoto in Japan are all located in a basin with protective hills in three directions, with the southward face open and with watercourses nearby. Beijing is exceptional as it is located on a plain and the required protective hills are somewhat distant from the city. That is why an artificial hill of about 45 m high was created behind the palace as a gesture of making up the geomantic deficiencies of the Chinese capital city.

Like major cities, many smaller towns and villages in East Asia also have geomantically important characteristics, being at the end of foothills, with an open front and background hills. Numerous Buddhist temples and other religious shrines in China, Japan, and Korea are also located in geomantically considered places.

Professional geomancers in East Asia chose auspicious sites for their clients who paid fees, and were also location (place) diviners as well as traditional folk geomorphologists and landscape consultants. In the practice of geomancy the following three images of the environment (attitudes toward the landscape or nature) are important:

First, the environment is treated as a magical being that can bless people auspiciously or affect them inauspiciously in a magical manner (Yoon 1980). A place that accumulates vital energy can make the occupiers happy and prosperous, while a place with no such energy can cause the people to suffer misfortunes.

Second, the environment is perceived as a personified being (Yoon 1980). The auspicious spot and its surrounding environment are treated as a functioning system which brings in vital energy, stores it, and makes it available to the occupier. For example, a local landscape system is identified as being akin to a sleeping cow, a sailing boat, and so forth. An entire local landscape or a portion of it can be named after and treated as any personified beings, depending on how they were perceived by a geomancer. A landscape which was beautiful and peaceful looking was considered auspicious, while ugly and dangerous ones were considered inauspicious.
Third, the environment is recognized as a vulnerable entity that can be easily damaged or repaired by human actions (Yoon 1980). Vital energy in an auspicious spot is vulnerable, because it is drawn from an unstable phase of a continuously transforming cycle of the Yin-Yang energy and can always be lost from an auspicious site if its landscape harmony is disturbed. A mining shaft drilled by a miner or the placement of a highway through the landscape of a sleeping cow can ruin the place, but the damaged landscape can be restored as an auspicious site by removing or moderating human disturbances.

Original Chinese geomancy was concerned with the relationships between a human-made structure (a house) in an auspicious spot and its surrounding landscape, especially its landforms. However, as time passed, and when the art of geomancy was applied on flat land with no protective hills on the right (white tiger) or on the left (azure dragon), a stream or a road was justified to substitute the necessary hills. Geomancy has been adapted into modern built-up urban areas. In urban situations, the characteristics of the neighboring house, road pattern, and geomantic directions are important in divining the auspiciousness of a house. Geomantic principles are applied now in the interior design of buildings and are even used in arranging office furniture. However, these later applications do not appear in ancient Chinese geomantic texts. Numerous geomantic textbooks written during different periods of Chinese history exist today, and the art of geomancy, or fengshui, is still practiced for site selection, city planning, environmental management, architectural theory, and interior design in China, Korea, Japan, and other East Asian countries.

A hazard, generally speaking, is an element of the environment that is potentially harmful to humans in the form of loss of life, property damage, and socioeconomic disruption. Hazards can be “natural” in origin and only become a hazard because of the juxtaposition of geomorphic forms, processes, and materials with human activities. Hazards can also be caused or exacerbated to some degree by human activities. When an event occurs that actually does result in impacts to humans, the hazard becomes a disaster. The degree to which humans contribute to a hazard/disaster is often difficult to discern. A new field of inquiry termed “attribute science” has developed to focus on this challenge.

Geomorphic hazards/disasters are those that originate from exogenic processes – processes that originate at or near the Earth’s surface from the action of water, wind, ice, and gravity. Geomorphic hazards are distinguished from geological hazards that originate deep within the Earth from the endogenic processes of volcanism or earthquakes. The distinction is not always clear between geomorphic hazards and other main categories of hazards: meteorological, hydrological, biological, technological, and social. For instance, floods are usually classified as hydrological hazards but river channel changes are considered a geomorphic hazard.

Geomorphic hazards considered here (Table 1) include:

- expansive soils,
- soil erosion, including dust storms,
- slope failures,
- ground subsidence and karst,
- periglacial,
- river channel changes,
- glaciers,
- coastal erosion,
- climate change.

Burton, Kates, and White (1978) listed the critical information needs regarding hazards:

- magnitude: high to low,
- frequency: often to rare,
- duration: long to short,
- areal extent: widespread to limited,
- speed of onset: rapid to slow,
- spatial dispersion: diffuse to concentrated,
- temporal interval: regular (e.g., annual, seasonal, diurnal) to random.

Expansive soils cause billions of dollars of damage each year to homes in the United States alone (Alexander 1993). The swelling is caused by chemical attraction of water to plates in certain clay minerals. Pure montmorillonite (or smectite) clay, for example, can expand 15 times when water is added. Soils with high gypsum

Content can also experience shrink-and-swell to the point where structural damage occurs. Most soils have a portion of clay that would cause 25–50% expansion. Damage to structures is likely if the soil expands more than 3%. In the US Department of Agriculture (USDA) *Soil Taxonomy*, expansive soils fall into the order of Vertisols, which cover about 2% of the ice-free land surface on Earth. It is critical to consult soil surveys when trying to avoid expansive soils or to plan for mitigation.

Soil erosion has been increasing steadily since the advent of cropland agriculture about 3500 years ago, primarily from fluvial processes of rainsplash, sheetwash, rills, gullies, and piping. Wind erosion is important in flat terrain, and slope failures become important in mountainous terrain. Perhaps as much as one-half of the topsoil on Earth has been lost in the last 150 years through erosion or degraded soils quality. Soil erosion becomes a hazard when rates of erosion exceed rates of new soil formation, progressively destroying soils structure, nutrient content, and fertility. Rates of soil erosion are naturally high in semiarid climates, where vegetation cover is sporadic and storm-period rainfall intensity is high. Land-use/land-cover change (from deforestation, agriculture, overgrazing, climate change, desertification, wildfires, etc.) can greatly accelerate soil erosion by water and wind. Soil erosion causes millions of hectares of land to be removed from cultivation each year. Soil erosion differentially affects poor countries such as Ethiopia and El Salvador, where arable land is limited, and farmers lack modern farming technology and training in soil conservation methods. Trimble’s (2012) award-winning narrative about historical agriculture and soil erosion in the upper Mississippi Valley hill country documented how agriculture initially triggered landscape destruction, impoverishment and instability. However, farmers eventually adapted...
their land use and settlement practices to recover and enrich the landscape.

Dust storms pose a hazard to health and property by blocking roads and causing highway accidents, filling irrigation ditches and canals, burying crops and ruining machinery, dispersing weeds and insects, depleting soils, and sandblasting plant roots. Dust storms play a role in human health, animal health, climate change, and ocean sedimentation. Dust storms can reduce visibility to less than 1 km and can reach altitudes greater than 10 km. They can be traced for thousands of kilometers on remotely sensed imagery. Dust from World War II tank battlegrounds in North Africa has been found in the Caribbean. The magnitude, frequency, and duration of wind exert key controls on dust production, especially when wind acts on a surface with an abundance of silt-sized sediment that is dry and low in organic material. The generation of dust is further enhanced on a surface with low vegetation density, low litter cover, low surface roughness, and a long fetch. In a geospatial analysis of dust storm potential in the Chihuahuan Desert, Marston (1986) found these variables combined to create highest dust storm potential in the broad basins of northern Mexico, where irrigated cropland had been abandoned or is seasonal, and in deteriorated rangeland and regions of desert shrub vegetation (Figure 1).

Slope failures cause an annual average of 25 deaths and losses of US$ 1 billion in the United States. One of the worst natural disasters occurred in Hsian, China, because of widespread slope failures triggered by an earthquake in 1556. A 1963 landslide of 238 million cubic meters into the reservoir behind Vaiont Dam in Italy created a wave 90 m high over the dam. Amazingly, the dam survived but 2600 people lost their lives downstream. The landslide was composed of fractured limestone blocks that slid on beds of clay and soft marl. The landslide had been monitored for three years prior to the disaster; it was moving between 1 and 30 cm per week. Rising groundwater and heavy rains caused a threshold to be exceeded for the massive movement.

Slope failures are pervasive in the Nepal Himalaya but linking cause and effect has been made difficult by the multiplicity effect in geomorphology—any one variable can explain some of the variation but the interactions between variables remain poorly understood. Marston, Miller, and Devkota (1998) showed that forest cover did not affect the occurrence of slope failures, but position above and below the main central thrust was shown to be important, as was slope aspect. Dahal and Hasegawa (2008) demonstrated that a threshold of rainfall intensity and duration initiated landslides. In April 2015, a magnitude 7.8 earthquake in Gorkha, Nepal, caused thousands of fatalities, destroyed entire villages, and triggered thousands of landslides, some of which blocked rivers to create yet another hazard (landslide dam outburst floods) downstream (Collins and Jibson 2015). Variables

![Figure 1 Dust storm from SE winds entraining dust from a broad basin in northern Chihuahua. Note that the borders of Texas, New Mexico, and Mexico have been added. Source: Aqua MODIS, 2003. Reproduced from NASA. Image dated April 4, 2003.](image)
that control slope failures in the Himalayas change from one time to another and contrast with the controlling variables in other mountainous areas of the world.

The direct hazard posed by slope failures on humans is illustrated by the work of Butler (2013). Slope failures (rockfalls, debris flows, rockslides, snow avalanche tracks) were mapped in relation to hiking/skiing trails and campgrounds that are heavily used each year by backcountry visitors to the national park (Figure 2). The National Park Service could use this information to educate backcountry tourists and to modify their location of trails and campgrounds.

As defined by Alexander (1993, 276), “subsidence is a type of mass movement that involves the downward displacement of surface material caused by natural or artificial removal of underlying support (collapse) or by compression of soils (consolidation).” The extraction of oil, gas, and groundwater has been demonstrated to cause subsidence in Long Beach, CA, in Venice, Italy, and in Niigata, Japan, as just three examples. The construction of the tower in Pisa, Italy, on soils of contrasting compressibility caused the tower to lean over the course of centuries. Soils on deltas consolidate over time as organic matter is oxidized and soils are compressed under their own weight. This enhances flooding hazards, in the Mississippi River delta region, for example. An interesting example is provided by the Dead Sea, which has been affected by river inflow being diverted for irrigation agriculture and other purposes. The water level has dropped over 7 m in the last decade and the lake shore has receded. Fresh groundwater has replaced the saline groundwater, dissolving the buried salt deposits and causing the ground to collapse.

Sudden collapse of the ground, forming sinkholes, is more common in karst terrain. The Florida peninsula is a structural arch of fractured limestone. Groundwater has dissolved the limestone, particularly where fractures intersect, to create caverns. When groundwater drops during extended droughts, the support provided by the water in caverns is lost and sinkholes appear. In the rapidly urbanizing Rio Grande Valley downstream from El Paso, TX, former agricultural fields are covered by impermeable asphalt and concrete. Gophers abandon the urban area for the few remaining fields that are surrounded by pavement. When farmers dump a meter of water on their field to leach salts from the soils, the gopher tunnels experience erosion by piping, sometimes leading to formation of a sinkhole in alluvium and ruining the farm.

Periglacial environments are dominated by the action of ground ice (ephemeral, seasonal, permanent) and mass movement. The active zone is affected by freeze–thaw cycles over diurnal and seasonal intervals of time. Permafrost underlies about 26% of the Earth’s land surface. Freeze–thaw action displaces larger particles more than smaller sediment, resulting in an upfreezing of stones and sorting the mix of sizes. Mass movement occurs by the process of frost creep on slopes, whereby repeated freeze–thaw cycles lead to a slow movement of material downslope. Solifluction involves the slow downslope movement of saturated soils during the summer thaw. An intriguing variety of periglacial landforms is created by these processes, including elongated thaw lakes, ice wedges, pingos, patterned ground, blockfields, and rock glaciers. Hazards are created when human activities and settlements encroach on periglacial landscapes. During thaw periods, the bearing strength of soils is lost, which leads to differential settling and frost heaving, and structural damage to buildings, roads, airfields, railroads, and utilities. In the cases where felsenmeer and rock glaciers are situated on a cliff, the melting of interstitial ice can lead to rockfalls, which
GEOMORPHIC HAZARDS

become a hazard for downslope human activities and settlements.

River channels change location by meander cutoffs, meander migration, and by avulsion. These changes can occur in the absence of human activities but can be exacerbated by humans through direct manipulation of the channel or through land-use/land-cover changes upstream. When rivers change course, land on the floodplain that would otherwise be available for farming and other human activities can be lost. Stream channel change is driven by the frequency and magnitude of peak flows on the one hand, and the resistance of stream banks (controlled by alluvial materials, large woody debris, and streamside vegetation) on the other hand. A landowner situated on the outside (cut bank) of a meander bend stands to lose a significant amount of land if erosion progresses as is normal. Often a river marks a property boundary or a political border. According to the law in many jurisdictions, if the river moves
by progressive meander migration, the border moves with it, causing the landowner on one side to gain land by accretion while the landowner on the other side loses land. The landowner who gained land may further rub salt into the wound of his or her neighbor by acquiring a permit to mine the river for sand and gravel. In the case where a river changes course by a sudden avulsion, the property line does not move with it, creating another set of problems and disputes.

Glaciers can create hazards for humans in at least five ways. First, glaciers and ice sheets that extend to the coast will experience calving of ice at the terminus. This generates icebergs, which then become a hazard for shipping. The Greenland and Antarctic ice sheets are notorious for this hazard, as are coastal glaciers along the southern coast of Alaska. Second, ice advances, although slow, can overrun villages and farms. This was known to have occurred in the Alps, Norway, and Greenland during the Little Ice Age. Third, surging glaciers can block water bodies, leading to potential outburst floods. This has occurred multiple times with the Hubbard Glacier in Yakatat Bay, AK, blocking the entrance to Russell Fjord. Fourth, ice avalanches from tall peaks can create a rock-ice avalanche and demolish towns that are located down valley. The collapse of the ice summit of Mount Huascaran in Peru in 1970 resulted in the deaths of 25,000 people. A smaller scale event in 1962 claimed 4000 lives. Fifth, glacier changes can lead to a glacial lake outburst flood (GLOF), or jokulhlaup. When valley glaciers retreat, they leave behind a moraine, which may dam water between the retreating glacier and the moraine. If the moraine experiences piping, it may collapse. If a rock-ice avalanche lands in the lake, it can create a wave that overtops the moraine dam, causing it to collapse. If an advancing valley glacier cuts off a tributary, it can create a lake behind the ice. The ice dam may collapse or a subglacial tunnel may enlarge to suddenly release the water, endangering life and property downstream. GLOFs are common in glaciated mountains and cases of imminent danger have been identified in the Himalayas, central Asia, the Andes, and the Alps.

Coastal hazards include erosion and sedimentation by waves and longshore currents. Coastlines are dramatically affected by tropical cyclones, hurricanes, and tidal flooding, but these are usually considered meteorological hazards. Tsunamis are triggered by earthquakes or large slope failures into a water body, so are not considered here. Alexander (1993) stated that five factors influence coastal erosion: exposure of the rocks and sediments to waves and currents; the supply of sediments (beach starvation or nourishment); the topography of the coast and neighboring continental shelf; the tidal range and intensity of currents; and the climate of the coastal area. Once again, it is worth pointing out that natural processes along the coast become hazards because of the intersection with human activities. The hazards depend on the geomorphic type of coastline.

Sandy beaches experience seasonal transfer of sand, offshore in winter, onshore in summer. Thus, in winter, beachfront homes lose a buffer against attack by storm-period waves, especially during high tides. Littoral movement of sand, another important process affecting the beach sand budget, is responsible for a variety of coastal landforms and can close the mouths to rivers, estuaries, and harbors if left unchecked. Sand spits and barrier islands are commonly breached by storm-period events, leading to a call for artificial beach sand nourishment. On the Arctic coast, the longer fetch for wind over ice-free ocean already appears to be creating higher waves and greater coastal erosion, especially where permafrost is melting and sea level rising.
Cliff coastlines experience direct wave attack throughout the year, with progressive cliff erosion and slope failures as a hazard. Wave-cut abrasion platforms, if present, serve to dissipate wave energy. The rate of cliff retreat needs to be studied by coastal geomorphologists, so coastal planning authorities can establish appropriate setback regulations. Along the central Oregon coast, cliff retreat from 1935 to 1975 was measured at 23 cm per year in marine sandstones/shales versus 5.3 cm per year in basalt over the same period.

Earlier mention was made about consolidation of delta deposits. Deltas will be subject to erosion if the rivers that originally deposited the sediment are not allowed to deposit new material on top of the consolidating sediment. This is the situation being faced along the Gulf coast shores of Louisiana, where about 4900 km² of coastal land was lost between 1970 and 2000. Some of this loss is attributed to saline water intruding into freshwater wetlands, killing the freshwater marsh grasses that hold the sediment in place.

Coral reefs protect the shore from the direct impact of waves, but coral are threatened in several ways. They are being attacked by a crown-of-thorns starfish, the population of which is exploding because their predators have been overfished. The coral polyps that create reefs are supported by algae. The coral die within weeks if the algae die, and algae are dying from warmer ocean temperatures and sedimentation.

Climate change will have an impact on all of the geomorphic hazards discussed here by affecting one or more of the seven dimensions of hazards defined by Burton, Kates, and White (1978) listed previously. However, global circulation models must continue to be refined to the point where predicting change is possible for geomorphic hazards. Geospatial analysis provides many tools for understanding and visualization of the results. It is clear that the geomorphic hazards discussed here are sensitive to climate, so the degree to which these controlling factors change deserves further study. Critical research is underway to identify the key indicator variables in geomorphic systems and their response to external driving forces.

Alcántara-Ayala, Irasema, and Andrew Goudie, eds. 2010. Geomorphological Hazards and Disaster Preven-
Geomorphology deals with highly complex assemblages of topographic elements or “geomorphic units” that exist in the real world. The units include different types of slopes in mountains and hilly lands (e.g., rocky cliffs, taluses, and other types of valley-side slopes), depositional and erosional landforms in piedmonts and floors of intermontane basins (e.g., river terraces, alluvial fans, and floodplains), and those landforms in coastal areas (e.g., deltas, sand dunes, and rocky benches). An assemblage of such units can be regarded as a single mega-unit, typically a drainage basin, which is sometimes called a “fluvial system” (Schumm 1977). Like this usage of the term “system,” an assemblage of geomorphic units is often referred to as a “geomorphic system.”

However, “geomorphic system” means much more than a mere assemblage of geomorphic units. It is also related to “general system(s) theory” (Bertalanffy 1951), which describes the structure of a system including the hierarchy and cascading of units and subunits; the behavior of a system, particularly interactions between units and subunits; and the temporal evolution of a system with responses to change in external conditions. Chorley (1962) pointed to the close connection between general system theory and geomorphology, and this way of thinking exerted a strong influence on subsequent geomorphological studies. Although recent geomorphological publications seem to put less emphasis on general system theory, this may not mean that the application of the theory has become obsolete. In a sense, geomorphologists well understand the ideas from general system theory and their usefulness as background knowledge for research, and they do not have to re-emphasize them. At the same time, the classic system approach in geomorphology has received some criticism in recent years and has been re-evaluated.

Development of the system approach in geomorphology

Alongside Bertalanffy’s general system theory, Chorley (1962) stated that some geomorphological papers published in the 1950s had already applied general system theory. These studies were strongly influenced by the morphometric and statistical analyses of drainage basins and stream nets established by Horton (1945). Since then geomorphologists have been considering drainage basins as geomorphological units with structural hierarchy, and their quantitative characteristics have sometimes been interpreted from the viewpoint of general system theory, especially whether the form of basins reflects or has adjusted to external environmental conditions.

Chorley (1962) emphasized the difference between a closed system and an open system. The former changes without a supply of energy or mass from outside, whereas the latter receives them. Although a system of either type tends to attain a time-independent steady state or
GEOMORPHIC SYSTEMS

equilibrium, the ultimate equilibrium condition of a closed system can be predicted only from the initial condition of the system. By contrast, that of an open system is the result of dynamic interaction between the system and the surrounding environment. The latter is more realistic in geomorphology because landforms are influenced by various external factors such as climate, tectonics, and lithology. Strahler (1952) put forward similar ideas concerning dynamic relationships between forms and processes associated with transformation of mass and energy. Equilibrium in geomorphic systems was interpreted using principles of thermodynamics (Chorley 1962), as in preceding applications of general system theory in other scientific fields. Chorley (1962) correlated closed systems with some classic geomorphological concepts or approaches, such as the cyclic model of erosion by Davis and the slope retreat model by Penck, but correlated open systems with newer geomorphological ideas, with more attention to geomorphic processes and interactions with the surrounding environment. It should be noted that G.K. Gilbert already had an idea comparable to open systems that evolve toward equilibrium in relation to his innovative approach of process geomorphology (Huggett 2007).

After the recognition of open systems in geomorphology, the adjustment of systems to external variables and resultant equilibrium or steady-state conditions received increased attention. As noted, the morphometry of drainage basins was interpreted from this viewpoint. Another example discussed early on was the adjustment of channel cross-section geometry and river longitudinal profiles to environmental conditions such as flow discharge (Langbein and Leopold 1964), which followed not only general system theory but also a concept of “grade” proposed by Mackin (1948). Other more complex landform units, such as ridges and hollows on hillslopes, were also considered to be interacted systematically and to change toward equilibrium (Hack and Goodlett 1960). Adjustment of geomorphic systems to tectonic conditions in terms of the balance between uplift rate and erosion rate, and resultant landforms in dynamic equilibrium, were also discussed (Howard 1965), providing a basis for subsequent investigations.

At the same time, complex relationships between landforms and the external environment were indicated. Geomorphic systems are often affected by episodic large events such as volcanic eruptions, glaciation, and megafloods which lead to a disturbance of system adjustment, sometimes in a catastrophic way. Also, responses of geomorphic systems to external changes tend to be nonlinear, including lag time, relaxation time, and thresholds. Schumm (1973) focused on this kind of threshold based on examples of both field studies and laboratory experiments. There is also feedback between a geomorphic system and outside; for example, topographic form affects the surrounding microclimate and the resultant microclimate affects future topographic change. In spite of such complexity, Howard (1965, 302) provided a general viewpoint for understanding geomorphic systems in relation to the history of geomorphic processes: “the influence of a past process having acted upon a geomorphic system is proportional to the intensity and duration of its action but inversely proportional to the elapsed time since it action.” Phillips (1988) further examined the role of spatial scales in geomorphic systems based on a review of literature and a case study in a desert stream.

The idea of landforms as open systems was combined with the concept of allometry or allometric growth. The concept was originally developed in biology, and Woldenberg (1966) was one of the first to introduce it to geomorphology. In allometric growth, the growth
rate of a part of a system is proportional to
that of another part or to that of the whole
of the system. The relation is expressed by a
power function or a straight line on a log–log
plot. Although Horton’s law is expressed as a
straight line on a log-normal plot, the integer
stream order represents a logarithmic increase
of absolute magnitude to the base of the stream
bifurcation ratio (Woldenberg 1966). Therefore,
Horton’s law and the regime theory of channel
gometry represented by power functions were
regarded as examples of allometry.

Chorley and Kennedy wrote a unique book,
Physical Geography: A System Approach (1971),
with strong emphasis on the system approach in
physical geography, particularly geomorphology
and hydrology. Another book by Bull, Geomor-
phic Responses to Climatic Change (1991), focuses
on responses of geomorphic systems to climatic
change. It deals with case studies from different
parts of the world, with a consistent emphasis
on system concepts such as relaxation time in
response to climatic change and sensitivity of
landforms. The viewpoint of the book simulated
additional discussion concerning relationships
between climate and landforms.

Re-evaluation of the system approach
and future perspectives

Although the complexity in the structure and
behavior of geomorphic systems has been rec-
ognized for a long time, studies conducted until
the end of the 1980s tended to assume that
general system theory in a classic sense is widely
applicable in geomorphology. This situation
clearly changed in the 1990s, and the applica-
bility of the theory was re-evaluated. This shift
reflected the introduction of nonlinear concepts
to geomorphology and related research fields.
The concepts include catastrophe, chaos, fractals,
self-organization, and dissipative systems.

Phillips (1992) noted that geomorphic systems
tend to exhibit complex and even random
behaviors and spatial patterns, mainly because
numerous individual process–response mecha-
nisms give rise to cumulative impacts in a system.
To solve this complexity, he introduced the the-
ory of nonlinear dynamical systems (NDS).
NDS theory deals with the complexity due to
the coupling of relatively simple systems using
specific concepts including chaos, dissipative
structures, and fractals, as well as bifurcation
and catastrophe theory. Phillips showed that the
application of NDS theory to mass flux provides
results corresponding to the classic concepts of
g geomorphic processes, aggradation, degradation,
and steady states, although the viewpoints of
NDS differ from classical thinking including
general system theory.

Another trend was criticism of equilibrium as
a key concept in geomorphological applications
of general system theory. Although general
system theory does not assume that all systems
are in equilibrium, it indicates that many systems
are approaching equilibrium and often close
to it. However, some subsequent publications
indicated that discrepancy from equilibrium
is much larger than expected, and terms like
“nonequilibrium” and “disequilibrium” were
emphasized (Renwick 1992). In addition, a
geomorphic system may change toward multiple
equilibria rather than a single equilibrium, which
also differs from the classic assumption of general
system theory or the concept of equifinality
(Phillips 1992). In extreme cases, systems may
have no particular normative state at all (Phillips
2009).

Newer concepts concerning system nonlinear-
ity have also been introduced to geomorphol-
ogy. One is self-organized criticality, originally
developed in physics as a property of dynamic
systems that have a critical point as an attractor.
Another concept introduced is the synchrony and
asynchrony of a system in relation to the number and connectivity of system components (Phillips 2012).

Although further new concepts useful for understanding complex systems will doubtless be introduced to geomorphology, researchers also clearly recognize extreme complexity in the behavior and structure of geomorphic systems. Elverfeldt (2012) indicated five major problems in system theory in geomorphology: (i) coherence of basic assumptions and concepts; (ii) openness and determinacy; (iii) the physical basis; (iv) equilibria; and (v) complexity and nonlinearity. In spite of such multiple problems, general system theory still seems to be one of the most important usable ideas in geomorphology. Nevertheless, only a small number of actual cases can be well explained by the theory even if newer related ideas are additionally introduced, because of the high complexity of landforms and environments in the real world. An important aspect is that some recent papers indicate the relatively close relationships between the current heterogeneous recognition of geomorphic systems and classic ways of geomorphological thinking.

In spite of recent progresses in the system approach in geomorphology, including applications to cases in the real world, the concept of geomorphic systems still seems to be a perspective that is more useful for general theoretical or philosophical discussion rather than for practical application. For the further development of geomorphology, it would be fruitful to find more concrete linkages between theoretical ideas of geomorphic systems and the actual development and structure of landforms. With knowledge accumulated through such efforts, the factors controlling the applicability of system theory in geomorphology will be more clearly and objectively understood.

Geomorphic thresholds

Michael Church
The University of British Columbia, Canada

The Oxford English Dictionary defines “threshold” (of a relevant sort; there are also doorsteps) as “a level or point at which something would start or cease to happen or come into effect; a limit below which a stimulus causes no reaction.” There are two definitions here, and both are relevant to geomorphology. The first might apply to some discontinuity in space or time – to a morphological transition such as a slope base or stream bank, or to a process change such as the onset or cessation of glaciation (a “threshold of the first kind”); the second definition implies a transformation in the response to an ongoing process (a “threshold of the second kind”), such as the much-studied threshold for (significant) sediment motion in streams. It is immediately perceived that “thresholds” in geomorphology may be considered in various ways depending upon context. The concept of thresholds was prominently introduced into geomorphology by the American geomorphologist Stanley Schumm (1973, 1979, 1980) as a means to explain the episodic and conditional changes he observed in landscape. He viewed thresholds and the accompanying idea of “complex response” as important correctives to earlier paradigms of continuous evolution of landscapes.

A 1980 volume on “thresholds in geomorphology” (Coates and Vitek 1980) signaled widespread acceptance in the discipline of the importance of thresholds. It contains a range of definitions, including:

- “... self-explanatory terms to denote existence of zones or critical conditions at which change in topographic form or process occurs” (Ford 1980, 345, quoting Frederking and Vitek from a conference presentation, cf. threshold of the first kind);
- “the point at which a stimulus begins to produce a response” (McKerchar 1980, 171, cf. threshold of the second kind);
- “... a boundary condition that separates two distinct but interconnected processes, fed by an identical energy source” (Fairbridge 1980, 43, cf. Chappell 1983);
- “a point or period of time that separates different modes of operation within part of a landscape system” (Bull 1980, 259);
- “boundary conditions ... that when exceeded can cause sudden and vast changes” (Coates and Vitek 1980, 5).

Schumm was largely concerned with landscape morphology, and one of his early examples of a geomorphological threshold was the distinction between ungullied and gullied valley floors in the semiarid American west. He showed a discriminant relation that depended on valley gradient (Figure 1a). He used this diagram to elaborate the concept by distinguishing “intrinsic” and “extrinsic” thresholds. An “intrinsic threshold” is one that occurs as the result of changes endogenous to the geomorphic system; an “extrinsic” threshold is one that is imposed by changes external to the geomorphic system. In the example of valley-floor gullying, an intrinsic threshold would be crossed if sediment accumulation on the valley floor increased the gradient to the point that gullying commenced; an extrinsic threshold would be crossed if an
increase in stream runoff (that is, a climate change) initiated gullyling. The gully threshold might be viewed as a threshold of the first kind if the morphological relations of gradient and landform are emphasized, or of the second kind if the underlying physical process – the point at which runoff becomes sufficiently powerful to initiate erosion – is the focus of attention. Extrinsic threshold crossings characteristically entail some processes intrinsic to the system, but intrinsic threshold crossings may occur independently of extrinsic forcing.

Begin and Schumm (1984) further developed this example and the concept of thresholds by pointing out that the valley-floor threshold is gradational or transitional (Figure 1b). They plotted relative shear stress in the discriminant diagram, showing that the gullied valley floors were distributed over a range of stress values. Intervening effects that would promote such a range might include the state of vegetation cover or character of the sediments on the valley floor, or simply time elapsed since a critical runoff event. A closely related threshold concept is that of the origin of channeled drainage, which has been studied by Horton (1945) with his analysis of the critical distance from a drainage divide to the inception of rills, and by Montgomery and Dietrich (1988) (Figure 2) with their analysis of the relation between source area and gradient at the inception of channeled drainage.

Transitional thresholds might often be modeled using logistic regression, a form of regression that quantifies the probability for a system to be in one
Figure 2  Correlation between drainage area at the point of channel initiation and local gradient at that place for three contrasting terrains on the American west coast. In this diagram, the data are plotted in terms of the critical point at which the threshold occurs. The data scatter shows that the threshold is a transitional one (Montgomery and Dietrich 1988, Figure 1d. Reproduced with permission from Nature Publishing Group.).

state or another, or in some transitional condition, given values of some controlling conditions. Figure 3 shows an example, the transitional probability for tributaries to Sukunka River (in northeastern British Columbia, Canada) to be significant sediment sources (as classified by the presence or absence of a tributary-mouth alluvial fan). Most, but not all, tributaries can be classified as either significant ($p = 1.0$) or nonsignificant ($p = 0.0$), but some do not fit this dichotomous distinction. The discriminating variables in the regression are the ratio of tributary to mainstem area (i.e., relative sediment source area) and the product of tributary gradient and area, a surrogate for tributary stream power.

Ferguson (1992) made a systematic classification of threshold concepts (Figure 4). His “sharp thresholds” are probably mainly thresholds of the first kind (such as a stream bank or glacier margin – a boundary where dominant process and landform change abruptly), whereas his “transitions” and “rate discontinuities” characterize thresholds of the second kind – that is, ones involving physical processes. Indeed, almost all physical processes in geomorphology will give rise to transitional thresholds because thresholds are almost never controlled by a single, simply characterized condition. Examples do exist, however: a glacier may be classified as either “polar” (base of the ice frozen to the substrate) or “temperate” (base of the ice at the pressure-melt temperature and lubricated). But this condition might be spatially variable.

An important characteristic of thresholds, introduced by Chappell (1983), is whether or not the threshold crossing results from persistent or transitory changes in the controlling boundary or forcing condition. Chappell defined cases in which the new state is the consequence of a persistent change in the boundary or forcing condition as “transitive,” a transition that could, presumably, be reversed if the controlling condition subsequently regressed toward its original state. Transitions in which the new state is the consequence of a temporary perturbation in the controlling condition, but where the response does not relax to its original state, he nominated as “intransitive.” The terminology is mathematical: a process is transitive if it is reversible, otherwise it is intransitive. Chappell’s concept of threshold is also closely analogous to the
concept of a “critical point” in physics or chemistry wherein a phenomenon (physical state; landform) may remain stable under a substantial range of variability in the controlling parameter, but then change radically under a small additional change (his opening example is that of an ice cube melting in a beaker, hence crossing the solid–liquid critical point of 0°C at atmospheric standard pressure). The analogy is useful when considering what may be a meaningful threshold in geomorphology.

Ferguson (1992) completed a characterization of threshold crossings by describing the nature of the response (Figure 5). He classified responses as “simple” or “complex,” according to whether the response element relaxes monotonically toward its new state, or oscillates. With these definitions Ferguson tied threshold concepts back to Schumm’s (1973) second conceptual contribution – that of complex response. An additional mode of response might be added in which the response variable partially recovers after the initial perturbation: a damped complex response that would imply either an initial overshoot of the new resultant condition or the influence of compensating elements in the environmental system.

The most prominent instances of thresholds of the second kind in geomorphology are those related to incipient land surface instability. The stability of surficial material on slopes is governed by material strength, given by the
Mohr–Coulomb equation, the full form of which is shown in equation (1),

\[ s = \epsilon' + \epsilon_r + [(1 - m)\rho_bgd_m + \rho_dgd_m\cos^2\theta \tan \phi'] \]  

(1)

in which \( \epsilon' \) is the effective material cohesion, \( \epsilon_r \) is pseudocohesion provided by root strength, \( \rho_b \) is material bulk density, \( \rho_{sat} \) is the density of saturated material, \( d_m \) is the depth of surface material above the potential failure plane, \( \theta \) is the hillslope angle, \( m \) is fractional saturation (in effect, \( d/d_m \)), where \( d \) is the depth of the saturated zone, \( g \) is the acceleration of gravity, and \( \phi' \) is the effective angle of the material’s shear resistance. Material strength is compared with the shear stress \( (\tau) \) on a candidate failure plane equation (2).

\[ \tau = [(1 - m)\rho_b + m\rho_{sat}gd_m\sin \theta \cos \phi'] \]  

(2)

\( F = s/\tau \), known as the “factor of safety,” indicates the likelihood of failure. The interesting aspect of this stability criterion is that it contains several variable quantities, including \( \epsilon' \), \( \epsilon_r \), and \( d \); hence, in terms of parameters that are fixed at a site, notably \( \theta \), or possibly \( d_m \) or \( \phi' \), the threshold will appear to be transitional. If failure occurs, a debris slide or debris flow, or a slump or block slide, happens depending upon the water content of
the material and the cohesion of the failed mass. On steep slopes and in hollows, debris slides or flows are most common.

In flowing water, the equivalent stability criterion is the Shields relation:

$$\tau^* = \frac{\rho gdS}{g(\rho_w - \rho)}D$$  \hspace{1cm} (3)

wherein $$\tau^*$$ is a dimensionless shear stress known as the “Shields number,” $$\rho$$ and $$\rho_w$$ are the material densities of sediment and water, $$d$$ is flow depth, $$S$$ is the energy gradient of the stream, and $$D$$ is the size of the grain to be moved (often assumed to be $$D_{50}$$ in mixtures). This is, again, a ratio of mobilizing and resisting forces (the numerator is just $$\tau$$, the shear force of the flowing water imposed upon a grain while the denominator is grain inertia), so $$\tau^*$$ plays the role of $$1/F$$ (mobilizing force and resisting force are inverted in comparison with $$F$$). In the original experimental investigations, Shields (1936) found $$\tau^* = 0.06$$, approximately, for narrowly graded sediments coarser than about 2 mm, but a substantial range of values, varying from 0.01 to greater than 0.1, has been recorded since and it has been established that the value of $$\tau^*$$ depends, amongst other things, on the value of $$S$$ (Lamb, Dietrich, and Venditti 2008).

In nature, a major factor in the variation of the Shields number is the structural arrangement of the sediment grains on the streambed (Church, Hassan, and Wolcott 1998), and this depends on flow history. Here, then, is an example of a variable threshold.

The actual critical value of both the thresholds just discussed depends on the recent history of the hillslope or stream. Accordingly, the critical state has been analogized to self-organized criticality. The ideal representation of this state is a dry granular pile, an example of which is a talus slope. Since it is dry, the critical limit value of $$\Theta$$ is about 35° (and the threshold is, exceptionally, relatively sharp), while repose angles after failure are somewhat lower. A similar threshold is the limit to relief represented by rock strength – in fact, by the weakest member of a rock formation – in mountains (Schmidt and Montgomery 1995). In streams, however, the critical value of $$\tau^*$$ depends on the state of the streambed at the end of the last event competent to move grains; hence it is a self-organized state of conditional criticality, and this is the case with many process thresholds in nature.

A different kind of threshold – which can perhaps be called a “state threshold” and is a threshold or series of thresholds of the first kind – is represented by changes in channel planform morphology in rivers. The classical empirical analysis gives $$S \propto 1/Q^{1/2}$$ as a discriminator between single and multithread channels, in particular between meandered and braided channels. This relation may be interpreted as a limit condition of stream power that can be accommodated by a single-thread channel system (i.e., $$SQ^{1/2} \sim$$ constant $$\rightarrow SQ/w \sim$$ constant, $$Q$$ being stream discharge and $$w$$ channel width, the combination being directly proportional to specific stream power). The implication is that, beyond some particular magnitude, the sediment load is too great to be moved through a single, increasingly wide channel, so that a division occurs into two or more channels, each of which can convey a part of the load. The discrimination was introduced by the American river engineer Emory Lane (1957) and, in its most famous form by Leopold and Wolman (1957) (which is a remarkably similar precursor of Schumm’s valley floor incision case). Figure 6 gives a developed form of the relation in which it is seen that the “downward” transition (from multithread to single-thread channels) is different than the “upward” transition. The reason for this is probably related to stream bank strength, which might be greater on the upward transition from a relatively stable single-thread channel than on the downward transition, when a single
channel is to be defined within a broader, multithread channel zone.

Many investigators have subsequently presented diagrams similar to Figure 6 with varying datasets, while others have investigated different discriminant functions. Xu (2004) investigated a range of simple, mainly geometric, indices using a large sample of rivers (150–196), both meandered and braided, and flowing in sand or gravel. Remarkably, he found that a fixed value of width/depth ratio, $w/d = 110$, misclassified only 8.7% of his sample. Fredsoe (1978), in an early stability analysis of alluvial channels, had found a result that suggested a discriminant value of about 50. Similarly, Eaton, Millar, and Davidson (2010) found a simple discriminant value of 60. None of these results has any physical meaning, but the range of numerical values implies that there is regional variability in the threshold, probably related to the character of the alluvial material. More strictly physically based criteria have been suggested but have no greater success in discrimination and need not be pursued here. They do, however, imply that the discrimination depends most strongly on $w/d$, which explains the success of the simple discriminant values given above.

Finally, thresholds play an important role in processes that control even the largest-scale features of the planetary surface. Relief production
GEOMORPHIC THRESHOLDS

occurs when rock material is displaced vertically by forces within the crust. In abrupt movements, a threshold is represented by the breaking or yield strength of the rocks associated with the movement. And this introduces yet another aspect of thresholds; they may be either “soft,” presenting such low yield strength that rock creep may occur essentially continuously and aseismically, or “hard,” having strength that yields only to great force and with great release of seismic energy.

Fieldwork and mapping have been, and continue to be, the foundation of geomorphological research to study surface processes, process–form relationships and feedbacks, and system couplings to understand landscape evolution. The field tradition in geomorphology has resulted in the ability of geomorphologists to make relevant assessments and develop maps of landscape change based on their conceptual knowledge developed through “experience, intuition and tacit knowledge” (Phillips 1999). The majority of field scientists, however, do not have the ability to quantitatively formalize and evaluate their conceptual knowledge and predict complex spatial patterns based on the spatial distribution of climatological, geological, biological, pedological, and morphometric information. Qualitative interpretation has been accomplished through the analysis of spatial patterns and environmental relationships, along with conceptual understandings of process and geomorphological systems. Reproducibility is then dependent on local geographic and geomorphological knowledge and experience. As argued by Church (1996, 147), field scientists have a “highly censored view of geomorphologically significant events” that is specific to a particular location at a single spatial and temporal scale.

The rapid proliferation of geospatial technologies has transformed the field of geomorphology. As a result, geomorphological assessment and mapping focuses on quantitative characterization of landscape properties and mathematical formalization and modeling of concepts, processes, and system dynamics. Specifically, mapping capabilities have been revolutionized by developments in geodesy, remote sensing, geographic information technology (GIT), geophysics, and high-performance computing and geocomputation (Bishop 2013). It is now possible to collect high-resolution locational, surface biophysical, morphometric, and near-surface spatiotemporal data that can be used to study and map the scale-dependent complexities associated with geomorphological systems and landforms. Similarly, new developments in geostatistics, geocomputation, geovisualization, and spatiotemporal models offer new ways to explore the variance structure in data, extract and synthesize information, and predict and formalize understanding. Given these capabilities, geomorphological research and digital geomorphological mapping (DGM) are increasingly dependent upon the syntheses of knowledge from geomorphology and geographic information science and technology (GIST).

Bishop and Shroder (2004) discuss the reciprocal nature of geomorphological and GIST issues that arise from complex spatial and temporal problems in earth science. These include spatiotemporal data collection, space–time representation, semantic modeling, scale, indeterminate boundaries, information extraction and integration, and geovisualization.
They conclude that geospatial technologies are dramatically improving the ability to study landforms, process mechanics and regimes, process–form relationships, the scale dependencies of surface processes and feedback mechanisms, and the polygenetic evolution of landscapes. The use of DGM, however, tends to be limited to relatively simple and empirical investigations that use satellite imagery and digital elevation models (DEMs) for assessing land-surface properties, topographic structure, erosion and deposition, and process regimes. The resulting interpretation of the Earth surface is used to address a variety of application problems related to volcanism, tectonics, hazards, hydrology, ecology, geology, and pedology. DGM and geomorphometry also facilitate assessment and mapping of specific features/landforms, including hillslopes, ridges, peaks, valleys, volcanoes, glaciers, dunes, floodplains, drumlins, and assemblages of landforms. Smith, Paron, and Griffiths (2011) provide a review of developments in geomorphological mapping, including types of data, methods, and mapping applications.

DGM efforts have been constrained by geographic area and mapping objectives, and various techniques and approaches do not necessarily have universal applicability in geomorphology. Many constraints are caused by the need to account for conceptual and technical issues that are not addressed in the mathematical underpinnings of techniques and analytical approaches. An attempt to better formalize understanding of mapping geomorphological systems involves research on semantic modeling, landform elemental object/unit segmentation, and assessment of the morphographic structure of the landscape. The mapping objectives, and therefore the difficulty of DGM applications, can range from relatively simplistic (e.g., land cover or topographic feature mapping) to extremely difficult (e.g., process regimes and polygenetic overprinting). The landscape can be mapped using a particular theme or combination of themes (geobotanical, morphometric, hydrologic, geologic, etc.), although these are notoriously difficult to accomplish given that software tools have not been designed to specifically address a multitude of geomorphological concepts and issues. Unfortunately, analytical success is often dependent on the scope of the mapping objectives and the degree of landscape complexity, meaning that issues of mapping accuracy and reproducibility remain unanswered. An improved conceptual and analytical framework to extract and integrate diagnostic landscape information is warranted, to ensure that DGM becomes fundamental to integrative science.

Geospatial technologies

Fundamental geospatial technologies utilized in DGM include global navigation satellite systems (GNSS), remote sensing (including geophysical sensors), and GIT. These technologies are used to obtain spatiotemporal data that contain detailed locational, biophysical, and structural information about the landscape and near-surface environment. Spatial analysis and pattern recognition algorithms can then be used to characterize landscape properties and produce thematic maps related to various geomorphological and environmental science themes.

Multispectral and multitemporal remotely sensed data are critical for geomorphological mapping, as surface biophysical properties inherently characterize the composition and land-cover structure of the landscape and permit change detection (Figure 1). The biophysical properties of the surface are related to surface processes and landscape stability. High-resolution and hyperspectral image data,
Figure 1 Multitemporal satellite imagery can be used to detect changes on the landscape. Spatial and temporal variations in spectral reflectance are detected using feature-tracking software to map the ice-flow velocity fields of alpine glaciers around the world (Ngojumba Glacier in Nepal). This information is required to assess climate change and geomorphological system response to climate forcing. Other applications include detecting mass movements and the migration of dunes and dune fields.

Along with digital image processing software, permit the enhancement of landscape features to differentiate complexities of the landscape. It is widely known, however, that surface compositional variations and land-cover spatial patterns may not directly characterize or delineate landform entities or landscape concepts/processes such as instability, erosion, deformation, and uplift. Nevertheless, geomorphologists routinely use aerial photography and satellite imagery, and interpret spectral and textural variations in reflectance to map landforms, particularly when working with data acquired over remote mountain landscapes and extraterrestrial planetary surfaces.

Topographic information from terrestrial and airborne LiDAR, off-nadir optical imaging, and microwave synthetic aperture and interferometric radar systems has dramatically increased the ability to address a variety of geomorphological mapping problems. Morphometric information about the landscape and changes in surface altitude permit detailed examination of the shape of landforms and directly enable estimates of rates of processes including erosion, deposition, ablation, and energy distribution and flux (Figure 2). The associated field of geomorphometry and the use of DEMs have dramatically influenced geomorphological research in a variety of environments by quantifying the shape and contextual characteristics of the topography. Key parameters such as slope angle, slope azimuth, and curvature metrics govern a variety of surface processes, including water and sediment transport, erosion, deposition, surface temperature, ablation, surface irradiance, precipitation, evapotranspiration, and physical and chemical weathering. Geomorphometry involves the principles of sampling the land surface, generating a digital terrain model, correcting errors and artifacts in the model, deriving land-surface parameters and terrain objects, and applications using parameters and objects. Geomorphometry incorporates the geosciences, computer science, and engineering, and is rapidly becoming a central theme in geomorphological research and DGM.
Digital elevation models and topographic solar radiation transfer models can be used to simulate the surface irradiance over the landscape: total direct irradiance (diurnal integration) variations over the Nanga Parbat Massif in Pakistan on August 15, 2013 (left); total diffuse-skylight irradiance (diurnal integration) variations over the Nanga Parbat Massif for the same day (right). Gray-scale values depict the magnitude of the irradiance component, with white signifying relatively high irradiance and black depicting relatively low irradiance values. Multiscale topographic effects dramatically influence the shortwave energy distribution over mountain environments. Surface irradiance is important for assessing evapotranspiration, drought, surface energy budget, and other aspects of geomorphological systems.

Geomorphometry also serves as a basis for land-surface segmentation and object characterization, which permit the identification and mapping of fundamental elementary forms and landform entities that evolve into and out of existence as the landscape evolves. This can be particularly useful to the understanding of the critical zone, where surfaces that characterize vegetation canopies, land surface, bare surface, soil horizons, stratigraphic layers, bedrock, and subsurface seismic structures can be analyzed spatially and information synthesized to more accurately map various aspects of geomorphological and complex critical zone systems. More detailed information about geomorphometry can be found elsewhere (Hengl and Reuter 2009).

The data derived from these evolving technologies are exceedingly rich and have driven significant advancements in data storage, management, analysis, and visualization capabilities. Geographic information systems (GIS) are now routinely utilized for DGM; however, users must develop complex workflows to manipulate, analyze, and combine information to generate geomorphological maps. Considerable energy is spent on learning GIS software and writing scripts/applications to produce parameters/indices and accomplish mapping tasks, as individual programs to map specific landforms or perform a specific type of geomorphological assessment do not usually exist. Currently, there are only a small handful of programs to produce
the most basic geomorphometric parameters, compared to the wide variety of parameters described in the literature.

The empirical nature of GIS analysis is extremely exploratory and dependent on traditional statistical techniques including statistical indices/metrics and the subjective use of weightings or sensitivity parameters to permit flexibility in obtaining results. It is important to understand that such empirical metrics do not necessarily characterize process or landform boundaries, but are recognized as proxies for fundamental landform properties. Most approaches to mapping attempt to decompose the altitude field based upon local criteria (i.e., homogeneity, heterogeneity, land-surface properties) in order to construct larger landforms or landscape spatial entities. Unfortunately, numerous geomorphological concepts are disconnected from analytical solutions, and a synthesis approach that accounts for knowledge and analytical reasoning is sorely needed. Nevertheless, GIT has been successfully used to address a variety of issues related to geomorphological concepts such as landform features, landscape and landform spatial organization, scale dependency, erosion mapping, deformation, uplift and neo-tectonics, landscape stability, hazards, process regimes, and relief production.

Mapping perspectives

Modern-day geospatial technologies permit the mapping of the functional and structural aspects of the land surface but different requirements dictate which mapping perspective should be used to address a DGM problem. For example, hydrological mapping is required to assess drainage networks and basins and the nature of surface runoff and stream/river flow. In the same way, assessing and mapping landscape evolution requires multiple perspectives that incorporate hydrological, geological, and morphometric information to characterize fluvial erosion, sediment transport, denudation, and relief production.

A common mapping perspective that has been widely utilized is the land systems approach. Mapping involves identifying spatial units that have a reoccurring set of land cover, topography, soils, and vegetation that characterize the climate, geology, and geomorphology. This approach tends to be limited to regional mapping because it depends on subjective criteria. This approach does not characterize the complex 3-D nature of landforms, although the inclusion of more quantitative information about the near-surface environment should allow for improved land systems differentiation.

Mapping from a geological perspective requires the integration of surface composition, mineralogy, and lithology with respect to geologic structure and tectonics. Hyperspectral remote sensing can be used to assess surface mineralogy and lithological variation. Image analysis and geomorphometry can be used for structural mapping efforts. Rock strength, deformation, and uplift can govern the topographic structure, as the interplay between erosion and tectonics may influence basin morphology, drainage density, relief production, and many other properties of the topography. There is considerable potential in using existing land-surface parameter algorithms to characterize subsurface data, as seismic, electromagnetic, and ground-penetrating radar data highlight subsurface properties, stratigraphy, and structure. Examining the substructure of landforms can provide a wealth of information for studying landforms and understanding the nature of polygenetic overprinting, as well as the role of the antecedent topography on landform evolution.
DGM can also be achieved from a morphometry and morphography perspective. As noted, the morphometry of the landscape characterizes the shape of landforms and the properties of the topography, while the morphography is the mapped description of the configuration structure. Maps of this type are rather rare, but maps of the fundamental first-order and second-order derivatives of the altitude field are common (Figure 3). These objects may be spatially aggregated and structured into a morphographic map. Producing multiscale morphometric parameters that characterize mesoscale properties of the landscape can greatly improve our understanding of processes and natural hazards.

Sediment transfer-cascade systems represent spatial structures that are interconnected by flows of mass and energy at various operational scales within the geomorphological system. For example, curvature can be used to delineate those portions of the landscape that depict mass movements within sub-basins and deposits of rock and debris at the base of valley floors. Such mapping provides the basis for development of models of sediment budgets.

Geomorphic genesis is a critical theme in mapping, as it serves as the basis for landform taxonomy. Process domain mapping is, therefore, an important goal of DGM. The ability to reliably depict a process domain, however, is notoriously difficult, as numerous surface processes and exogenic and endogenic forcing factors need to be accounted for. Furthermore, the complex nature of polygenetic evolution must be addressed, such that process–form relationships that are diagnostic in nature serve as the basis for mapping. For example, it is

Figure 3  Slope angle map (left) and unsphericity curvature map (right) over the western Himalayas in Pakistan. The morphometric properties provide insight into the distribution of geomorphological features and the processes responsible for their formation. Mountain valley floors and large alpine glacier surfaces exhibit relatively low slope angles (dark gray tones) and high unsphericity (white gray tones) values depict more planar surfaces. Steep slopes and high altitudes also depict relief production, while changes in the spatial variation of morphometric patterns also depict lithological variations (northeastern area versus the NW-SE central region).
very difficult to map a tectonic uplift zone, since the morphometry, morphography (the description of the morphology), and geological conditions must be differentiated from the surrounding landscape that is not undergoing uplift. Object-oriented mapping can be used to assess deformation and uplift by examining relief production, basin geometry, and drainage density and organization.

Mapping the age of landforms and surfaces is very difficult to accomplish using traditional geospatial technologies. There is a paucity of high-quality temporal data, so spatial information is often used as a proxy for time. For example, if the surface roughness of a particular landform is relatively high compared to another surface, that surface may be considered to be older if surface roughness is assumed to increase with time. This is complicated by the lack of spatial uniformity and (temporal) steadiness of the processes acting on the landscape. In many complex environments, rates of erosion and deposition are not accurately known; this has led to controversy in the literature about the role of different processes in the evolution of mountain systems and aeolian landscapes on Earth and on Mars.

The complexity of the landscape has required geomorphologists to adopt an empirical approach versus a more formal mapping framework or system based upon landform taxonomy, semantic modeling, knowledge, process–form relationships, and landscape evolution modeling (LEM). An argument can be made for both approaches based upon findings to date; however, the complexity of DGM seems to warrant a more systematic approach for addressing conceptual and technical issues. A variety of algorithms and approaches to DGM have emerged in recent years providing for new capabilities that should significantly advance understanding of landscape development and change. At the same time, advancements in geomorphology have identified a need and opportunity for geospatial technology solutions.

**Mapping issues**

Rapid progress in geospatial technologies has raised a number of questions concerning the conceptual and technical aspects of DGM. Bishop et al. (2012) discuss a variety of concepts, issues, and research directions for DGM, and highlighted the capabilities and limitations associated with geospatial technologies. In general, very few researchers have attempted to formalize DGM and account for the plethora of concepts that are important in advancing this part of geomorphology. There does not appear to be a consistent conceptual or analytical framework by which to map the landscape at multiple scales, although there is a need for new geospatial technology solutions to generate standardized information.

**Landscape complexity**

An ongoing and fundamental issue in mapping involves representing spatiotemporal data, as data models and structures do not currently account for the attribute and dimensional complexity of the landscape including the near-surface environment and critical zone. Static cartographic snapshots in time (i.e., GIS layers) do not adequately address spatial and temporal variation in terms of operational scale dependencies. Furthermore, entity models do not adequately account for environmental variation and the issue of indeterminate boundaries of landforms and phenomena. Object-oriented data models have been proposed, while others have indicated that a hybrid approach to representing the landscape with fields of objects enables flexibility and better integration of data and information. Choice of data structures is an
important consideration, as attempts are made to represent complex properties of geospatial data and permit efficient information extraction and storage. New representation schemes offer many new possibilities for DGM that can address boundary, geometry, topology, process, scale, and information integration issues.

**Semantic modeling**

Landform semantic modeling is another important topic. The terminology that is used to characterize and map landforms/landscapes can be different in a variety of disciplines and even within the same subdiscipline of geomorphology (e.g., ridge versus foredune in coastal environments). Formalization and repeatability in DGM is, therefore, dependent upon landform definitions that determine semantic representation of landforms. The main objective of semantic modeling is to provide for a correct semantic definition of landform that is useful to all disciplines, and to incorporate, composition, geometry, and spatial topological information, such that a semantic definition is consistent with taxonomic schemes and system dynamics. It is challenging to formulate basic definitions that account for human perception, process, scale-dependence, geometry, spatial topology, indeterminate boundaries (Figure 4), and a multitude of geomorphological concepts related to a specific environment. For example, mountain peaks (Figure 5) can be mapped with different spatial distributions depending upon the use of concepts such as summit, prominence, symmetry, scale, relief production, and total rock mass. Semantic modeling can be thought of as a way to bring together data and information, concepts, perceptions, and functionality that can be adhered to by different disciplines and applications. Semantic modeling and representation requires that error and uncertainty are explicitly addressed.

**Scale**

Another fundamental issue is the complex topic of scale. Numerous perspectives exist and geomorphologists should be aware of geographic, cartographic, measurement, operational, and computational scale definitions (Bishop et al. 2012). Inherent in any treatment of scale is the recognition of the complex linkages of spatiotemporal concepts and the multiplicity of spatiotemporal scales associated with phenomena, processes, and systems. Therefore, research into process–form relationships and the spatiotemporal organization of the landscape is fundamental to DGM. In particular, special emphasis must be placed on identifying the operational scale of processes and ensuring that this scale is linked to the computational scale at which data are analyzed and information is integrated. Another important scale concept is the
Figure 5  Field photograph of K2 located in Pakistan (8612 m). Many mountain peaks exhibit different geometric shapes, degrees of prominence, and scale-dependent relief. Many mountains are part of a ridge system that exhibits multiple summits. Humans perceive mountains in different ways depending upon their location and application interests.

anisotropic nature of spatiotemporal variation on the landscape, as the spatial structure of the topography can be highly directionally dependent through the influence of geologic structure and deformation, and the spatial variability and nature of surface processes (Figure 6).

Polygenetic evolution

Since dynamic simulations can be used to study the nature of polygenetic evolution, LEM is another critical issue related to DGM. Parameterization schemes that account for the conservation of mass and energy characterize the process mechanics of weathering, regolith production, erosion, deposition, and uplift by a variety of agents including the wind, water, ice, and gravity. Landscape simulations can be programmed to produce maps of landscape properties, the magnitude of processes, and depict the spatial distribution of process regimes. This is in contrast to simplistic spatial relationships that
Figure 6  Three graphs characterizing the anisotropic variation in relief for three points on the Texas Sand Sheet near Padre Island National Seashore.

are used to assess and map the landscape using GIS. Given that geospatial technologies and GIS are not yet well suited for addressing temporal concepts and spatiotemporal dynamics, LEM links process, morphometry, spatial topology, and additional information in a holistic way, such that landscape system characterization and mapping are possible. Such dynamic mapping capabilities are important to go beyond traditional space-dominated DGM.
Analytical reasoning

An important series of related issues that has not been adequately addressed includes knowledge representation, information integration, and analytical reasoning. Numerous developments in sensor technologies now provide more information about the landscape. Nevertheless, a multitude of challenges are faced regarding information integration and visualization of spatiotemporal data. A rigorous framework has yet to be established by which it is possible to associate or use data and information as proxies for important geomorphological concepts. Theoretical geomorphology is rich with spatiotemporal concepts and conceptual models that attempt to formalize our understanding of geomorphological processes and landform evolution. Recent developments in artificial intelligence and fuzzy systems allow current knowledge to be represented, multiscale data/information to be integrated, and analytical reasoning to be employed to assess and model landscape evolution based on direct and indirect causative relationships. This is required, as some aspects of geomorphological assessment and problem-solving do not appear to be mathematically tractable, or cannot be derived from first principles. Geocomputational approaches to DGM can be used to test the utility and significance of concepts and variables in LEM. This is demonstrated in the context of another issue related to validating conceptual models and field observations.

Analytical reasoning permits formalization of process–form relationships and information integration analogous to human cognition, and therefore can be used to examine internal and external geomorphic forcing functions that can be highly variable across a range of spatial and temporal scales. Geocomputational approaches can be quite powerful when integrated with new spatial and temporal data and various algorithms that make it possible to quantify landscape morphology, assess surface biophysical interactions, link process with form, and characterize the scale-dependence and polygenetic nature of the landscape. There is the potential for significant advancements in geomorphology if knowledge and conceptual understandings of landscape change can be formalized and tested through analytical reasoning. For example, aeolian instability can be predicted using an analytical reasoning approach through the formalization and conceptualization of understanding of how prolonged drought conditions limit the ability of vegetation and surface moisture to stabilize the surface (Figure 7).

Future directions

Geomorphological maps are an important source of information for studying geomorphological systems and the critical zone. They are also essential for assessing and managing natural resources and planning for sustainability. Their significance and utility is based upon information fusion and a systems integration perspective, as surface biophysical properties, landscape morphometry, spatial topology, and near-surface properties and structure can be represented, mapped, and visualized uniquely using geospatial technologies. Rapid advancements in sensor technologies, data collection, and analysis and modeling have brought about many new developments and capabilities. Access to data and information has dramatically increased, thereby increasing DEM availability and the impact of geomorphometry on geomorphology. There are, however, many data and representational issues with incorporating multispectral, multi-temporal, and near-surface information into a geomorphological mapping framework. This
Figure 7 South Texas Sand Sheet showing northern and southern lobes within the King and Kenedy Ranches (a). A simple analytical reasoning model was used to predict aeolian instability (Houser, Bishop, and Barrineau, 2015). The instability concept (aeolian transport or no aeolian transport) is the output of the model and predicted aeolian instability (dark speckling) is presented (b).

will require a more rigorous conceptual, representational, and information synthesis approach that includes advancements in geomorphology and GIST.

Advancements in science are driven by theoretical and conceptual developments from a variety of disciplines including GIST and geomorphology. Scientific progress has not kept pace with new and rapidly evolving geospatial technologies. Similarly, the scientific significance of various geospatial technology solutions has yet to be discovered in geomorphology and DGM. Consequently, research directions should attempt to focus on science–technology solutions for characterizing and understanding landform evolution and complex geomorphological systems. Geographers can contribute important solutions that enable the prediction of spatial landforms that result from forcing factors, processes, and polygenetic landscape evolution. This requires that knowledge and conceptual understandings are transformed into models, representation schemes, and analysis and modeling approaches that facilitate problem-solving and decision-making.

Geospatial technologies and numerical modeling will allow geomorphologists to formalize process–form and process–pattern relationships in the very near future. However, research involving new geostatistical approaches to analysis of spatiotemporal variation is sorely needed in order to characterize the complex evolution of landforms and landscapes over space and time. Furthermore, it is necessary to test model parameterization schemes to determine if external forcings, process mechanics, multiscale topographic forcings, and feedbacks are appropriately characterized and produce results that can predict landform evolution. Research involving the integration of LEM and DGM represents a new direction.

Progress is also required on formalizing geomorphological knowledge, evaluating and determining the utility of taxonomic schemes and semantic modeling to better formalize
DGM, and to make sure that information synthesis can be integrated into a spatiotemporal topological framework that permits consistent and repeatable results. While it is recognized that there is tremendous diversity in methodological approaches for addressing mapping applications, and that progress in mapping soils, vegetation, terrain, landforms, lithology, and other applications will continue, an integrative framework and standardized information products appear to be warranted. As Bishop et al. (2012) have indicated, progress in this direction will elevate the status of DGM in the science community and permit routine use of geomorphological maps in integrative science and practical problem-solving.

Further reading

The discipline of geomorphology has a long history that has been expertly reviewed by Chorley, Dunn, and Beckinsale (1964), Chorley, Beckinsale, and Dunn (1973), Beckinsale and Chorley (1991), Burt et al. (2008), and Orme and Sack (2013). The role of various national schools has been recounted by Walker and Grabau (1993).

Prior to the nineteenth century, geomorphology was hugely influenced by the belief that the Earth was created by divine intervention only 6000 years ago and had been molded subsequently by catastrophes like Noah’s flood. The time span for geomorphological processes to operate and for forms to develop was very brief. However, towards the end of the eighteenth century ideas began to change, and scientists such as Hutton, Playfair, and Lyell argued for the importance of gradual subaerial denudation over millennia. Gradualist and uniformitarian ideas took hold, the conception that the Earth was old and had a long history was appreciated, and the fluvialists argued for the dominance of rivers in denuding the landscape through slow, long continued action (Kennedy 2006). However, these radical ideas did not go unchallenged. There were some structuralists who believed that valleys were essentially clefts or rents in the ground surface rather than the product of stream erosion as had been maintained by Playfair. There were also the diluvialists who invoked the biblical Flood to explain many geomorphological phenomena.

The glacial theory

In the 1820s and 1830s some scientists started to suggest that glaciers and ice caps had once been much more extensive and could account for much of what was then called “drift.” The most famous exponent of the glacial theory was Louis Agassiz, who developed this concept on the basis of work in the Alps in his Discours de Neuchâtel (an address to the Société helvétique des sciences naturelles of 1837). The glacial theory was not well received by some members of the geological establishment. Lyell found that it was incompatible with his uniformitarian ideas, as in a sense it was, and attributed many of the allegedly glacial phenomena to marine submergence and wave action. Moreover, well into the twentieth century some British geomorphologists continued to argue that glaciers protected rather than eroded the landscape. The significance of the Ice Age beyond Europe was soon recognized and Agassiz’s views were adopted in the USA. A further major development in glacial ideas occurred in the 1870s when it became recognized that there had been more than one glacial advance and that these had been separated by warm phases, called interglacials. In addition, Croll recognized that orbital fluctuations could have caused multiple alternations of glacial and interglacial periods. These trends led to the work of James Geikie, who in The Great Ice Age (1874) appreciated the importance of interglacial periods, and to the
classic and durable Penck and Brückner model of glacial chronology in the Alps. Scientists also started to be intrigued by other sorts of climatic change that might have occurred in nonglaciated regions. Lake basins, of the type that abound in the Basin and Range Province of the American West, with their spectacular abandoned shorelines, gave particularly clear evidence of hydrological change. By the time of World War I a picture was emerging of the scale of climatic change that had taken place in lower latitudes and of the very substantial alterations that had taken place in climatic belts as made evident not only by desiccated or shrunken lakes, but also by old river systems and ancient sand dunes.

River valleys and the power of fluvial denudation

Although Hutton, Playfair, and Lyell had made clear the role of rivers in landscape development, the acceptance of fluvialism was not a straightforward matter as there were many phenomena that appeared to cast doubt upon whether valleys had actually been produced by rivers (Kennedy 2006). In the 1860s, however, geomorphologists began to appreciate once again that rivers molded valleys and were capable of achieving a great deal of geomorphological work and planation. There were various reasons for this. First, increasing acceptance of the power of former glaciers to cause wholesale transformation of the landscape and to produce features such as lake basins and hanging valleys explained away some drainage anomalies. Second, catastrophic/structural views on valley development were viewed with less favor. Third, when geomorphologists moved away from the relatively stable, sod-covered landscape of the British Isles to places like the Pacific islands or the mountains of Ethiopia, they encountered strong evidence of the power of rivers. Fourth, data on sediment loads of rivers demonstrated that they could indeed achieve a great deal of work. The power of fluvialism, however, became sealed as a fundamental concept in geomorphology because in the American West, including the Grand Canyon, there was abundant and dramatic evidence for the power of rivers. This had a great impact on American geomorphologists such as J.W. Powell, C. Dutton, G.K. Gilbert, and W.J. McGee. This work, together with that from French hydraulic engineers, was used in France to good effect by La Noë and Margerie. Their espousal of fluvialism transformed French geomorphology at the end of the nineteenth century.

Rock decay

During the nineteenth century great strides were made in the understanding of physical, chemical, and biological weathering processes (Goudie and Viles 2008). Knowledge of weathering phenomena owed a great deal to the development of an independent science of pedology, or soil science, most notably by scholars like Dokuchaev in Russia. One particular aspect of weathering-related studies was the science of limestone (karstic) relief and solution processes. Prime importance must be accorded to work on the Dinaric Karst and in particular to the extensive studies of Jovan Cvijić. His Das Karst-phanomen (1893), and many subsequent works, laid the theoretical foundations of many of our current ideas, though Serbian scholars had made some important studies before him.

Mountain building

During the nineteenth century there was considerable interest in how mountains formed and
in motions of the Earth’s crust. Suess in Austria and Dana in the USA proposed that mountains formed through compressive stresses generated by a gradual thermal contraction of the whole Earth. Suess argued that on a contracting Earth, mountains resulted from a wrinkling of the crust to accommodate a diminishing surface area. The contraction theory was the dominant paradigm for most of the nineteenth century (Oldroyd 1996, 171).

Another important concept was isostasy. This was made evident by studies in formerly glaciated terrains which would have been affected by downwarping and upheaval in response to ice cap advance and recession, respectively. This was the birth of the theory of glacio-isostasy. During his classic study of pluvial Lake Bonneville in the western USA, G.K. Gilbert found a dome-like pattern of uplift of former shorelines and inferred that this indicated hydro-isostatic recovery following lake desiccation. Using his experience from the American West, where many mountains appeared to be composed of igneous rocks intruded into sedimentary sequences, Dutton, who invented the term “isostasy” in 1882, argued that crustal deformation could be understood as a response to isostatic compensation. He postulated that uplifted portions of the continent are eroded, that material is transported to coastal regions, and that the weight of this material causes subsidence along the continental margins, which causes displacement of materials at depth, with this material moving laterally and producing igneous intrusions and further uplift of the continent. Gilbert built upon Dutton’s ideas and noted that in the Basin and Range Province mountain building was associated with many faults and with crustal extension rather than crustal contraction. The significance of crustal tension was also recognized by Gregory who, working in the context of East Africa, was the first to use the term “rift valley.” The hypothesis that mountain building could result from continental drift developed in the early twentieth century through the work of Taylor and Wegener.

Davis and the cycle

William Morris Davis was the leading American geomorphologist of the late nineteenth and early twentieth centuries. His great contribution was to produce in the 1880s and 1890s a deductive model of landscape evolution, called the cycle of erosion or the geographical cycle. Davis believed that landscapes were the product of three factors: structure (geological setting, rock character, etc.), process (weathering, erosion, etc.), and time (stage) in an evolutionary sequence. Stage was what most interested him. He suggested that the starting point of the cycle was the uplift of a broadly flat, low-lying surface. This was followed by a phase he termed “youth,” when streams become established and started to cut down and to develop networks. Much of the original flat surface remained. In the phase he termed “maturity” the valleys widened so that the original flat surface had been largely eroded away and streams drained the entire landscape. The streams began to meander across wide floodplains and the hill slopes became gradually less steep. In “old age” the landscape became so denuded that a low-relief surface close to sea level (a peneplain) developed, with only low hills (monadnocks) rising above it.

Initially Davis’s model was postulated in the context of humid temperate (“normal”) conditions, but it was then extended by Davis and successors to other environments, including arid, glacial, coastal, savanna, karstic, and periglacial landscapes. Chorley et al. (1973) argued that Davis’s cyclic model was not very successful in Germany. Here, W. Penck’s model of slope evolution, often seen as the antithesis of Davis,
involved more complex tectonic changes than that of Davis, and he regarded slopes as evolving in a different manner (by slope replacement rather than slope decline) through time. An alternative model of slope development by parallel retreat leading to pediplanation was put forward by L.C. King. His model, developed in South Africa, represents an amalgam of the views of Davis and Penck: episodic uplift resulting in both downwearing and backwearing, with the parallel retreat of slopes leading to the formation of low-angle rock-cut surfaces (pediments) which coalesced to form pediplains. By the mid-twentieth century the Davisian model was becoming less dominant. This was partly because there was a growing awareness of crustal mobility that could not sustain notions of initial uplift followed by prolonged structural quiescence.

Denudation chronology and long-term evolution

For geomorphologists, the explanation of how landscapes came to attain their present form has always been a major objective. Up to the 1960s, many workers adopted an historical approach to landscape evolution, their aim being to identify the sequence of stages of erosional development that demonstrated how contemporary landscapes had been sculpted from hypothetical initial fairly uniform and featureless topographies. This sequential approach came to be known as “denudation chronology” (Jones 2004). Classical denudation chronology sought to identify evidence of past planation surfaces and erosional levels in a landscape, in whatever way they formed, and to place them in a time sequence. During the first half of the twentieth century, this became a major preoccupation of geomorphologists in America, under the influence of D.W. Johnson, in Britain, where S.W. Wooldridge was a dominant figure, and in France, where H. Baulig’s study of the Massif Central established a blueprint for subsequent work. Since the 1960s there has been less interest in classical denudation chronology, for that decade witnessed the onset of radical changes to prevailing views of the past arising from growing knowledge about global tectonics and Quaternary climate change. Moreover, many geomorphologists concentrated on understanding the role of present-day processes rather than trying to establish a long-term evolutionary history based on often small fragments of ancient landscapes preserved in the present landscape. However, more recently still there has been an expansion of studies of long-term landform evolution based on such techniques as cosmogenic nuclide and apatite fission analyses. These can give us data on the ages of ancient landforms and on the rates at which they have been denuded over millions of years.

Climatic geomorphology

In the twentieth century, particularly in Germany and France, climatic geomorphology was a major approach. One strand of the development of climatic geomorphology was the study of periglacial and permafrost processes by European explorers of the vast subarctic regions of North America and Eurasia, though it was Lozinski who provided the first unifying concepts of periglacial geomorphology just before World War I. Other distinctive cold climate phenomena were also recognized, including nivation and solifluction. Among the phenomena that scientists studied in lower latitudes were loess, desert dunes, desert weathering, coral reefs, deep weathering, laterites, and inselbergs. Von Richthofen, working in China, cogently argued that loess, a largely nonstratified and nonconsolidated silt,
probably had an eolian origin and was produced by dust storms transporting silts from deserts and depositing them on desert margins. The colonization of the Sahara by the French from the 1880s onwards led to some of the first serious work on desert dunes. However, dunes were not the only field of interest of desert travelers, for the exploration of deserts in the nineteenth century gradually led to the emergence of studies that established the nature of desert processes and their differences from those in other environments. French scientists were very active in the Western Sahara and accumulated a great deal of vital information on the full range of desert landforms. Also notable was the work of Walther, who worked in the deserts of North Africa, Sinai, the USA, and Australia. His *Das Gesetz der Wüstenbildung in Gegenwart und Vorzeit* (1900) was the first full-scale book devoted to desert geomorphological processes and he championed the role of such mechanisms as thermal fatigue (insolation) weathering, salt weathering, and deflation. The development of ideas on the role of wind in drylands is discussed by Goudie (2008). Geomorphologists gradually came to see the distinctive nature of humid tropical landforms and processes and appreciated the extent of deep weathering and laterite formation in the tropics in comparison with higher latitudes. In the USA, Davis recognized “accidents,” whereby nontemperate and nonhumid climatic regions were seen as deviants from his normal cycle of erosion and, inspired by Passarge’s work in the Kalahari, he introduced his arid cycle. Some regard Davis as one of the founders of climatic geomorphology, although the leading French climatic geomorphologists, Tricart and Cailleux, criticized him for his neglect of the climatic factor in landform development. Much important work was undertaken on dividing the world into morphoclimatic regions with distinctive landform assemblages in France (e.g., Birot), Germany (e.g., Büdel), and New Zealand (e.g., Cotton).

**G.K. Gilbert and dynamic equilibrium**

G.K. Gilbert was a remarkable and innovative American geomorphologist whose name is most often associated with what is often termed “dynamic geomorphology.” This blossomed in the second half of the twentieth century, and was defined by Strahler as an approach which treats geomorphic processes as “gravitational or molecular shear stresses, acting on elastic, plastic or fluid Earth materials to produce the characteristic varieties of strain or failure which we recognize as the processes of weathering, erosion, transportation and deposition.” This is exemplified in Gilbert’s *Report on the Geology of the Henry Mountains* (1877), his study of the convexity of hill tops, and his work on the transportation of debris by running water. In some areas of geomorphology, studies based on an analysis of force and resistance occurred earlier than in others (e.g., Terzaghi’s work on slopes and rock mechanics in the 1920s, Bagnold’s work on eolian forms and processes in the 1930s, Hjulström’s studies of processes in gravel rivers in the 1930s, the work of various physicists, such as Nye, Glen, and Perutz, on glacier dynamics in the 1950s, and Johnson’s study of shore processes and shoreline development).

**The latest phase**

Since the 1960s there have been at least four major developments – plate tectonics, the revolution in Quaternary science, quantitative process-oriented geomorphology, and the use of remote sensing – that have taken place. These
have been reviewed by Burt et al. (2008) and Orme and Sack (2013).

Particularly since the 1960s, geomorphology has been concerned with the study of exogenic processes, often at a detailed and Newtonian reductionist level. Indeed, there are two major types of Earth surface process, generally labeled as exogenic and endogenic. This produces a paradox in terms of temporal scales. The former refers to processes that are ultimately fueled by the sun’s energy and usually operating through the climate system, such as weathering of rocks and erosion and sediment transport by water, ice, wind, waves, and organisms. This has often involved studies with a short timescale and at a local spatial scale. Classic and influential examples of this genre are that by Leopold and coworkers on fluvial processes (1964) and that by Yatsu on weathering (1988). Endogenic, on the other hand, refers to those processes powered by energy from the inside of the Earth, such as volcanic and tectonic processes. These operate over long timescales and large regional extents. They have received increased attention as a consequence of the plate tectonics paradigm that has developed since the 1960s, and have contributed to a greater understanding of the global pattern of phenomena such as volcanoes, rifts, mountains, and seamounts. Remote sensing has enabled the mapping and identification of landforms at a regional or global scale. Endogenic processes have also contributed to our knowledge of rates of denudation and channel incision in areas of orogeny. Some of the most interesting current work has shown that climate, as well as the erosional development of the landscape, feeds back into the ongoing tectonic processes. The study of rates of chemical weathering and physical denudation under different climatic and tectonic conditions has been boosted by a concern with how these processes relate to the global carbon cycle. The reductionist exogenic process geomorphology and the new models of long-term landscape evolution, associated with new ideas on plate tectonics and novel geochronometric techniques, need to be combined more effectively than in the past.

The revolution in Quaternary science, much of it resulting from studies of ocean cores, has revealed the duration, frequency, magnitude, and timing of climatic changes in the Late Cenozoic. New dating technologies and methods for reconstructing past environments have been fundamental (Anderson, Goudie, and Parker 2013).

Processes have been studied in detail using new methods of instrumentation, including data loggers, flumes, wind tunnels and the like, but above all geomorphologists adopted quantitative methods (including morphometry), statistical analysis, systems thinking, and model building. Among the processes that have received major attention are those associated with the role of plants and animals, as shown by the emergence of biogeomorphology and zoogeomorphology as major subdisciplines.

Geomorphologists have become much involved with the application of their science and with the investigation of a range of natural hazards. The roles of the geomorphologist in hazard research are many. Of great importance are: the mapping of hazard-prone areas; constructing the history of occurrence of past hazardous events; establishing their frequency and magnitude; predicting the occurrence and location of future events; identifying sources of sediment in catchments; monitoring geomorphological change; and using knowledge of the dynamics of geomorphological processes to advise on appropriate mitigation strategies. In recent years the capabilities of geomorphologists in these roles have increased and the application of geomorphology to the solution of environmental problems has developed. Techniques such as remote sensing
and geographic information systems (GIS), dating (by means, for example, of lichenometry, optical luminescence, and dendrochronology), instrumentation of slopes and other phenomena with data loggers, and computer modeling, have all made major contributions. Geomorphologists are involved with designating and advising on the conservation of geomorphological sites that are of especial value as World Heritage sites, Geoparks, and Geosites. They have also developed a belated interest in the geomorphological consequences of future global changes. Climate change will work in tandem with various anthropogenic activities, including changes in land cover and land use. Geomorphologists have also recognized that submarine geomorphology is an important field, not least for assessing the development of offshore hydrocarbon reserves, as has occurred, for example, on the Nile delta and the Angolan and Congo fans. Landslides, turbidity currents, salt dissolution features, and the like pose problems for pipelines and rigs. Another burgeoning area of international research is into the geomorphology of other bodies in our solar system, such as Mars, Titan, and Venus.

Geophilosophy

Keith Woodward
University of Wisconsin–Madison, USA

Geophilosophy employs a range of spatial concepts to reimagine the discipline of philosophy. Invented by French philosophers Gilles Deleuze (1925–1995) and Félix Guattari (1930–1992), it does not constitute a formal intervention in or contribution to the discipline of geography. Rather, the “geo” prefix offers several challenges to widely held views that philosophy: (i) concerns the historical progress or development of reason and (ii) entails the search for “transcendent” (top-down) truths. Recognizing that the history of philosophy “is marked by detours and contingency,” Deleuze and Guattari (1994, 88) create a system of spatially distributed concepts, each of which is “immanent” to (bottom-up, emergent from) its complex situations (for example, its relations to its own “internal” components and to other “external” concepts). “[T]hinking,” in other words, “takes place in the relationship of territory and the earth” (Deleuze and Guattari 1994, 85). Geophilosophy remains concerned with abstract philosophical ideas (“concepts”), but does not view these as generalizations detached from site-specific, messy materialities. Instead, geophilosophical concepts are “differential”: they emerge with the contingencies of sociospatial differences and encounters, of proximity and entanglement, and of dynamic material relations.

Although geophilosophy is not formally named until What is Philosophy? (1994), it arguably runs throughout Deleuze and Guattari’s collaborations. The geographical lexicon provides Anti-Oedipus (1969) and A Thousand Plateaus (1980) with several key concepts that reconfigure the stakes of philosophy, most notably de/re/territorialization, landscapity, and milieu. Spatial abstractions (lines, planes, smooth and striated space) also play prominent roles in these works. Further, in A Thousand Plateaus, Deleuze and Guattari are careful to identify the practice of mapping (as opposed to tracing) with several elements associated with difference and openness. All of these are implemented primarily to address and transform philosophical problems. Still, geophilosophy’s theoretical innovations have since spurred new developments in geographic theory and practice.

Geography was slow to embrace Deleuze and Guattari during its “poststructuralist” heyday. It was not until the 2000s that they began to figure regularly in critical geographic interventions. One of the benefits of “differential” theories such as geophilosophy is that they lend themselves to seemingly infinite theoretical variations. For this reason, this entry does not exhaust geography’s many interrogations, redeployments, and applications of Deleuze and Guattari. After assessing geophilosophy’s critical tradition and key concepts, it reviews several major incorporations by geography: the role of “minor theory”; the spaces of the body examined by nonrepresentational and affect theory; the “ontological turn” that reexamined
GEOPHILOSOPHY

the nature of space from the perspective of difference; and new geographic approaches to human–environment relations inspired by “new materialism,” “vital materialism,” and the “zones of indiscernibility” between the human and the nonhuman.

Philosophy and geography

The name “geophilosophy” takes its cue from several earlier twentieth century experiments with the prefix “geo” by nongeographic disciplines. In addition to the well-known concept of “geopolitics,” the most prominent among these are French Annales School historian Ferdinand Braudel’s “geohistory” and adaptations of Portuguese psychiatrist François Tosquelles’s milieu therapy known as “geopsychiatry.”

Geohistory concerns broad sociospatial structures (such as the conditions of capitalism) that repeat through everyday social lives in disparate spaces and across long durations of historic time. As Braudel puts it, geography “helps us to rediscover the slow unfolding of structural realities, to see things in the perspective of the very long term,” which he describes as “the almost imperceptible movement of history” (Braudel 1972, 23). This structural perspective guides his history of capitalism, which asks why it emerged successfully in Europe when similar favorable conditions had not engendered it elsewhere during previous centuries. Incorporating social and physical geography helps Braudel avoid teleological narratives in favor of complex spatial conditions that accompany lengthy historical periods. Thus, geohistory uses geography as “no longer an end in itself but a means to an end” (Braudel 1972, 23).

Geopsychiatry adapts sociospatial connections in local communities for psychotherapeutic ends. During World War II, Portuguese psychiatrist François Tosquelles brought “milieu therapy” to the French psychiatric hospital in Saint-Alban en Lozère. He argued that, rather than hiding patients behind the walls of institutions, they should be encouraged to immerse themselves in the surrounding communities. Due in part to the presence of the resistance fighters it sheltered during World War II, the hospital became “an open place integrated into local life and involved in what the Société du Gévaudan called ‘geopsychiatry,’ which coordinated psychiatric and traditional local activities” (Dosse 2010, 42). The French therapist Jean Oury brought geopsychiatric practice from Saint-Alban to the experimental psychiatric clinic La Borde, where it would be enlisted in Guattari’s own therapeutic practice.

“Philosophy is a geophilosophy,” Deleuze and Guattari explain, “in precisely the same way that history is a geohistory from Braudel’s point of view” (Deleuze and Guattari 1994, 95). In beginning to grapple with this proposition, consider Deleuze and Guattari’s rejection of Western philosophy’s historic privileging of reason. In response, they identify philosophy with the supreme geographic concept: contingency. Following Braudel, they describe the birth of philosophy as a lucky accident that arose from many contingent sociogeographic relations. The victory at the Battle of Salamis in 480 BCE, they explain, freed Greece – for the first time – from the constant threat of Persian conquest. The subsequent period of newfound political autonomy and, for a time, cooperation among the city-states of the Delian League introduced transformations to Greek social, cultural, and political life. This “milieu of immanence” (Deleuze and Guattari 1994, 87) was friendly to philosophy, but the Greek sociopolitical and educational environments were hostile to philosophers. Consequently, the pre-Socratics took their education in Egypt and subsequently brought that knowledge back to Greece. Thus
while the Greek deterritorialization (political autonomy and cooperation) fostered new social and political ideals that philosophy would embrace—“immanence, friendship, and opinion” (p. 88)—it was the arrival of minor outsiders (Egyptian philosophers) into that milieu that gave rise to the Western philosophical system. In other words, Deleuze and Guattari suggest, the hallowed questions that have guided Western philosophy’s search for truth may well be the products of historical accidents and contingent geographic proximites.

While the history of philosophy will matter to few geographers, many attach importance to the broader implications of this geophilosophical reading. It suggests that philosophy and social theory are not the products of pure abstractions, historical structures, or “armchair thinking.” Rather, Deleuze and Guattari insist that theory arises from complex, situated, and contingent relations in sociospatial life. This liberates thought and theory from Western pretenses about necessity and truth. Further, it places geography in a pivotal—if differential—position with respect to the creation of theory and the work of theorizing. Geography, Deleuze and Guattari suggest, is more than just “physical and human, but mental, like the landscape. Geography wrests history from the cult of necessity in order to stress the irreducibility of contingency” (1994, 96). In aligning geography with “thought” (normally the domain of philosophy), geophilosophy presents the Earth as a plane upon which concepts and materials arrange themselves, create systems, solidify, create new arrangements, or simply explode.

Geophilosophy

The centrality of contingency likewise plays a role in the way that geophilosophy is performed. When Deleuze and Guattari identify the philosopher’s task with the creation of concepts, they are once again describing a spatial process. Each concept, they argue, consists of multiple internal elements (for example, “geo” and “philosophy” or “geo” and “psychiatry”) that operate in proximate relation to one another and create a novel concept whose meaning, as we saw above, is constituted by those interacting elements. Thus, on the one hand, a concept is a “multiplicity,” a system composed of complex entries, exits, and intersections (much like rhizomes or maps). On the other hand, a concept is a “singularity”: its meaning is specific to its particular constitutive elements.

Concepts also have external relations: they sit in proximity to or distance from other concepts. For example, Deleuze and Guattari do not identify geophilosophy with geohistory, but rather place the former in proximate relation to the latter. Geophilosophy operates in a similar way to Braudel’s concept, but with very different internal elements. Finally, concepts always operate within a field of problems that Deleuze and Guattari call a “plane of immanence”; that is, the “image of thought” (a way of thinking) that serves as the “prephilosophical intuition” (or, nonphilosophical given) upon which each philosopher constructs concepts. Occasionally, a philosopher creates a new problem that gives rise to a new plane of immanence. Descartes’s famous formulation “I think, therefore I am,” for example, created a new way of thinking about the relationship between thought and existence that happened to take for granted (as a prephilosophical intuition) the status of the “I.” Many others would add further concepts to Descartes’s new plane of immanence until Kant introduced a new plane through the creation of the “I” as a philosophical concept (Deleuze and Guattari 1994, 52–56).
A Thousand Plateaus is a treasure trove of concepts and planes (which Deleuze and Guattari sometimes call “plateaus” or “planes of consistency”) drawn from a range of different disciplines – anthropology, history, linguistics, literature, politics, political economy, and sociology, among others. There, the “multiplicity” offers a corrective of sorts to social theory’s tendency to represent the world’s complexity through a relatively small, relatively simple set of structures. Deleuze and Guattari turn to these many disciplines to exhume their differential thinkers and ideas: particularly those who developed strategies for describing multiplicity and variation in opposition to overarching structures. Matching these “minor” thinkers, Deleuze and Guattari develop an approach that discovers small similarities (or “repetitions”) in lines of thought from multiple disciplines. Each chapter in the book proceeds like a transversal line intersecting several other disparate lines. For example, their geometrical concept “numbering number” aligns, among other things, the politics of antistatist social formations with a character’s irregular steps in one of Frank Herbert’s Dune novels and with Julia Kristeva’s feminist treatment of semiotics in art and science. Thus intersecting proximate and contingent fields, disciplines, and problems, A Thousand Plateaus models several strategies and methods for creating concepts.

Geographic concepts guide many of these multidisciplinary encounters. However, contemporary geographers have been better served where they have been cautious with respect to geophilosophy’s geographic elements. For much of the twentieth century, French geography remained intoxicated by the work of Vidal de la Blanche, whose geographical approaches tended to be static and literary (Dosse 1997, 314–315). Although it is not clear what degree of exposure Deleuze and Guattari had to the discipline, it was almost certainly geography in the Vidalian tradition. It was not until the mid-1970s that French political geographer Yves Lacoste founded the critical geography journal Hérodote, whose first issue featured “Questions on Geography,” the famous interview between its editors and Michel Foucault. A Thousand Plateaus’ concept of “landscapity” draws upon “Paysages,” Maurice Ronai’s article on landscape from the same issue of Hérodote. Ronai links landscape to “a very particular semiotic system and very particular apparatuses of power” and argues that landscape is “one of the sources of geography, as well as one of the sources of its political subordination (the landscape as ‘the face of the fatherland or nation’)” (Deleuze and Guattari 1987, 533). However, such engagements with critical geography are rare. The majority of Deleuze and Guattari’s geophilosophical concepts arise from transversal encounters with the more traditional, conservative lines of French regional geography. Among these, their adaptation of “territoriality” (along with deterritorialization and reterritorialization) is the best known. For geophilosophy, this set of spatial concepts describe the process by which gathering of bodies (organisms, materials, or even utterances or concepts) constitute a territory by occupying a space. The concepts are differential because they incorporate the dynamic ways that those spatial relations also “deterritorialize” – depart to “reterritorialize” on something else. Deleuze and Guattari’s great transversal innovation is that this process characterizes not only political geographic relations, but also those of affects on areas of the body, capital flows across the Earth, ideological investments in a social field, and even thought itself. Indeed, they claim that the last of these processes holds revolutionary potential for geophilosophy and fuels the creation of a “new Earth.”
Deleuze and Guattari did not receive broad, sustained critical attention in geography until the 2000s. Throughout much of geography’s “poststructuralist” period, they remained overshadowed by their contemporaries – especially Michel Foucault and Jacques Derrida – due in part to critical geography’s excitement over semiotics and epistemology (the study of knowledge) in the wake of the cultural turn. Added to this, many thinkers across the social sciences and humanities during the last quarter of the twentieth century were deeply critical of the Western ontological tradition. Ontology was dominated by a small group of privileged white males who, despite the narrowness of their demographic, tended to insist upon the universality of their experience and their claims about the nature of existence. Consequently, many critically oriented human geographers rejected ontology in favor of a more dynamic set of epistemological problems that explored the circulation of power relations within language, signs, and discourse. Unlike Foucault, Derrida, and many others, Deleuze remained a metaphysician. While his collaborations with Guattari covered a range of concerns from politics to ethics and semiotics to psychology, they are ultimately contributions to ontology – albeit, an ontology that differs greatly from the Western tradition.

Because Deleuze and Guattari figured only marginally in geography’s early treatments of postmodernism and poststructuralism (1980s–1990s), they were sometimes conflated with the projects of very different thinkers, such as Derrida’s deconstruction. By the mid-1990s, Marcus Doel published a series of papers that singled out Deleuze and Guattari’s project, and celebrated certain thematic elements that he claimed shattered contemporary geographic spatiality – particularly the in-between-ness of “becoming” (as opposed to “Being”) and the inclusivity of the “and” (as opposed to the “or” of dialectics). This offered helpful first steps, but such treatments also deepened misunderstandings by emulating Deleuze and Guattari’s quirky prose and fetishizing the liberatory dimensions of their thought at the cost of ignoring their cautiousness. A more careful and faithful early reading appeared in Cindi Katz’s (Katz 1996) analysis of “minor theory.” If “major” theories tend to deal in titanic dichotomies such as “nature/culture,” minor theory concerns the many entry points that such abstractions overlook. The “major” attempts to identify and capture the entirety of the world within its two categories. The “minor” seeks to describe the rich variety of differences that arise through grounded relations. Appearing at a moment when geographic debates over Marxism and feminism had reached an impasse, Katz’s contribution helped introduce geography to an alternative language that embraces difference as a positive element in political theories and struggles. The appeal of minor theory can still be glimpsed today, for example, in efforts by the Zapatistas and the World Social Forum to create modes of global solidarity that connect disparate social movements.

During the late 1990s, interest in acute variations in bodily affections and perceptions, along with the openness of the body to its outsides – the geophilosophy of the body, if you will – gave rise to “nonrepresentational theory.” This area, spearheaded by Nigel Thrift’s explorations of the embodiment and affect, studies of bodily relations that occur without (or before) presenting themselves to conscious, intentional thought. It draws extensively upon Deleuze and Guattari by challenging the sovereignty of subjectivity and emphasizing instead bodies’ constitutive engagements with externalities and environments. Nonrepresentational geographers such as Mitch Rose and John Wylie, for example, employed
GEOPHILOSOPHY

geraphical problems to build rich studies
that re-center landscape as a formative element
in embodiment, subjectivity, and politics.

In 1996, Jane Jacobs wrote a brief introductory
commentary in *Environment and Planning D*
that gathered many of Deleuze and Guattari’s
geographical borrowings under the umbrella
title “geophilosophy.” Nearly a decade later, in
2004, Mark Bonta and John Protevi’s *Deleuze
e Geophilosophy* offered an extensive glossary
of Deleuzoguattarian concepts drawn from
geographic discourse. Inspired by the work of
philosopher Manuel DeLanda, who situates
Deleuze and Guattari’s project in the context of
science, Bonta and Protevi’s treatment empha-
sizes the real and potential relationships between
concepts and the complex environments and
ecosystems. *Deleuze and Geophilosophy’s* focus
upon natural systems and physical science antici-
\(\ldots\)pated geography’s “ontological turn” during
the mid-2000s – the period during which
Deleuze and Guattari achieved greater critical
prominence. During this time, for example,
Sallie Marston, John Paul Jones III, and Keith
Woodward’s (2005) rejection of geography’s
epistemological darling, scale, in favor of “site
ontology” – immanent, site-specific accounts
of complex spaces – was largely inspired by the
“differential ontology” of Deleuze and Guattari.

By the late 2000s, geographers increasingly
invoked geophilosophy to articulate spatial com-
plexity in a variety of contexts. In his critique
of capital and agrarian development in India, for
example, Vinay Gidwani (2008) contrasts the
political complexities of geophilosophy with the
almost Manichean dichotomies of traditional
development discourse. Yet, Gidwani avoids
privileging minor or major tendencies, recog-
nizing that each works off the other, producing
complex situations on the ground. Thus, for
example, the limited connections between privi-
leged and marginal social bodies and the rigid
protocols that further curtail their interaction can
be momentarily overturned by the contingencies
of policy decisions. Development becomes “an
abstract machine that reorganizes the condi-
tions – or ecology – of human life for its better-
\(\ldots\)ment” (Gidwani 2008, 70) but that remains
problematically inconsistent. Other thinkers bring
geophilosophy to bear upon complexities engen-
dered by social difference and localized bodily
movement. Arun Saldanha (2007), for example,
examines the arrangements, arrivals, and depar-
tures of different racialized groups within
shared public spaces (de/re/territorialization) as
dynamic components in localized dimensions of
sociospatial viscosity.

Extending beyond the sociospatial dimensions
of Deleuzoguattarian approaches to geography,
the early 2010s have been characterized by an
interrogation of “new materialism” or “vital
materialism,” which draws upon the ontolog-
ical turn to trouble the difference in lingering
dichotomies such as human/nonhuman and
life/environment. For thinkers, such as Bruce
Braun (2015), this has meant wrestling with
the entanglements between differential, non-
linear treatments of nature and neoliberalism’s
efforts to capture these emerging perspectives
in its governance apparatus. Others employ the
Deleuzoguattarian concept “assemblages” (or
*agencements*: a collection of disparate materials
that displays active organizational characteris-
tics) to describe complex aggregates of organic
and inorganic material. This has inspired some
geographers to consider socioenvironmental
implications of, for instance, corporate and
governmental experiments in “biomimicry”
(the robotics engineering that mimics biological
organisms). Elizabeth Johnson (2010) explores
techo-science’s current efforts to “‘reverse engi-
\(\ldots\)neer …’ the observable behaviors expressed in
\(\ldots\)ological life” (2010, 179) and their implications
for new regimes of technology, environments,
and “biomimetic capitalism.” Johnson is wary to make too much of what appear to be strong Deleuzian currents of affectivity in such experimentation. Suffice it to say that biomimetic techno-science involving in/organic physiological movement and its potential capitalization intersects multiple lines from diverse planes (biological, technical, social). Finally, projects such as Johnson’s introduce important questions about the potential gap between, on the one hand, geophilosophy’s countless exciting theoretical possibilities and, on the other, its evacuation of many of the moral and political guardrails found in traditional social theory.

A new Earth?

This is not to say that geophilosophy does not offer nuanced approaches for engaging political questions of oppression and revolt. However, these have definite limits. Because it is grounded in contingency and immanence, geophilosophy is incapable of offering prescriptive transcendent or general statements: “Not being a power, philosophy can’t battle with the powers that be, but it fights a war without battles, a guerrilla campaign against them” (Deleuze 1995, vii). What does such a campaign mean in an era of “global,” deterritorializing capital and environmental crisis? Near the close of each of their major collaborations, Deleuze and Guattari describe geophilosophy as a system capable of thinking a “new Earth” (Deleuze and Guattari 1987, 510). This is not an appeal to utopianism, a concept that remains subject to history (Deleuze and Guattari 1994, 110). Rather, their new Earth is associated with “absolute deterritorializations” and “becomings” that are “more geographical than historical” (p. 110). In short, a new Earth is rendered possible by the ability to experiment with new modes of thinking and to invent a “new people” (p. 101).

Geophilosophy offers, in other words, a revolutionary dimension of a philosophy capable of thinking in terms of contingency and difference: a differential political thinking.

GEOPHILOSOPHY

Further reading

In 1943, German sociologist, Werner Cahnman (1943, 56), offered a definitive conspectus of geopolitics:

The features of significant parts of the earth’s surface as explored by geographers provide Geopolitics with a framework into which political events must fit themselves if they are to lead to success in the long run. To be sure, the actors upon the political scene are free to depart from such a framework now and then, but the close relationship of political events to the earth’s surface will certainly make itself felt sooner or later. (Cahnman 1943, 56; emphasis by entry author)

According to Cahnman, the influence of environment over the actions of humans is considered to be a natural rather than a historical relationship in geopolitical thought and practice. Essentially, Cahnman is engaging in a form of environmental determinism insofar as he upholds that the environment, conceptualized as the “natural world” that exists “out there,” is the primary cause or determining factor in geopolitical interactions and activities.

The intricate relationship between geopolitics and the (physical) environment, as highlighted by Cahnman, is not an intuitive one. In the field of international relations (IR), for example, it has been argued that political realism (often simply known as realism), which focuses on the military security of states to the neglect of other factors (including environmental ones) in shaping world politics, has been the dominant approach/perspective (Walker 1993). Realism is often associated with the “Westphalian model” of world politics that involves a world allegedly characterized by the territorial sovereignty of states, an anarchic international arena, legal and political equality between states, the inherent right of states to use force to settle disputes, and limited interstate cooperation. For many IR realist scholars, political life embodies a fundamental contrast between life inside and life outside of the state. Within the state, it is possible to live the “good life” and to become part of society characterized by citizen, community, and culture. Outside the state, the notion of an international community of people is effectively abandoned and replaced by an interpretation that judges IR to be populated by self-interested states motivated by their own agendas rather than collective improvement. The principal political force here remains the nation-state, with war, violence, and uncertainty constituting global norms as struggles for power ensue among different state actors.

Those who believe that the Westphalian model does not adequately capture the complexities of modern political life have, however, hotly disputed realist views of politics. One line of criticism is leveled at the approach favored by IR realist scholars, who seem to be more concerned with the role and behavior of states, to the detriment of other agents such as firms, non-governmental organizations, and international
bodies, whose contributions are often significant in shaping distinctive political agendas. But, more crucially, there have been serious concerns raised about the tendency of realists working in the IR tradition to view the international system as an anarchical domain occupied by states (regardless of their social and cultural backgrounds) that function in an undifferentiated manner. According to Singer (1981), interactions between states do not operate in a vacuum and IR research will be severely impoverished if the role of the environment is being ignored. In his words, “most of the variations in the behavior of nations in conflict will be accounted for, not by their internal attributes, but by variation in their environment” (Singer 1981, 7; emphasis by entry author). Interestingly, Singer’s notion of a geographically sensitive analysis of IR can be located in the early works by (classical) geopolitical writers. Traditional geopolitics has similarly been underwritten by many of the assumptions of realism concerning the nature of the international arena and the significance of state sovereignty and national interests. However, in contrast to realist conceptions of world politics, political geography and geopolitics have focused on the power of the (physical) environment (e.g., land and sea) in shaping IR. Classical geopolitical scholars such as Mackinder (1904) endowed the “Heartland” of Eurasia with the potential to influence world politics at the expense of the so-called rimlands and surrounding outer crescents (Figure 1). Geographical features, characteristics, and divisions in this sense were considered timeless, and thus immune to human alteration. Geography was, thereby, reduced to the role of simply providing a territorial stage on which the interactions of states unfolded.

Mackinder’s work, alongside other classical geopolitical writings, is representative of what O’Lear (2013, 305) terms as “realist-inspired geopolitics of the environment.” What this essentially means is that an objective characterization of the world’s natural environmental features underpins the study of statecraft and the divination of patterns of global politics. In such a formulation, geopolitics has an intellectual value given its capacity to uncover the environmental challenges facing different states so that their vital interests can be protected through force if necessary. But as this entry will illuminate, the rise of critical approaches in geopolitics has raised important questions about the problematic assumptions that belie the seemingly neutral relationship drawn between the environment and military geostrategizing at a global level. Specifically, by adopting a critical geopolitical perspective in looking at how two contemporary environmental concerns – climate change and resource scarcity – are bounded up with geopolitical calculations and praxis, there is a wish to underscore the ways in which power is fully implicated in environmental overtures of geopolitics. This entry simultaneously embodies an effort to go beyond criticism in order to rethink environmental geopolitics for ushering in modes of living that are not only socially just but also ecologically less destructive.

Critical geopolitics, power, and the environment

As a broad set of writings that first emerged in the early 1990s, critical geopolitics came under the radar of the geographical discipline through the seminal works of O’Tuathail and Agnew (1992) and O’Tuathail (1996). This pioneering research quickly proliferated into an extensive array of publications that helped to shape the intellectual boundaries and trajectories of the now established field of critical geopolitics. Influenced by poststructuralist philosophies
particularly emanating from Michel Foucault and Jacques Derrida’s works, the key concern for critical geopolitics is to expose and challenge the various mappings of dangers, risks, and threats used to legitimate political power. If such a perspective is applied to look at the interface between geopolitics and the environment, epistemological pathways are opened up to “decode narratives about how environmental features pose risks to society and how environmental resources empower society and narratives about dangerous or desired human-environment interactions” (O’Lear 2013, 305). This is reminiscent of Castree’s reminder that although environmental problems may be real, there is no one singular, “best” solution to tackle such problems. Instead, he urges us to examine the geopolitics behind representations of environmental problems – the dominant discourses that define and establish the norms for managing environmental challenges – so as to “contest existing geopolitical arrangements, uncovering power relations inherent in them and the possibilities for more just interstate relations” (Castree 2003, 437; original emphasis). In other words, it is imperative to delve deeper into whose perspectives on environmental geopolitics are being privileged and whose interests are being marginalized in the process.

This is not to suggest that classical geopolitical engagements with the environment are no longer relevant and are replaced by these critical theoretical impetuses. Contrary to that, the project of critical geopolitics exists precisely to cast watchful scrutiny on the continued proliferation of classical variants of geopolitics with their echoes of environmental determinism. The latest revival of classical geopolitics is what Megoran (2010, 187) calls “neoclassical geopolitics,” which refers...
to “ways of thinking about the effects of geography on IR that explicitly locate themselves within the Mackinder–Haushofer–Spykman tradition, but which creatively rework it with reference to changed social, economic, political and cultural factors.” One widely cited example of neoclassical geopolitics is Robert Kaplan’s 2012 book, *The Revenge of Geography*, where he adapts Mackinder’s compelling slogan “Man [sic] and not nature initiates, but nature in large measure controls” to account for geopolitical patterns and developments in current times. Geography, according to Kaplan, remains the biggest shaper of geopolitical forces and the map will provide good indications of where the major geopolitical fault lines lie. Within this formulation, Kaplan (as with Mackinder) uses “geography” and “the map” as synonymous with the physical environment. He goes on to gather up select trends and presents them as ominous threats to what is implicitly held to be the benign world order secured by American military power. In particular, he points out that population growth threatens to fill out the empty spaces on the map and create a conflict over scarce resources as states compete for territory, food, and water. These compounded problems of economic destitution, environmental degradation, and violence would be most gravely felt in the poorer parts of the world, which will turn them against the economically advanced nations such as the United States. Kaplan’s message is thus clear: America needs to recognize that these circumstances have destabilizing effects to world order and should thus take proactive steps to alleviate such threats.

In contrast, geographers such as Simon Dalby, Juliet Fall, and Gerald Toal have engaged in critical geopolitical readings of Kaplan’s work. They argue that Kaplan’s thesis hinges on sweeping generalizations and is limited in explaining the actual situation on the ground. Dalby (2007) highlights how Kaplan conveniently ignores larger structural factors, such as the geohistorical context of violence and environmental degradation (e.g., colonial politics and neocolonial arrangements), in shaping geopolitical outcomes of those “less developed” and “threatening” places that he talks about. Toal, on the other hand, points out that by tenuously linking environmental scarcity with geopolitical violence, Kaplan’s agenda appears to be closely tied to America’s hegemonic interests on the world stage. In sum, these disparaging voices draw on a critical geopolitical perspective to question a realist geopolitical representation of the environment.

This example clearly exemplifies how different geopolitical traditions have diverging conceptions of the environment. While classical geopolitics equates the environment with the “natural” world that has circumscribing effects on human behaviors (see entry on Nature), critical geopolitics has refuted the idea of an ontologically separate environment that is outside of human existence by focusing on how the environment is represented, used, and impacted by different actors in the pursuit of specific geopolitical agendas. In recognizing how human activities and wellbeing are entangled and intertwined with the environment in multiple and complex ways, critical geopolitics share similar concerns with recent discourses about the Anthropocene. Indeed, there is increasing consensus that human activities and technologies have produced alterations to the biosphere at an unprecedented scale, prompting some Earth system scientists to conclude that a new geopolitical era known as the Anthropocene is being ushered in (Crutzen and Stoermer 2000). Although placing humans at the heart of environmental change, the Anthropocene does not, however, imply that everyone is equally exposed to both environmental benefits and impacts. As Dalby (2007) has pointed out, acknowledgments of
the Anthropocene must be accompanied by critical investigations into the power geometries that have led to disparities between groups of people and between the environments they inhabit. In other words, attuned attention must be bequeathed to understanding the dominant economic and political structures that manipulate environmental systems to create staggering gaps between “haves” and “have-nots” in terms of economic wealth and environmental health (O’Lear 2013). Such is the role of critical geopolitics in the epoch of the Anthropocene, to question such inequalities and rethink our collective role and responsibility as humans become key agents of geological change. This critical agenda, which Dalby (2007, 2013) has championed for as “Anthropocene geopolitics,” will be adopted in the following sections to investigate two environmental concerns that have been the subject of intense debates and interest in recent years: climate change and resource scarcity.

The critical geopolitics of climate change

On May 10, 2013, the New York Times announced that “the level of the most important heat-trapping gas in the atmosphere, carbon dioxide, has passed a long-feared milestone” (Gillis 2013). Reaching a daily level of 400 parts per million (ppm), atmospheric concentrations of CO₂, scientists estimate, are higher than at any time in human history since the Pliocene. This report is a microcosm of the larger concerns within the policy and academic arena about the significant repercussions to human societies brought about by anthropogenic climate change. Indeed, climate change is not only the issue at stake here, but it is also a symbolic marker of the larger transformations underway, processes that now frequently invoke discussions in terms of the putative new geological epoch of the Anthropocene.

In lieu of the recognition that fossil-fueled industrial capitalist humanity is driving climate change in era of the Anthropocene, responses have thus far been state-centered, relying on the actions of different national governments in reducing the emission of greenhouse gases. For instance, the Kyoto Protocol under the United Nations Framework Convention on Climate Change aims to control the amount of carbon emissions by slotting states into the categories of Annex 1 or Annex 2, depending on their contributions and capacities to reduce emissions. Other international meetings/conventions, such as the World Climate conferences, also involve state delegates as key participants, which once again imply the legitimacy of state actors in deciding on agreements to govern the world’s climate future. What this means is that states have the absolute authority in formulating and implementing domestic laws and regulations regarding emissions levels to bring about the greater good of positive environmental change at the global scale.

But criticisms abound of these seemingly benign state initiatives to alleviate the impacts of climate change. O’Lear (2013) explains that many of such criticisms are concerned with the “territorial trap” fallacy that is inherent in statist accounts of climate change. In privileging the state’s role in combating climate change, critics have asserted that there is a willful ignorance of the ways problems and solutions associated with climate change cut across national boundaries and cannot be contained by states working independently of one another. Furthermore, it has been argued that there are unequal power relations among states and, by maintaining a state-level focus, those powerful countries can then have the liberty to decide on the “best” approach to climate change that suits their
interests, often resulting in the marginalization of “less developed” nations. For instance, Paterson and Strivelope (2007) have examined state-centered articulations of climate change. They uphold that by naturalizing an understanding of climate change based on territorial states, certain perspectives and solutions appear legitimate. Citing the case of ex-US President Bush’s refusal to participate in the 1997 Kyoto Protocol that aims to reduce greenhouse gases on a country-by-country basis, Paterson and Strivelope show how the United States appealed to the notion of parity to defend America’s action. Bush’s reasoning was that since developing countries were not required to cut their emissions as drastically as their richer counterparts, they would have an unfair economic advantage and threaten US security. Yet, as others have pointed out, it is only just that the United States takes on the bulk of the responsibility given that it is the world’s biggest producer of greenhouse gases, contributing 22% of total emissions. Dalby (2013) takes further issue with what he sees as the increasing securitization of climate change. He notes that the formal military apparatuses of a number of “Northern” states are beginning to take concrete steps to “secure” their states against the risks of climate change. These include discussions of climate and security in key military planning documents of states such as the United States and United Kingdom, and scenario exercises on extreme contingencies in these same states are beginning to incorporate environmental dimensions. Dalby is, however, highly critical of climate change functioning as a factor in states’ calculations of grand strategy. He warns that such negative formulations of security will ultimately lead to spatial exclusion — discourses related to the necessity of (military) pre-emption of climate threats by powerful states are foreboding signs of the global extension of imperial power, domination, and violence. Besides highlighting the negativities arising from the securitization of climate change, critical voices have also emerged to contest the increasing marketization of climate change as part of states’ risk adaptation strategy. There is a keen interest in drawing attention to the undesirable consequences as a result of climate change solutions being embedded within circuits of capital. For instance, Elliott (2013) focuses on the case of the United Nations reducing emissions from deforestation and forest degradation (REDD+) program, which essentially embodies the view that countries, companies, communities, or individuals could be paid to manage forests and reduce deforestation in recognition of the role forestry has in carbon sequestration and the significance of land-use change in annual carbon emissions on a global scale. In this sense, REDD+ acknowledges that powerful economic imperatives are needed to discourage forest clearance and envisages a North–South flow of finances in order to fund its multiple initiatives. Elliott (2013), however, points out such a top-down policy driven primarily by global, Northern agencies and governments could have serious negative impacts on forest-dependent communities and indigenous peoples in the Global South, whose cultures and livelihoods are closely linked to those forests. There is also an ethical question to be raised with regard to carbon markets, whereby state (or corporate) interests pay for carbon credits to be used within schemes such as REDD+ while continuing to pollute and extract fossil fuels elsewhere (potentially at a cost to other people). More fundamentally, Elliott argues that REDD+ does not address the underlying drivers of deforestation (e.g., reducing demand for agricultural or timber products). Hence, as illustrated from the example of REDD+, mitigating climate change through capitalist logics and rationalities raises concerns about diverting attention away from
tackling the root causes of climate change while, at the same time, perpetuating the pattern of dispossession for marginalized nation-states and their communities.

The critical geopolitics of resource scarcity

A second environmental issue that has been given heightened prominence in the so-called era of the Anthropocene is resource scarcity (see entry on Natural resources). Rees (2013), a scholar with the Cambridge University’s Centre for the Study of Existential Risks, has crucially argued that climate change and resource scarcity are two of the biggest ecological shocks that humans’ incessant demands have inflicted on the biosphere. It is hardly surprising that such a perspective exists, given the long-standing worry that accelerated population growth and the advent of fossil-fueled capitalist societies have put immense stress on the planet’s resources.

The rising concern of resource scarcity in the Anthropocene has often been bounded up with discussions of “environmental security” (Dalby 2007). The establishment of such a relationship is not something novel given that, back in the 1980s, Cold War environmental security discourse (i.e., instabilities and disruptions to society as a consequence of environmental problems) was already a dominant theme. The assumption here is that resource scarcity might cause conflict and, on the largest scale, warfare between states. According to these advocates of the scarce resource wars hypothesis, people or nations will fight one another so as to secure access to resources necessary for their survival. The underlying implication is that the more scarce the resource, the more intense the conflicts. While there has been anecdotal evidence advanced to corroborate this view, several counterarguments exist to question whether the scarce resource war perspective can indeed be generalizable. First, resource scarcity and population pressures can lead to socioeconomic innovation, including a diversification of the economy, which often results in a more equitable distribution of power across society. Second, the scarce resource wars theory fails to take into account the possibility of international trade and market mechanisms in counterbalancing localized scarcities and shifts in resources. Finally, resource-poor countries can also invest in human capital, rather than simply protecting and relying on existing resources. In such cases, “the likelihood of violent conflict decreases as human capital develops (e.g., through education, trading, and manufacturing skills) and the economy diversifies, and governance becomes more representative and accountable” (Le Billon 2001, 564). Japan and Singapore are two classic examples that are said to embody the essence of these counterarguments— their resource-impoverished condition did not prevent the peaceful development of these two economically high-achieving states. Hence, in sum, there are limitations to the resource scarcity perspective, especially with regard to its inability to explain why a scarcity of valuable resources is not a necessary or sufficient precondition for conflicts/warfare.

In lieu of the aforementioned weaknesses, scholars working in the critical geopolitics tradition have proposed alternative frameworks to create more nuanced understandings of the “problem” of resource scarcity (Le Billon 2001; 2013). These works do not deny that natural resources such as timber, water, and diamonds may indeed shape how and where conflict unfolds. However, they are concerned that accounts related to resource conflicts often imbue natural resources with an agency that they do not actually have. They are also united in their view that context is important in teasing
out the diverse range of processes and dynamics at work, rather than assuming a straightforward relationship between resource scarcity and conflicts. Le Billon (2001; 2013) is a good reference point for this body of literature. Drawing inspiration from Zimmerman, who argues for the need to look at Earth’s natural endowments as socially constructed, Le Billon brings to the fore that, whether or not nature is transformed into a resource, it is related to human desires, needs, and perspectives. He goes on to suggest that resources and a place’s vulnerability to conflicts are intimately connected to different factors such as their susceptibility to being looted and the geographical concentration/location of resources, whether the resource in question involves production or extraction, and the extent to which a country’s resources are heavily tied to the global economy through colonial powers, private/commercial interests, and domestic elites. It is hard to do full justice to Le Billon’s nuanced expositions here but, in general, the more dependent a country is on its resource sales to the global markets, the more opportunities there are for different forces to manipulate such lucrative networks for their own benefits, thereby increasing the risks of violence. Additionally, if the resource involves extraction, violence is most likely to take the form of territorial or state control. Lastly, the more accessible a resource is to various parties (i.e., its susceptibility to being looted), coupled with its concentration in a certain geographical area, enhances a place’s susceptibility to conflictual relations.

With similarities to Le Billon’s arguments, Dalby (2003) offers a critique of the ill-defined nature of the scales and contexts through which the complex geopolitics of resources has been analyzed. To quote him at length:

Resources are not just resources; renewables and non-renewables have different qualities. Contexts matter too; the exploitation of oil reserves is different in many ways from use of marginal farmland. Subsistence activities are likely to have different social dynamics from the large-scale commercial exploitation of mineral materials. (Dalby 2003, 5075)

Hence, according to Dalby, the different scales and contexts of resources need to be clearly specified, especially given that these geographical specifications of security, when left unquestioned, often aid in the production of narratives of resource scarcity to form cartographies of risk and danger in the interest of promoting political agendas. A clear example of this is the ways in which some states in the Global North have drawn on fears of conflict over scarce resources to formulate interventionist policies. US foreign policy, in particular, has long focused on maintaining the “stability” of authoritarian regimes in the wider interests of regional security. The task of critical geopolitics, then, as Dalby (2003) upholds, is to expose the geographical assumptions that are inherent in abstract generalizations of resource conflicts, thereby providing possibilities for thinking differently about environmental threats and insecurities.

Towards “planetary” thinking?

The discussion thus far has centered on harnessing a critical geopolitical perspective to look at issues to do with the environment. Regardless of the different conceptions of the environment (from thinking of it as the natural world to seeing it as part of human systems in the epoch of the Anthropocene), this entry contends that critical geopolitics has enabled the consideration of the role of power in human–environmental relationships. More specifically, critical geopolitics contributes to the challenging of the specifications of dangers, threats, and risks that underpin the representation of the environment for certain
political agendas/interests. But following recent calls for critical geopolitics to go beyond critique and provide alternative ways forward for the betterment of society, this entry concludes by delving briefly into recent “planetary” thinking in order to reflect on more socially and ecologically just geopolitical responses to the environment in the current era of the Anthropocene. According to Spivak (2003, 72), the “planet is the species of alterity, belonging to another system; and yet we inhabit it, on loan.” If this perspective is linked to the environment, it can similarly be argued that through our collective global agency of human impact on the environment, we are all united by our identity as planetary subjects. We are part of a biosphere that we are actively remaking, rather than separate species on a planet or separate nations competing for space. The geopolitics of this is especially important: interconnections and cooperative ventures are key to governing the Earth system (Dalby 2013). In this sense, the Anthropocene is not the terminal phase, an apocalyptic end to all things as some have suggested. Rather, it is the next phase that requires collective effort as planetary beings to find ways/avenues to evolve, adapt, and change in response to the environment (Dalby 2013).

GEOPOLITICS OF THE ENVIRONMENT

Geopolitics

Paul Reuber

University of Münster, Germany

Geopolitics is a practice of knowledge production that focuses on linguistic, cartographic, and pictorial constructions of geopolitical representations at regional and global scales. “Irrespective of whether the word geopolitics is used or not, the conventional understanding today is that geopolitics is discourse about world politics, with a particular emphasis on state competition and the geographical dimensions of power,” Ó Tuathail (2006/1998, 1) has observed. Since its biodeterminist and geodeterminist framing in the late nineteenth and early twentieth centuries, the term “geopolitics” has expanded to include a wide range of explanations and reputations (Dodds, Kuus, and Sharp 2013). Therefore, an exact definition is difficult, if not impossible, because of its semantic ambiguity and – given the variety of approaches and conceptual positionings – its embodiment of contrasting and contradictory meanings (Reuber 2009). Geopolitics deals with:

- the geopolitical representations of the “self” and the “other” in politics, media, and science;
- the geopolitical discourse itself as a linguistic formation of space and power;
- the “doing geopolitics” of political actors who draw on hegemonic geopolitical imaginations in order to legitimize their political reasoning and practices;
- the academic deconstruction of geopolitical discourses and practices from a critical geopolitical perspective, or rather a post-structuralist political geography.

These four facets not only illustrate the wide range of perspectives represented by the term “geopolitics”; they identify it – following the conceptualizations of Laclau and Mouffe’s (1985) discourse theory – as one of the most powerful “empty signifiers” of the political geographies of modernity. With regard to the content, or meaning, associated with particular signifiers, the term “empty” does not imply a sense of meaninglessness – in fact, quite the opposite. Through its overdeterminism, it acquires and balances a variety of meanings within different fields of reference. Thus, “geopolitics” assumes an indistinctness which gives it a propensity for immersion within various segments of society, ranging from politics – through political think tanks and policy-related disciplines – to the media, and even bar room clichés. In short, “Geopolitics … is an essential part of everyday life” (Dodds 2007, 21).

Within the academic community, this plurality is reflected through a considerable heterogeneity of underlying approaches, which may move toward quite different forms of theoretical concepts and empirical analysis. What scholars from the fields of international relations and political geography publish today under the label “geopolitics” can range from implicit natural
determinist contributions to practice-oriented forms of spatial analysis, and even on to structuralistic and poststructuralistic approaches. Therefore, a critical reading of related publications is strongly recommended. To organize the field, it may be helpful to point out the deep epistemological gap which separates two opposing approaches.

1 A traditional, “realist” form of geopolitics attempts to identify the “natural” and “cultural” driving forces of geopolitical developments at regional and global scales. It portrays geopolitics as a “reliable guide of global landscape using geographical descriptions, metaphors, and templates such as ‘iron curtain,’ ‘Third World,’ and/or ‘rogue state.’ Each of these terms is inherently geographical because places are identified and labeled as such. It then helps to generate a simple model of the world, which can be used to advise and inform foreign and security policy making” (Dodds 2007, 4). The examples mentioned earlier fall into this category – especially those actively engaging in the construction of geopolitical representations of the “self” and the “other.” In the event that they develop into hegemonic concepts, they could be immediately relevant, for instance, within the frameworks of geopolitical identities, political practices, armed conflicts, and so on.

2 A critical, constructivist form of geopolitics (critical geopolitics and poststructuralist approaches) recognizes geopolitical imaginations and their putatively “natural” geographies of “us” and “them” as discursive formations, or rather, as ever-changing constructions of global spatial orders of power on the world political map. Such concepts for analyzing geopolitical representations are discussed in further detail in other entries in this encyclopedia. Each of these contributions reconstructs historic geopolitical narratives by drawing on the theoretical framework of constructivist approaches, especially discourse analysis and semiotic analysis. “So rather than simply assume that labels such as ‘iron curtain’ and ‘axis of evil’ have a certain heuristic value, we proceed to question how they generate particular understandings of places, communities and accompanying identities” (Dodds 2007, 5). The deconstruction of geopolitical representations, in particular, argues against the re-emergence of strongly traditional (and, sometimes, natural deterministic) ideas for which geopolitics is the doctrine of the influence of physical space on the politics of a state. Constructivist reasoning in political geography indicates how such a conceptualization of geopolitics leads to an ideological, as well as an epistemological, cul-de-sac. They take the geopolitical discourses themselves as the objects of their analysis. The issues to address from this point of view are the construction of discursive and cartographic representations, and how these representations intersect with other political imaginations and practices.

Even though variant 1 provides the framework for a wide array of “strategic studies” located, today, within a gray zone between applied political science and political consulting, from a discourse analytical perspective these analyses are not considered to be “real” depictions of (geo)political constellations of power. Rather, they are a form of “doing geopolitics” that legitimizes political scenarios and practices through the postulation of innate geopolitical regionalizations and antagonisms, while supporting them with ostensibly “objective” academic arguments.
Box 1 The nation-state as the fundamental “territorial trap” of the geopolitical imagination

Since the modern period, the nation-state was considered to be the territorial framework for countless geopolitical strategies of containment and exclusion. The powerful social construction of nation-states as “imagined communities” (Anderson 1983) has made them persistently successful as a kind of “natural” entity through which struggles over political identity, sovereignty, and power have been organized over the last two centuries. Even in recent times of increasing globalization, the role of the nation-state appears to have held its ground despite the undeniable loss of power to transnational networks of “global governance.” John Agnew (1994) calls the rigid fixation on the spatial container of the nation-state a “territorial trap.” This expression characterizes the virtual ontologization of the territorial principle as a crucial framing of social, and especially political, structuring. According to Agnew, the territorial trap is based on three main assumptions that must be analytically separated, but that overlap in social practice. The territorial “logic” of modernity is based on the premises that (i) the sovereignty of the modern state requires a territorial organization of power; (ii) internal and foreign policy are strictly separated; and (iii) the territorial state serves as a kind of spatial container of national societies.

(cf., e.g., Samuel Huntington’s clash of civilizations approach and Thomas Barnett’s geopolitical construction of core and gap regions).

In this mode of representation, the nexus between society and space becomes the leitmotif of the geopolitical imagination. Framing social differences in terms of spatial representations leads to a “purification of space” (Sibley 1988). By this kind of discursive practice, the “self” and the “other” are organized along spatial categories and ascribed with boundaries (e.g., the nation-state, see Box 1). Such constructions can be found as powerful geopolitical representations in all historical epochs (see next section). Their logics and geographies may vary according to the hegemonic discourses of their time (e.g., if they exploit expressions such as race, class, or cultural diversity when constructing putative homogeneous spaces), but their basic logic of construction stays the same. Based on these assumptions, geopolitical discourses can be regarded in a Foucauldian sense as politically contested formations of power and space. They serve as historically alterable narratives and, apart from stable phases in which they may appear to be virtually objective formations, are subject to constant negotiation and renegotiation.

Geopolitics and geopolitical representations in different historical periods

Following the arguments outlined, it is apparent that geopolitics and its geopolitical imaginations are situated within their social and/or discursive contexts. This means that geopolitical discourse is subject to change. In order to illustrate this more clearly, concise – albeit
Box 2 The state as an organism: Ratzel’s biodeterministic construction of German geopolitics

The basic element of Ratzel’s mode of construction consisted of the nation-state’s dependency on the biological dynamics of natural selection. Friedrich Ratzel (1844–1904), who had shifted his scientific career from zoology to geography, built his political geography on a positivistic, natural-scientific conception of the world. His construction of the relationship between politics and space is primarily determined by the physical-geographical characteristics of the nation-state. Another crucial point in his construction is the biological framing of the nation-state as an “organism.” The nation-state, in this respect, is ascribed the traits of a living being and is considered to be “healthy” and “strong” only when capable of growth or, in other words, territorial expansion. Thus, this Darwinian representation of geopolitics is used to legitimate imperialism and expansionism. Following Ratzel’s reasoning, as its civilization continues to develop, the nation-state needs more and more space in order to sustain a healthy, growing population. In this manner, the struggle for more space automatically leads to conflicts between nation-states.

Throughout his writings, Ratzel (repeatedly) makes a close connection between population growth and territorial expansion, putting this claim into practice with regard to the German empire as it approached World War I:

Wherever you look space is won and space is lost. Setback and progress everywhere; there will always be reigning and serving peoples. Even the peoples must be anvil and hammer. In no case Germany must limit itself to Europe; as a world power among world powers it can only hope to protect the ground for its people that it needs to grow.

(Ratzel 1906, 377; author’s translation)

In this manner and through supposed “scientific” arguments, Ratzel provided the geopolitical basis for the German empire’s colonial policy and Flottenpolitik. Even after World War I, the connection between politics and scientific geopolitical representations led to a significant expansion of political geography at the universities. With his discursive logic of growing space, Ratzel laid the foundation for the development of the ideology of living space (Lebensraum).

exemplary – accounts of geopolitical framings throughout different historical eras are discussed in the following sections: (i) geopolitics in the historical context of Darwinism, nationalism, imperialism, and colonialism; (ii) geopolitics in the broader historical context of National Socialism; (iii) geopolitical representations during the Cold War; and (iv) new geopolitical representations after the end of the Cold War.

“Classical” geopolitics: geopolitics in the historical context of social Darwinism, nationalism, imperialism, and colonialism

The search for interrelationships between space and politics is much older than the term “geopolitics.” Ó Tuathail (2006/1998, 1) explains how the birth of classical geopolitics dates back to the ages of imperialism and colonialism which developed and peaked toward the
end of the nineteenth century: “All words have histories and geographies and the term ‘geopolitics’ is no exception. Coined by a Swedish political scientist named Rudolf Kjellén, the word ‘geopolitics’ had a twentieth century history that was intimately connected with the belligerent dramas of that century” (Ó Tuathail 2006/1998, 1). Behind this terminology resides much of the conceptual framework of classical geopolitics developed by Friedrich Ratzel; the central component of his approach to geopolitics was a biological reconceptualization of the nation-state (Staatsorganismus). Ratzel, considered by many today to be the founder of political geography, infused some of the popular biological theories of his time with concepts of “the social” and “the political” (see Box 2). Thus, his organic state theory provided a discursive formation rooted in environmental determinism that would serve as the basis for subsequent theoretical developments within international geopolitics.

Historical reconstructions help to clarify how these theses, which today sound rather absurd and illogical, could have been accepted during their time as plausible rationalizations. This was primarily the result of the development of classical geopolitics into a hegemonic discursive field including several popular “isms” characterizing the nineteenth century such as natural determinism, environmental determinism, (social) Darwinism, nationalism, imperialism, and colonialism. In this powerful mode of construction, geopolitics appears as an expression of (assumed) natural spatial order. These particular discourses can be found in the Geopolitik from intellectuals of statecraft such as Alfreed Mahan and Nicholas Spykman in the United States, Friedrich Ratzel and Karl Haushofer in Germany, Rudolf Kjellén in Sweden, and Halford Mackinder (Box 3) in Great Britain. Their geopolitical imaginations supported the self-representation of the modern Western world as the “superior” culture, and subtly suggested the colonization of “premodern” others to be a necessary, if not “humane,” process.

**Box 3  Mackinder’s geopolitics**

Some of these nineteenth-century binary imaginations achieved a level of prominence that can, to some degree, still be found in present geopolitical discourses. For example, the construction of an antagonism between land and sea – or rather land power and sea power – formed the basis for Sir Halford Mackinder’s (1861–1947) construction, which became an important part of Anglo-American geopolitics. In 1904 Mackinder presented his theories at the Royal Geographical Society. His classification and division of the world political map into states of sea and land power formed the basis of many geopolitical imaginations. Russia is seen as the power center of the continental empire – the “heartland” (also known as the “pivot area”) – while the rest of the world, focused on the importance of oceanic influence, is arranged around this arc. This area is referred to as the “rimland” (including nations like Japan, Great Britain, and the United States). The balance of power throughout this dual-world system is the main focus of any developments within the field of foreign policy. Mackinder considered Eurasia to be the pivot of world politics since conflicts occur mostly in the rupture zones, and also argued that, by controlling this area, one could control the world, including dominating the sea power nations.
The purpose of geopolitics at that time had little to do with measuring and mapping the physical world; that was more along the lines of the newly developed and expanding sciences of applied geography and cartography. Geopolitics’ focus was much more toward constructing geopolitical representations of the self and the other on a global scale. This approach outlines the “seductive qualities of geopolitical discourse … [It] transforms the opaqueness of world affairs into an apparently clear picture” (Ó Tuathail 2006/1998, 2). In this way, geopolitics created and/or reproduced powerful geographies of difference on the world political map: the Orient versus the Occident, the Southern Hemisphere versus the Northern Hemisphere, the East versus the West, sea powers versus land powers, and so on.

During the nineteenth century, geopolitical representations began increasingly to influence the foreign policy zeitgeist of European politics. They included political practices that gave rise to countless wars in Europe from 1870 to 1945 as rival empires competed for power. In a similar way, they influenced the global order by serving as discourses of legitimization to support and validate imperialist, colonialist, and National Socialist politics of their times (see Schultz 1987).

Karl Haushofer and the geopolitics of National Socialism

Karl Haushofer (1869–1946) was one of the most influential scholars responsible for integrating the geopolitical imaginations of his time with National Socialist ideology. Haushofer, who considered Ratzel his mentor, shaped the German geopolitical discourse more than any other individual during that era. During World War I he was an officer who rose to the rank of major general. After World War I, he began his career as a professor of geography at the University of Munich. He published many books and papers, and was editor of the Zeitschrift für Geopolitik from 1924 to 1944. Haushofer’s position in the Third Reich was shaped by his close relationship with Rudolf Hess and the political standing of his sons, Heinz and Albrecht, in the Nazi regime. Through these contacts, Haushofer achieved a reputation that enabled him to directly influence the policy of the Third Reich. Thus, in the years between World War I and World War II, geopolitical representations achieved a hegemonic position in discourse, in Germany at least.

Rudolf Hess, one of Haushofer’s students, played a significant role in this development when Hess and Hitler were imprisoned together in Landsberg. Haushofer and Hess influenced Hitler and helped to create important parts of the initial ideological framework of National Socialism (e.g., the demand for more Lebensraum (living space)). Curiously, Haushofer did not become a prominent public figure within the National Socialist government. According to many historians, this was because he was satisfied with his important role of operations in the background.

Historical evaluation of Haushofer’s role will no doubt continue. There are interesting contrasts between the different representations of German and Anglo-American historical reconstructions. According to Anglo-American reconstructions, all geopolitics within the German-speaking sphere were developed by Haushofer, who is represented as the scientific brain behind Hitler. American perception of his importance was further encouraged by a Hollywood-produced propaganda film which portrayed Haushofer and his Geopolitical Institute as the headquarters of National Socialism. As Ó Tuathail (2006/1998) notes, Haushofer and his imaginary Geopolitical Institute in Munich
supported the growing public awareness in America of the role of geopolitics. The American geopolitician Edmund A. Walsh, who participated in the Nuremberg trials, could not conceal his admiration for Haushofer. In his interrogation of Haushofer Walsh did not criticize his general mode of geopolitical representation itself but simply accused him of pursuing the wrong type of geopolitics. Walsh’s demand for a “true” – as opposed to a “false” – geopolitics (re)locates the discipline within the democratic structure of Western society.

**Cold War geopolitics**

The years after 1945 were characterized by new forms of geopolitical representations that developed, to a much greater extent than before, in the scientific and political think tanks of the United States. Their goal was mainly a reframing of the American relation to the Eurasian continent. From a discourse theoretical perspective, it is interesting to note the extent to which these new representations relied on long-standing geopolitical imaginations, such as those of Mackinder (see Box 2) and Spykman. They incorporated the old argument of a “natural” line of conflict between a Western sea power (now the United States) and a central land power (now the Soviet Union). The practical consequence of such a geopolitical representation was the assumption that the political situation after 1945 did not allow for a stable order on the Eurasian continent without a permanent American presence. This was a strategy used to prevent the expansion of the Soviet land power. The geopolitical construction of Mackinder’s heartland theory is more than apparent here; it was the core element of the new geopolitical doctrine of the Cold War.

In 1947 Walter Lippmann, an American journalist, was the first to formulate the geopolitical imagination of an upcoming “cold war.” This was the beginning of the discursive construction of ideological blocs on the world political map. From the American perspective, it was a fight for liberty, democracy, and a market-based economy against communism, repression, and a command-based economy. From the Soviet Union’s perspective, “the good” and “the evil” were framed more or less the other way around. On March 12, 1947, the American president Harry S. Truman announced a similar, new form of geopolitical representation to the American Congress. With its dualistic approach and universalistic claim (liberty vs totalitarianism), it polarized parts of the world that had so far not been influenced by postwar geopolitics. After the Truman Doctrine, a key component of US foreign policy was to deliver active support to all people and states whose putative liberty appeared to be endangered by communism, socialism, or internal left-wing militant minorities. The first examples were Turkey and Greece, but – with hindsight – also (Western) Germany. For decades, the Truman Doctrine was utilized as the discursive legitimation of the American policy of containment and as the basic leitmotif of the Cold War. Another key component of this geopolitical representation was the “domino theory” proposed by US president Eisenhower on April 7, 1954, according to which, if one state falls (i.e., becomes communist) its neighboring states would fall in succession. In this manner, the geopolitical representation of the Cold War served the political goals of the superpowers.

After two decades, the 1970s, in many ways, marked a turning point in international relations. The ideological discourses surrounding the American–Soviet power struggle decreased, while other political framings grew in significance.
**GEOPOLITICS**

The pluralization of Western geopolitical representation after the end of the Cold War

As the Cold War came to an end, the geopolitical representation of a world composed of ideological blocs and iron curtains fell apart. Against this backdrop, it is not surprising that, in the early 1990s, a series of new geopolitical narratives had already begun to appear. Each of them claimed to offer plausible discursive framings for the changing global constellations of power (Ó Tuathail, Dalby, and Routledge 2006/1998).

Among them were, for example, geoecological narratives. Early representations originating from discussions in the 1970s and 1980s focused on the limitation, exploitation, and degradation of environmental resources (e.g., debates about the destruction of tropical rainforests, desertification, deforestation, nuclear power, greenhouse gases, etc.). While these discussions were, at first, confined to a niche group of people from affluent Western societies, they have, in recent times, become pertinent to wide-ranging scenarios in international security debates fueled, among others, by some of their well-known spin doctors. Since the Intergovernmental Panel on Climate Change (IPCC) reports, there has been a notable increase in more specific discourses on the “geopolitics of climate change” (for an analysis of this debate see Mattissek and Wiertz 2011), including risk scenarios such as “climate wars.” In this particular area, the discursive logic once again falls back on deterministic constructions which are on their way to becoming integral parts of political consulting and policymaking.

A similarly implicit form of global geopolitics arose at the beginning of the 1990s as an effort to substitute geoeconomics for geopolitics. According to Luttwak, political conflicts were increasingly being fought with economic weapons in the era of expanding (mainly economic) globalization. Visions of a network society, including new forms of global governance, were challenging the traditional relationship of politics and space – especially the role of the nation-state in international relations. Within most geoeconomical imaginations, the nation-state remains a relatively significant factor in the system as a whole. However, there are also conceptualizations, such as Manuel Castells’s network society, which predicts a less powerful role for the nation-state. Castells’s view represents a shift from a “space of places,” in which the institutions of the nation-state are the centers of (geo)political power, toward a “space of flows,” in which globally expanding networks are the most powerful economic and political structures.

The establishment and discursive power of such representations have changed greatly as a result of the conflicts and wars of the last two decades. Since their development at the beginning of the 1990s, new and alternative geo-“political” framings have emerged in both politics and the media. To bring the variety of these “politics of geopolitics” into some kind of perspective, one might work out two lines of geopolitical representation: (i) the geopolitics of fragmentation and conflict and (ii) the geopolitics of universalism and hegemonic superpower.

The geopolitics of fragmentation and conflict

This geopolitical narrative arose soon after the end of the Cold War and climaxed in the aftermath of the terrorist attacks of September 11, 2001. During this period, the discourse of a clash of civilizations, which had been promulgated by Samuel Huntington and immediately used by him to discursively frame the Balkan Wars, was ubiquitous in the media and in public opinion.
This kind of geopolitical imagination gave new life to an underlying discourse of global cultural difference that had developed in Western modernity over more than two centuries. Seen from this perspective, “Huntington’s thesis is not about the clash of civilizations. It is about making global politics a clash of civilizations” (Ó Tuathail 1996, 149).

Geopolitics of universalism and hegemonic superpower

The second major geopolitical narrative of the post-Cold War era serves the imagination of a new hegemon – the singular superpower, the United States. In his concept of “the end of history?” Francis Fukuyama represents the United States as the ultimate democratic state. His ideas are informed by a reductionist interpretation of Hegel’s idealistic philosophy of the end of history. This construction, in all its simplicity, marks the beginning of a geopolitical narrative that helps to pave the way for a new discourse of American hegemony in a post-Cold War world. Following a teleological and universalistic path of representation, the end of history thesis contains an underlying geopolitical narrative. This narrative is only a short step away from George Bush Sr’s doctrine from the First Gulf War, and it has informed important parts of the geopolitical representations and mappings of US foreign policy since 9/11.

The 9/11 attacks on New York and Washington formed the “discursive event” in the face of which the emerging geopolitical representations rose to prominence. At the same time, these events may be regarded as a shift in the geopolitical representations of power. For the first time, the traditional order of “modernity” (the Westphalian system of territorially defined nation-states) was challenged by an enemy organized (and acting) according to the principles of network societies. In the aftermath of 9/11, politics and the media have impressively shown how difficult (if not impossible) it was to comment on and to react to the attacks beyond the spatial framings and representations established in traditional geopolitical discourses. Thus, the narration about the conflict had to be (and was) partly reframed as a “war between nation-states.” Following Dalby (2003), this telling was indispensable because the geopolitical reasoning of modernity operates within an ontological framework of nation-states. It became, once again, the most important symbol framing political reactions and media reports.

The demand to “localize” the al-Qaeda terrorist network necessitated their attachment to a particular place; thus, Afghanistan was established as a target because of the enemy presence located there. This framing rests on geopolitical imaginations which have been developed in the previous decade, for example, by Michael Klare’s “rogue state” doctrine, by George H.W. Bush’s “axis of evil,” and – more generally speaking – by “failed state” discourses. All in all, the new storyline of a global “war against terrorism” turned very quickly into one of the most powerful doctrines of international geopolitics.

The subtle interplay between the two aforementioned geopolitical representations of hegemony and fragmentation were particularly helpful for this development. Both served as framings for numerous political speeches, as well as media reports and commentary. The majority of these geopolitical representations reified the underlying concept of a cultural fragmentation of the world, from which the necessity of strong US leadership supported by a “coalition of the willing” could be derived. Based on such an imagination, the wars against Afghanistan and Iraq could be justified more easily for the world public. Additionally, Huntington’s rhetoric of
conflict fits not only into the discourses of Western military strategists and politicians but also into the saga of the Islamic jihad. Thus, the clash of civilizations narrative produced a discourse that even antagonists such as Osama bin Laden could easily adopt (Agnew 2001).

Geopolitical imaginations like these are, of course, not the only narratives found within international relations academia. As a result of changing circumstances at the beginning of the new millennium, other variations entered the scene. For example, Thomas Barnett’s geopolitics of core and gap outlined a new world map for the Pentagon. In this representation, the war against Iraq marks a kind of geopolitical and historical turning point – the moment when Washington “really” took over its role as a guardian of strategic security. Barnett’s simplistic geopolitical world order entails regions with stable governments, high standards of living, and good connections to and throughout the globalized network society where democracy, liberal media, civil security, and human rights protection are part of the basic normative assumptions of society, which he calls the “functioning core.” At the same time, regions less touched by globalization and which suffer from repressive regimes, widespread poverty, disease, and – most importantly, in Barnett’s opinion – chronic conflict, in which coming generations of global terrorists are brought up, are denoted as the “arc of instability.”

Many of these geopolitical imaginations show how parts of the currently circulating representations of global and regional fragmentation and/or hegemony draw on key arguments coming from the discursive “archives of geopolitics” (Reuber 2011). For example, representations of global cultural differences had already been developed in the West since the beginnings of modernity (Gregory 1994). Zbigniew Brzezinski’s geopolitical imagination of Eurasia as a grand chessboard includes elements of geopolitics developed by Spykman and Mackinder. Tensions between Russia and the Western European states are often represented as a kind of relaunch of Cold War discourses and/or as long-standing geopolitical power constellations of “the East” versus “the West.” Together, they show, once again, how powerful geopolitical discourses are in framing the world political map and its ongoing clashes, conflicts, and wars.

A geoportal is a type of web portal that is used to find and access geographic information and associated geographic services (e.g., display, editing, analysis) via the Internet. Geoportals are important for the effective use of geographic information systems (GIS) and are a key element of Spatial Data Infrastructure (SDI).

A web portal is most often a specially designed website that brings information together from diverse sources in a uniform way. Usually, each information source is assigned a dedicated area on the site for displaying information (a portlet); often the user can configure which ones to display. A portal may use a search engine to permit users to discover content that fits their demand. In addition, web portals may offer other services such as discovering, viewing, and downloading data. In the 1990s, many governments committed to creating web portal sites for their citizens. These included primary portals to the respective governments as well as portals developed for specific audiences. Examples of government web portals include: Australia.gov.au for Australia, USA.gov (in English) and GobiernoUSA.gov (in Spanish) for the United States, Gov.uk for citizens and businesslink.gov.uk for businesses in the United Kingdom, and Health-EU Portal (http://ec.europa.eu/health/index_en.htm) for issues related to relevant health topics from across the European Union (EU).

The main technical concept behind a web portal is to present the user with a single web page that brings together or aggregates content from a number of other systems or servers. The application server or architecture performs most of the crucial functions of the application. This application server is in turn connected to database servers, and may be part of a clustered server environment. For portals that present application functionality to the user, the portal server is in reality the front piece of a server configuration that includes some connectivity to the application server.

Over the last two decades, many governments and private companies have invested tens of billions of US dollars in the development of geographic information, largely to serve specific communities (e.g., agriculture, urban/rural planning, and mining) within local, state, national, international, and even global contexts. The focus has increasingly shifted towards a platform for integrating geographic information by means of SDIs. SDIs facilitate access to existing geospatial data and services necessary to successfully use GIS. Moreover, SDIs facilitate the exchange and sharing of geospatial data between stakeholders within the geographic information community. This community mainly includes mapping agencies, universities, governmental and nongovernmental organizations, and private companies.

Geoportals can be considered as gateways to SDI. They are not a repository where data are simply stored, but can be seen as a one-stop shop for geospatial data, sourced from numerous agencies. The performance of geoportals can vary enormously depending on numerous factors, such as the functionalities offered, the quality of the information offered, and a user's capacity.
Geoportals are named differently across the geospatial community. Examples of other names used are “geo registry,” “geospatial one-stop,” “geospatial platform,” “geospatial data service,” and “spatial portal.” Although different names are used, it is obvious that the goals for searching and accessing geospatial data and services remain the same.

Geographic information providers, including government agencies and commercial companies, use geoportals to publish descriptions (in terms of geospatial metadata) of their geographic information and/or supply access to a wide range of geospatial data, such as topography, soil, administrative units, addresses, and land use. Geographic information consumers, professional or casual, use geoportals to search and access the information they need. Thus geoportals play an increasingly important role in the sharing of geographic information, and help to avoid duplicate efforts, inconsistencies, delays, confusion, and wasted resources.

Geoportals often include, among others, discovery, web mapping and/or download services. Discovery services allow users to search for geospatial datasets and services on the basis of the content of the corresponding metadata and to display the content of the metadata. The web mapping services make it possible, at a minimum, to display, navigate, zoom in/out, pan, or overlay viewable geospatial datasets, and to display legend information. The download services enable copies of geospatial datasets, or parts of such sets, to be downloaded and, where practicable, accessed directly. Examples of other web services that are sometimes included are gazetteer, geoprocessing, (coordinate) transformation, authentication, ordering, and e-commerce services.

In order to ensure interoperability among the geospatial datasets and services provided by geoportals, standards are essential. These geospatial standards are required to store, transfer, and visualize the datasets in a systematic and compliant way, or to describe them in terms of metadata. Moreover, standards are also needed to apply web services and make them compliant with relevant standards. These standards are developed by standardization bodies, such as the International Organization for Standardization (ISO), Open Geospatial Consortium (OGC), and World Wide Web Consortium (W3C).

In 1994, the US Federal Geospatial Data Committee (FGDC) established the National Geospatial Data Clearinghouse (NGDC; http://www.fgdc.gov/dataandservices), aimed at facilitating efficient access to the overwhelming quantity of existing geospatial data (from federal agencies) and coordinating its exchange, with the objective of minimizing duplication (in the collection of expensive geospatial data) and assisting partnerships where common needs exist. The NGDC is considered the earliest implementation of a geoportal.

Since 1994, the number of countries implementing national geoportals has steadily grown. As of February 2014, around 120 countries have an operational national geoportal in place and 12 countries initiated projects to launch a geoportal in the short-term. Most countries in Asia, Europe, the Middle-East, Oceania, North America, and South America have established a geoportal for their nation, whereas most countries in Africa still have not established such a portal. However, several African initiatives to launch national geoportals appear promising. These national geoportals are evolving worldwide in tandem with national SDIs. A body of literature published in scientific/popular journals and conference proceedings describe the existing experiences (e.g., see conference papers of the Global Spatial Data Infrastructure Association).

First released in 2003, the Geospatial One-Stop (GOS) geoportal was developed as part of a US e-government initiative. Unlike the
National Spatial Data Infrastructure (NSDI) Clearinghouse Network, GOS was built around a centralized metadata catalog database, with an architecture that links users to data providers through a web-based geoportal. The user of GOS may employ a simple web browser (thin client) or may interface directly with a GIS (thick client).

In September 2011, GOS was retired and its content became part of the broader open data site (Geo.)Data.gov (http://catalog.data.gov/dataset). At the same time, the United States federal government launched the Geospatial Platform (http://www.geoplatform.gov/), which represents a shift from focusing on cataloging references and resources, to providing shared web services for nationally significant datasets, an application program interface (API) for developers, and end-user applications (built on those web services and the API).

Geoportals are also implemented at administrative levels other than the national one. These geoportals mainly differ in the size of their spatial coverage, their governance, and the organizations involved in their management. Global geoportals cover the whole world, are based on strong cooperation, and are managed by international organizations, while local geoportals cover a relatively small area (e.g., size of a city, municipality, or county), are more based on clear governance rules and working structures, and are usually managed by local authorities. Each of these geoportals is briefly introduced, followed by some examples.

Global geoportals are electronic facilities that provide access and mechanisms to search geospatial data from all over the world. An example is the GEOSS Portal (http://www.geoportal.org) which is operated by the European Space Agency and the Food and Agriculture Organization of the United Nations. It provides a web-based interface for searching and accessing Earth observation datasets, information, imagery, services, and applications. As such, it aims to connect users around the world to a variety of datasets, services, and portals that provide reliable, up-to-date, integrated, and user-friendly information – vital for the work of decision-makers, managers, and other users of Earth observations.

More recently, there has been a proliferation of geoportals for sharing of geographic information based on an international region. An important example of a regional geoportal is the INSPIRE
Geoportals (http://inspire-geoportal.ec.europa.eu/). This is Europe’s access point to the Infrastructure for Spatial Information in Europe (INSPIRE). The INSPIRE Geoportal has been established using standards and specifications from European, international, and industry consensus-building processes. Where appropriate and possible, this geoportal links to national geoportals and to relevant theme/sector-specific data and services. This geoportal does not store or maintain the data; these are distributed in the many national and thematic/sectorial servers across Europe, and are maintained by the organization responsible for the data. The INSPIRE Geoportal publishes and provides access to metadata and data, and facilitates the delivery, display, and analysis of geographic information. The user can discover and view maps of his/her choice letting the geoportal contact the necessary servers to combine the data.

Other examples of international geoportals are the GeoSUR Portal, Mountain Geoportal, and Central Asian Countries Geoportal. The GeoSUR Portal (http://www.geosur.info/) provides an entry point to geospatial data published by Latin American and Caribbean public agencies. The data may be consulted directly by means of several web services or through metadata services. The Mountain GeoPortal (http://geoportal.icimod.org) is a gateway for geographic information and knowledge resources to support mountain development policies and practices in the Hindu-Kush Himalayan region (which includes: Afghanistan, Bangladesh, Bhutan, China, India, Myanmar, Nepal, and Pakistan). The Central Asian Countries Geoportal (http://www.cac-geoportal.org) mainly aims to distribute geoscientific information to support increased investments in the mining sector of Kazakhstan, Kyrgyzstan, and Tajikistan, and to assist those countries in their efforts related to climate risk management.

Geoportals are also implemented at the level of a state, province, or a similar level of government. An excellent example of this category of geoportals is the IDEC Geoportal – Catalan abbreviation for SDI Catalonia (http://www.geoportal.cat/geoportal/cat/index.jsp, Spain). This geoportal is the gateway to access geospatial information related to the Catalanian state. The Geoportal of IDEC gives access (in Catalan, Spanish, and English) to metadata and web mapping services and provides large amounts of geospatial data and services to the public. For example, almost a billion service requests were made between 2010 and 2012. These included 244 972 requests for discovery services, 732 082 496 for viewing services, 261 878 706 for download services, and 7923 for transformation services. There are also thematic applications addressing the following themes: Planning, Land and Property; Leisure and Entertainment; and Geology. The IDEC Geoportal is accessed by ± 50 000 visitors monthly.

Other interesting State/Provincial geoportals are: Geopunt.be Flanders (geopunt.be, Belgium), Geoportal.rlp – Rhineland Palatinate (http://www.geoportal.rlp.de, Germany), Bayern Geoportal – Bavaria (http://geoportal.bayern.de/georealbayern, Germany) Geoportal Kyzylorda (Baikonyr) region (http://map.e-kyzylorda.gov.kz, Kazakhstan), GeoStor – Arkansas State (http://www.geostor.arkansas.gov, USA), Abu Dhabi Geospatial Geoportal (http://geoportal.abudhabi.ae/geoportal, United Arab Emirates), Geoportal of Province Drenthe (http://www.drenthe.info/kaarten/website/geoportaal, The Netherlands), and New Mexico Resource Geographic Information System (http://rgis.unm.edu, USA). In Switzerland, most cantons manage excellent geoportals, such as Geoportal Canton Bern (http://www.apps.be.ch/geo/de), Geoportal Canton Luzern (https://rawi.lu.ch/themen/geoportal), and
During the past several years, an increased number of local geoportals have been developed. These geoportals are mainly implemented for areas such as a city, municipality, or county. Excellent local geoportals are: Geoportal Kreis Pinneberg (http://www.geoportal.kreis-pinneberg.de, Germany), Geoportal Münsterland (http://www.geoportal-muensterland.de, Germany), Geoportal Waiblingen (http://geoportal.waiblingen.de, Germany), Geoportal BCN–Barcelona (http://www.bcn.cat/geoportal, Spain), Geoportal Campiña de Jerez (http://campinajerez.geoportales.com, Spain), Madrid Geoportales (http://madrid.geoportales.com, Spain), Town in Map ’s-Hertogenbosch (http://geoproxy.s-hertogenbosch.nl/apps1/geoportal.html, The Netherlands), and City of Raleigh Geoportal (http://maps.raleighnc.gov/geoportal, USA). An interesting example of a local geoportal is the one for Eeyou Istchee (http://www.creegeoportal.ca, Canada), which delivers geospatial information to Cree communities to support research, discussion, planning, and decision-making related to resource management and tourism development. This geoportal incorporates Cree traditional knowledge datasets in combination with information and base maps (vector and satellite images) from other distributed data sources.

More recently, there has also been a proliferation of geoportals for sharing geographic information based on themes such as environment, geology, culture, tourism, archeology, and statistics. The following geoportals focus on a specific theme. The NatCarb Geoportal (http://www.netl.doe.gov/research/coal/carbon-storage/carbon-storage-natcarb) provides geographic information concerning carbon sequestration in the USA. The EPA Geoportal of the Irish Environmental Protection Agency (http://gis.epa.ie) is designed to make data about the environment easier to find, browse, and understand. The OneGeology-Europe Geoportal (http://onegeology-europe.brgm.fr/geoportal/viewer.jsp) allows users to make digital geological data more easily accessible and useable. The Spain is Culture Geoportal (http://geo.spainsculture.com/index.php/es) from the Spanish Ministry of Education, Culture, and Sport provides information about cultural sites in Spain; meanwhile GeoVisitGuatemala (http://www.geovisitguatemala.com) provides users access to relevant tourist information about Guatemala. The Archeological Atlas of the 2 Seas (http://www.a2s-geoportal.eu) is a gateway to underwater heritage. It aggregates information about archaeological sites that lie beneath the Channel and the North Sea (Europe), as well as sites situated on the foreshore, dating from prehistoric to the present time. Finally, the national statistics agency of Colombia developed the SIGE Geoportal (http://www.dane.gov.co/geoportal), which provides facilities to access statistical information for the territory of the Republic of Colombia.

Other geoportals are an initiative of a specific sector. A good example of a sectorial geoportal is the Scholars Geoportal (http://geo1.scholarsportal.info), which is a web portal of the Ontario Council of University Libraries consisting of a consortium of 21 academic libraries in the province of Ontario (Canada) acting under the authority of the Council of Ontario Universities. It provides access to millions of articles and electronic books, as well as numeric and geospatial data files for the use of researchers and students of its member libraries.

Finally, some geoportals concentrate on just one specific type of geospatial data. For example, the Russian Federal Space Agency (Roscosmos) launched a geoportal (http://geoportal.ntsomz.ru) that provides access to remote sensing images.
of the Earth only. The images are acquired by Russian remote sensing satellites and updated on a daily basis. It has around 900,000 monthly visitors.

Two examples that will likely set the future direction of geoportals are the OpenGeoportal initiative and the EnerGEO Knowledge Geoportal. OpenGeoportal (http://opengeoportal.org) is a collaboratively developed, open source, federated geoportal used to rapidly discover, preview, and retrieve geospatial data. It is also a collaborative effort to share resources and best practices in the areas of application development, metadata, data sharing, data licensing, and data sources in support of geospatial data repositories. The OpenGeoportal brings together geospatial professionals, developers, metadata specialists, and librarians in order to develop facilities to discover and acquire geospatial data across many organizations and platforms. The initiative also focuses on the development of The Open Geoportal Cloud Federation for sharing innovative ideas and best practices around open source SDI. The EnerGEO Knowledge Geoportal (https://energeo.researchstudio.at/) is an EU EnerGeo project that aims to provide a versatile modeling platform that will enable planners, environmentalists, and governments to calculate, forecast, and monitor the environmental impact of changes in energy mixes on local, regional, and global scales. This gateway to web-based geospatial resources enables users to discover, view, and access geospatial data, services, and applications made available by several providing organizations. Likewise, data providers use the Geoportal to make their geospatial resources discoverable, viewable, and accessible to others. These resources can be metadata records, geospatial datasets, web services, videos, SharePoint® documents, RSS feeds, KML (formerly Keyhole Markup Language) documents, metadata catalogs, and more.

**Further reading**

Georeferencing is the process of linking between an entity and a spatial footprint. For example, a linguistic sign, such as a piece of text like the mention of a place name (e.g., Paris) or postal address (e.g., 7 Cosin Court, Cambridge, CB2 1QU, England, UK), can be associated with a particular place on Earth referred to by such an expression, which may be a polygon or a centroid (i.e., a geospatial “center of gravity”) given as latitude and longitude, for instance.

This entry discusses georeferencing as a concept, and furthermore, it describes the nature of georeferenced datasets, the motivation for and history of creating online georeferenced datasets, means to automatically obtain them using toponym resolution, and some applications enabled by it.

Automatic georeferencing as a method (as applied to textual document collections in particular) is described below as a combination of a named entity recognition and classification (NERC) process that recognizes and classifies mentions of places (NERC specifically for geographic named entity types only is also known as “geoparsing”) combined with a toponym resolution process that disambiguates, if necessary, using linguistic and spatial context, that is, it selects one single, most likely intended, spatial interpretation among a set of candidate locations looked up in a gazetteer (a database comprising toponyms, geographic feature types, and spatial footprints). A candidate location (or candidate for short) is a potential referent, that is, the set of all theoretically possible interpretations of places with the same name.

Motivation

A text collection (or any other collection of things, for that matter) is said to be “georeferenced” if particular elements of that collection are linked to a spatial footprint (if we limit our investigation to terrestrial geography, we may speak of a “geospatial” footprint). Researchers have attempted to georeference collections of videos, collections of photos uploaded to photo-sharing websites (digital photographs often contain location information by making use of GPS, the Global Positioning System), and collections of mostly textual documents, including digitized historic manuscripts and webpages from the World Wide Web.

Any georeferenced collection has the advantage that it is capable of being processed by computer with regards to carrying out spatial operations on it (plotting maps, filtering by country, etc.); for example, using the set of words as the representation of a story does not permit us to compute the geographic distance between two stories, one about Mountain View, CA, the other one about San Francisco, CA. But once the stories are connected with a spatial footprint, we can calculate the distance to be 52.32 km (or 32.51 miles) from the numeric latitude/longitude representation of the cities’ respective centroids. Furthermore, there are numerous applications in the natural sciences and medicine: for example, in botany we may want to georeference a document collection.
describing sighting of particular plants, in order to determine the geographic distribution of species. Or an epidemiologist may want to visualize the spread of a disease based on aggregating georeferenced reports about disease outbreaks.

Where spatial metadata such as GPS coordinates are not available, spatial information may be annotated manually, but due to the time and cost required, manual processing is not a viable solution for larger datasets; automatic methods for adding spatial metadata to textual collections have thus been investigated.

History

After some initial, isolated system development efforts in the areas of digital libraries (Smith and Crane 2001), web search, (Ding, Gravano, and Shivakumar 2000), and the defense sector in the 1990s, academic research interest began in the natural language processing community marked by a workshop held at the Joint Conference on Human Language Technology and the Annual Meeting of the North American Chapter of the Association for Computational Linguistics (HLT-NAACL) in Edmonton, Alberta, in 2003 (Kornai and Sundheim 2003), where new algorithms, systems, and applications were presented. An early landmark publication was the monograph by Hill (2006) on georeferencing, the publication of which, however, occurred while research on the topic, especially on algorithms, was still nascent.

Around the same time the Cross-Language Evaluation Forum (CLEF), a European forum for researchers interested in information retrieval in different languages, carried out a shared task (i.e., an international evaluation campaign for benchmarking the state of the art under controlled conditions), called “GeoCLEF” on geographic information retrieval evaluation (Gey et al. 2006). From the campaign emerged a sense that the problem was harder than anticipated, and the evaluation itself posed some challenges (such as geographic diversity of queries and documents in the evaluation collection). Independently, a series of workshops on geographic information retrieval (GIR) have also been held since 2004 as satellite events at geographic and natural language processing conferences (Purves and Jones 2004) to bring the information retrieval and geographic information systems (GIS) communities together.

As a result of the HLT-NAACL, CLEF, and GIR workshops, interest was stimulated in various research communities, which spurred the development of novel methods for toponym resolution and geography-aware search. However, emerging approaches that applied “toponym resolution” (Leidner 2007) to create metadata tags in order to transform implicitly georeferenced collections into explicitly georeferenced collections suffered from the lack of evaluation datasets, a shortcoming which was eventually (at least partially) addressed by the TR-CoNLL and TR-MUC4 corpora (Leidner 2006) and the TRML (Toponym Resolution Markup Language) and SpatialML mark-up languages (Mani et al. 2008).

More recently, toponym resolvers have made use of knowledge-based resources like Wikipedia for inducing statistical classifiers (Speriosu 2013), and adaptive systems for processing document collections performing stream-oriented toponym resolution in feeds of news or social media (i.e., user-generated content) have been developed (Lieberman and Samet 2012).

Terminology

Looking at the linguistic expression of spatial signs, we can distinguish between a toponym, which denotes a single sign (e.g., Long Island) versus a geographic expression, which is a complex
sign (e.g., 10 km north of Paris), for which linguistic rules of semantic compositionality apply. If *spatial grounding* is any association of an entity (such as a linguistic sign) with spatial footprints, then we can distinguish between (address) geocoding, the mapping from postal address records (such as those that can be found in relational databases used for advertising; governments are increasingly under pressure, due to the Linked Open Data movement, to make postal address data and ZIP code information curated from taxpayer income available free of charge) to geospatial footprints and *toponym resolution* (TR), a term coined in Leidner (2006) to denote the mapping from place names mentioned in “unstructured” text to geospatial footprints.

Toponym resolution as a task is challenging for two reasons: (i) *geo/non-geo ambiguity* refers to the potential for confusing toponyms with other words that are not associated with a location – for example, the Turkish city of Of can be confused with the English particle of (which is capitalized at least at the beginning of sentences) – and (ii) *geo/geo ambiguity* is the potential for confusing different referents for a toponym (Paris can refer to Paris, France, or to Paris, Texas, USA, for example). There are millions of named places on Earth, many of which share the same name: for instance, there are over 1600 attested places called Santa Ana. The same geographic names have historically been used by emigrant settlers to denote their new homes, leading to referential ambiguity of place names for machines and sometimes for humans as well. Occasionally, the original name was modified (as in York versus New York).

Toponym resolution requires a number of steps: (i) identifying place names in texts via geoparsing, (ii) retrieving candidate location information from a gazetteer, and (iii) resolving toponyms by selecting one particular candidate from the retrieved set. A toponym resolver performs all three tasks, either sequentially or in an integrated fashion.

A *gazetteer* is a database comprising toponyms, geographic feature types, and spatial footprints, and it provides a mapping toponym $\rightarrow$ feature $\times$ footprint (Hill 2006). Toponym resolution requires the use of gazetteers, since the candidate places to choose from are external world knowledge that cannot be derived from linguistic principles alone (i.e., pragmatic rather than semantic in nature). Geoparsing is the task of identifying the names of places in textual documents (introduced above as NERC). A *toponym resolver* is a program that can carry out the toponym resolution task automatically; it typically contains a geoparser to identify mentions of places and a gazetteer to look up candidates to be chosen from. By analogy, a geocoder carries out the geocoding task automatically on address record data instead of unstructured (prose) text.

A georeferenced document collection contains metadata that links postal addresses, toponyms, geographic expressions, or other location-related textual signs with spatial footprints that refer to the locations in the world external to the text. The addition of such metadata annotation transforms implicitly georeferenced data (e.g., a mention of Paris) into explicitly georeferenced data (e.g., a mention of Paris marked up with XML (Extensible Markup Language) tags referring to the intended Paris’s latitude and longitude). So geocoders and toponym resolvers both turn implicitly georeferenced datasets into explicitly georeferenced datasets.

**Methods**

Methods for toponym resolution can be grouped into two broad categories: (i) heuristic-based methods, which utilize rules informed by human intuition or observations, and (ii) learning-based
methods, which are informed by statistical associations (correlations) acquired from the mentions of toponyms in a training corpus (a ground truth reference dataset annotated by humans) and the associated features of the contexts in which they occur.

Heuristic-based methods

A detailed survey of the literature is given in Leidner (2007). Hauptmann and Olligschlager, as cited in Leidner (2007), propagate readings from explicitly disambiguated contexts (London, Ontario) to other mentions of the same token without any contextual cues (London), thus implicitly applying the common heuristic “one sense per discourse”: it assumes humans never mix different Londons in the same document without giving explicit guidance for the human reader.

Others, such as Smith and Crane (2001), rely on more spatial heuristics, such as the iterative computation of a geographic region of interest: a centroid for a document is first calculated by creating a bitmap of frequency-weighted mentions of toponym candidates (all candidates considered equally likely initially); then, candidates further away from the centroid than two standard deviations are discarded, which leads to a revised centroid. A sliding window containing four mentions of ambiguous toponyms is then used to incrementally resolve each of them, using local rules such as disambiguation patterns, and the per-document centroid as background knowledge.

Perhaps the single most effective heuristic is using population knowledge to favor candidate toponym interpretations that have a higher population, a technique that works particularly well for news documents.

Another type of evidence is the spatial minimality heuristic, which forms the basis of the “minimum bounding polygon” assumption (Leidner, Sinclair, and Webber 2003). The latter can be stated as: “For a set of toponyms in a document or paragraph, always assume the interpretation that minimizes the area of the smallest polygon that contains all candidate referents.” In other words, as can be seen in Table 1, this heuristic exploits the fact that toponyms mutually disambiguate each other because of the higher likelihood that places in geographic proximity to each other are also more likely to get mentioned together. The spatial minimality heuristic also works with superordinate and subordinate toponyms represented as centroids, but should be restricted to application within one event or story to be most effective.

In an attempt to organize how the various approaches relate to each other, Leidner (2007)

| { Berlin; Potsdam; Babelsberg }  | →  | Berlin, Germany |
| { Fairburn; Berlin; Green Lake } | →  | Berlin, WI, USA |
| { West Berlin; Bishops; Dicktown } | →  | Berlin, NJ, USA |
| { Kensington; Berlin; New Britain } | →  | Berlin, CT, USA |
| { Copperville; Berlin; Gorham } | →  | Berlin, NH, USA |
| { Atlanta; Moultrie; Berlin } | →  | Berlin, GA, USA |
| { Berlin; Prouty; New Berlin } | →  | Berlin, IL, USA |
presents a synthetic typology comprising 16 types of spatial and linguistic knowledge (heuristics, pieces of evidence) used in systems up to that time, and an analysis of the various systems in which they are applied.

**Learning-based methods**

An early method of machine learning-based approaches to toponym resolution is the generation of synthetic training data in nearly limitless supply by taking identified toponym mentions that are already uniquely resolved due to subsequent mentions of geographic cues, and by treating these as class labels for training (Smith and Mann, as described in Leidner 2007). After training, the classifier is capable of tagging mentions of “Paris” with the tag “TX,” effectively recovering the most likely candidate seen in the training data, given the particular linguistic context, that is, we apply the class labels to disambiguate toponyms from a test text based on the class characteristics associated with the identified toponyms. For example, “Paris, TX” is treated as a training data point “Paris” with the tag “TX,” and a naïve Bayes classifier using a sliding window of context words as input feature vectors can be trained so as to be able to correctly tag “Paris” with its “TX” pseudo-tag in a version of the data with the pseudo-tag removed. Given enough training material, this reportedly worked over 87% of the time. The downside of the method is that not all toponyms are necessarily annotated by easy-to-identify cues often enough to train one classifier per toponym successfully.

Speriosu (2013) describes a set of learning-based classifiers. The strongest presented approach uses machine learning to construct one model per toponym using so-called indirect supervision: his method WISTR (Wikipedia Indirectly Supervised Toponym Resolver) uses a document centroid and generates training instances at the toponym level using a lookup of toponyms in a separate training corpus (based on the body of all Wikipedia articles which contain manually crowdsourced geographic references) with candidate locations close to location labels on the documents containing them. For example, the Wikipedia articles “Portland Youth Philharmonic” and “Widgery Wharf” have both been manually georeferenced by Wikipedia’s authors (Speriosu 2013). From this information we can infer, for instance, that $P(\text{Portland, Oregon} | \text{“music”}) > P(\text{Portland, Maine – “music”})$ and $P(\text{Portland, Oregon} | \text{“wharf”}) < P(\text{Portland, Maine – “wharf”})$, where $P$ represents probability. Any “Portland” mentions yet to be disambiguated are more likely to be in Oregon if “music” occurs in the textual environment, but are more likely to be in Maine if “wharf” occurs in the textual environment. The reason is that there exists the Wikipedia entry for Widgery Wharf in Portland, Maine, so the word “wharf” bears a stronger statistical association with Maine than with Oregon. Likewise, the georeferenced article “Portland Youth Philharmonic” is about music, hence the word “music” has stronger statistical ties with Portland, Oregon, than with its counterpart in Maine. The WISTR method is a supervised resolver that incorporates more knowledge than heuristic-based resolvers, while not requiring any hand-annotated training instances of the same type as the evaluation instances used (beyond the already-existing manual georeferences in Wikipedia).

Furthermore, Speriosu (2013) also frames toponym resolution as an instance of the traveling purchaser problem (a generalization of the NP-complete traveling salesman problem), where he explicitly models the individual resolution power of the WISTR classifier and spatial minimality as two components of a cost function to be optimized for each document. Ant colony optimization techniques are then used to find
approximately best solutions, but the method is not reported to surpass results of the simpler WISTR method.

**Evaluation**

**Evaluation methodology**

When building any system, it is important to be clear and explicit about how to evaluate success. A complete experimental protocol requires (i) controlled (comparable) conditions in which alternative methods are compared to each other, which in the case of toponym resolution means using both the same gazetteer and the same evaluation dataset, (ii) specifying a metric to quantify system quality, and (iii) specifying the methods compared in a way that can be replicated, at least in principle.

There are many different ways in which a system comprising different subtasks (identifying toponym mentions, disambiguating them) may be evaluated. Leidner (2007) distinguishes between “in vitro” (component) evaluations, where a perfect (oracle) ability of recognizing place names is assumed, to measure a toponym resolver’s ideal-case behavior, and “in vivo” (system) evaluations, which, especially when contrasted with in vivo scores, attest to a methods robustness in the face of systematic errors caused by upstream name taggers.

For example, Amitay et al. (2004) evaluated their Web-a-Where system by running it over three web collections, and using human post hoc judgments to measure the correctness of tagging place names while using the Open Directory Project’s (ODP) location categories as reference answers against which to compare their system’s geofocus algorithm (which has a reported accuracy of 38% for the latter task).

Leidner (2007) was the first controlled study that compared the performance of various heuristics, previously proposed as well as novel, as well as various system combinations, using both the same gazetteer and the same, manually georeferenced, test data collection. The motivation behind it was that prior work had either not reported quantitative performance metrics, or quantitative results were of limited use, as they could not be compared due to differences in the task or even task difficulty.

**Evaluation datasets**

A core prerequisite for building georeferencing systems such as toponym resolvers is the availability of ground truth datasets that can be used to compare system-generated spatial metadata with that ground truth to evaluate the accuracy of the systems. Reference data comprises the original data (such as historic or news documents) and spatial metadata in some standardized annotation format, which may be an application of XML.

Leidner (2006) presents the annotation format TRML, an XML application, and Mani et al. (2008) present SpatialML, the design of which was informed by TRML and for which translations from and to TRML have been defined. Leidner (2006) also describes TR-CoNLL, a dataset that was dedicated specifically for the evaluation of toponym resolution by adding a spatial metadata layer on top of an existing news corpus already commonly used in named entity tagging research. TAME, a web-based editor for generating such datasets, is also presented. Leidner (2007) uses TR-CoNLL and TR-MUC4, another corpus of intelligence analyst reports marked up with spatial metadata. The rationale of using the two datasets in particular was to be able to compare general news stories, which have a rather global geofocus, with stories that describe specific events, focusing on a particular region (e.g., Central America). Both corpora contain annotations
for all toponyms with latitude and longitude information. TR-CoNLL has been used by many research groups in academia, industry, and governments to evaluate different systems.

An alternative evaluation corpus is presented by Overell and Rüger (2006), who describe an evaluation based on a random sample of 1000 Wikipedia pages manually annotated with place names and latitude/longitude information against the Getty Thesaurus of Geographic Names (TGN). The advantage of Wikipedia is its convenient license, which avoids copyright limitations of the data. However, the use of the Getty Thesaurus, a commercial resource, reintroduces these issues. The encyclopedic style of Wikipedia is also more distinct from “general prose” than news articles.

State of the art

Achieving explicit georeferencing for textual data automatically through applying toponym resolution remains a challenging task. Precision (P), Recall (R), and their harmonic mean, F-Score, are the most common metrics used to report the quality of toponym resolution methods.

Leidner (2007) finds that minimality-based heuristics such as spatial minimality (implemented as “assign the interpretation of all toponyms that minimizes area of the bounding rectangle”) and a variant of Yarowsky’s rule from word sense disambiguation (“assume one referent per discourse”) are strong pieces of evidence, together with the maximum population heuristic and contextual patterns. In combination, these rules outperform earlier methods like Smith and Crane (2001). However, the maximum population heuristic alone often beats more complex methods and systems.

Speriosu (2013) reports 62.2% F-Score (P = 74.0%, R = 53.6%) for his learning method WISTR on a held-out test-set portion on TR-CoNLL using automatic NERC to recognize place names. For the same portion of the data, a simple “maximum population” heuristic achieves an F-Score of 60.2% (P = 71.7%, R = 52.0%) with less computational effort. This means that nearly three out of four toponym mentions processed can be mapped to the right coordinates, but that only about half of the toponyms could be resolved. Findings by Leidner (2007), Speriosu (2013), and others also suggest that population is a very strong predictor for the place intended by a toponym mention, and it appears that combining methods, as well as making use of external knowledge, is required to perform significantly better. However, population statistics are not always available, an issue that holds especially for smaller places. Complementarily, local textual evidence (such as contextual patterns) has been found, in general, to be more helpful with global-scope news corpora, whereas spatial evidence (such as the spatial minimality heuristic) have been found to be more valuable with corpora that have a more narrow, “zoomed-in” geofocus, such as intelligence reports.

To achieve significantly higher results, larger training corpora and more investigations into the combination of sources of evidence will be required, and better ways to make toponym resolution automatically adaptive to the text type and specifics of the corpus under consideration should be studied. A broader scope for improvement of robustness of existing techniques could be provided by the exploitation of the confidence level of interim resolution decisions.

Applications

Once a document or document collection has been processed by a toponym resolver, this opens up many possibilities for applications (Leidner
We can distinguish between applications that directly deliver value to the user and such applications that feed into further automatic processing to serve another end.

The most common applications of georeferenced collections are map visualization, spatial summarization, and interactive browsers. Each toponym grounded by resolving it to a centroid given as a latitude and longitude coordinate pair can be placed on a geographic map. A web-based system can retain the link between text and space by providing a hyperlink from the textual occurrence to a point of interest (POI) on the map, which permits navigation back and forth between the textual and the geospatial views.

Spatial summaries are visual surrogates that permit an at-a-glance overview, aggregating the locations mentioned in georeference collections. While tag clouds often serve that purpose for nonlocation key words, georeferenced collections can provide better spatial surrogates for toponyms in the form of polygons or point clouds, indicating the frequency of mention of locations in a story or collection by representing increased density via rendering them as darker colors (spatial heatmaps), for example.

Going beyond static maps, georeferenced collections permit interactive exploration using special browsers or applications and web browser plugins such as Google Earth (http://www.google.com/earth/; formerly known as Keyhole), which uses KML (Keyhole Markup Language), an XML application, for marking up locations, which can be rendered in custom-purpose layers on a three-dimensional model of the globe, which can be rotated, looked at, zoomed in and out, and hyperlinked with other documents (Speriosu 2013).

All of these mapping applications can serve a range of purposes, such as (i) the mapping of crime “hot spots”; (ii) intelligence analysis to spot patterns in terrorist attacks in order to prevent them; (iii) to inform political and commercial decisions such as taking unstructured textual sources (e.g., complaints on social media) into account when making decisions about where to place a new school so that it can serve the largest number of households, or where to place an additional branch of a chain so as to serve their respective constituents best – these latter problems could traditionally only consider structured household or census data, whereas georeferencing additionally permits the use of data sources made up of textual (“unstructured”) prose to supplement the evidence; (iv) the georeferencing of digitized historic text collection in order to support historic research (Smith and Crane 2001), an important part of digital humanities scholarship – geographic boundaries are changing due to changes in physical geography or administrative reorganizations, and to map between historically accurate boundaries remains a challenge.

A fundamentally important function of computer processing is to support a user’s search for information. Georeferenced datasets are more searchable because they support spatial filtering as an advanced search operation, for example to retrieve and show on a map only those documents that mention a particular city, region, or country. Since documents may contain toponyms of various feature types and levels of granularity (from continent to village), keyword matching is not enough to identify location (a text about the political unit the United Kingdom of Great Britain and Northern Ireland or about the geographic unit of the British Isles may just mention London, but is relevant to an information need expressed in a query as “UK” by implication). While it is possible to model geographic or geopolitical part-of relationships as taxonomies or ontologies and to use a purely term-based approach, query expansion with all subterms is likely to retrieve...
many irrelevant documents. In contrast, a spatial filtering approach can be informed by the actual polygons associated with explicitly mentioned toponyms, as was attempted in the SPIRIT geographic search engine at the University of Sheffield and some participants at GeoCLEF mentioned above. Web search engines can benefit from assigning a geographic scope to a webpage at indexing time (Ding, Gravano, and Shivakumar 2000), although different notions of place can (and should) be distinguished (location of the web server, location of the author of a story, location of where an event happens, etc.). Given a particular area of interest, expressed as a pair of a centroid and a diameter or as a polygon, incoming news stories from a feed can be georeferenced, and matched against such a so-called geofence. In case the story mentions an event inside the area of interest, an automatic alert can be initiated.

Once both large georeferenced collections of documents and comprehensive gazetteers are available, spatial reasoning opens up further possibilities for automatic processing. If a city is mentioned to have been the target of two terrorist attacks in a year, and if we further know via gazetteer lookup what country the city is in, then an information need regarding the number of terrorist attacks in that country can be calculated bottom-up from all such individual events in cities in the country under consideration.

Answering geospatial questions is a natural application that can benefit from the reasoning capabilities mentioned above. Once toponyms in documents are georeferenced, questions like, Which town north of Springfield did Peter travel to? can be answered correctly and automatically, given a document, even if Peter traveled to two different towns (if the second town was mentioned as being south of the Springfield referred to). In a similar way, distance questions can be answered numerically, that is, based on an actual distance calculation rather than by extracting a text fragment stating the distance in sentence form, as such textual fragments are unlikely to exist for all pairs of any two toponyms (Leidner 2007). The increased use of mobile devices suggests spatial technologies like georeferencing will grow in importance in the future.

Geospatial metadata

David J. Cowen
University of South Carolina, USA

In the general context, metadata is data about data. For example, the metadata for a phonecall would include information about the sender, receiver, location, date, time, and duration. The library card catalog is the most common example of a metadata collection and the Dewey Decimal System is a familiar classification system for describing specific items. Nutritional labels on packaged food products are mandatory metadata descriptions. In a digital Internet environment metadata provide the basis for search, interchange, and even mapping. Therefore standardized metadata entries have emerged in almost every industry. For example, the Exchangeable image file format (Exif) adopted by the photography industry provides fields for latitude and longitude that can be added from a GPS unit in a camera or with GIS software.

The widespread emergence of geographic information system (GIS) files, geospatial databases, and Earth imagery, and the desire to exchange them, prompted the development of standardized geospatial metadata. According to the Federal Geographic Data Committee (FGDC), geospatial metadata represent the who, what, when, where, why, and how of a geospatial data set (FGDC n.d.a). Generally, the metadata for a resource should enable a potential user to determine its fitness for use for a specific application. This would include the following types of information:

- means of creation of the data;
- purpose of the data;
- time and date of creation;
- creator or author of the data;
- location on a computer network where the data were created;
- standards used.

Beyond high-level characterizations, the metadata should provide information about the technical and legal details pertaining to acquiring and using the data. In a similar way to the library patron performing a search on a digital card catalog, the GIS user can use metadata about a geospatial data asset to determine whether to acquire it.

The clearest legal statement regarding geospatial metadata was issued by the US Office of Management and Budget as part of the 2002 Circular No. A-16 Revised, “Coordination of Geographic Information and Related Spatial Data Activities”:

Metadata are information about data and/or geospatial services, such as content, source, vintage, spatial scale, accuracy, projection, responsible party, contact phone number, method of collection, and other descriptions. Metadata are critical to document, preserve and protect agencies’ spatial data assets. Reliable metadata, structured in a standardized manner, are essential to ensuring that geospatial data are used appropriately, and that any resulting analysis is credible. Metadata also can be used to facilitate the search and access of data sets or geospatial services within a Clearinghouse or data library. All spatial data collected or derived directly or indirectly using federal funds will have FGDC metadata.

(Office of Management and Budget 2002)
GEOSPATIAL METADATA

During the 1980s the growth of GIS technology was supported by the large-scale conversion of traditional maps by federal agencies such as the US Geological Survey and the Bureau of the Census. At the same time, state and local governments began to develop their data. Most of this data creation was intended for internal use, with little consideration for data exchange. In fact, data exchange was hindered by complex vendor-specific proprietary data formats. Furthermore, there was little consideration for spatial data quality or documentation. When GIS implementation migrated from mainframe computers to minicomputers, workstations, and ultimately personal computers, new users often wished to incorporate existing GIS data. This expansion encouraged partnerships based on shared approaches to data creation and distribution. The notion of a spatial data infrastructure gained important legal status in the United States with President Clinton’s 1994 Executive Order 12906 to create the National Spatial Data Infrastructure (NSDI) (Federal Register 1994). This executive order defined the NSDI as “the technologies, policies, and people necessary to promote sharing of geospatial data throughout all levels of government, the private and non-profit sectors, and the academic community.” The goal of the infrastructure was to reduce duplication of effort between agencies, to improve quality and reduce costs related to geographic information, to make geographic data more accessible to the public, to increase the benefits of using available data, and to establish key partnerships with states, counties, cities, tribal nations, academia, and the private sector to increase data availability. From the beginning, metadata was viewed a critical part of the NSDI. In fact, Executive Order 12906 included a timetable for implementation:

Beginning nine months from the date of this order, each agency shall document all new geospatial data it collects or produces, either directly or indirectly, using the standard under development by the FGDC, and make that standardized documentation electronically accessible to the Clearinghouse network.

(Federal Register 1994)

The FGDC Standards Working Group established the first Content Standard for Digital Geospatial Metadata in 1994 and the current standard in 1998 (FGDC 1998). The standard describes the data elements and provides details about how they were produced. The general information contained in the metadata standard fall into the following categories.

- **Identification**: What is the name of the data set? Who developed the data set? What geographic area does it cover? What themes of information does it include? How current are the data? Are there restrictions on accessing or using the data?

- **Data quality**: How good are the data? Is information available that allows a user to decide if the data are suitable for his or her purpose? What is the positional and attribute accuracy? Are the data complete? Were the consistency of the data verified? What data were used to create the data set, and what processes were applied to these sources?

- **Spatial data organization**: What spatial data model was used to encode the spatial data? How many spatial objects are there? Are methods other than coordinates, such as street addresses, used to encode locations?

- **Spatial reference**: Are coordinate locations encoded using longitude and latitude? Is a map projection or grid system, such as the State Plane Coordinate System, used? What horizontal and vertical datums are used? What parameters should be used to convert the data to another coordinate system?

- **Entity and attribute information**: What geographic information (roads, houses,
The creation of XML-structured metadata for geospatial data and services has facilitated discovery across the Internet. Metadata linked to servers provide hyperlinks to online resources such as map services, data download locations, data access services, and even applications. Web-crawling tools can utilize these XML files to search for data, harvest them, and create organized collections of data themes. These collections or clearinghouses provide a larger “card catalog” for data publication and discovery. Since all clearinghouse servers are peers, it is possible for communities to form common metadata services. These servers may be installed at local, regional, or central offices. In some cases, these clearinghouses serve as access points for data download. In others, the metadata provides a link to the owner who controls access. While many organizations freely expose their data and encourage download, others may require payment and licensing agreements. For example, the GIS Inventory System established by the National States Geographic Information Council (NSGIC) organizes the metadata provided by state and local governments to build statewide spatial data infrastructures (NSGIC n.d.). As part of its mission, the FGDC created many of these distributed clearinghouses that conformed to specified formats. Now, using the Geospatial Platform, users can search the metadata for US federal geospatial assets. From this cloud-based portal, a user not only has access to the description of the data but can often download it or incorporate the data into a project as a service without needing to duplicate the data (FGDC n.d.b).

The Content Standard for Digital Geospatial Metadata (CSDGM) of 1993 became a model for international standards efforts. In 1996 the International Standards Organization (ISO) began an effort to create an international metadata standard. The ISO process took several years of
GEOSPATIAL METADATA

consensus building by representatives of several nations. This effort resulted in the 2003 release of ISO 19115 Geographic Information – Metadata (ISO 2003). The emergence and adoption of an international standard for metadata was a major step forward in the maturity of geospatial disciplines. The international metadata standard incorporated the basic objectives for data discovery, fitness for use, data access, and transfer. It retained the critical information about spatial extent, quality, temporal dimension, and distribution for individual data features, as well as datasets and series. The developers of the ISO standard sought to expand metadata to a wide range of geographic products, such as web services, data catalogs, and clearinghouse activities. It incorporated open domains and optional elements that enabled greater flexibility than the United States standard individual dataset descriptions. While the CSDGM was written as a text document, ISO metadata was created using the Unified Modeling Language (UML), which can be represented in a consistent XML format. This effort has been fostered by the Open Geospatial Consortium (OGC), which released Geography Markup Language (GML), an XML grammar for geospatial features (OGC n.d.).

In 2010 the FGDC adopted the following components of ISO 19115.

- ISO 19115 – 2: 2009 Geographic information – Metadata – Part 2: Extensions for imagery and gridded data, including the base ISO 19115 metadata standard plus extended elements for the description of imagery, gridded data and data collected using instruments, e.g. monitoring stations and measurement devices …
- ISO 19110: 2005 Geographic information – Methodology for Feature Cataloging: An affiliate standard that supports the detailed description of feature types (e.g., roads, rivers, classes) in a manner similar to the CSDGM Entity/Attribute Section. The standard can be used in conjunction with ISO 19115 to document geospatial data set feature types or independently to document data models or other feature class representations.
- ISO 19119: 2005 Geographic information – Services – Amendment 1: Extends the service metadata model and serves as an affiliate standard that supports the detailed description of digital geospatial services including geospatial data portals, web mapping applications, data models and online data processing services. The standard can be used in conjunction with ISO 19115 to document services associated with a specific data set/series or independently to document a service.
- ISO 19139: 2007 Geographic information – Metadata – XML schema implementation: An XML document that specifies the format and general content of an ISO 19115 the metadata record. (FGDC n.d.c)

Recently, representatives from the United States and Canada developed the North American Profile (NAP) for the ISO metadata standard. The creation of the NAP represents a cooperative effort to establish a common geographic metadata standard that meets the needs of both nations and supports the North American Free
GEOSPATIAL METADATA

Trade Agreements (NAFTA). The NAP conforms to the ISO standard but is considered to have a more complex and robust structure than ISO 19115. Specifically, it has fewer mandatory and more optional elements, and also incorporates extended as well as new elements to capture more specific information. It uses a hierarchical structure that creates packages of metadata that can be reused and combined to form new metadata records. It also provides support for the documentation of new geospatial data topologies and technologies including geodatabases, web-mapping applications, data models, and data portals. Finally, it also provides opportunities to include suggested best practices for populating metadata elements in a manner that enhances the quality and usefulness of the metadata.

One of the strong points of the NAP is the inclusion of topic categories that are not part of the CSDGM metadata records. The following set of 19 high-level subject categories provides a standardized means of quickly sorting and accessing thematic information: farming; biota; boundaries; climatology meteorology atmosphere; economy; elevation; environment; geoscientific information; health; imagery base maps earthcover; intelligence military; inland waters; location; oceans; planning cadastre; society; structure; transportation; and utilities communication.

In the long term, the NAP of ISO 19115 will become the stable metadata standard for North America. The FGDC is currently working to educate users about the NAP and to accelerate its adoption. A major component of this effort includes the establishment of a Metadata Transform Working Group that is led by the National Oceanic and Atmospheric Administration’s (NOAA) National Coastal Data Development Center (NOAA n.d.). This group is developing software tools that ease the transformation of existing metadata files into the NAP. These developments are based on Extensible Stylesheet Language Transformations (XSLT) which is a language for transforming the XML documents. The GIS industry has matured since the mid-1990s. Both producers and consumers have recognized the benefit of documenting geospatial data and services. Prompted by executive-level mandates, the FGDC developed and promulgated the use of standardized metadata. Backed by software developers, the completion of metadata has become a critical part of GIS best practices. XML-based metadata has enabled the creation of web-based clearinghouses that are used to discover and acquire a wide range of geospatial resources. The structure of geospatial metadata is now an international standard that facilitates the development and exchange of data. The adoption of a specific multinational profile for North America is a further sign of the increased importance of geospatial data and services for commerce, logistics, and policy.

GEOSPATIAL METADATA

The Semantic Web was brought to life in May 2001 following the publication of a highly influential article in *Scientific American* by Tim Berners-Lee, James Hendler, and Ora Lassila (2001). The authors were certainly well known. After all, Sir Tim Berners-Lee was the inventor of the World Wide Web, Hendler was a professor of artificial intelligence who pioneered web-scale knowledge representation languages and was managing the DARPA (Defense Advanced Research Projects Agency) Agent Markup Language (DAML) program, and Lassila was serving on the World Wide Web Consortium’s (W3C) advisory board and had just finished the specifications for the new machine-understandable Resource Description Framework (RDF). Their article outlined a vision for a next-generation web-based infrastructure in which content would be described semantically. This would make it accessible to humans and machines alike in a way that would empower intelligent personal assistant systems to draw conclusions from existing data and to connect multiple data sources on-the-fly to perform complex tasks.

Interestingly, the first example given in the *Scientific American* article is a geospatial one. The authors envisioned a Semantic Web agent that is able to check for local health-care providers within a 20-mile radius of a home by knowing and understanding a user’s health coverage plan. More than a decade later, semantically enabled intelligent personal assistants such as Apple’s Siri are available on most modern smartphones, millions of webpages contain semantic markup, and Google maintains a knowledge graph to enrich query results by directly answering questions instead of merely returning a ranking of webpages.

To understand the value proposition of the Semantic Web as well as design decisions made for its various technologies and standards, it is important to briefly revisit the history of the field. According to Berners-Lee, the reason for the success of the World Wide Web lies in its decentralized nature, its focus on being a social medium, not merely a technological one, and its unique perspective on robustness and reliability. The early web had no built-in mechanism to rate the quality or veracity of content, no hierarchical structure that would favor one site over the other, and no means to ensure that contents were readily available, no matter how important they were. In other words, information on the web can be contributed by any person and about any topic; unavailable sites and servers are a necessary evil but do not affect the overall infrastructure.

Instead of the design-oriented Hypertext Markup Language (HTML) used to create webpages, the vision of a Semantic Web required novel content-oriented languages that would not only describe the resources embedded in webpages, but also make those descriptions understandable by machines in a way that would allow them to infer new information, to combine statements about multiple resources, and to communicate across software agents and humans. Such languages would need to represent entity
data (e.g., the locations of specific health-care providers), as well as model knowledge about types, properties, and relations between entities (e.g., that insurance plans have different coverages with respect to health-care providers). It became clear early on that the principles that made the web successful would also have to guide the Semantic Web and its knowledge representation languages.

For example, an intelligent personal assistant must be able to deal with incomplete and even contradictory information. Similarly, and in clear contrast to querying databases, an agent should not infer that a certain statement does not hold true due to a lack of information. To give a concrete example, a database of US state capitals will answer a query for whether Santa Barbara, California, is a state capital with no as this record is not present in the database. On the Semantic Web, however, we cannot assume that all resources are currently present and accessible. Thus, an agent would only infer that Santa Barbara is not a state capital if (i) this negated statement is explicitly present in some data source, or (ii) if the definition of the type CapitalCity specifies that there can be only one capital per US state and Sacramento is already defined as California’s capital, and if the agent can exclude that Santa Barbara is an alternative name for Sacramento. This assumption is often referred to as the open world assumption (OWA), while the alternative approach typically used in databases is known as the closed world assumption (CWA). Similarly, the assumption that different names, such as Santa Barbara and Sacramento, always also point to different entities is known as the unique name assumption (UNA). As argued above, knowledge representation languages for the Semantic Web do not make this assumption.

With respect to veracity and handling contradictory information, the Semantic Web again makes use of the lessons learned from the World Wide Web. On the web, anyone can say anything about any topic, at any time and from anywhere. This is often called the AAA (or AAAAA) slogan. Therefore, the Semantic Web describes resources in terms of statements about them, not in terms of (true) facts. Additionally, reasoning services focus on drawing inferences instead of checking constraints. For example, a Semantic Web reasoner can infer the new statement that Santa Barbara is part of Germany from the two statements that Santa Barbara is part of California and that California is part of Germany, as well as from the terminological knowledge that partOf is a transitive relation. Whether the initial statements and, thus, the newly inferred statement are actually true is out of scope for Semantic Web reasoners. If necessary, the trustworthiness of a statement can be assessed by examining additional provenance information, restricting the query to certain established datasets, or by comparing the statement to other statements about the same entities from other datasets.

This raises the question of how the Semantic Web ensures interoperability, that is, how statements from different sources can be combined in a meaningful way. Syntactic interoperability, that is, enabling the exchange of data via common data formats, is handled by a set of open and freely available standards for knowledge representation languages, exchange formats, and serializations defined by the W3C. The Semantic Web’s approach to semantic interoperability follows a well-known paradigm from artificial intelligence research, namely to ensure consistency on the local knowledge-base level while allowing for inconsistencies on the global level. The aforementioned knowledge representation languages enable data providers, (research) communities, and individuals to formally specify the meaning of the used vocabulary, thereby restricting the possible interpretation of terms toward their intended meaning (semantics).
These specifications of conceptualizations are called ontologies.

For example, one can specify that the resource Santa Barbara is of type City and that cities are defined as permanent human settlements that are larger than towns. While such descriptions are meaningful to humans, the used terms do not mean anything to computers. Therefore, ontology languages are equipped with a model-theoretic formal semantics that defines in mathematical terms how to draw valid logical consequences from an ontology. For example, to encode that all cities are human settlements in a machine understandable fashion, one would make use of the subClassOf relation that is formally defined as a reflexive and transitive relation which implies that the extension of one class is a subset of the extension of another class. As being a city now logically entails being a settlement, the two axioms (i) Santa Barbara is of type City, and (ii) City subClassOf Settlement, imply a third axiom as a logical consequence, namely (iii) that Santa Barbara is of type Settlement.

Using such axioms, data providers can annotate their data and thereby enable humans and machines to interpret the used terms. While each (local) ontology should be free of contradictions, there is no need for universal agreement. For instance, in the state of California, the concepts of City and Town are synonyms and thus the above definition of cities being larger than towns does not hold, while it is true for Utah. In a web-scale environment, the role of Semantic Web technologies is not to enforce a single view on the world but to make different views and their underlying conceptualizations explicit.

Knowledge representation languages

The Resource Description Framework (RDF) (Brickley and Guha 2014; Cyganiak, Wood, and Lanthaler 2014) is a language for representing statements in the form of so-called triples of the form subject–predicate–object, where each of the entries is identified by a Uniform Resource Identifier (URI). RDF predicates are also called properties. In many cases, the object of one triple is the subject of another triple and, as a consequence, multiple triples form a structure that is often referred to as an RDF graph, namely a network of interconnected statements. An example for such triples would be adl:SantaBarbara adl:partOf adl:California, where adl is a so-called namespace identifier which expands to a proper URI such as http://adl-gazetteer.geog.ucsb.edu/. RDF consists of basic language constructs such as rdf:type which declares that a given resource is of a certain type, rdfs:subClassOf and rdfs:subPropertyOf with the meanings specified above, as well as rdfs:domain or rdfs:range to define the domain and range of relationships (RDF predicates). RDFS is the RDF schema language. With respect to the previous example, three statements could be encoded as follows: adl:SantaBarbara rdf:type adl:City, adl:City rdfs:subClassOf adl:Settlement, and adl:SantaBarbara rdf:type adl:Settlement. The resulting RDF graphs often consist of millions of triples that represent facts about information resources, such as webpages, as well as non-information resources, such as cities. The W3C SPARQL (SPARQL Protocol and RDF Query Language) standard serves as a query language over RDF graphs stored in a so-called triple store. Simplifying, SPARQL and triple stores can be thought of as the Semantic Web counterparts of the Structured Query Language (SQL) for databases. However, there are substantial differences which cannot be discussed here in detail. For instance query federation, that is, searching over multiple triple stores, is out of scope for SQL but key to querying the distributed Semantic Web.
While RDF makes it possible to express relatively simple statements, such as the one above, it is often necessary to deal with more complex knowledge and inferences which cannot be expressed satisfactorily in RDF. For this purpose, the W3C has standardized the Web Ontology Language (OWL) (Hitzler et al. 2012). The formal basis of OWL is mathematical logic, more precisely a subset of first-order predicate logic with counting quantifiers commonly known as a description logic (Hitzler, Krötzsch, and Rudolph 2010). OWL is partly compatible with RDF, and its capabilities are exemplified here by extending the example presented above. It could, for example, be formally represented that \text{SB} and \text{adl:SantaBarbara} are two names for the same thing, which would yield the inference that \text{SB} is a settlement (because \text{adl:SantaBarbara} is). As another example, consider the sentence “Santa Barbara and Sacramento are different,” together with “Each state has exactly one capital,” “California is a state,” and “Sacramento is the capital of California” – the last two can in fact be expressed in RDF as well as in OWL, while the first two can be expressed in OWL but not satisfactorily in RDF. In this case, we would be able to infer that Santa Barbara is not the capital of California. Inferencing (or reasoning) can be automated, although in general it is a computationally very intensive task. OWL provides a significant number of logical language constructs, including conjunction (logical \text{and}), disjunction (logical \text{or}), and logical negation (\text{not}), as well as quantifiers and counting quantifiers and a few more constructs from the realm of logical knowledge representation.

Linked data

The ecosystem created by hundreds of interlinked, semantically annotated, and openly available RDF-based data hubs is called the linked data cloud (Bizer, Heath, and Berners-Lee 2009) and contains billions of triples from a variety of domains including prominent geographic datasets, for example, digital gazetteers. At the same time, the term “linked data” also refers to design principles and specific technologies used to create this cloud. Essentially, and in contrast to today’s document web, the web of linked data employs named and directed links between typed data in the form of statements. Instead of being stored in closed data silos, linked data are globally referenceable by URIs, and, thus, triples can be constructed over multiple hubs, for example, to state that a certain resource called Brussels in the ADL dataset is the same (\text{owl:sameAs}) resource referred to as Bruxelles in a French gazetteer. The combination of URIs, formal ontologies, and open data, also enables federated queries for all relevant statements about Brussels, no matter whether they originate from a historical gazetteer, an administrative source from a government, or volunteered information, for example, from LinkedGeoData, which offers linked data access to OpenStreetMap.

The four main design principles of linked data are as follows.

1. URIs should be used to denote things, including noninformation resources, such as cities or mountains.
2. HTTP URIs should be used so that things can be referred to (e.g., linked) and dereferenced (looked up) by humans and machines alike. An appropriate form of representation should be displayed based on content negotiation, for example, to present an HTML file to a human user that is visiting a URI, while RDF should be served to a machine.
3. W3C-based standards such as RDF or OWL should be employed to provide information about things when their URIs are dereferenced.
4 Data should link to other data, by using their URIs to develop a densely interconnected global knowledge graph.

The successful publication of proper linked data, however, requires a collection of further technologies and strategies (e.g., for minting URIs) that cannot be discussed here in detail. In general, the quality and usefulness of the data will largely depend on the quality of the defined ontology (vocabulary) as well as on additional information that provides a context for its proper usage, such as provenance information and other metadata about RDF datasets.

The value proposition of the Semantic Web

While the previous paragraphs outlined the history of the Semantic Web and illustrated selected technologies, they do not explicitly state the value proposition of the Semantic Web and linked data. The main goal of the Semantic Web is to foster the publication, retrieval, reuse, and integration of data without restricting its heterogeneity. More specifically, Semantic Web technologies break up data silos and enable federated queries over multiple data sources, ease data conflation and co-referencing by providing globally unique and dereferenceable identifiers in the form of URIs, provide human- and machine-readable knowledge representation languages to encode statements and conceptual models, thereby enabling machine reasoning, improve interoperability beyond syntax, support the development and deployment of sustainable cyberinfrastructures via an open standardization process, and provide semantically rich querying capabilities beyond simple keywords.

A major novelty introduced by the Semantic Web is the focus on making data smart instead of developing smart applications. The rationale behind this paradigm shift is the insight that smart data will make future applications more powerful, interoperable, robust, and reusable, while smarter applications do not improve data along the same dimensions (Janowicz et al. 2015). By empowering data and by moving the so-called business logics out of the source code, Semantic Web applications and infrastructures can be developed and deployed by using off-the-shelf software such as reasoners, query engines, triple stores, faceted browsing frameworks, and link discovery tools. As most Semantic Web technologies rely on open W3C standards, exchanging data between specific systems is usually possible with minimal effort. In combination with a variety of open source tools, this makes the Semantic Web (and linked data) sustainable for the future and is one reason for its increasing popularity among data providers and consumers.

Challenges in realizing the Geospatial Semantic Web vision

While Semantic Web technologies, linked data, and ontologies have become widely used and recognized in research, governments, and the industry, a variety of challenges remain to be addressed before the Semantic Web can truly become the next generation of the web. Some of these challenges are listed here, focusing particularly on those that are of interest to geographic information science (GIScience) and geography.

While the Semantic Web was envisioned with heterogeneity in mind, semantic heterogeneity remains one of the most challenging aspects of interoperability and cyberinfrastructure research. Currently, the geospatial semantics community is moving toward using so-called ontology design patterns as a strategy to develop a wide range of purpose-driven ontologies that can handle
different viewpoints and levels of granularity, yet still remain interoperable due to a commonly used set of patterns.

A related problem is the so-called knowledge engineering bottleneck: it is difficult to arrive at suitable formal definitions for domain vocabularies. A wide variety of methods and tools have been developed during the past few decades to help knowledge engineers and subject matter experts reach agreement and formalize scientific workflows, nomenclature, and so forth. Today, machine learning techniques and crowdsourcing are combined with established methods to scale knowledge engineering. Additionally, work on areas such as ontology alignment and matching reduces the need to arrive at common definitions.

With respect to linked data, the discovery of links between resources, co-reference resolution, federated queries, and learning and extracting linked data from semistructured and unstructured resources (e.g., textual description of places) are among the most pressing research areas. The handling of scale and temporal and spatial scopes of statements remain open research challenges as well.

Finally, from a more conceptual perspective, an overall framework for semantic reference systems that enables the precise and reproducible interpretation of all components of geospatial information in terms of their measurement scales and observation procedures is still missing.

Geostatistics
Phaedon Kyriakidis
Cyprus University of Technology

Geostatistics is a branch of spatial statistics that deals with the analysis of spatially distributed data. The formal origins of geostatistics can be traced in mining engineering applications in the 1960s, as well as in related work in forestry and meteorology (Cressie 1990). Since then, many theoretical developments have taken place and geostatistical applications have spread across numerous and diverse scientific disciplines, ranging from earth sciences to environmental and atmospheric sciences to socioeconomic applications. Important points in time in the history of geostatistics include the publication (in French) of the original work of Matheron in the 1960s (Matheron 1962; 1963) and its English follow-up (Matheron 1971), the more practical publication Mining Geostatistics (Journel and Huijbregts 1978), geared towards the mining industry, the best-selling and widely accessible book An Introduction to Applied Geostatistics (Isaaks and Srivastava 1989), Cressie’s classic treatise Statistics for Spatial Data (Cressie 1993), which disseminated geostatistics to more mainstream statistics, and the comprehensive geostatistical textbooks Geostatistics for Natural Resources Evaluation (Goovaerts 1997) and Geostatistics: Modeling Spatial Uncertainty (Chilès and Delfiner 1999).

The three major and broad thematic areas of geostatistics include: (i) the analysis and interpretation of spatial patterns in geographical data, particularly the analysis and modeling of spatial association; (ii) the integration of attribute data from different sources and resolutions towards the objective of spatial interpolation (or spatial prediction); and (iii) the assessment of uncertainty in spatial prediction and its propagation to outputs/results of spatial operations or of models with spatially distributed inputs and/or parameters. This entry provides an overview of the main concepts involved in these three thematic areas of geostatistics, highlights relevant applications, and discusses current trends and future directions.

Quantifying spatial association

Geography deals with the analysis and interpretation of spatial pattern, an integral aspect of which is the notion of spatial association, also known as spatial autocorrelation through Tobler’s first law of geography. In quantitative terms, spatial association can be expressed in its most basic form in terms of either similarity (correlation) or dissimilarity (variation) between attribute values measured at different geographical units (also termed supports), for example, rain gauges (points) or pixels of a remotely sensed image (regular tessellation). In geostatistics, and for the case of attributes of interval or ratio measurement scale, spatial association is typically quantified by the sample or empirical semivariogram (Isaaks and Srivastava 1989), formally defined as the expected value of squared semi-difference between pairs of attribute values. To compute such an expected value, that is, an average quantity, pairwise squared semi-difference values are grouped into distance classes based on the (Euclidean) distances between their corresponding measurement locations. The average squared attribute semi-difference for each group is then
Figure 1 Example of a sample or empirical semivariogram (blue asterisks) of precipitation data (measured in mm) obtained from 77 rain gauge stations in Northern California; the number of data pairs used to compute the average semi-variance within each distance class is displayed on top of the asterisks. The red curve corresponds to a fitted semivariogram model with the following parameters: total sill = 8.5 mm², range = 120 km, and nugget contribution = 0.5 mm²; see text for details.

plotted against the average pairwise distance for that group; the resulting plot is termed the “sample semivariogram plot” (see Figure 1). For simplicity, the term variogram, that is, twice the semivariogram, is also widely used in the geostatistical literature.

Alternatively, the plot of average similarity between attribute value pairs in different distance classes versus average pairwise distance is termed a “sample covariogram” or “sample correlogram,” depending on whether pairwise attribute similarity is expressed as (i) the product of the differences between two attribute values from the attribute mean, or (ii) its standardized version dividing the former by the attribute variance.

For attributes exhibiting positive spatial autocorrelation, the sample (semi)variogram is expected to reveal an increasing pattern with distance; the reverse pattern is expected for the sample covariogram and correlogram. It is the particular shape of the spatial association plot, that is, how quickly (in terms of distance) the correlation reaches the zero value or what the shape of the plot is at small distances, that provides a first step towards a quantitative version of Tobler’s first law of geography. Evidently, different attributes and different data sets will result in different sample spatial association plots; it is the expected overall shape that Tobler’s first law postulates, not the nuances of each particular plot.

It is often desirable to also consider the orientation of the vectors defined between pairs of data locations in addition to the length of such vectors, that is, in addition to distance alone. In this case, orientation classes are also used for grouping pairwise (dis)similarity values; the resulting plots are termed “directional sample” variograms or correlograms and are used to elucidate different patterns in attribute variation in different directions, that is, to reveal anisotropic (as opposed to isotropic) spatial variation. The term “omnidirectional” variogram or correlogram is often used to indicate that the grouping of pairwise (dis)similarity values is only based on distance and not on orientation. Other types of spatial information, for example, altitude or land-use type, regarding the data locations and their surroundings or environmental conditions, can also be used to produce more meaningful groupings of pairwise (dis)similarity values depending on the particular application at hand.

In the case of two attributes, for example, temperature and elevation, the above spatial association measures can be extended to the bivariate case, termed “sample cross-variograms” or “sample cross-correlograms”; the variograms or correlograms of temperature data and of elevation
data then receive the prefix “auto” in their respective terminology. A cross-correlogram essentially involves a series of correlation coefficients computed from lagged data of two different attributes, for example, from measurements of elevation and temperature considered at different locations. The classical correlation coefficient between collocated measurements of, say, temperature and elevation is then regarded as the value of the cross-correlogram at zero distance. The case of more than two attributes involves multiple combinations of auto- and cross-measures of spatial association, and often becomes cumbersome to handle, particularly in the case of many (>3) attributes. Alternatively, multivariate spatial association can be quantified by noting that a squared difference between attribute values constitutes a squared Euclidean distance metric in attribute space. The multivariate sample variogram is then expressed as the sum of all sample auto-variograms of different attributes, and quantifies overall dissimilarity across multiple attributes as function distance. As a simple summation of auto-variograms ignores the correlation across attributes, a more representative measure of multivariate spatial association involves the Mahalanobis distance metric for describing pairwise dissimilarity. In this case, the resulting multivariate measure of spatial association involves a weighted average of all sample auto- and cross-variograms. Such measures of multivariate spatial association are widely used in ecology, under the umbrella term “Mantel correlogram,” to quantify spatial association in, say, abundance of different species measured at different sites; here each species is regarded as a different attribute and the corresponding abundance values are considered data of multiple attributes (Legendre and Legendre 2012).

In the case of nominal (categorical) data, for example, soil types or land cover classes, spatial association is quantified using a binary (0/1) indicator transform of the categories observed at the data locations. In other words, each category corresponds to a set of binary indicator data, and there are as many such sets as categories. In geostatistics, indicator variograms and indicator correlograms have been traditionally used to quantify spatial association for each category (Goovaerts 1997). The analysis of categorical data, however, is an inherently multivariate problem, since the indicator data for each category are essentially data on a different binary attribute. Consequently, the quantification of spatial association in categorical data also calls for the analysis of bivariate indicator cross-variograms and cross-correlograms for each pair of categories. A more natural alternative for describing spatial variation in categorical data is transition probabilities, quantifying the probability of transitioning from a location with one category to another location with the same or a different category as a function of distance (Chilès and Delfiner 1999). The set of all auto- and cross-transition probabilities for a particular distance class is functionally linked to the indicator auto- and cross-covariance values for that distance, and provides a coherent means for describing joint (between the same category and across different categories) spatial variation in nominal data.

All measures of spatial association described above are characterized as global measures, in that they involve averages of pairwise (dis)similarity values across all data pairs within a particular distance class. Local measures of spatial association can be defined as average pairwise (dis)similarity values involving each data value and its neighbors; in this case, the computation of pairwise association is limited to only those location pairs within some distance class from each data location. The result is a map of local association measures, for example, local variogram values, whereby a local association value corresponds to each data location. In the multivariate case,
local multivariate variograms have been used, particularly in remote sensing, for quantifying multivariate image texture. In this case, the reflectance values recorded at different spectral bands constitute data of different attributes, and the objective is to furnish a model of image texture across multiple spectral bands; such texture information is often used for enhanced classification of remotely sensed data.

Modeling spatial association

The sample semivariogram or correlogram is often computed from a limited set of sample data, and represents averages of pairwise (dis)similarity values for each distance class; such empirical measures are therefore subject to sampling fluctuations or error. In addition, semivariogram or correlogram values are only available for a limited set of distance classes; one cannot simply consider more classes, because this leads to smaller classes, hence to fewer pairs of attribute values within each class and consequently more fluctuations and less reliable (dis)similarity averages. What is required is a model of spatial association as a continuous function of distance; this model actually pertains to the continuous spatial distribution of attribute values of the population from which the particular sample data set was derived (Isaaks and Srivastava 1989). However, not any function of distance can be used as a model of spatial association. Permissible or valid covariance models, for example, ensure that any weighted linear combination of covariance values is non-negative, no matter the weights involved. This requirement stems from the fact that such a weighted combination expresses variance, and variance cannot be negative; functions that satisfy this requirement are called positive definite functions.

Several parametric functions of distance, such as the spherical, exponential, or Gaussian functions, are known to be positive definite and are widely used as correlogram or semivariogram models in practical applications (Chilès and Delfiner 1999). The shape of the function at small distances, for example, linear or parabolic, is linked to the smoothness of the postulated attribute surface; a Gaussian model, for example, implies a very smooth attribute surface such as atmospheric temperature or pressure. Apart from function shape, typical model parameters in the isotropic case include: (a) the sill, linked to the variance of the sample data, and (b) the range, that is, the distance at which the sill is reached and beyond which spatial correlation is expected to be nil. For models reaching their sill asymptotically, such as the exponential and Gaussian functions, the range is often defined as the practical range, that is, the distance at which 95% of the sill is reached (see Figure 1). More flexible (and more complex) models are available, for example, the Matérn model, which also include a third parameter that modulates the shape of the semivariogram function at short distances; the Matérn model, for example, yields as particular cases the Gaussian, exponential, and power law semivariogram models.

Anisotropic semivariogram models also exist for furnishing different patterns of attribute spatial variation in different directions in a consistent manner (Isaaks and Srivastava 1989). The type of anisotropy whereby the sill of the semivariogram model attains the same value in all directions, but the locus of equal range values in different directions forms an ellipse in two dimensions (2D) or an ellipsoid in three dimensions (3D), is termed “geometric anisotropy.” In this case, an affine transformation (rotation and scaling) is first applied to the vectors defined between any two locations so that isotropic functions can subsequently be employed; the parameters of
the affine transformation are linked to the range of the model in different directions and to the orientation of the major and minor axes of the ellipse in 2D.

More complex parametric models of spatial association can be built as weighted linear combinations of permissible (and possibly anisotropic) nested models (Goovaerts 1997). Such composite models correspond to a postulated attribute surface comprised by an additive superposition of independent nested component surfaces. Each constituent surface is characterized by its own semivariogram model and the (partial) sill of that model expresses the contribution of the variance of that particular nested surface to the overall variance of the composite attribute surface. The composite model used most often in practice corresponds to an arbitrary semivariogram model plus a nugget effect component (see Figure 1). The nugget effect appears as a discontinuity of the semivariogram model at very small distances and corresponds to random attribute spatial variation, measurement error, or spatial variation occurring at scales smaller than the smallest distance between data locations. Composite semivariogram models are also used as zonal anisotropy models, a type of anisotropy whereby an extra component of spatial variation appears only in a particular direction; zonal anisotropy is handled in practice by including in the composite semivariogram model a nested model with geometric anisotropy with very large (infinite) range in one direction.

In the multivariate case, joint models of spatial association are needed to provide consistent modeling of all auto- and cross-variograms defined between multiple attributes. One cannot simply postulate a permissible auto- or cross-variogram model for each sample auto- or cross-variogram, as the entire set of all such univariate and bivariate models must be jointly permissible; the intrinsic coregionalization model (ICM) and the linear model of coregionalization (LMC) provide two solutions to this problem, the latter being the most widely used model in practice (Goovaerts 1997). Last, nonparametric spatial association models can also be constructed, but those are less frequently used in practice as they are rather difficult to generalize, particularly in the multivariate case.

In many practical applications, a parametric variogram model is first selected for the postulated attribute surface, and model parameters are subsequently estimated so that the discrepancy between the model and sample variogram values is minimized. The fitting procedure is typically carried out through iterative numerical optimization algorithms, such as weighted nonlinear least squares with more importance (larger weight) given to the fit at small distances. Other candidate variogram models can be considered and the fitting procedure can be repeated for selecting the best model based on standard goodness-of-fit criteria, such as the root mean squared error or the Akaike information criterion (Chilès and Delfiner 1999). Such a semiautomatic procedure is often encouraged, yet caution has to be exercised to avoid erroneous and physically unjustified results, particularly in data-poor situations. The variogram model fitting step is a key component of any geostatistical study, but is also considered the “art” of geostatistical practice. Although automatic and semiautomatic fitting procedures are also available for the multivariate case, fitting a spatial association model characterizing jointly univariate and bivariate (dis)similarity across data of multiple attributes quickly becomes cumbersome as the number of attributes increases. This complexity in multivariate spatial association model fitting often leads to spatial regression models based on collocated (not lagged) data,
described in the section “Spatial interpolation and kriging,” to be preferred in practice in the multivariate case.

**Random fields and stationarity**

A variogram model fitted to a sample variogram pertains to the population of attribute values from which the sample data are thought to originate. In geostatistics, that unknown population is conceptualized as a field with a continuous spatial distribution, whereby distances between point locations (as opposed to objects such as polygons) are readily defined. The unknown spatial distribution of the population is regarded as a realization (an outcome) of a random function or a random field, that is, an infinite collection of georeferenced and spatially correlated random variables, one random variable defined per location (Isaaks and Srivastava 1989). In the multivariate case, postulated attribute fields of different attributes, for example, temperature, elevation, and solar radiation, are regarded as realizations of a multivariate random field. Multiple constituent random variables are now defined for each location, one variable per attribute; random variables of the same attribute at different locations are spatially auto-correlated, whereas random variables of different attributes at the same or different locations are spatially cross-correlated.

The random field concept is perhaps more easily conveyed via its discrete counterpart, the random vector, a finite set of georeferenced and spatially correlated random variables, through a spatiotemporal distribution analogy. Consider, for example, the case of a limited set of rain gauges recording daily precipitation values over some time period. In other words, consider the set of precipitation time series at the corresponding rain gauge locations, and assume for the moment that all time series are equally informed, that is, there are no missing values for any day. Invoking the random vector construct, for each rain gauge location there is a corresponding random variable and the rainfall value at each rain gauge is regarded as a realization (outcome) of that random variable for the particular day. The univariate statistics, for example, mean, of precipitation could in principle be different from one location to another, for example, due to orographic effects or distance from the coast, and consequently, one could define a location-specific (local) mean for each random variable. Likewise, the covariance or the correlation coefficient between two precipitation time series could vary across location pairs, depending on the environmental characteristics prevailing at any two rain gauges. In other words, the correlation coefficient between any two random variables could be different depending on the particular pair of locations corresponding to those variables.

Geostatistics, however, is typically employed for the analysis of spatial data; hence the spatiotemporal analogy described above is difficult, actually impossible, to operationalize in a purely spatial context. In the case of spatial data, there is only one available realization of the random variables at the data locations, this corresponding to the sample data values. Consequently, one cannot estimate a local attribute mean, or a pairwise correlation coefficient between attribute values at any two data locations. In the first case, there is only one attribute value at each data location, and in the second case, there is only one attribute pair at each pair of data locations. To circumvent this deadlock due to the lack of time replicates of attribute values, working assumptions are typically invoked, allowing the use of spatial replicates of attribute values from different locations for the purpose of computing
meaningful statistics (Journel and Huijbregts 1978).

First-order stationarity is a model assumption stating that all constituent random variables of a random field have the same mean (a first-order moment of a distribution); in other words, the attribute mean is location invariant. Second-order stationarity includes the assumption of first-order stationarity, and in addition states that: (i) the variance (a second-order moment of a distribution) of any random variable exists (is finite) and is constant - this variance value is termed the “a priori variance” of the random field; and (ii) the covariance and the correlation coefficient between any pair of random variables are only a function of the magnitude (and possibly orientation) of the vector linking corresponding locations at which those two random variables are defined. A weaker assumption than second-order stationarity is that of intrinsic stationarity, whereby: (i) the attribute mean is assumed to be locally constant - this implies that random variables at locations not too distant from each other are assumed to have the same mean; and (ii) the attribute variance need not be finite but could increase as the study region becomes bigger and more data become available. In practical terms, intrinsic stationarity is the reason that the sample variogram has emerged as the preferred measure of spatial association in geostatistics: it can still be defined for cases where the covariogram and the correlogram cannot, and it does not require knowledge of the attribute mean, which is difficult to obtain if it is deemed spatially varying. Last, the assumption of stationarity in one form or another is often invoked when performing basic geostatistical spatial interpolation under the umbrella term “kriging,” although several variants of kriging have been developed to relax that assumption (see below).

Spatial interpolation and kriging

Spatial interpolation is the procedure of estimating or predicting unknown values of an attribute of interest at nonsampled locations from known measurements of the same (in its simplest form) attribute at sample locations. Spatial interpolation is widely used for attribute surface creation in multiple fields, as it is often the case that the locations where interpolation is performed coincide with the nodes of a regular grid. The terms “source location” and “target location” are often used for the sample locations and the locations where interpolation is performed, to emphasize the transfer of information from the former to the latter; the corresponding attribute data and unknown attribute values at those two sets of locations are termed “source data” and “target values,” respectively. A plethora of spatial interpolation methods have been developed to date, each involving its own assumptions and procedures (Isaaks and Srivastava 1989). Two main families of spatial interpolation methods, however, can be distinguished: (i) deterministic interpolation methods, in which a unique attribute value is predicted at each target location, once the parameters of the particular method have been selected; and (ii) statistical or stochastic interpolation methods, in which a distribution of possible attribute values is furnished at each target location, given, again, all the parameters adopted from the particular method.

Deterministic spatial interpolation methods include, among others, nearest neighbor interpolation, bilinear interpolation, triangulated irregular network interpolation, inverse distance weighted (IDW) interpolation, and spline interpolation and its variants (cubic splines or thin-plate splines). Of these methods, perhaps the most widely used is IDW interpolation, as it is simple to explain, easy to implement, and widely available in commercial as well as open
source software packages. IDW is, in principle, a parametric spatial interpolation method, as it allows for different importance to be placed on the distance between the source and target locations via an exponent parameter; the most widely used values being 1 and 2, corresponding to simple inverse distance weighted interpolation and inverse distance squared interpolation, respectively.

Kriging is a geostatistical, hence stochastic, spatial interpolation method, which qualifies as the best linear unbiased predictor (BLUP), that is, under the least squared error or minimum error variance optimality criterion, the best predictor of a target value as a weighted linear combination of source data, given a known or previously estimated variogram or covariogram model (Cressie 1993). The term “kriging” was coined by Professor Georges Matheron as a tribute to the pioneering work of Dr Daniel Krige in the early 1960s. Similar to many deterministic spatial interpolation methods, kriging can be performed using all the source data available (global interpolation) or only a limited set of source data within a search neighborhood around the particular target location where interpolation is performed (local interpolation). In the latter case, the search neighborhood is defined based on the range of the (semi)variogram model; for anisotropic models, that neighborhood becomes an ellipse in 2D and an ellipsoid in 3D. In addition, and similar to other spatial interpolation methods, kriging is an exact interpolation method, in that the predicted target value at a target location coinciding with a source location yields the known source value at that location. Depending on the assumptions made regarding expected attribute values at the source and target locations, different variants of kriging have been developed in the literature; such variants furnish similar predictions in regions where source data are abundant and different predictions in regions away from the source locations (extrapolation regions).

In its most basic form, simple kriging (SK) assumes a known expected attribute value (mean) both at the source and at the target locations; in other words, SK requires knowledge of a location-specific (local) attribute mean (Chilès and Delfiner 1999). The target prediction is then expressed as a weighted linear combination of source data, plus a weight attributed to the known mean at the target location. The SK weights are obtained by solving a linear system of equations, known as the SK system, which involves source-to-source covariance values between source data locations and source-to-target covariance values between source and target locations. All these covariance values are derived from the covariance model, based on the length (and possibly orientation) of the vectors defined between location pairs. Similar to most methods of spatial interpolation, the SK weights account for the proximity of the source to the target locations. Contrary to other interpolation methods, however, the SK weights also account for the configuration of the source data locations. In addition, and through the particular covariance model adopted, the SK weights also account for the expected smoothness of the attribute surface, as well as for the redundancy of the source data – the contribution of source data located in clusters is reduced in the computed target value. The weight attributed to the known local attribute mean at the target location is the complement to 1 of the sum of the SK weights given to the source data. That known local attribute mean in SK need not be constant, it just needs to be known (hence certain) or previously estimated without considering the uncertainty inherent in such an estimated quantity.

Ordinary kriging (OK) is typically performed in a local interpolation mode and is the most
widely used kriging variant in practice when no auxiliary data on other attributes are considered in the interpolation procedure. In OK, a constant but unknown local attribute mean is assumed for the target location and all source locations within the search neighborhood; this amounts to the assumption of local first-order stationarity. That unknown mean is implicitly estimated in conjunction with the kriging weights using an augmented linear system, called the OK system. This system includes a unit sum constraint for the resulting weights, since the local attribute mean is not known as it is in the case of SK. Universal kriging (UK) is another variant of kriging, whereby the local attribute mean within a search neighborhood is expressed as a parametric linear function of coordinates (or polynomials thereof), as in the case of trend surface analysis. Additional linearity constraints are appended to the kriging system, resulting in a further augmented system, called the UK system, for estimating simultaneously the parameters of that linear function as well as the interpolation weights given to the source data within each search neighborhood. Under certain choices of the (semi)variogram model adopted, for example, the linear or power model, universal kriging predictions are equivalent to those derived via spatial interpolation with splines. Last, when the attribute data are expressed as a parametric linear regression model on data of other attributes within each search neighborhood, the corresponding kriging procedure is termed “kriging with external drift” (KED), and furnishes local estimates of the regression model parameters accounting for spatial autocorrelation in the regression error term (using generalized least squares), as well as SK weights for the spatial interpolation of the residuals derived at the source locations from that regression model.

In the local regression approach for spatial interpolation furnished by KED, the data of the auxiliary variables should be collocated with those of the attribute of interest at the source locations (for estimating the parameters of the regression model) and at the target locations (for predicting the corresponding target values). Such an isotopic or equally sampled design, however, is often not realized in practice; in this case, data on multiple attributes can alternatively be integrated in spatial interpolation via cokriging. The cokriging weights furnish the contribution of each source data value, be it of the same attribute as the primary attribute of interest or of a different attribute, to the target prediction as a function of auto- and cross-variogram values. The solution of the corresponding cokriging system of equations calls for a permissible joint model (such as the LMC) for all auto- and cross-variograms defined between all pairs of attributes involved. Augmented cokriging systems can also be defined, as in the univariate case for relaxing the assumption of a constant attribute mean within the search neighborhood for each of the variables involved in spatial prediction.

Several variants of kriging can be distinguished depending on whether: (i) the source data contain measurement error – in factorial kriging spatial interpolation that error component is assumed to be additive and independent of the signal (a measurement’s meaningful component) and is filtered out from (not added to) the predicted target values; in this case, kriging is not an interpolation method but a smoothing method, since source data values are not reproduced due to their measurement error characteristics; or (ii) a non-Gaussian assumption is justified for the attribute data – lognormal kriging, Poisson kriging, indicator kriging, and disjunctive kriging are some of the different extensions of kriging available for dealing with non-Gaussian data.

Perhaps one of the most important reasons behind the success of geostatistics and its wide
adoption in numerous and diverse scientific disciplines is its ability to cope with data of different spatial resolutions, in other words, its ability to integrate and utilize measurements pertaining to different supports (Journel and Huijbregts 1978). In punctual or point kriging, the most widely used mode of kriging in practical applications, the source data and target values pertain to the same point support. In block kriging, source data are typically of point support whereas target values pertain to pixels or polygons or blocks in 3D; in this case, target values are typically defined as (possibly weighted) averages of point values within their corresponding supports. In downscaling kriging, source data pertain to pixels or polygons whereas target values are defined on point supports. Last, in geostatistical areal interpolation, both source data and target values pertain to supports of arbitrary shape and orientation. In all the cases above, the form of the kriging system remains the same, but the different covariance values used in that system, as well as the corresponding linear equality constraints, are modified to account for the data resolution differences. It is worth noting that, in the downscaling case, kriging predictions when upscaled reproduce by construction the sample areal data used for downscaling, no matter the particular variogram model used; this implies that kriging furnishes resolution-consistent predictions.

Spatial uncertainty

Being a stochastic interpolation method, kriging provides an estimate of the prediction error variance at each target location. That prediction error variance is zero at the source data locations (except in the case of factorial kriging where that variance reverts to the measurement error variance) and increases away from the source data locations. In the second-order stationary case, the simple kriging prediction error variance at a target location further away than the variogram range from source locations tends towards the sill of the variogram model used. In general, that variance is larger for the case of ordinary kriging due to the additional uncertainty in the estimation of the local mean within each search neighborhood, and further increases for the case of UK and KED due to the additional uncertainty in estimating the parameters of a local regression model linking the attribute of interest to coordinates or other auxiliary variables.

The kriging error variance is homoscedastic in its simplest form, that is, it does not depend on the source data values but only on the relative position of the target location with respect to the source locations, on the configuration of the source locations, and on the particular variogram model used (Goovaerts 1997). This property renders the kriging error variance useful in sampling design applications: different locations can be selected as candidate locations for placing additional source data, the kriging error variance values are computed for at all target locations using each of the candidate locations as additional source location, and the best configuration of new source locations is selected so as to minimize, for example, the average kriging error variance or the maximum kriging error variance.

In the multivariate Gaussian case, the prediction error variance at a target location along with the corresponding kriging prediction at that location furnishes the parameters of a local Gaussian probability distribution of possible attribute values given the known source data, possibly including data on relevant auxiliary variables used for spatial prediction, as well as the particular variogram model adopted. That probability distribution is often used for propagating (either analytically or numerically through statistical simulation) the local uncertainty in
interpolated attribute values, for example, pollution levels, to quantify uncertainty in the results of local geographic information system (GIS) operations involving one grid node at a time, for example, the local probability for grid nodes in residential land cover type to exceed a particular pollution threshold.

Interpolated attribute surfaces, however, often either (i) undergo spatial operations involving more than two locations at a time, for example, slope computation from elevation or other focal or zonal operations in a GIS, or (ii) serve as inputs to environmental or socioeconomic models with spatially distributed inputs or parameters; for example, the spatial distribution of rainfall is a critical parameter in models of overland flow and runoff computations. In such cases, knowledge of the local kriging attribute prediction and variance at a set of target locations, considered one at a time, is not adequate for uncertainty propagation purposes. The preferred means for uncertainty propagation in this case is geostatistical Monte Carlo simulation (Goovaerts 1997). For example, in 3-D hydrogeological investigations involving flow and transport in heterogeneous porous media, the spatial distribution of hydraulic conductivity (a property indicating how fast solute can flow through the pores of a rock formation) is often parameterized in terms of a lognormal random field model. Realizations from such a random field constitute alternative numerical models of the 3-D spatial distribution of hydraulic conductivity, all of which reproduce: (i) any measurements of conductivity at their sample locations, (ii) the variogram model of that attribute, and (iii) any relationships with relevant auxiliary data, such as those provided by geophysical surveys. These alternative realizations are then used, along with physically based simulators of flow and transport, in a Monte Carlo framework for evaluating, for example, the uncertainty in the spatial distribution of solute concentration due to the uncertainty in the spatial distribution of hydraulic conductivity and possibly other relevant variables.

Trends and future directions

Geostatistics has spread through the years from its mining engineering origins to a wide spectrum of applications in the earth and environmental sciences – actually, in almost any field where spatial analysis is applied. Since its conception, geostatistics has been associated with practical engineering applications, and it is often the case that developments in geostatistical theory and applications are driven by engineering problem-solving. A major recent thrust of geostatistical development is driven by the need to characterize more realistically the complexity and heterogeneity of the spatial distribution of attributes, for example, rock type and porosity, involved in reservoir characterization in the oil and gas industry. This need has led to the advent of multiple-point geostatistics (Mariethoz and Caers 2014), whereby spatial patterns involving more than two points at a time (a variogram is a two-point statistic) are “learned” from training images; such images are numerical models, for example, scanned cross-sections of outcrops, remotely sensed images, even hand-drawn images by geologists, that represent prior (before data acquisition) repositories of spatial patterns. These learned spatial patterns, not falling in any parametric or nonparametric statistical model, are then “exported” to the real reservoir via simulation and fused with actual data to provide realistic models of spatial heterogeneity and complexity. Besides oil and gas applications, multiple-point geostatistical applications can be found in mining, hydrogeology, geomorphology, and remote sensing.
Recent developments in geostatistics have also addressed the need to include in the spatial prediction endeavor data on models that operate on (use as input) the spatial distribution of the attribute that is being predicted; for example, when interpolating hydraulic conductivity, data of pressure tests might be available. The task of accounting for model output data when predicting the spatial distribution of model inputs falls in the realm of inverse problems (Chilès and Delfiner 1999). Such problems have been traditionally studied in mathematics and physics, but fruitful recent developments have emerged from a geostatistical perspective, with applications in reservoir engineering, hydrology and hydrogeology, remote sensing, and atmospheric sciences.

The inclusion of time as an additional data and modeling component has also been one of the major areas of development in geostatistics (Cressie and Wikle 2011). Several space–time variogram and covariance functions have been proposed in the literature for modeling joint attribute variation in a spatiotemporal context. Dynamic space–time models linking partial differential equations with geostatistics have also been developed to account for the dynamic evolution of spatiotemporal processes. It is expected that more of these developments will sooner rather than later find their way into commercial, for example, GIS, software and consequently enable the even wider application of geostatistics.

Last, the advent of model-based geostatistics (Diggle and Ribeiro 2007) to address spatial data with non–Gaussian distributions is another notable theoretical development. Although non–Gaussian geostatistical models have been proposed in the past through the work of Mathéron on bivariate isofactorial models, this new general framework has been widely adopted particularly in spatial statistics and represents a major breakthrough. Along the same lines, Bayesian inference in a hierarchical framework has also been a major theoretical development, along with computational algorithms for rendering inference in such a framework feasible in practical applications.

Geostatistics has been dealing with large data sets from its conception; theoretical and practical developments throughout the years have been traditionally tailored to address issues pertaining to large data sets. New technologies and advances in computing and computational statistics, however, have been instrumental in bringing the field of geostatistics (and spatial statistics in general) closer to that of computer science. This convergence trend is expected to continue as new methodologies for big data analysis and modeling become available. Last, as is the case with many scientific fields, the dissemination of geostatistics in different disciplines has been immensely facilitated by the development of computer hardware and relevant software. As both open source and commercial geostatistical software become increasingly available, it is expected that geostatistical methodologies will find their way to an even wider spectrum of applications where geographical methods of spatial analysis and modeling are involved.

Geotargeted alerts and warnings

Michele M. Wood  
*California State University, Fullerton, USA*

Historically, publics have been warned of imminent threat using outdoor sirens, electronic media, route alerts (wherein officials travel through the streets with loudspeakers), and tone alert radio (TAR). Recent technological advances have made it possible to deliver geotargeted alert and warning messages to mobile devices. In the context of risk communication alerts and warnings, geotargeting refers to efforts to transmit risk communication messages only to those individuals physically located within the geographic area at risk (National Research Council 2013). This new technology, in effect, can place a warning “siren” in the pocket of every individual who owns and carries a cellular phone or other mobile device. How this new technology may influence the manner in which people receive and respond to public warnings has a bearing on the further development of risk communication theory and also on emerging warning practice.

The need to warn the public about imminent threat has long been a challenge for human populations. Researchers have studied the effects of alerts and warnings in a disaster context for more than half a century. “Risk communication” refers to real-time information exchange between experts or officials and those who face a hazard or threat to their health or wellbeing; its purpose is to enable those at risk to make informed decisions to mitigate the effects of the threat and take appropriate protective action (WHO 2015).

The emergency alert system (EAS) is a national warning system in the United States that was approved by the Federal Communications Commission in 1994 and implemented in 1997, replacing the former emergency broadcast system (EBS, in place from 1963 to 1997), which, in turn, replaced the control of electromagnetic radiation system (CONELRAD, in place from 1951 to 1963). EAS is coordinated at the federal level by the US Federal Communications Commission (FCC), the US Federal Emergency Management Agency (FEMA), and the US National Oceanic and Atmospheric Administration’s National Weather Service (NOAA’s NWS). EAS is now one part of the US integrated public alert and warning system (IPAWS).

IPAWS is the nation’s infrastructure for delivering emergency alerts and warnings to the public. It represents a modernization and integration of the nation’s alert and warning infrastructure, allowing public safety officials to alert and warn the public about imminent threats using EAS, wireless emergency alerts (WEA), the NOAA weather radio, and other public alerting systems, using a single interface. IPAWS is managed by FEMA. In the event of a national emergency, the President may use IPAWS to communicate to the public with merely 10 minutes notice.

The WEA service allows customers who own “WEA capable” wireless telephones and other enabled mobile devices to receive geographically targeted alerts about imminent threats to safety in their geographic area. The WEA system was established pursuant to the Warning, Alert and Response Network (WARN) Act and delivers alerts using a special broadcast channel in cellular
GEOTARGETED ALERTS AND WARNINGS

telephone systems. WEA was originally called CMAS, the commercial mobile alert system, or PLAN, personalized local alerting network. Rollout of the WEA service began in April of 2012. Wireless service providers participate in WEA voluntarily as part of a public–private partnership between the FCC, FEMA, and the wireless industry. Alerts from authenticated public safety officials are sent through IPAWS to participating wireless carriers and are then pushed by the providers from cell towers to mobile devices that are physically located in the designated or affected warning area. The WEA service provides three types of messages: presidential alerts, imminent threats to life and safety, and AMBER alerts (child abduction bulletins by law enforcement). The messages appear like text messages and are limited to 90-characters. Initially, the NWS created and used templates for nine different types of WEA warnings. These were based on EAS messages, but edited to adhere to the limited WEA message length. WEA capable device users are enrolled in the WEA service as a default setting and can opt out of all but the presidential alerts. One of several components of IPAWS, the WEA service is designed to complement, not replace, other IPAWS supported warning communication channels.

The common alerting protocol (CAP) is a digital format for exchanging information that allows a consistent alert message to be disseminated simultaneously over multiple communications systems. With multiple systems using CAP, a single alert can trigger a wide variety of public warning systems, increasing the likelihood that members of the intended audience will receive the alert by one or more communication channels. CAP provides the capability to geographically target alerts to a defined area using federal information processing standard (FIPS) codes, which designate counties and subdivisions within counties to define the targeted warning area, or by using a list of polygon vertex coordinates to specify the boundaries of the targeted area. The NWS and wireless carriers have developed ways to define even smaller polygons.

A brief discussion of what is known about designing effective warning messages will provide useful context for understanding issues associated with geotargeted alerts and warnings.

Warning messages

Modern social science research on the topic of warnings began in the 1950s with the funding of two studies by the National Academy of Sciences. The first study (Wallace 1956) was an exploratory investigation of individual and community behavior in response to the devastating and unprecedented 1953 tornado in Worcester, MA. That study documented the absence of any official warning to the public about the tornado, as well as an associated 54 deaths and 438 major injuries. The investigator concluded that if an official warning had been issued to the public, up to 90% of the at-risk population might have taken cover, thereby greatly reducing morbidity and mortality caused by the tornado. The second study (Mack and Baker 1961) examined how people respond to air raid sirens, and concluded that, generally speaking, the general public did not understand what air raid sirens meant. This early social science research on warnings, as well as the research that followed, was brought together by Mileti and Sorensen (1990) in a synthesizing state-of-the-art report on risk warning communication. This work included a detailed warning bibliography, which later yielded two annotated bibliographies – one on warnings and the other on public education about disaster preparedness. The effort documented five key elements of imminent threat warnings as well
as five critical style elements. The five message elements documented by Milteti and Sorensen were incorporated in the design of CAP. Their work provided the foundation for the structure of the nation’s WEA messages.

The warning literature distinguishes the terms “alert” and “warning.” Providing an alert is akin to “ringing a bell” – such messages are designed to gain the attention of those potentially at risk, and motivate them to seek additional information. A warning, on the other hand, is designed to provide more complete information about what event has occurred and what actions should be taken to reduce risk. WEA messages, because of their constrained 90-character length limitation, function more as alerts than as true warnings. It is likely, however, that as length constraints initially imposed on WEA messages expand over time, longer WEA messages may be able to provide members of the public with sufficient information about what has happened and what guidance is recommended to enable them to make informed decisions about the protective actions they should take, thereby functioning as true warning messages.

**Sense-making**

After receiving a warning message, individuals engage in efforts to make personal sense out of the situation. This process of “sense-making” occurs during what is sometimes referred to as the “response gap” – the time between receiving a message and responding to it. Mileti and Sorensen (1990) documented five activities that occur as part of the warning message sense-making process: understanding, believing, personalizing, deciding, and searching and confirming. In order to make sense of a warning message, receivers of the message must first understand and attach personal meaning to the message. In addition to understanding the message, receivers must also determine whether or not they believe the message. That is, they must conclude whether the risk, warning, and contents of the message are accurate. Personalization refers to the process of conclusion that one is, in fact, the intended target of the message and that one, indeed, is no longer safe. Deciding refers to forming an idea about an appropriate course of action. Searching and confirming refer to searching for information from other sources to confirm what one understands, believes, personalizes, and what one decides to do or not do in response to the warning message.

**Message content**

The social science research record provides evidence that warning messages will be more effective, that is, the messages will have a higher probability of motivating appropriate and timely protective actions taken by the general public, if they contain the five key warning message topics documented by Mileti and Sorensen in their 1990 report. These five key topics are a description of the hazard and its consequences; protective action guidance; the location and population at risk; the time by which the public should begin taking the protective action as well as the time by which taking the protective action should be completed; and, finally, the message sender or source. These key warning topics provide information about what, when, where, why, and who. The social science warning literature provides evidence that warning messages are more effective at motivating appropriate protective action when they provide information to the public about the impending hazard by describing the event, the consequence of the hazard’s impact, the threat posed, and how taking the recommended action will reduce the hazard’s consequences. Specific guidance about
recommended protective actions should be provided to maximize health and safety, and explicit information about exactly how to take the action should be included. Protective actions linked to basic human values (e.g., “evacuate to keep your family safe”) more effectively motivate warning response than recommendations communicated without connection to such values. To be effective, warning messages must also specify the location of the event, indicating exactly who will and who will not be affected, using physical geographical boundaries to explain the location where people who need to take protective action are located. The use of maps to add visual information about who should and who should not take protective action may help people readily determine whether or not they are at risk (i.e., personalize the message). Warning messages also are more effective when they provide explicit information about time, including a cutoff time indicating by when recipients should begin taking the recommended protective action, as well as a cutoff time indicating by when they should complete taking the action. Finally, messages are more effective when they state the message source, or who the message is from, based on what constitutes the most credible/believable source for the overall population at risk. Given the diverse nature of the multiple publics served by a single alert or warning message, a panel of mixed sources typically is more effective than any single source. Messages that include both official and familiar sources are most effective.

The templates initially used by the NWS in the WEA service included these five key warning topics with one exception. Time in the research literature refers to when people at risk should begin and complete taking a protective action, whereas time in a WEA message refers to when the message expires or is no longer in effect.

Message style

The social science warning literature, as documented by Mileti and Sorensen (1990), provides evidence that five style elements contribute to effective warning messages. These are clarity, specificity, accuracy, certainty, and consistency. Warning messages that are simply worded, free of jargon, and use words that average members of the general public can understand have greater clarity and are more effective than other messages. Specificity refers to precise, nonambiguous information about the area at risk, the actions people should take, the nature and potential impact of the hazard, the amount of time people have to engage in protective action before hazard impact, and the source of the message. Message accuracy refers to the extent to which a message contains information that is correct, complete, current, and error free. Certainty refers to warning messages in which information is stated with authority and confidence, including during those situations in which there is ambiguity. Certainty is especially important in the language chosen for communicating recommended protective actions. Consistency refers to a message’s coherence. Warning messages are more effective when they have external consistency and internal consistency. Messages can have increased external consistency by explaining changes from prior messages, and can have increased internal consistency by not containing information that conflicts or is contradictory, such as, “radiation is in the air, but do not worry.”

Hazard type

Different types of hazards are perceived by the public in different ways. For example, some hazards are more familiar, and some hazards are associated with higher pre-event levels of perceived risk and dread. The historical research, however, indicates that the message content
elements described above are pertinent to all hazards. Thus, it is possible to standardize the types of information included in warning messages, including information that can help increase message personalization, such as geolocation information about the area affected and who is at risk.

Nonmessage factors

Social science research includes the effect of nonmessage factors that are associated with message response. These factors include status (e.g., age, gender, ethnicity, and acculturation); roles of responsibility within and outside of the family (e.g., family size, number of children, number of pets, having a united family, and greater community involvement); hazard experience (i.e., personal experience with prior disasters); pre-event knowledge about the hazard and protective action; environmental cues or indicators in one’s environment that reinforce the presence of the hazard (e.g., smoke and ash indicating the presence of fire); and social cues or indicators in one’s social environment that reinforce the presence of the hazard (e.g., seeing and hearing about others who are taking the recommended protective actions).

Geotargeted alerts and warnings

Within the context of alerts and warnings, geotargeting is a two-step process that involves first defining the targeted area and then delivering a message to individuals located within that area. Lack of precision is a concern during both steps. There may be lack of precision in defining the region and in delivering the message. For example, when the most granular level allowable for a given system is an entire county, and only a portion of the county is at risk, the defined area at risk may be imprecise. Likewise, given current technology, there may be lack of precision in delivering the message to only the affected region.

Systems that provide geotargeting

Several systems currently provide geotargeted alerts. These include the “reverse-911” systems that can dial groups of landline telephone subscribers, wireless-based systems such as EAS, the WEA system in which alerts are transmitted to cellular phones and mobile devices using cellular broadcast technology (only the cell towers that correspond to the defined geographic area broadcast the message), and the NOAA weather radio, which uses dedicated radio frequencies and special purpose receivers to deliver alerts, allowing users to subscribe to geographic areas of interest.

Using geotargeting to communicate risk

The benefit of geotargeted alerts and warnings is that they allow messages to be tailored based on the nature of the particular hazard at a given geographic location and the protective actions that are appropriate for people who are physically present in the given area. Receiving a geotargeted message can strengthen message personalization, or belief that one is indeed at risk and, therefore, should take protective action. Given adequate training and system knowledge, geotargeted messages can take the place of lengthy descriptions of which areas are affected by the hazard, allowing for greater focus on descriptions of what happened (i.e., the hazard) and what should be done about it (i.e., recommended guidance); this is of particular importance for systems with message length constraints. Research involving a food recall experiment has shown that, when a message is
GEOTARGETED ALERTS AND WARNINGS

geotargeted, not only does it attract more attention but message recipients better understand the potential risk they face (Frisby, Veil, and Sellnow 2013).

Communicating geotargeted information

There are three main methods by which geotargeted information about what geographic area is affected and who is at risk can be communicated to message receivers (National Research Council 2013). The first method for communicating geotargeted information in an alert or warning message is to provide text-defined geolocation information. This approach is appropriate for systems that can transmit only text information. Text may be used to define geolocation by using a general statement such as, “Tsunami warning in this area until 12:00 Pacific Standard Time, take shelter now. – NWS.” A benefit of this approach is that the message is short and will work for formats where message length is constrained, such as the WEA service. A potential concern is that without an investment in public outreach and education, recipients may wonder whether or not the message actually does, in fact, apply to them. Another text-based approach to defining geolocation is to specifically name the geotargeted areas, as in the following example message: “Radiological hazard warning in Los Angeles, Orange, and Riverside counties until 12:00 AM PST. Take shelter now. – DHS.” In this example, the areas affected are specifically named, but messages constructed in this way may be longer than possible on some systems, and the areas named may be geographically larger (and therefore may be defined with lower precision) than the actual geographic areas affected. A more precise text-based approach is to name the boundaries of the area affected, as in the following example: “Fire warning in the area bounded by North West Parkway/E-470 on the north, Highway C-470 on the south, Highway 285 on the west, and the eastern boundaries of Adams and Arapahoe counties until 12:00 AM PST. Take shelter now. – NWS.” While this approach lends more precision to the definition of the targeted area, it also adds more length to the message. Furthermore, naming the boundaries can be problematic in terms of identifying boundaries that appropriately define the area at risk and that are readily understood by message recipients. This approach can be particularly challenging to visitors of the area, who may be less familiar with the locality.

A second approach to communicating geotargeted information in an alert or warning message is to use maps. Shading and coloring can be used to distinguish areas affected from those that are not. Inclusion of a location marker indicating the message recipient’s location relative to the area at risk can provide further personalization. This approach is dependent on having sufficient technical capabilities in the system. Maps can be difficult to read on small screens, such as cellular phones, and when resolution is low. Moreover, not all message recipients will be skilled at interpreting maps, which may lead to confusion about what has happened and what areas are affected. This can cause message receivers to spend additional time seeking further information to confirm the initial message, thereby increasing response delay, and possibly increasing subsequent death and injury.

A third approach to communicating geotargeted information in an alert or warning message is to use geodefined message delivery while indicating to the recipient that the message was, in fact, targeted. An example of this approach might be to say, “If you receive this message, you are at risk.” This approach is most appropriate when the warning system allows for fine-grained location definition.
Concerns regarding geoprivacy

In the context of geotargeted alerts and warnings, security involves ensuring that only authorized persons are able to send alerts, message cannot be modified to misinform the public, and messages cannot be suppressed through damage to (or overload of) the delivery system. Privacy refers to an individual having control of what information is exposed to whom, when, and for what purpose. Geoprivacy refers to an individual being secure from unwanted observations and tracking. Techniques exist to preserve geoprivacy while still providing location-based services. In areal masking, for example, location information is only sent when a person enters a particular region; it would not be necessary to track travel within the region. iGeoLoqi has developed tools incorporating such techniques. In 1992, Darrell Ernst began developing technology to geotarget alerts while preserving privacy. Using this technology, an alert would be sent to a wide area, and a location-aware device would determine whether or not the alert was relevant to the device owner. Because the device assesses and filters messages itself, the ability of authorities who send messages to track where end users are located would not be necessary.

The Federal Trade Commission has provided a list of “Best Practices for Mobile Privacy.” These include provision of timely privacy disclosures to consumers and obtaining explicit consent before allowing apps to access and collect sensitive data; the development and implementation of a visual dashboard displaying types of data accessed by various apps; the design, testing, and implementation of a set of simple icons to communicate privacy practices; and consideration of offering a “Do Not Track (DNT)” option, among other recommendations (Federal Trade Commission 2013).

Technologies for geotargeted alerts and warnings

Several recently developed capabilities have facilitated the future development of a geotargeted alert and warning system (National Research Council 2013). These include the CAP standard for formatting alerts, which includes geographical locations by FIPS code or vertices of polygons to define the geographic regions affected, information about the source and nature of the alert, and the recommended action to be taken. In addition, cellular phones and other mobile devices “know” where they are physically located based on mandated Enhanced-911 location capabilities, global positioning system (GPS) receivers, and nearby wireless access (Wi-Fi) sites. Computing devices, such as laptops and desktops, can be outfitted to establish their location and wired devices can use the physical location of the networks to which they are attached to do the same. Applications on any of these devices can be used to receive and communicate geotargeted alerts and warnings. Because devices “know” where they are located, they can use that information in combination with the geographic information coded in alerts to deliver the message only to those individuals physically located within the specified at risk location. Moreover, increased geotargeting resolution is becoming available.

A variety of traditional technologies can be harnessed to provide geotargeted alerts and warnings (National Research Council 2013). Telephone alerting using reverse-dialing alerts can be used by officials to auto-dial landlines or mobile telephone numbers of registered users in a given geographic area using a prerecorded message. Drawbacks include the fact that dialing large sets of numbers can overwhelm local phone switches, the significant decrease in the number of households with landlines limits system reach, reverse dialing systems do little to increase access
GEOTARGETED ALERTS AND WARNINGS

to those with disabilities, and such systems are expensive. Radio broadcast technologies also provide opportunities for transmitting geotargeted alerts and warnings. National Public Radio (NPR) is currently investigating the use of broadcast repeaters to extend the reach of radio alerts and to enable geotargeting of alert and warning messages and also the use of radio broadcast systems (RBDS) to evaluate the efficacy of using household receivers to send text information to people with hearing impairments. The NOAA weather radio (NWR), originally developed in the 1950s and 1960s, uses the specific area message encoding (SAME) standard to geotarget alerts about weather observations to those in flight or at sea. SAME was adopted in 1988 as the first geotargeted alerting standard. It allows NWR to target at the FIPS code level (i.e., generally at the county level). Cable television also can be used to deliver geotargeted alerts and warnings. Alerts received by EAS currently are distributed to all of a cable system’s subscribers, even to individuals who may live outside of the area affected. It may be possible to modify cable boxes to that they “know” their location and can filter messages to provide more precise geotargeting.

Technologies for geotargeting alerts over the Internet also can be used (National Research Council 2013). Geotargeting based on Internet protocol (IP) address currently exists but is limited and relies on privately managed databases that match IP addresses to physical addresses. An alternative approach would be to incorporate alert information, including geography, in an information source that a user frequently monitors, such as Facebook, which would then send the alert to all subscribers in a given state, for example. Services that stream video over the Internet, such as Netflix, YouTube, and Hulu Plus, are increasingly replacing traditional broadcast and cable television for which alerting systems already exist. These services could be modified to receive and display geotargeted alerts delivered by the video stream and displayed by the content viewing application.

The location of mobile device users may be determined in a variety of ways (National Research Council 2013). This traditionally has been accomplished using GPS or cellular tower triangulation. More recently, Wi-Fi access point signals have been used by Skyhook Wireless to match access point and cell tower signals to a proprietary location database. Mobile device location also can be determined based on over-the-air television broadcast signals using TrueFix TV Positioning, developed by TruePosition. Here, location is determined using signal arrival times, which are directly proportional to the distance to the transmitter, with the benefit that the technology can be used in indoor and urban environments, where GPS signals are unable to penetrate building structures. Similarly, UpLink Time Difference of Arrival (U-TDOA, also developed by TruePosition) uses the time of signal arrival at multiple cellular towers. Finally, indoor geolocation of mobile devices can be determined using additional data sources. GPS and other signals used to determine location do not readily penetrate buildings, making accurate indoor geolocation more difficult. Qualcomm has worked on developing a technique that uses the additional data sources of Wi-Fi measurements, building maps, and phone sensors such as accelerometers, gyroscopes, and compasses, to determine indoor positioning.

Current and future technologies for geotargeting alerts to mobile devices include geotargeting of short message service (SMS) messages, third-party application capabilities, and carrier geotargeting of WEA messages. Almost universally supported and widely used to send and receive text messages, SMS can be used to deliver geotargeted alert and warning messages
GEOTARGETED ALERTS AND WARNINGS

The Open Geospatial Consortium has been working to develop a standard (Open GeoSMS) for communicating location information in SMS messages. Location can be displayed in a mapping tool or used to retrieve satellite images. Using third-party applications on a mobile device in combination with the device’s location information also can be used to deliver geotargeted alerts and warnings. For example, iMap Weather Radio, developed by Weather Division Technologies, communicates NWS alerts to the public, providing some of the key features of a NWR (e.g., alerts cause the phone to wake up automatically). Finally, carrier-specific geotargeting methods to deliver WEA messages can be used. Challenges and opportunities for improving geotargeting include the use of the long-term evolution (LTE) standard, in which cellular IDs are assigned to individual antennas on each tower, rather than the tower as a whole, potentially allowing for greater precision. GPS could be used to determine location but this approach poses many challenges, including network congestion and poor indoor and underground performance. It may be the case that the alerting system does not need to accomplish the geotargeting. A phone’s position may instead be determined by a combination of technologies previously described, and the phone can make the determination as to whether or not an alert applies to its location. The greatest opportunity for improving the ability of geotargeted messages to motivate public response with the least impact on networks and devices may be to expand the amount of information provided by allowing pagination, or a series of messages that together provide the full warning message text.

Future research

A report of the National Academy of Sciences 2013 workshop on geotargeted alerts and warnings lists key areas for ongoing and future research (National Research Council 2013). These key research areas include discovering how to facilitate and improve public warning response to geotargeted alert and warning messages, the value of geotargeted information, the best ways to develop and deploy new technology, how to best respect privacy and meet security needs, and effective strategies for facilitating and encouraging practitioner use of geotargeted alert and warning systems.

Much research on ways to facilitate and improve public response is currently underway. Key topics include opportunities for optimizing message content, structure, and delivery; the extent to which more precise geotargeting may reduce morbidity, mortality, human suffering, and other disaster related costs; the best method of communicating locations at risk and the recommended protective actions for each location in order to reduce the amount of time individuals spend seeking additional information (i.e., reduce response delay); system opt-out rates, their causes, and strategies for encouraging people to opt back in; ideal message repetition frequency; and strategies for determining message effectiveness during a given event.

Given the variety of ways in which geotargeted information can be presented (i.e., general text-based information indicating one is at risk, text including a place name for the area at risk, a map, or some combination of these), research regarding the optimal display of such information is needed. This includes discovering what combinations of text and maps are most effective in encouraging message recipients to take action, what is the most effective size of geotargeting boundaries, what is the most effective way to display maps, how does map literacy affect public warning response, what design and visualization principles are most effective for geotargeted alerts and warnings, and how can
GEOTARGETED ALERTS AND WARNINGS

targeted message be made as accessible as possible, particularly for those with disabilities?

Several research gaps exist concerning the development and deployment of new geotargeted alert and warning systems. These gaps include how to quickly adapt technologies developed by the private sector for delivering geotargeted alerts and warnings, as well as understanding what legal, regulatory, technology standard, or other barriers might hinder the rapid deployment of new geotargeted alert and warning technologies. Another research gap involves understanding the manner in which special purpose alert and warning systems (e.g., WEA) and more general purpose messaging systems (e.g., Twitter and other social media) may best work together to provide effective alerts and warnings to the public, including discovering how these systems might complement or interfere with each other. How to design new technologies that allow the inclusion of maps, images, and links that allow the forwarding of alerts and warnings to others, and that incorporate the needs of at-risk populations with physical or mental disabilities, and what strategies can be used to decrease bandwidth requirements, are additional research needs. Finally, future research should address how to best close the gap between what is known about how publics respond to alert warning messages and the technology available for delivering geotargeted alerts and warnings.

The use of geolocation information related to mobile devices raises concerns about user privacy. One important future research need is determining whether or not users have the requisite knowledge to provide explicit consent for using geotargeted mobile alert and warning systems. Another important research area is how to design future alerting systems so that they incorporate privacy and security concerns “up front” as opposed to attempting to address these concerns after the system is designed or deployed.

A final privacy-related research question is, to what extent might concerns about government regulation or negative public relations inhibit developers from incorporating geolocation information into new technologies, and discourage private providers from participating in new systems for alerting the public?

In terms of real-world application, guidance to help practitioners in government roles make decisions about how and when to issue alerts and warnings is needed. Understanding the barriers and facilitators to experimenting with, adopting, and increasing use of new alerting systems and geotargeted alerts, as well as the best roles for involving practitioners in system design, can help facilitate more appropriate use of emerging systems by practitioners.

With the advance of information technology, mobile devices such as smart phones, navigators, and tablet PCs have become the major platform for various services. Location-based information has become the major stream of applications. However, there exists an interoperability issue when different systems or services try to communicate. Therefore, standards and formats are important for exchanging location-based data. Geotargeting protocols are the protocols used for transmitting location-based information from sensors, the Global Positioning System (GPS), and mobile devices that can provide their own location coordinates. Among the standards, GeoSMS (Geo Short Message Service), WaterML, and SWE (Sensor Web Enablement) are introduced in this entry.

GeoSMS

Mobile devices such as mobile phones, vehicle navigators, and tablet PCs can be aware of current location through embedded GPS or other global navigation satellite system (GNSS) positioning services. With this location-aware feature, all kinds of location-based services (LBS) appear to be the most popular services and applications in daily life. However, there exists an interoperability issue among those LBS applications when it comes to “talking to each other” because different devices or applications may represent the location information in different formats. Standards for location reference are essential for service developers to create more powerful applications that traverse different platforms and systems.

The Open Geospatial Consortium (OGC) Open GeoSMS could be the most simple but useful geospatial standard for LBS, providing developers with an extended Short Message Service (SMS) encoding and interface to facilitate communication of location content between different LBS devices or applications. SMS is the open text communication service standard most used in phone, web, and mobile communication systems for the exchange of short text messages between fixed line or mobile phone devices. Open GeoSMS uses this existing, widely supported protocol to define an extended format with simple location content in geographic coordinates for achieving interoperable communications; meanwhile, there is still human readability of the content. No extra hardware or communication infrastructure is required for implementing this standard. It was first proposed by the Industrial Technology Research Institute (ITRI) of Taiwan in 2008, and became an OGC standard in 2012.

Format and usages

The Open GeoSMS expression uses the following structure: HTTP/HTTPS (Hypertext Transfer Protocol/Secure) URI (Uniform Resource
GEOTARGETING PROTOCOL STANDARDS

Identifier) followed by payload in a new line. The first line of an Open GeoSMS message is an HTTP/HTTPS that indicates the server that will process the SMS string. It is mandatory and contains location information in coordinates and a postfix in the query string as “&GeoSMS,” which ends the first line of the message. The URI is supported by most web services whose main purpose is to provide receivers with access to web services, such as map service, advertisement services, or other services from telecom providers.

The location information should be shown in the query string of the URI. The parameter element name “geo” is recommended but it is not mandatory. However, the coordinates should be expressed as latitude and longitude in the WGS (World Geodetic System) 84 datum as defined in EPSG (European Petroleum Survey Group) 4326. Coordinates should be in the decimal degree format without quotation symbols, and should be bounded by $\pm 90^\circ$ and $\pm 180^\circ$, respectively. Positive latitudes are north of the equator while negative latitudes are south of the equator. Positive longitudes are east of the Prime Meridian while negative longitudes are west of the Prime Meridian. Latitude value goes before longitude, separated by a comma.

The postfix string “&GeoSMS” in the query string of the URI is also mandatory and can provide extra information indicating the type of message in order to be pre-processed by the server. For example, “&GeoSMS=OP” means that the message is optional and represents an operation description to identify a specific operation for a specific application. “&GeoSMS=P” means that the message is simply a point of interest (POI).

The following is an example of geo-messages by Open GeoSMS.

http://maps.geosms.cc/showmap?location=23.9572,120.6860&GeoSMS

Debris flow alert! Use emergency evacuation route now!

where “http://maps.geosms.cc/showmap?” is the URI of a map service, “location=23.9572,120.6860&GeoSMS” is the location parameters and postfix string, and “Debris flow alert! Use emergency evacuation route now!” is the text content.

Then, the encoder of this geo-message can parse it and display the message in a digital map according to the location it specifies.

Applications of GeoSMS

The Open GeoSMS was first successfully adopted to facilitate disaster management around the time that it became an OGC standard due to its light weight and easy-to-use features for communication during disasters. Many experiences of huge disaster rescues have shown that coordination among rescue forces and humanitarian organizations from different nations is essential but difficult to achieve, mainly because of the lack of a platform and mechanism to collect precise and up-to-date information relating to those incidents and the survivors.

Among those platforms for rescue coordination and information dissemination, the most famous one may be Ushahidi, the open source software for information collection, visualization, and interactive mapping. Each website powered by Ushahidi is created based on its establisher’s need for data or information in a particular geographical area. They can define their own data categories to fit their needs as well as the media by which the public can submit data based on their observations, such as email, SMS, Twitter, or online forms on the website. In the case of the Haiti earthquake of 2010, data categories included deaths, emergencies, threats, responses, missing persons, and so on. Obviously, GeoSMS messages are one of the most convenient media
for reporting emergency information due to the nature of their standardized location reference and string messages.

The Sahana project, initiated by volunteers in Sri Lanka to help people suffering in the aftermath of the Asian tsunami of December 2004, is another free and open source software disaster management system. The system, developed in Phase II as a generic disaster management tool, was further developed with the sponsorship of the Swedish International Development Agency (SIDA), IBM, and the US National Science Foundation (NSF). It has been used by governments and nongovernmental organizations (NGOs) in the Philippines, Pakistan, Indonesia, and Sri Lanka. Sahana is also adopting OGC Open GeoSMS (Figure 1) and used the Android application contributed by its founder, ITRI, as an official app. This open source app supports incident reporting, task dispatch, and peer-to-peer team communications.

Besides its applications for disaster management, OGC Open GeoSMS has also been used in commercial products. Applications for
roadside assistance and taxi booking services have been implemented in Taiwan using this standard. OGC Open GeoSMS messages are sent like regular SMS without Internet connection, tagged with the sender’s location, and travel across heterogeneous platforms of different service providers. Unlike other service providers, Taiwan’s solution does not require users’ location by call center, which means users do not have to struggle using natural language to describe where they are. Figure 2 shows some use cases of sending OGC Open GeoSMS messages between taxi drivers and passengers. Figure 2a is the GeoSMS message sent to a passenger after his/her request is addressed. Figure 2b is a special case of GeoSMS message sent by the passenger to the taxi driver when the passenger needs to change the pick-up point during the waiting period. In both cases, GeoSMS messages can minimize the potential problems of imprecision of location reference and uncertainty, and thus make the business of taxi services more secure.

WaterML

WaterML 2.0 is a standard information model for the representation of in situ water observations data, with the intent of allowing the exchange of such datasets across information systems. It is based on Observations and Measurements (O&M) 2.0 and implemented as an application schema according to the rules of Geography Markup Language (GML) 3.2. Through the use of existing OGC standards, it aims at being an interoperable exchange format that may be reused to address a range of hydrological data exchange requirements.

The core aspect of the model is in the correct and precise description of hydrological time series. Interpretation of time series relies on understanding the nature of the process that generated them. Thus, WaterML 2.0 customizes the more generic O&M 2.0 specification to the specific requirements of the hydrology domain.

The basic element of WaterML 2.0 documents is the wml2:Collection, which features one or more wml2:observationMember elements. These members each equal an actual time series and include information about the measuring site and location as well as the parameter, the process, and the actual result.

The feature of interest is defined as a sampling feature which is equivalent to a station or site that provides the data. Metadata include location and time zone information as well as gauge datum and monitoring type. Several other parameters are available with the specification and more can be added by self-definable optional parameters.

The observation data can be stored as either categorical or measurement time series in the om:result element. The short description here refers to the more common measurement time series. Metadata are divided into time series-based metadata which is valid for the whole time series (e.g., if the series is cumulative,
GEOTARGETING PROTOCOL STANDARDS

Figure 4  Souris River basin. http://nd.water.usgs.gov/floodinfo/souris.html. Reproduced from USGS.

equidistant, etc.) and metadata which is valid on a per value basis. This allows the unit, quality, and interpolation information as well as several other fields for each value individually (or defining a default value) to be stored. The last part of the result is the list of values with according timestamps as a sequence of wml2:point elements.

Time series observation data with various conditions can be encoded as WaterML format; however, wml2:metadata that describe metadata of an entire dataset and wml2:point elements that describe each measurement are the most important elements in WaterML.

WaterML application

Recently, the GIS (geographic information system) Center of Feng Chia University was involved in the project CHISP-1 (Climatology and Hydrology Information Sharing Pilot Phase 1), which was initiated by the OGC. This project aims to develop a highly standardized system in cooperation with other contributors to solve the integration problem of two case study watersheds at the border of Canada and the United States (Milk River basin and Souris River basin). Even though both countries used OGC standards when designing their own national systems,
gathering and analyzing the data is complicated because of the differences in realization of the standards when expanded and also because some services aren’t provided. Because of the lack of cross-border data, flood warning systems in each country were unable to use data provided by the other for the same watershed, which resulted in a lack of early warning services.

Several water catchment basins cross this border. The pilot region considered two basins with portions in both the United States and Canada. The Milk River (Figure 3) basin includes parts of Alberta, Saskatchewan, and Montana and the Souris River basin (Figure 4) includes parts of Manitoba, North Dakota, and Saskatchewan.

Not only in North America, but also in Europe, regulations stimulate transboundary cooperation. The European Flood Directive (EFD) facilitates data sharing between member states in order to reduce risk for affected populations and to increase effectiveness by reducing spending on data collection. The EFD also allows for common flood responses to deal with urban areas situated on either side of the border. Transboundary operations may also strengthen cooperation between responsible authorities and increase confidence.

The CHISP project was planned to use the solutions of standard services and to demonstrate how to build up a system using software components as building blocks, which would also mean reusable solutions and interoperability. Currently, data from both the Canadian and the US side appear at their national datacenter, which is harvested by a CHISP Harvester module. Harvester constantly gathers data and stores the data in the database, updating existing data where necessary. This method does not need any user interaction to run. This Harvester service is also able to convert data between different data formats (e.g., WaterML 1.1 and WaterML 2.0). Harvester also notifies the Broker module about changed records.

The user can subscribe to different areas of interest by using email addresses and defining threshold levels of a parameter of interest. This notification service accepts multiple subscriptions at the same time with different thresholds, and also provides an upstream service which means users will be notified whenever the water level exceeds the threshold at any point in the upstream catchment.

The Broker process can be scheduled to compare the latest stored data with user presets. When a new recorded value is over the threshold, Broker automatically notifies the user by email and also via CAP (Common Alerting Protocol) alert from the MASAS (Multi-Agency Situational Awareness System) hub. Using the link provided, the user can log in to the service and check the diagram of historical data for each area of interest, announce a flood warning, and order intervention.

The operability of the system was demonstrated by a historical flood event which occurred in 2011 on Milk River between April and May. The CHISP-1 project exemplifies how cooperative developers can set up a system by following standards. Additionally, established standardized outputs can easily serve data for other purposes; inputs ensure flexible expandability for further developments.

First, significant achievements in this implementation have been made by an interoperable system framework that provides a capability for an EM (emergency management) analyst (or anyone) to view transboundary upstream hydrometric (and groundwater) data via the web in near real-time.

Second, this study implemented a Harvester capability to automatically retrieve and store time-series WaterML2 data for streamflow and water level, and to identify if an identified
threshold value had been reached on a near real-time basis.

Last but not least, this study demonstrated interoperability through integration of OGC SOS (Sensor Observation Service), WPS (Wi-Fi Protected Setup), WNS (Web Notification Services), and CSW (Catalog Service for the Web) services along with the OASIS (Organization for the Advancement of Structured Information Standards) CAP standard to provide near real-time threshold monitoring and notification to support alert mechanisms across international boundaries and jurisdictions.

**SWE**

SWE architecture is developed and maintained by OGC members with the aim of communicating between sensors and sensor-like elements. The SWE framework is designed to create network access through a common interface.

Rain gauge
Wire sensor
Water level meter

Figure 6  The debris flow monitoring system architecture.

SWE technology mainly includes SensorML (Sensor Model Language), O&M, SOS, Sensor Planning Service (SPS), and Sensor Alert Service (SAS). The goal of SensorML and O&M is to provide a standard format for data and information communication. Data publication (or broadcast) is achieved by the web services, the concept of Service Oriented Architecture (SOA), namely the services of SOS, SPS, and SAS. XML syntax is used in SensorML for sensor modes, and in the O&M data exchange interface to describe the observation or measurement of sensors. SOS provides the users (or other programs) with access to one or more sensors and their measured values. SPS provides users (or other programs)

Figure 7  The user interface of the debris flow monitoring system.
GEOTARGETING PROTOCOL STANDARDS

Figure 8 A request of and response to the “GetObservation” operation.

with the feasibility of collecting data from one or more sensors and submitting collection requests.

SWE has been developed for years and is quite mature on sensorwise applications. Sensors and sensor systems usually have exclusive access to their management, control, and data exchange, and typically allow no online services. SWE with OGC web services, however, provides the solutions to the demands of open data exchange on sensors and systems (see Figure 5).

Figure 9 The framework of the SWE cloud.

SWE offers integrators the following:

- open interfaces for sensor web applications,
- “hooks” for IEEE (Institute of Electrical and Electronics Engineers) 1451, TML (Transducer Markup Language), CAP, WS-N (Web Services Notification), ASAP (Asynchronous Service Access Protocol),
- imaging device interface support,
- opportunity to participate in an open process to shape standards,
- sensor location tied to geospatial standards,
- fusion of sensor data with other spatial data,
- ties to IEEE and other standards organizations.

The main adopted or pending OGC standards in the SWE framework include:

O&M – the general models and XML encodings for observations and measurements (http://www.opengeospatial.org/standards/om).
SensorML – standard models and XML schema for describing the processes within sensor and observation processing systems (http://www.opengeospatial.org/standards/sensorml).
PUCK – a protocol to retrieve a SensorML description, sensor “driver” code, and other information from the device itself, thus
Figure 10  The observation of a debris flow event in Taiwan, 2012.
Figure 11  The data publication of the debris flow event in Taiwan, 2012, using the SWE protocol.
enabling automatic sensor installation, configuration, and operation (http://www.opengeospatial.org/standards/puck).

**SOS** – an open interface for a web service to obtain observations and sensor and platform descriptions from one or more sensors (http://www.opengeospatial.org/standards/sos).

**SPS** – an open interface for a web service by which a client can (i) determine the feasibility of collecting data from one or more sensors or models, and (ii) submit collection requests (http://www.opengeospatial.org/standards/sps).

**SWE application: debris flow monitoring in Taiwan**

There are at least 400 sensors used in debris flow stations in Taiwan. One of the important issues of the debris flow monitoring system is the sensor data integration on a platform. To solve the issue, the SWE framework was implemented in the monitoring system.

The debris flow monitoring system has implemented the “GetCapabilities,” “DescribeSensor,” and “GetObservation” components of SOS operations. Figure 6 is the architecture of the debris flow monitoring system in the SWE framework. The sensors installed in the monitoring station call the operation “InsertObservation” and send the observation to the SWE server through Internet communication. Other applications can connect to the SWE server and use the “GetObservation,” “GetCapability,” or “DescribeSensor” operations to get observation information, service capabilities, or sensor capabilities from SOS operations. Figure 7 is the user interface of the debris flow monitoring system based on Google Earth. Figure 8 illustrates a demonstration of SOS.

Social media and ambient geographic information

The emergence of web 2.0-enabled technologies has impacted human interaction and participation by allowing the general public to publish and disseminate information, and to establish connections. Social media have emerged over the past decade as the prototypical paradigm of this newfound capability, with the term used as a reference to a wide spectrum of digital interaction and information exchange platforms. Broadly, this includes blogs and microblogs (e.g., Blogger, Twitter and Weibo), social networking services (e.g., Facebook and LinkedIn), and multimedia content sharing services (e.g., Flickr and YouTube). Driven by massive participation, the content contributed and disseminated through such applications has emerged as a new big data paradigm. Here we define big data with respect to three properties, that of volume, velocity, and variety. Social media data combine high data volumes with rapid streaming rates (velocity) and content variability. For example, at the time of writing Facebook is managing petabyte-scale data as it processes 2.5 billion content elements and over 500 terabytes of data daily. Twitter traffic also sees on average 5700 tweets posted per second, for an average traffic of nearly 500 million tweets per day. Even at 140 characters per tweet, this can result in terabytes of new data contributed daily when one considers the accompanying metadata and added multimedia content. Similarly, Flickr hosts billions of photos, with over half a billion uploaded in 2013 alone. Ingesting, visualizing, and analyzing such massive amounts of data is a substantial challenge. Harnessing the increasingly geographical nature of these contributions can provide a unique prism through which to comprehend and analyze their content, and a means to support their visualization.

Social media content is often geo-tagged, either in the form of precise coordinates of the location from where these feeds were contributed, or as toponyms of these locations. Prior work on harvesting and analyzing social media such as Twitter has indicated that, on average, the percentage of precisely geolocated (at the level of exact coordinates) tweets ranges typically between 0.5 and 3%. Depending on the area of study and underlying conditions, this rate may occasionally go higher. For example, a dataset collected from Japan following the Fukushima disaster reflected a data corpus where 16% of the tweets were precisely geolocated (Stefanidis, Crooks, and Radzikowski 2013). This spike is attributed to the fact that the dataset from Japan reflected a technologically-advanced community that was on the move, in which case users were tweeting using primarily their mobile devices. Both of these situations, namely the proliferation of technology in a society and an increased use of mobile (and other location-aware) devices to post tweets, tend to produce higher rates...
of geolocated content. In addition to precisely geolocated tweets, studies have reported that approximately 40–70% of tweets come with a descriptive toponym related to the self-described user location. Regarding imagery and video contributed as part of social media, a recent study has indicated that approximately 4.5% of Flickr and 3% of YouTube content is geolocated (Friedland and Sommer 2010). However, geotagging is not the only geographical content of such information, as references to events and corresponding locations reflect a substantial portion of social media traffic.

The geographic content of social media feeds represents a new type of geographic information. It transcends the early definitions of crowdsourcing or volunteered geographic information (VGI) (Goodchild 2007), as it is not the product of a process through which citizens explicitly and purposefully contribute geographic information to update or expand geographic databases. Instead, the type of geographic information that can be harvested from social media feeds can be referred to as ambient geographic information (AGI) (Stefanidis, Crooks, and Radzikowski 2013); it is embedded in the content of these feeds, often across the content of numerous entries rather than within a single one, and has to be somehow extracted. Nevertheless, it is of great importance, as it communicates instantaneously information about emerging issues. At the same time, it provides an unparalleled view of the complex social networking and cultural dynamics within a society, and captures the temporal evolution of the human landscape.

Driven by these trends, social media feeds are becoming increasingly geosocial in the sense that they often have a substantial geographical content, thus enabling the exploration and analysis of social media in the geographic space. For example, it is possible to identify the trail of a tweet as it is retweeted within the user community (Figure 1), or construct a social network describing the follow connections among numerous users. For the first time we are able to explore the physical presence of people together with their on-line activities, and to link the cyber and physical activities on a massive scale.

Before discussing the geovisualization of social media, it is important to define what is meant by the term. Geovisualization is short for geographic visualization, which utilizes advances from a variety of fields including visualization in scientific computing, exploratory data analysis, and geographical information systems to provide new ways of presenting geographical data for theory building and understanding (MacEachren and Kraak 2001). In many cases, the geovisualization of social media feeds predominantly takes the appearance of web map mash-ups, in essence portraying the location of social media usage on a map. Such an early attempt to visualize social media is shown Figure 2. As can be seen, the focus in this type of geovisualization is on communicating where user contributions are being made from, and to show their content without any further analysis. While this approach is informative, it often falls short of capturing the depth, richness, and complexity of the information that can be gleaned from social data. As a result, a need for more advanced geovisualization approaches that are capable of better capturing and communicating the complexity and multidimensionality of social media arises. It is worth noting that this need is not unique to social media content alone – geovisualization at large went through a similar evolution from web map mash-ups at the dawn of the web 2.0 era to more interactive visual analytics in order to support advanced knowledge discovery.

The challenge of geovisualizing social media stems from the very nature of social media data. Unlike more traditional spatial data sources, social media is comprised of an intertwined
tapestry of links and associations between users weaved with both explicit and implicit content and context. This complex structure is the result of several key constructs that shape public participation in social media (Kietzmann et al. 2011).

- Identity: Social media services are built around the notion of user identities, as well as the extent and means through which users can reveal and share this identity within a social media venue. Some social media services enforce a certain degree of identity sharing, while others permit users to maintain high levels of anonymity. Identity mechanisms in social media often allow users to publish their location as part of their profile, either in the form of their actual coordinates, or as a self-declared location (e.g., city of residence or zip code). Such information is essential for geovisualizing social media contributors or contributions.

- Sharing: Social media platforms enable users to distribute, receive, and exchange information. Sharing in social media often takes place around user-generated content objects, such as text, audio, and video – which can be georeferenced at the time of creation or at the
time of sharing. Social media services often provide users with the ability to control the degree of sharing these content objects, from making them accessible to only a small group of selected users, to releasing them widely to all users in a given social media setting. Sharing activities can be based on established links and relationship to other users, or can be created through shared interests or goals.

- Communication/conversation: While sharing relates to the ability to publish information, it is communication that makes social media what it is. The ability to communicate through social media is central to its enablement, while the ability to engage other users in conversation is instrumental in establishing associations and links between users. These links are not simply binary, but rather may span various levels of importance, ranging from active and purposeful links (e.g., retweet or mention in Twitter, or “like” in Facebook) to more passive ones (e.g., follows in Twitter). These complex communication mechanisms often result in a hierarchy of connection groupings (e.g., communities).

- Relationships: Through communication, social media users can establish various types of associations among them, to form larger user communities. Just like communication
links, these relations too may vary in terms of importance. While some social media services rely heavily on well-defined relationships (e.g., LinkedIn), others provide a much looser environment for establishing such relations (e.g., blogs). These relationships may be driven by physical space relationships (e.g., finding work colleagues on Facebook and expanding an existing relationship into cyberspace), they may reside entirely in cyberspace (e.g., initiated entirely in cyberspace, linking two distant users), or may be created in cyberspace and become mirrored into the physical space.

Generally, social media services incorporate all of these constructs at various degrees of sophistication and service levels, resulting in different emphasis areas and target audiences (Hanna, Rohm, and Crittenden 2011). While this results in what appears to be a highly heterogeneous social media landscape, there are three distinct commonalities that can be found across the different constructs, and provide meaning and content to social media data, namely:

- locations of nodes, as they allow us to project cyberspace interactions back to the physical spaces occupied by their participants;
- links that are formed among various network nodes through interaction, expressing the formation of relationships and larger communities;
- content that is shared between nodes to establish links (e.g., two nodes may be connected through a discussion on a specific topic).

Indeed location is of particular importance as it allows the embedding of information about users, links, and content in relation to the physical world, thus providing the ability to view, explore, and analyze social media in a well-structured domain that supports reasoning. Geovisualization, therefore, has a pivotal role in leveraging these advantages and enabling the analysis of social media data for knowledge production.

Geovisualizing social media

The depiction of various types of links between individuals, such as family ties and kinship relations, has a long history that can be traced back to medieval times. However, the visualization of social ties as graphs has a relatively short history, which was driven primarily by the development of mathematical graph theory, as well as computational graph drawing and analysis algorithms. The premise behind this type of visualization is that social networks can be represented as graphs, in which nodes represent individuals and edges represent relationships or interactions. While this visualization paradigm has been explored extensively in particular in the context of social network analysis (Freeman 2000), the geovisualization of social network graphs and social media has remained largely unexplored until recently. In order to better understand the different approaches to the geovisualization of social media, it is beneficial to classify them according to the type of information they aim to highlight: structure, dynamics, and content. Each of these approaches is reviewed here.

Geovisualization of network structure

The geovisualization of network structure focuses on highlighting the underlying social network that can be derived from social media data. The visualization of social networks is typically carried out by embedding the social network graph in an abstract network space that...
GEOVISUALIZATION OF SOCIAL MEDIA

is not related to physical space. As these graphs tend to be large, a graph layout algorithm is used to organize nodes and edges according to some optimization criteria (e.g., organized nodes with respect to the number of edges they are connected to or with respect to their importance to the network's structure). There exists a multitude of algorithms for such layouts, from random layouts to force-based or tree-based layouts (Bender-deMoll and McFarland 2006). As a result of applying such algorithms, each node is then assigned a set of coordinates in the abstract network space and is drawn accordingly.

An example of such visualization is shown in Figure 3a, which utilizes a force-based layout to visualize a social network of a shared interest group as derived from Twitter. The same network can also be embedded in geographical space if the geographic coordinates of the graph nodes are known. An example of such visualization is shown in Figure 3b, in which graph nodes from Figure 3a are redrawn using the geographical coordinates that were derived from social media data as the layout scheme.

This visualization shows the social network spread throughout the United States, including Alaska, Hawaii, and Puerto Rico. As can be seen, embedding the social network in the geographical space provides immediate insights into where members of the interest group are located as well as how members in different regions of the country are connected. It is interesting to note that due to the density and coverage of the group members, this visualization depicts quite vividly the shape of the contiguous United States even without a background continental map.

Geovisualization of network structure dynamics

Within geography, there has been a long tradition in studying and visualizing networks (e.g., roads, railway lines, and utility systems) (Haggett and Chorley 1969). However, such networks tend to remain static and not change their topology and characteristics frequently. On the other hand, social media, and the social networks that are derived from them, tend to

Figure 3 An example of a network structure of social media users (nodes) and their interactions (edges) (a) and the same network laid out in a geographical space (b).
be much more dynamic. This dynamic nature originates from the rapid change of content, users, and links over time that often occurs in social media. For example, during a political election period social media users can respond to ongoing social media campaign by decreasing or increasing their communication activities on specific topics, or by creating, terminating or modifying their relationship to other users. In such cases, capturing the dynamic changes that occur in the underlying social network across electoral districts is of particular importance.

Visualizing such network dynamics poses a particular visualization challenge, which has been tackled in three primary ways (Ahn et al. 2011): the visualization of network summary statistics of the network over time, the visualization of a series of network “snapshots,” and the use of animation. These approaches can also be applied for geovisualizing the dynamics of social networks. For example, Figure 4 shows the geovisualization of interactions within an online community in the aftermath of the Boston Marathon bombing of 2013. The figure shows how users from across the world are interacting as they exchange information about the event. At the first instance, 10 minutes after the event, the discussion is mainly Boston-centric, in the sense that, therein lies the highest concentration of nodes. However, over time, the global community becomes involved in this discussion, marking a transition from a

![Figure 4](image-url)
local to a global event. Moreover, as can be seen from Figure 4, the network (i.e., the connections between people) is continuously changing over space and time. This “snapshot” approach can be further expanded through the use of animated maps, in which change in the network topology and node characteristics can be viewed dynamically over time.

In addition to the visualization of the network structure over time, it is possible to visualize various social network metrics, for example the in-degree or out-degree of a node, using visual variables such as color and size. An example of this technique is shown in Figure 4, where the size of discs representing each network node is proportional to the node degree, and the width of each arc connecting two nodes is proportional to the volume of traffic between them.

Geovisualization of social media content

Moving beyond the spatial and temporal geovisualization of social media networks, visualizing content derived from social media also poses a substantial challenge. Similarly to the importance of links, content in social media is essential as it provides both thematic and contextual information from which knowledge can be derived. One commonly used method to visualize thematic information is the use of tag-clouds (or word-clouds), in which tags are extracted from a text corpus and organized in a graphic layout. In this layout, the significance of tags (for example, their relative frequency or rank in the corpus) is typically expressed through font size or color. A distinct advantage of tag clouds is their ability to effectively summarize large amounts of data and present it in a qualitative manner. In doing so, tag clouds enable the rapid synthesis of textual information towards knowledge generation.

Tag clouds can be coupled with geographic information visualization in order to communicate the associations between a geographic space and a thematic space. An example of the use of tag clouds in social media geovisualization is depicted in Figure 5a, which shows a social media harvesting system (GeoSocial Gauge) (Croitoru et al. 2013) that couples a map display and the related tag cloud of tweets about the conflict in Syria. Here, the density of tweets is shown as a density map over a world map. Other systems, such as SensePlace2 (MacEachren et al. 2011) and Ushahidi (Norheim-Hagtun and Meier 2010), provide similar capabilities. It is worth noting that in addition to density maps, social media activity can be visualized using a tessellation scheme, such as a square-based tessellation or a hexagon-based tessellation (Figure 5b). Similarly, Slingby et al. (2007) presented an applet prototype for overlaying tag clouds on geographic maps in order to explore large spatiotemporal datasets.

Much like social network layouts, tag cloud layouts can take various shapes, from a simple paragraph style to various geometric shapes such as a circle or an ellipse. Recently, as the interest and use of tag clouds in social media visualization has increased, geographic layouts have also emerged. For example, Nguyen and Schumann (2010) proposed the Taggram – a technique for exploring textual geotagged information through a tag cloud visualization. In this technique textual information is embedded inside a map region (e.g., a boundary polygon of a country) by iteratively placing tags according to their rank order and the remaining available space in the region. Similarly, De Chiara et al. (2012) proposed a Tag@Map approach, in which tag clouds are georeferenced and laid out in a simplified boundary of a given territory polygon. It is important to note that the guiding principles of combining tag clouds with a
geographic layout for summarizing and exploring social media content can also be applied to other types of media, such as sound, images or video. For example, Jaffe et al. (2006) presented the tag map generation approach, in which a collection of Flickr geotagged photos is first summarized through a clustering and ranking process, followed by laying out representative photos on a map.

Similar to the dynamics in the topology of social networks discussed above, content in social media also tends to be highly volatile. Themes, topics, and keywords, often rise and diminish at varying temporal scales that can range from minutes to hours, days, and weeks. Visualizing such temporal and spatial variations is of great interest, as it provides an important first step towards the identification of patterns of topic propagation and variation, which can support the prediction of topic and message spreading, as well as the evaluation of effects or outcomes of such activities. The dynamics of social media content can be visualized through the coupling of a dynamic activity that shows the location of social media contributions as a function of given time granularity, and content (or user) rankings that correspond to each time interval. An example of such visualization using Twitter data is shown in Figure 6. Here, changes in Twitter contributions density are shown in the geographic domain (as shown in region B), while changes in content (hashtags) and user activity are shown as a series of ranked lists. In the case of hashtags (or keywords) such lists correspond to a tag cloud (as shown in region C), as they communicate both the relative frequency of the terms within the dataset. Using this approach, users are able to explore spatial and thematic changes using an interactive time slider (as shown in region D). Additionally, it is possible to visualize the change in particular content elements (in this case hashtags) through a set of corresponding time series plots (as shown in region F).
Figure 6  Visualizing social media content dynamics by coupling a Twitter stream viewer (A), a Twitter activity density map (B), and a ranked list top hashtags (C) and top authors (E), a time slider (D), and author/hashtags time-series graphs (F).
Visualization of social media analysis

Social media content is multifaceted, as it expresses a combination of location, connections between people, opinions, reactions, and their temporal variations. Accordingly, the deeper analysis of social media can reveal many levels of knowledge, some of which can be better perceived when viewed spatially, and therefore becomes relevant to geovisualization. This section presents some representative examples and a discussion about the visualization of such products of analysis.

Cluster analysis

Cluster analysis has become a popular tool in the study of social media due to its ability to aggregate individual user locations into groups and identify activity hotspots or event epicenters. There exists a multitude of spatial clustering methods to detect such epicenters, ranging from geostatistical approaches to spatially-aware and pure probabilistic approaches (Christakos 2000). An example of a spatially-aware clustering method, which has become popular in recent years, is the density based spatial clustering of application with noise (DBSCAN) (Ester et al. 1996). DBSCAN builds on density as a measure for defining and detecting clusters. While algorithms such as DBSCAN offer several distinct advantages, including the ability to distinguish noise in the data, accommodate arbitrary cluster shapes, and perform clustering without prior knowledge about the number of clusters, they fall short of accounting for the highly dynamic nature of social media. This temporal characteristic of the data is particularly important as it allows monitoring activities and events as they unfold and provides further insight into the nature of the underlying activities. To address this issue stream-based clustering algorithms can be used, in which clusters are created, updated, and dissolved as a stream of geolocated points is ingested. An example of using this approach to analyze and geovisualize social media activity is shown in Figure 7. In this example, clusters

Figure 7  Visualizing spatiotemporal clusters of tweets following the 2013 Boston bombing. Red circles indicate the approximate radius of each cluster, and color is used to indicate time.
were generated using the DenStream algorithm (Cao et al. 2006) to show the different hotspots of Twitter activity related to the 2013 Boston bombing as they evolved several hours after the event. Circles are used to delineate the different clusters, where the radius of each circle is derived from the spatial span of each cluster, and color is used to communicate the time at which each cluster was created.

**Community detection**

The interest in community detection has increased dramatically over the last few years due to the proliferation of social media. Communities are of particular importance in social media analysis as they convey the underlying organization and structure of social media users, which often leads to a better understanding of the role groups of users have in the social space, as well as to insights into how information propagates between user groups. The incorporation of geographic information, such as user location, brings a new dimension to the detection and study of communities, as it allows exploring how the formation and activities of communities relate to the physical space. Various approaches have been proposed for detecting communities in social networks. Papadopoulos et al. (2012) proposed a typology of community detection approaches consisting of cohesive subgraph discovery, vertex clustering, community quality optimization, network division, or community structure modeling. Recently, Plantié and Crampes (2013) presented an extensive survey on social community detection and proposed a classification method of the different approaches to the problem based on the inputs and outputs of each approach. Their survey indicated that most community detection algorithms use a graph (network) as input and provide a partition of the graph as output, where the partition is formed through a top-down process, a bottom-up process, or a clustering process. Once detected, it is possible to geovisualize communities by plotting them in a geographic space. An example of this approach is shown in Figure 8, in which the three largest communities in the social network of an interest group (Figure 8a) are plotted over the contiguous United States (Figures 8b, 8c, and 8d). In this example the Louvain method for detecting communities (Blondel et al. 2008) was utilized.

Another example of interest groups could be those related to a geopolitical issue, for example the Syrian civil war (Figure 9). In this figure countries are clustered together based on a mentions network from geolocated Twitter data. The mention network is defined by users directly referring to other users within their tweet. These networks are aggregated to the country level (e.g., user A from country A mentions user B in country B) and through the Louvain-clustering method, distinct and significant communities are identified. While these communities could be represented in a table, their spatial relationships would be lost. By simply shading in the choropleth map based on membership, spatial patterns between communities become noticeable. For example, the Arab League forms two distinct clusters while Canada and the United States are in a different community (Crooks et al. 2014).

**Sentiment analysis**

Social media data are opinion-rich as people express their sentiment and views about specific topics and events. Accordingly, it is possible to mine from such data not only references to events or topics but also the public’s disposition towards them. This can be accomplished by utilizing tools for sentiment analysis from the computational linguistics community. For
example, Figure 10 shows the keywords, locations, and sentiment assessment of Twitter traffic in support of (Figure 10a, green), or against (Figure 10b, red) President Obama at a given moment in time. The figure is also communicating the complex need behind visualizing social media content. While some information exists at the level of individual user contributions, it is their aggregation that reveals more useful insight. For example, in this case one can easily identify stronger positive clusters on the West Coast compared to more negative clusters in the South, which reflect the established geographical political leanings in the United States. Furthermore, by coupling the visualization of the spatial and thematic analysis (e.g., in terms of keywords, sentiment), the bigger picture that is emerging from social media contributions can be better communicated. This joint visualization of content and place is becoming a standard approach in today’s social media geovisualization systems (e.g., SensePlace2, GeoSocial Gauge).
Figure 9  Visualization of communities derived from a Twitter mentions network relating to the Syrian civil war.

Figure 10  Visualizing positive (a) and negative (b) sentiment in a discussion pertaining to President Obama. Each figure shows clockwise from top right, individual messages, color coded into positive (green) and negative (red) sentiment, the overall sentiment of the messages, a word cloud of the top 50 key words, and a map of locations of the originating messages.

Emerging challenges

With an estimated 50 million tweets and 1.5 million Flickr images posted every day, social media content is rapidly emerging as a new opportunity and challenge for the geospatial community. The challenge is related to the substantial computational constraints imposed
by processing and analyzing such massive data that comprise diverse content and are streaming at very rapid rates, and as such it is a big data challenge. Additionally, this also presents a complexity challenge as the content of these data is highly interconnected and dynamic, establishing networks across multiple themes, locations, and time instances. Analyzing and visualizing this content in order to communicate its multifaceted nature and support the discovery of valuable knowledge is, therefore, a substantial challenge. This entry has provided examples of typical geovisualization capabilities for social media data, and showed how their visualization in a geographic context supports such knowledge discovery. In addition, it highlighted the tight coupling of spatial and social analysis that is needed to fully exploit the geosocial content of social media.

This charge to geovisualize social media content is pushing the boundaries of traditional mapping. Focusing only on the visualization of buildings and infrastructure no longer sufficient, as new social media sources require the visualization of abstract concepts like the flow of information in a society, contextual information associated with places, and the emergence of communities. Such challenges offer a unique opportunity to better link the quantitative and qualitative analysis in geography. For the first time, social media data allow us to observe and study the human social system as it is affected by and affects the world around it. Unprecedented insight is gained on this constantly evolving complex organism, where people’s roles and activities are adapting to changing conditions, and effect events in space and time. As this insight is multidimensional and highly complex, the geovisualization capabilities presented here are just a first foray into this challenge, which will undoubtedly evolve as they are driven by advancements in our analysis capabilities.

While pursuing these newfound opportunities it is necessary to remain cognizant of the associated privacy issues, in order to ensure the proper use of this public domain information. This challenge exceeds the simple anonymization of such data. A variety of private attributes can easily be revealed through the integrative analysis of multiple datasets. At the same time, the availability of geotagged information further complicates these concerns, as studies have shown that the analysis of human mobility data (e.g., cell phone tracks), allows the unique identification of individuals by using as few as four spatiotemporal points in these trajectories, even when coarse geolocation information is made available (de Montjoye et al. 2013). Accordingly, the broad range of information that is communicated through social media, an aggregate of location, social connections, and personal views is accentuating the need to re-conceptualize the concept of privacy, as suggested by Elwood and Leszczynski (2011).

Germany: Deutsche Gesellschaft für Geographie (DGfG) (German Society for Geography)

Founded: 1995
Location of headquarters: currently Passau
Website: http://dgfg.geography-in-germany.de
Membership: 25,000 (as of 2014)
President: Werner Gamerith
Contact: werner.gamerith@uni-passau.de; office@geographie.de

Description and purpose

The Deutsche Gesellschaft für Geographie (DGfG) is the umbrella organization for the geographical associations and societies in Germany. The DGfG represents the interests of geographers who work in schools, colleges, and in practice. It is committed to providing the content and significance of geography as a school subject, as a science, and as a practical discipline in the community. The DGfG coordinates the activities of the professional geographical associations and represents their common goals in the general public.

Journals or major publication series

Current activities or projects

There are more than thirty working groups within the DGfG, all making an important contribution to research and the development of geographical theories and methods. The DGfG organizes the German Congress for Geography (DKG), which takes place every two years at a university in Germany, Austria, or Switzerland. The DGfG awards outstanding scientific and journalistic performances. The national committee of the International Geographical Union (IGU) in Germany fulfills, in cooperation with the DGfG, the international tasks of the association’s work.

Germany: Gesellschaft für Erdkunde zu Berlin (Geographical Society of Berlin)

Founded: 1828
Location of headquarters: Berlin
Website: www.gfe-berlin.de
Membership: 300 (as of 2014)
Chairman: Hartmut Asche
Contact: mail@gfe-berlin.de

Description and purpose

Originally, the Geographical Society of Berlin was founded to promote research in geography, geosciences, and neighboring disciplines and communicate the results to the public. This last aspect is of prime importance so as to provide a platform for the intellectual exchange between the scientific community in the geosciences and the wider public — through lectures, discussion, field trips, and so forth. Additionally, the society publishes a scientific journal, Die Erde (The Earth) — first published in 1949, however, a forerunner to the journal “Annual Report of the Activities of the Geographical Society of Berlin” was first published in 1833.

Journals or major publication series

Die Erde. www.die-erde.org

Current activities or projects

Lectures and other events are organized where a wide range of geographical and geoscientific issues are discussed, often in cooperation with other institutions, for example, the German-Korean Society, the German Association for Applied Geography, and so forth.

With the help of the Humboldt-Ritter-Penck Foundation the society finances scholarships for student research projects.

Brief history

The society was founded in 1828 by Heinrich Berghaus and Carl Ritter in association with Alexander von Humboldt and other eminent Prussian scientists of the time. This makes the society the second oldest of its kind in the world after its sister society in Paris. All through the nineteenth century the Berlin Geographical Society took a leading part in the exploration of Africa, Asia, and the Polar regions and in disseminating geographical knowledge in Germany and all over the world. Among the society’s
GERMANY

presidents were Carl Ritter, Heinrich Barth, Gustav Nachtigal, Adolf Bastian, Ferdinand von Richthofen, and Albrecht Penck. The society’s building at “Palais Fürstenberg,” Wilhelmstraße 23 in the center of Berlin, served as an important intellectual and societal meeting place since 1899. In the interwar years of the twentieth century, Friedrich Schmidt-Ott served as president and Albrecht Haushofer – geographer, expert in geopolitics, author and a member of the opposition against Hitler – was general secretary and journal editor. After World War II, the society was reestablished in West Berlin, in close proximity to the Freie Universität Berlin. It won back its eminent role under the presidency of Ferdinand von Friedensburg, former mayor of Berlin, and in 1966 the society moved into its own building in Berlin-Steglitz, with lecture hall, library, and offices. After 1990 the society was able to re-obtain its historic library, which was in East Berlin, and regained importance for the geographical communication of unified Berlin and its hinterland.

Submitted by Christof Ellger
The term “ghetto” has been historically used to reference an urban form that reflects intense poverty, crime, family disruption, and reliance on government assistance. This conception has deep roots in Oscar Lewis’s famous culture of poverty theory. First developed in the 1960s within the field of anthropology, this theory asserts that the ghetto was created and sustained by a cycle of intergenerational poverty rooted in human pathology and defective culture. Currently, the name ghetto is also popularly used to describe the spatial confinement of any social group (immigrant ghetto, student ghetto, artistic ghetto).

More recently, however, efforts have been made to reclaim and infuse this term with more progressive meanings and to examine its nature as spaces of neglect that are complex manifestations of societal processes (Wilson 2007). Following this line, geographer Tom Slater (2009) identifies three factors to distinguish a ghetto from an ethnic enclave (e.g., Italian, Irish, Polish) and to distinguish this urban form from other marginal spaces that emerge from different societal processes. First, ethno-racial control and containment by external overarching powers explain it. Second, social and spatial segregation is extreme and rigid. Third, these urban forms become permanent and structural. In short, a ghetto here is “a space deployed by discriminatory authorities to isolate, contain, and exploit a single ethnoracial group; a place to cast out (permanently) a group outcast from society” (Slater 2009, 492).

Many scholars have argued that the historical roots of the term can be traced to Roman persecutions of Jews. The subordination and expulsion of Jews from mainstream society was initially fueled by the spread of Christianity. As a result, Jews were placed under strict regulations throughout many European cities, for example, Jews were forbidden from owning land outside the ghetto. During the Middle Ages, these ghettos consisted of Jewish quarters in overwhelmingly Christian cities (e.g., the famous Warsaw Ghetto). In some cases, the ghetto was a Jewish quarter with a relatively affluent population (for instance, the Jewish ghetto in Venice). In other cases, ghettos were places of deprivation and during periods of population growth, ghettos (as that of Rome) had narrow streets and tall, crowded houses. Around the ghetto stood walls that, during pogroms (i.e., violent massacres or persecution of an ethnic or religious group), were closed from inside to protect the community, but from the outside during religious holidays to prevent the Jews from leaving during those times. The Jewish ghetto in Venice of the fourteenth century constituted the blueprint for cities throughout Europe (e.g., Rome, Frankfurt, Prague, and Amsterdam) as fears about disease and moral upheaval attributed to Jews spread across the continent and resulted in the involuntary segregation. Some scholars have noted that while intense overcrowding, disease, and deprivation characterized Jewish ghettos, they were also terrains of collective consciousness, solidarity, and social organization. This particular duality has given way to the emergence of its own
institutions and administrative priorities behind ghetto walls (e.g., synagogues, schools, markets, and their own justice system). This also resulted in reaching for more or strengthening existing solidarities among Jewish dwellers, even between Jews that experienced strong divisions (e.g., Ashkenazim and Sephardim).

The character of ghettos has varied through times. As Jewish ghettos were gradually dispersed during the nineteenth century, the term served as a model for all urban ghettos that have formed since, such as the African American ghetto created during the industrialization era in the United States (see later, Chicago’s South Side), the buraku of Japan, and the myriads of townships of apartheid South Africa. In American cities, including Chicago, the changing dynamics of the process known as ghettoization have paralleled shifts in racial-ethnic composition and underscored the effects of major public policy failures.

Ghettoization in the United States

According to race theorists, US ghettos, such as Chicago’s South Side, have been the product of a series of strategic decisions by white people aimed at relegating minorities, in particular black people, to substandard residential areas. Studies have shown that white people have used racial violence, binding legal documents, and other strategic means of preventing black people from moving into predominantly white communities. More contemporary research has shown that whites have undertaken a range of methods to preserve race-based residential inequities. These included the physical improvement of particular urban areas at the expense of other spaces.

To elaborate from a historical perspective, modern African American ghettos began in the 1920s and 1930s with the Great Black Migration, escaping from intense racism and poverty, and seeking employment in the booming industries of the north. Unskilled labor was desperately needed to feed the vibrant Fordist capitalism and the drive of urban elites to amass and control cheap labor. Initial magnets for these migrants were Detroit, Cleveland, New York, Baltimore, and Chicago. The most studied example is Chicago’s South Side, and a cluster of adjoining neighborhoods that by 1920 were congealing into a Black Belt. This area housed 92% of Chicago’s entire black population by 1930. By 1940, with growing industrialization and immigration, black ghettos had grown in these cities (for example, Chicago’s Black Belt housed 190,000 people).

Following World War II, segregation in these cities profoundly advanced due to the influence of federal government initiatives in encouraging rapid suburban expansion. Mortgage loans for white families and the construction of highways enabled transportation between downtown employment centers and the suburbs that ultimately led to what became known as “white flight” to the suburbs. Paralleling this movement, “urban renewal” emerged nationally that helped sculpt both the content of these African American ghettos and the economic viability of other housing submarkets. By the 1950s, housing authorities, under the rhetoric of urban renewal, further contributed to concentrating African Americans. These authorities’ urban renewal programs were thought to help boost the economy through the destruction of “blighted” neighborhoods and downtown blocks, replacing them with new and vibrant downtowns including new office buildings and industrial campuses. Disproportionately, these supposedly blighted neighborhoods were
low- and moderate-income black. Due to the construction of highways and demolition of disinvested areas, people were relocated in overcrowded and blighted ghettos and massive public housing projects built alongside the highways. Public housing was ultimately turned into warehouses for the black urban poor, widely termed “second ghettos.” Invariably, projects were monstrous in scale, usually over ten acres in size and housing thousands of people.

The effects on black ghettos were devastating. These projects profoundly isolated and stigmatized black residents. Between the early 1950s and early 1960s, for example, the Chicago Housing Authority built around 35 housing projects, constituting 38,600 units, 98% of which were built in predominantly black neighborhoods. Thus, Chicago’s Robert Taylor Homes and Stateway Gardens housed 26,000 and 6,900 people in 28 buildings and 8 buildings, respectively. Urban renewal policies along with discriminatory real-estate practices (e.g., redlining and zoning) and the threat of violence in adjoining white neighborhoods consolidated mechanisms of racial exclusion to ensure that ghettos expanded and persisted. In fact, ghettos persisted through the 1970s due to the withdrawal of major industries and other employers from Chicago’s inner-city neighborhoods.

Since 1970, the massive economic restructuring experienced in many Rust Belt cities, known as deindustrialization, resulted in a degree of economic deprivation and racial segregation that has yielded the term “hyperghettos,” referring to poor, inner-city African American neighborhoods. As an outcome of recession and deepened deprivation, the 1960s and 1970s became tumultuous years for Rust Belt cities and their black ghettos. It is widely chronicled that the riots brought a mix of hope and despair. Physically devastated neighborhoods, buildings, and storefronts did not soon recover in most Rust Belt cities. On the other hand, the riots brought attention to these marginalized areas. Soon, the riots brought revamped policies, for example, new social spending on black ghettos. Medicare and Medicaid were created and the food stamp program funding more than doubled. However, this social spending on ghetto conditions was short lived with the advent of structural changes in local, regional, and national economies.

By the early 1980s, the introduction of neoliberal policies across urban America profoundly impacted the already declining industrial base. In Chicago, for example, from 1972 to 2000, manufacturing employment plunged by nearly 260,000 jobs (and thus decent blue-collar wages). Soon the industrial economy was replaced with a service economy that consisted of low-wage service jobs with no social protection, unionization, or opportunities for promotion. In this context, the neoliberal (or post-Fordist) ghetto has become differently constituted and socially organized from its Fordist predecessor. To many scholars, the neoliberal state has systematically dismantled the welfare state, and has replaced it with a punitive “workfare” state which forces people, especially young black men, into the service economy sustained by low-wage and unprotected labor. In this vein, citizens rejected by the service economy often enter the punitive and penal neoliberal state and face police, courts, jails, and prisons. Thus, citizens failing to exercise the core neoliberal principles of self-responsiveness, self-industriousness, or self-entrepreneurship became subjects to the impulses of mass incarceration. This has led scholars to argue that ghettos and prisons have become interconnected with the punitive spatial entrapment and management of the black urban poor.

Scholar Loïc Wacquant has become one of the major proponents of this perspective in his work *Urban Outcasts*. Although he received major criticism for the methodology used to compare
the *banlieues* or peripheral working-class areas in Paris, France, and the south side of Chicago, his work posits critical questions and points. He notes that today’s US hyperghettos are constituted by a blending of racial discrimination, class inequality, and state inaction, where the retrenchment of the welfare state and the reduction of employment opportunities along with the precarization of labor, are supported by intensive police activity and the constant threat of the penal apparatus. To Wacquant (2007), and contrary to the legacy of the Chicago School of Sociology, the contemporary ghetto does not suffer from social disorganization, but is organized differently in response to aggressive policies and forces that seek to marginalize and exploit this terrain. Yet, studies conducted by other sociologists suggest that in such areas, the licit and illicit meld together via the economic arena and political sphere. Other researchers focus on the constant movement of individuals who simultaneously inhabit licit and illicit markets and find in both opportunities and income (Portes 2007).

Countering Wacquant’s (2007) notion of black ghettos, Wilson (2007) argues that in neoliberal times, we are experiencing a new type of black ghetto, what he terms, a “glocal black ghetto.” This type of ghetto has become more impoverished and more stigmatized and marginalized than before. Wilson suggests these characteristics have deepened and could not have been possible without an elaborate enabling rhetoric of fear, the “global trope.” This rhetoric, serves up ghetto containment strategies as logical and important in a new supposed global reality. This containment, offered as one part of concentrating public and private resources in downtowns, is identified as the best survival tactic for cities in this new era, making the black ghettos a common “city enemy,” therefore deepening its isolation and exclusion.

Public policy debates

Social scientists and policymakers alike continue to be concerned with improving living conditions and opportunities for ghetto residents. Nevertheless, liberal, moderate, and conservative authorities remain in disagreement about how to alleviate social problems in these distressed communities. Some of the more popular policy prescriptions include the enforcement of federal fair housing legislation and the prosecution of discriminatory housing market practices such as redlining and unfair lending practices. Some less popular strategies include community reinvestment through inner-city “enterprise zones” and gentrification of ghetto areas with special provisions for neighborhood residents to return following restoration. Nevertheless, many scholars have sought to reclaim the term from a growing sense of inappropriate usage and have revisited it in order to frame policies more accurately and sensitively.

Gini coefficient

Frank Witlox
Ghent University, Belgium

The Gini coefficient, also called Gini index when expressed as a percentage, is a measure for inequality. It expresses the inequality on a scale from zero to one (the Gini index ranges from zero to 100), where “0” represents perfect equality and “1” perfect inequality. The Gini coefficient, named after Italian statistician Corrado Gini (1884–1965), is commonly used to express the income inequality of a nation. However, it is also used on different scales or to measure different variables. Corrado Gini developed this coefficient (and index) as a response to the index measuring concentration of income distribution proposed by Vilfredo Pareto in 1895 and 1897. The index now known as the Gini index was first written down in 1914 in a research paper titled “Sulla misura della concentrazione e della variabilità dei caratteri.” The indices described in the paper were based on the so-called Lorenz curve, that is, a graphical way to display and calculate inequality.

Lorenz curves give a graphical representation of inequality. They plot the cumulative share of income earned (y-axis), whereas the x-axis shows the cumulative share of people ranked from lowest to highest income. The closer the curve gets to the 45° line of equality (everybody earns the same amount) the more equal a society is. The more the curve bends towards the axes (one person earns all the money) the more unequal a society is (Figure 1). The Gini coefficient can be calculated by dividing the area A (area between the line of equality and the curve) by the sum of A and B (total area beneath the line of equality). Therefore, the greater the area A, the higher the Gini coefficient, and thus the higher the inequality.

Mathematically, this can be represented by the formula:

\[
R = \frac{\sum_{i=1}^{n-1} p_i - q_i}{\sum_{i=1}^{n-1} p_i} 
\]

with the cumulative proportion of the population

\[
p_i = \frac{i}{n}
\]

and the income

\[
q_i = \frac{A_i}{A_n}
\]

of each individual i. The individuals are ranked from poor to rich according to their income, numbering them 1, 2, 3, … , n; n thus being equal to the total amount of individuals. A is the cumulative proportion of income and calculated as follows:

\[
A_i = \sum_{k=1}^{i} x_k
\]

According to this formula of Gini, R is always a number between zero and one; zero standing for perfect equality and one representing perfect inequality. This formula can be applied to the Lorenz curve. The numerator, when divided by n, equals the concentration area between the Lorenz curve and the 45° line of equality.
Figure 1 Lorenz curve.

The denominator – again when divided by \( n \) – equals the triangular area underneath the line of equality, with vertices \((0, 0), (\frac{n-1}{n}, 0)\), and \((1, 1)\). When used for relatively large populations

\[
\frac{n-1}{n} \approx 1.
\]

Other formulas can be found in the literature. For example, the Gini coefficient can also be calculated by using the formula (Van Ourti and Clarke 2008):

\[
G' = \frac{2 \sum_{i=1}^{n} y_i \cdot R_i}{n \cdot \bar{y}} - 1
\]

with \( i \) the “individual” 1, 2, 3, …, \( n \) (ranked from poor to rich); \( y \) the income; \( \bar{y} \) the average income; and \( R \) the ranked fractional income, calculated as:

\[
R = \frac{1}{n} \cdot (i - \frac{1}{2})
\]

This formula still needs correcting because now the Gini coefficient can never reach the upper bound of one. Therefore, the obtained result \((G')\) needs to be multiplied by \( \frac{n}{n-1} \) before having the actual Gini coefficient \((G)\):

\[
G = G' \cdot \frac{n}{n-1}
\]

Jasso (1979) puts forward an even different formula:

\[
G = \frac{n+1}{n-1} - \frac{2 \sum_{i=1}^{n} i \cdot y_i}{n(n-1) \cdot y}
\]

where \( y \) is the income; \( \bar{y} \) the average income; \( i \) the rank of the individual 1, 2, 3, …, \( n \), yet ranked from rich to poor, as opposed to the previous formulas. Thus, a higher weight is given to poorer people in this formula. It is imperative that the ranking happens in the correct order (rich to poor, or poor to rich) so that the Gini index is a positive number.

The above formulas are all based on the Lorenz curve. There is, however, also a more direct way to express the Gini coefficient:

\[
G = Cov(y, F(y)) \cdot \frac{2}{\bar{y}}
\]

Here the Gini index expresses the covariance \((Cov)\) between income \((y)\) and the cumulative distribution of the same income \(F(y)\). Again, \( \bar{y} \) is the average income.

Although the Gini index is most frequently linked to the distribution of income or wealth, it has also been applied in the medical domain, ecology, education, astronomy, social development, agriculture, and so on.

In transport geography, the Gini coefficient is used to measure traffic concentration at, for example, seaports, airports, intermodal terminals. The coefficient offers information on these various transportation nodes only in a descriptive manner. Notteboom (2006), for example, uses
the Gini coefficient in a seaport context not only to assess (spatial) inequality but also spatial concentration. It can thus provide insight in the spatial dynamics of seaport systems. The following formula of the Gini coefficient can be easily applied to ports:

\[
G = 1 - \sum_{i=0}^{n} (\sigma y_{i-1} + \sigma y_i)(\sigma X_{i-1} + \sigma X_i)
\]

with \( \sigma X \) the cumulative percentage of number of ports, \( \sigma y \) the cumulative percentage of cargo throughput; and \( n \) the number of ports.

A Gini coefficient with the value “0,” in this case, means that one port accounts for the total volume of cargo throughput, while the value “1” represents a port system where all ports are equal in size.

A different example is the Gini coefficient applied to education. To measure relative inequality in education (whether all groups in society have equal access to education or not) a new index, the education Gini \( (E_L) \), was put forward. Thomas, Wang, and Fan (2000) use the following formula to calculate the education Gini based on education attainment distribution:

\[
E_L = \left( \frac{1}{\mu} \right) \sum_{i=2}^{n} \sum_{j=1}^{i-1} p_i |y_i - y_j| p_j
\]

with \( \mu \) the average years of schooling of the population; \( p_i \) and \( p_j \) the proportions of population with certain levels of schooling; \( y_i \) and \( y_j \) the years of schooling at different education attainment levels; and \( n \) the number of levels/categories in attainment data.

The Gini coefficient, and its various derivatives, has multiple advantages. Ray (1998) emphasizes that the Gini index meets all four criteria for inequality measurement. Ray named these criteria: (i) the anonymity principle (names are irrelevant); (ii) the population principle (size of the population does not matter); (iii) the relative income principle (absolute income of a person is irrelevant); and (iv) the Dalton principle (when there is a change in the distribution of income and a part of the income of a richer person is redistributed to a poorer person – when this does not affect the ranking of the individuals – this will result in a greater equity). Moreover, it is possible to work with negative incomes, as long as there are not several large negative incomes. Although the Gini index is scale invariant (i.e., a relative index), it is not translation invariant. When an equal amount of money is subtracted or added to all incomes, the Gini index will increase or decrease accordingly.

The Gini coefficient, however, also has various shortcomings. It is a relative measurement of inequality, so care must be taken when comparing various Gini indices. Although there is a similar income distribution, the absolute wealth may be decisive in the impact the inequality has on people (poor people in a rich country versus poor people in a poor country). When data are grouped by categories or into ranges (e.g., when there is no information available on an individual level) a bias will occur. This also complicates comparisons between multiple Gini coefficients. Furthermore, the same Gini index can be obtained by different income distributions.

Table 1 shows two different distributions

GINI COEFFICIENT

(and thus two different Lorenz curves) with the same Gini index.

It must be kept in mind that the Gini coefficient, as such, measures the inequality in income, but there are other useful indicators that complement this coefficient (e.g., absolute income, income mobility) to further examine the inequality in income of a society. These can help compare various Gini coefficients, counteracting the discussed disadvantages of the Gini index noted above.

GIS for transportation

Shih-Lung Shaw

University of Tennessee, USA

Transportation, which serves a critical role in facilitating economic, social, and other activities in modern societies, faces the challenges of efficiency, safety, and sustainability while accommodating increasing demand for travel around the world. Geographic information systems (GIS), which are designed for the management, analysis, and visualization of geographically referenced data, have been used to address problems in a wide range of application domains. When geographic information technology is used to manage and resolve issues related to transportation planning, design, operation, maintenance, and decision-making, it is known as geographic information systems for transportation (GIS-T).

Because of the uneven spatial distributions of natural resources and population, it is necessary to move resources and goods between places to meet varying demands. People also need to travel to conduct economic, social, and cultural activities, and to fulfill other needs that take place at different locations. Travel is therefore considered a derived demand. Transportation, which facilitates the movement of people and goods, is consequently a necessity in the daily lives of the modern world. Both human mobility and accessibility in most parts of the world have improved significantly as a result of advancements in transportation technology. However, increasing travel demands also lead to new challenges. Traffic congestion is now a common challenge in most major cities around the world. Globally, over 1 million people are killed in traffic accidents each year. Air pollution and environmental impacts related to transportation are important concerns in some parts of the world. Meanwhile, globalization requires transportation and logistics systems that can move goods and people around the world in a timely and efficient manner. To address all of these challenges, it is necessary to develop transportation systems that are efficient, safe, and sustainable. Litman (2013) suggests that transportation planning is experiencing a paradigm shift from an emphasis on mobility (i.e., physical travel) to accessibility (i.e., ability to reach services and activities). The use of information technologies, including geographic information technology, to improve people’s ability to reach activities and services is viewed as one effective way to address the transportation challenges in today’s world.

Geographic nature of transportation

Transportation systems encompass transportation infrastructures as well as traffic flows. Transportation infrastructures consist of networks of highways, railroads, airports, bus terminals, and train stations as well as other support facilities such as traffic signs, signals, and railroad crossings. They are built to facilitate flows of people and goods between different places. From a transportation planning perspective, traffic flow volumes among different places need to be estimated and forecast in order to know where, when, and what types of transportation infrastructures are needed to connect different locations. Decisions about the placement of transportation infrastructure are important...
and have major implications for the rise or fall of different places and the flows between them. It is evident that transportation is geographic in nature and GIS can help manage existing transportation systems and investigate how current transportation systems can be adjusted to become efficient, safe, and sustainable transportation systems.

Location plays an important role in transportation operations and management. Transportation agencies must know where highways, railroads, bus routes, airports, ports, bridges, traffic signs, and other transportation facilities are located in order to manage and maintain them. Traffic flows take place between different origin-destination pairs (e.g., air passenger flows from London to Paris) through transportation network links and nodes. Transportation agencies must have adequate tools to manage and analyze geographic data relating to transportation facilities and traffic flows. Geographic information systems are well received by the transportation community because they offer useful functions to manage, analyze, and visualize transportation data in a geographic context that are intuitive and relevant to transportation operations and management.

In addition to knowing the location of transportation features, the connectivity between different links and nodes in a transportation network is another piece of critical information for many transportation operations. For example, passengers only need to know that a flight can take them from Beijing to New York City; they do not need to know the exact location of the flight path. In this case, only the connectivity between network links and nodes as topological relationships between different locations needs to be recorded. Many subway and bus route maps use schematic diagrams to illustrate the connectivity between different routes rather than their correct geometric representations. Geographic information systems for transportation are capable of representing both geographic locations and topological relationships to facilitate mapping as well as analysis functions required by various transportation applications.

**Past development of GIS-T**

Because transportation is closely related to locations, places, flows, and interactions, geographic information systems, which are designed for managing geographic data, performing geographic analyses, and visualizing geographic relationships and patterns, are well suited to transportation applications. Although the use of GIS to address transportation problems can be traced back to its early days in the 1960s, GIS-T began to gain momentum in the 1970s partly as a result of the development of the Geographic Base Files/Dual Independent Map Encoding (GBF/DIME) program by the US Census Bureau to support the 1970 and 1980 population censuses. GBF/DIME files represent transportation features such as roads and railroads plus administrative and census boundary lines as vector features (points, lines, and polygons). The concept of topology, which describes spatial relationships between the vector features, is used in GBF/DIME files to manage the connectivity of network links and nodes as well as the adjacency of polygons. With maps encoded as a set of topologically connected points, lines and polygons make it possible to develop useful transportation applications such as network analysis. GBF/DIME files also included street address range data on road segments that enable geocoding functions in GIS to quickly locate any given street address and to develop applications such as using a shortest-path algorithm to provide navigation guidance. A national coverage of street networks in GBF/DIME files, along with
the demographic and socioeconomic data collected from population census surveys, offered valuable data sources to the transportation community. Many US transportation agencies from the federal level to the local level began to implement transportation applications with GIS. An increasing number of GIS-T papers and panel sessions also appeared at conferences in the 1980s, including annual meetings of the Association of American Geographers (AAG), Geographic Information Systems and Land Information Systems (GIS/LIS) conferences, and GIS-T symposia sponsored by the Association of American State Highway and Transportation officials (AASHTO).

GIS-T experienced a rapid growth period in the 1980s and 1990s as GIS software products began to offer data management and analysis functions designed specifically for transportation applications. For example, transportation agencies often record the locations of transportation features and events using linear referencing systems (e.g., a traffic accident occurring at milepost 62.5 on Interstate Highway 40 in the State of Tennessee, USA). A dynamic segmentation data model was developed to manage linearly referenced transportation data, and this data model was quickly incorporated into commercial GIS software products. Many transportation analysis functions (e.g., shortest-path algorithm, vehicle routing problem) and transportation models (e.g., facility location models, travel demand models) became available in GIS software to solve different types of transportation problems. Consulting firms and GIS software products focused on transportation and logistics applications also appeared on the market. TransCAD, a commercial GIS software product designed specifically for transportation and logistics applications, was released in 1985. Furthermore, a three-phase project sponsored by the National Cooperative Highway Research Program (NCHRP) of the US Transportation Research Board (TRB), which included NCHRP 20–27: Adaptation of Geographic Information Systems for Transportation (1990–1993), NCHRP 20–27(2): Development of System and Application Architectures for Geographic Information Systems in Transportation (1994–1997), and NCHRP 20–27(3): Guidelines for the Implementation of Multimodal Transportation Location Referencing Systems (1998–2001), along with several other NCHRP GIS-T reports, highlighted the attention that GIS-T received during this period.

In preparation for the 1990 population census, the US Census Bureau improved GBF/DIME files to release Topologically Integrated Geographic Encoding and Referencing (TIGER) files which have been widely used as the base map of many GIS-T applications.

Goodchild (2000) offered an assessment of GIS-T status and challenges at the turn of the twenty-first century. He characterized GIS-T evolution into three stages: map view, navigation view, and behavioral view. The map view focused on the inventory and description of transportation systems and often represented transportation features as centerlines similar to most print copies of street maps. GBF/DIME files and TIGER files basically followed the map view with a topological data model to ensure logical consistency of links and nodes in a network. Although GIS databases created under the map view allowed for the representation and inventory of transportation features, the one-dimensional centerline representation suffered inherent limitations in accurately representing roads and intersections for transportation applications that are two- or three-dimensional in nature. At the same time, the centerline representation of links and nodes in a network is well suited for navigation purposes such as finding the best route to travel from point A to point B on a street network. The navigation view,
however, has additional requirements beyond the map view to deal with various navigation situations. For example, it is important to know if a road segment is a one-way street or if a left turn is permissible at a street intersection. One solution developed by the GIS community is to include *turntables* in GIS databases to represent various allowed turn movements at network intersections. The centerline representation under the map view also cannot properly handle relationships between different traffic lanes (e.g., turn lanes vs through lanes) or off-network traffic (e.g., vehicles in a parking lot or in an open field). Furthermore, navigation sometimes involves transfers between different travel modes (e.g., walk, transit, drive). Alternative network representations of traffic lanes, off-network traffic, and multimodal transfers have been proposed to address these requirements for navigation applications. The behavioral view focuses on the behavior of discrete objects (e.g., person or vehicle) moving between different places on and off networks. Hägerstrand’s (1970) time geography suggests a useful framework to study individual activities under different types of constraints in a space–time context, which includes a concept of the space–time path that tracks individual trajectories in a three-dimensional space consisting of a two-dimensional space plus a third dimension of time. The concept of space–time path fits well with the activity-based approach in transportation that is considered a more realistic way of understanding travel behavior than the conventional trip-based approach. The behavioral view employing time geographic concepts has received significant attention since the 1990s. Recent studies under the behavioral view have also employed computer simulation models to study travel behaviors and extended the classical time geography to better reflect changes in human activities due to advancements in information and communications technology such as the widespread use of mobile phones and the Internet.

**Current status of GIS-T**

GIS-T has now become such a part of daily life that we benefit from it without noticing that we are using it. Many transportation agencies and companies across the world are utilizing GIS to help them manage transportation applications ranging from asset management, planning and design, operations, emergency response, environmental assessment, and transportation modeling, to marketing and logistics. Transportation agencies in many countries have also implemented intelligent transportation systems (ITS) to monitor traffic conditions and to facilitate transportation operations. Data collected by ITS have enabled many useful GIS-T applications. For example, an increasing number of cities now offer online applications that allow people to monitor real-time bus locations and to set an alarm to alert them when a bus is due to arrive at a particular bus stop within a user-specified time interval. This service allows people to better manage their time and avoid long waits at bus stops. ITS data also facilitate GIS-T applications in accessing real-time traffic conditions, parking availability, road closures, and other related information via computers or smart mobile devices. A worldwide map of transportation systems can now be easily accessed through online services such as Google Maps or MapQuest. Many people use navigation systems in their vehicles or online navigation services to find the location of a street address or a place of interest (e.g., restaurant, bank, school), as well as to find the best route for traveling between different locations on a transportation network. It can be argued that GIS-T has become an important part of the infrastructure that enables
many useful transportation-related services in the modern world.

The current status of GIS-T can be assessed through perspectives of GIS-T as spatial databases, as analysis and modeling platforms, and as communication tools (Shaw 2010). GIS-T databases are now able to handle data from various sources and in different formats. Vector representations of transportation networks for one-way streets, turn movements, underpasses/overpasses, multimodal transportation systems, traffic flows, and other relevant data are widely used today. Remote sensing data such as satellite imageries and LiDAR (Light Detection and Ranging) data are also frequently used with vector data in GIS-T databases. In addition to the data collected and published by government agencies, an increasing amount of data is now created and contributed by private companies and the general public. With the widespread adoption of information and communications technology (e.g., the Internet and smartphones) and location-aware technology (e.g., Global Positioning System (GPS), Wi-Fi positioning system (WPS)) in today’s world, private firms and the public not only are users of GIS-T services provided by government agencies but can also become active contributors to GIS-T data collection and applications. For example, OpenStreetMap (www.openstreetmap.org) is a collective effort of volunteers to create a worldwide street database based on their local knowledge, GPS tracks, and other public data sources. Waze (www.waze.com), on the other hand, is a community-based traffic and navigation application that allows users to share real-time traffic and road information. Such volunteered geographic information (VGI) and crowdsourced data contributed by the user community enables GIS-T databases to be rapidly and inexpensively updated.

It is useful to have rich GIS-T spatial databases for the inventory and maintenance of current transportation systems and services. However, a major goal of GIS-T is to address and solve the different transportation problems and challenges facing the modern world. It is therefore important for GIS-T to offer analysis and modeling functions in support of transportation applications. There have been a large number of analysis methods and models that have been developed independently from GIS to address a wide variety of transportation problems such as network analysis, travel demand analysis, environmental impact assessment, traffic engineering design, and transportation logistics. Each analysis method or model may have its own data requirements and data structure, which may not be compatible with the data model used to build GIS-T databases. As a consequence, integration of these analysis methods and models with GIS-T databases can be a challenge.

Several approaches can be used to integrate analysis methods and models with GIS-T databases. It is unrealistic to expect the inclusion of all transportation analysis and modeling functions in general-purpose GIS software designed to support a wide range of GIS applications. In this case, data conversion programs can be developed to handle data exchanges between an external transportation analysis/modeling system and GIS-T databases. This approach, which is known as loose coupling, provides a way to benefit from both GIS and other external software. A tight coupling approach creates closer interconnections between GIS-T databases and an analysis/modeling system. With an open development environment offered in some GIS software packages, a transportation analysis or modeling procedure can be implemented using a GIS programming language supported by the open development environment to deliver problem-solving applications. Finally, there are
GIS FOR TRANSPORTATION

GIS software systems developed specifically for transportation and logistics applications. In such systems, GIS-T databases are fully integrated with built-in transportation/logistics analysis and modeling functions. Nevertheless, no single GIS software product is likely to cover all transportation analysis/modeling procedures. Each application developer should choose an approach that best fits their needs.

Most transportation professionals and policymakers and the public have limited knowledge of GIS-T principles. It is important to present complex analysis procedures to them in an intuitive and easy-to-understand manner, as Google has done by keeping the platform simple for users. Web-based GIS-T applications have significantly improved information access and allowed users to interact with online applications to answer specific questions. A government agency can share GIS-T databases and applications with other units in the agency and the public. GIS-T user interfaces can be customized to meet the knowledge level and needs of different user groups. Internet-based public participation GIS (PPGIS) applications can also be implemented to facilitate communications in transportation decision-making processes such as soliciting public participation in transportation improvement programs. We may not hear about GIS-T as often today as we did in the past, but this is not an indication that it has become irrelevant. On the contrary, it suggests that GIS-T has matured and become a part of our daily lives.

Future directions for GIS-T

The main objectives of developing geographic information systems for transportation are to facilitate the current operations of transportation systems and to tackle future transportation challenges. Our goal is to achieve efficient, equitable, safe, and sustainable transportation systems and services. However, this goal cannot be achieved without considering future GIS-T trends. Although there are many ongoing research topics that could influence future directions of GIS-T, here the focus will be on web GIS/cloud computing/CyberGIS, big data, three-dimensional and dynamic GIS, and a hybrid physical-virtual world. As discussed, GIS-T should provide communication tools to make information and services accessible to transportation professionals, policymakers, and the public. Web GIS has not only made GIS-T data accessible online, but also made applications available online for monitoring transportation operations (e.g., tracking current locations of buses or delivery trucks), improving transportation efficiency (e.g., adjusting traffic signals based on real-time and projected traffic), and promoting sustainable transportation (e.g., developing web applications in support of a new model of shared rides such as Lyft). The recent move toward cloud computing, which delivers services on demand via the Internet, can free users from maintaining GIS hardware, software, data, and applications on site, and can be scaled to accommodate future expansion.

“Big data,” a term now in wide use, will have major impacts on the future direction of GIS-T. Volume, velocity, and variety are frequently used to describe the major characteristics of big data. Big data volume is not new to the transportation community, which has long worked with a large number of transportation links, nodes and features, large volumes of remote sensing data, and data collected continuously from various sensors used in intelligent transportation systems. Velocity in the big data era refers to the speed of data production as well as the processing speed needed to handle big data volumes. Traditional computing approaches have
limitations in processing and analyzing big data. High-performance computing (HPC) presents an alternative to speed up the processing of big geospatial datasets by using multiple computing units to process the same task in a coordinated manner. Many transportation problems can be partitioned either by geographic areas or by tasks and then distributed to different computing units for processing. For example, we can find the best route for different users by simultaneously running their requests on different computing units. GIS-T also incorporates a wide variety of datasets in support of different transportation tasks and applications. For example, data collected from intelligent transportation systems can include continuously streamed video and other real-time traffic data. Mobile phone tracking data has become a valuable data source for gaining insights on human mobility at a scale that conventional surveys cannot deliver. Smart transit fare cards now provide detailed origin–destination data for individual travelers. Transportation researchers have also used online social network data to study travel and activity patterns. It is important for GIS-T to manage these large and diverse datasets in an integrated environment to support geographic query, analysis, and visualization functions for transportation studies. Future GIS-T needs to support multiple data models with an open data/science approach and to take advantage of advances in CyberGIS to address challenges in the big data era.

GIS-T developments are also moving toward three-dimensional and dynamic databases and applications. The conventional GIS topological data model has served GIS-T well in the past. However, its planar enforcement requirement is designed for a two-dimensional space, whereas transportation systems and operations are basically three-dimensional in nature. Furthermore, pedestrian navigation systems, which involve off-network trips and navigation in three-dimensional buildings, have attracted significant attention in recent years. Recent GIS data models have relaxed the planar enforcement requirement to permit some three-dimensional analysis functions (e.g., a three-dimensional navigation network for multifloor buildings), but they do not yet support a complete set of 3-D operations. We also begin to see photos and images displayed with 3-D vector features to create augmented reality environments that are useful in navigation and other transportation applications. Time is another dimension that the GIS community has worked on for several decades. Time may appear to be a simple concept in our daily lives, yet it is very challenging to develop a temporal GIS data model that can properly manage, analyze, and visualize historical as well as dynamic data (e.g., real-time tracking of moving vehicles or people, continuously changing traffic flows). The map layer approach employed in the conventional GIS data model is static in nature since each map layer represents the state of a theme at a particular time (e.g., a land-use map in 2010). We must either update an existing map layer or create a new map layer to reflect changes over time. This approach may be sufficient to handle changes between different time points but it is inadequate to represent and analyze processes that take place at various spatial and temporal scales, especially if we want to treat time as the fourth dimension to investigate possible causal relationships between different processes. With the widespread adoption of sensor and mobile technologies, an increasing amount of real-time data is being collected, and the public also increasingly expects to access real-time or near real-time data to assist with travel activities. This is why we have seen a surge in online applications such as Hail a Cab, which allows users to locate and summon a taxi in real time (or schedule a future pickup), or Uber and Lyft, which offer online services for
users to find vehicles for hire or ride sharing. To accommodate these changes, there is no doubt that GIS-T must move from static to dynamic approaches in the future.

Finally, it is important to note that technology advancements are changing the way that economic, social, and transportation systems operate in the modern world. Batty (2013) suggests cities should be understood as a system of networks and flows beyond the simple view of places in space. In particular, the growth of online shopping has changed people’s shopping behaviors and products’ shipment patterns. Online social network services and the Internet in general have changed individual time-use patterns, while smartphones and other mobile devices allow us to constantly stay connected and be more spontaneous in planning activities and trips. Many of the activities we carry out in virtual space using information and communications technology can influence our activities in physical space, and vice versa. These changes are likely to lead to different economic and social systems, which in turn suggests that we may need to design and develop very different transportation systems to meet future societal needs. GIS-T, which now represents and analyzes entities, activities, and interactions taking place in physical space, may become inadequate for this changing world. Future GIS-T must offer an integrated physical–virtual environment that allows us to manage, analyze, and visualize activities in both physical and virtual space as well as interactions between what happens in physical space and what occurs in virtual space.

Geographic information systems for transportation have evolved into a mature application field of GIS over the past few decades. As the world continues to change, our needs for transportation will change accordingly. GIS-T, along with other technology advancements, can assist the transportation community in tackling the challenges and to design better transportation systems and services to meet future needs.

Before geographic information systems (GIS) were introduced to the world, and to the world of academic geography, place and the uniqueness of place was considered all-important. In the 1950s and early 1960s the uniqueness of place was challenged by the rise of quantitative and theoretical approaches to geography. In the 1960s the rise of geographic information systems gradually led to an ascendancy of a spatial and scientific approach to geography. By the late 1980s, GIS were providing jobs for students who were educated and trained to use and develop these new software tools. However, throughout the decades since GIS were developed there were those in the discipline who celebrated the uniqueness of place and the value of qualitative geography and a plethora of nonquantitative and aspatial approaches to geography. This entry will show how, during the last two decades, GIS have attempted to accommodate and assimilate these approaches and how those working in GIS have come to respect both the uniqueness and similarities of places.
Steinetz, Parker, and Jordan also recognized the implied use of overlay analysis in the results of a competition for the design of a new plan for the city of Düsseldorf in Germany that were published in 1912. Steinetz and his colleagues described other studies that used overlay procedures throughout the first half of the twentieth century, but it was not until the work of Jacqueline Tyrwhitt and Jack Whittle appeared in the *Town and Country Planning Textbook; An Indispensable Book for Town Planners, Architects, and Students* (cited and discussed by Steinetz, Parker, and Jordan 1976) that detailed and explicit accounts of the overlay process and ensuing spatial analysis were explained. The technique was quickly popularized by many others including, most famously, Ian McHarg (1969). Because of the popularity of McHarg’s book, *Design with Nature* (now cited well over 3000 times in the academic literature), he is regarded as having had a prodigious influence on the development of GIS, but *Design with Nature* did not provide a description of a methodology for computerizing the overlay process, although such a methodology is indeed articulated in the article by Steinetz, Parker, and Jordan (1976).

It is important to note that before software and hardware systems were developed that were formally recognized as “geographic information systems” there were numerous developments that occurred within the classified military arena. Clarke and Cloud (2000), for example, have provided a detailed assessment of the importance to the development of the associated field of analytical cartography of the US CORONA program of reconnaissance satellites that was operated by the Central Intelligence Agency from 1959 to 1972 along with the associated SAGE program for processing the imagery.

**The era of geographic information systems**

In their account of the early history of GIS, published as part of the first major review of the field, Coppock and Rhind (1991) divided their retrospective into four periods: (i) the pioneer period from the mid-1950s to approximately 1975; (ii) the government-supported, experimental period beginning in the mid-1970s and ending in the early 1980s; (iii) the commercial period from the early 1980s to 1990; and (iv) the user dominance era starting in 1990. For all four periods Coppock and Rhind discuss the significance of conceptual developments, progress and improvements in software and hardware, and the contributions of academia, commercial enterprises, and governments. This discussion follows Copock and Rhind’s schema. For an alternative view of the early days of GIS see Foresman (1998). Foresman’s edited book is noteworthy for providing a more operational and raster-oriented coverage of the origins of GIS, and for including many chapters written by the “pioneers” of GIS. His chronology of the evolution of GIS includes a number of overlapping “ages”: the pioneer age, mid-1950s to the early 1970s; the research and development age, the very early 1970s to the mid-1980s; the implementation and vendor age, the early 1980s to the the mid-1990s; the client applications age, the early 1990s to the early 2000s; the local and global network age, the late 1990s onwards into the 2000s. These developments are then correlated with developments in academic geography, computing, and environmental awareness.

**The pioneer period: the mid-1950s to the mid-1970s**

Conceptual developments during this period included the overlay or “layer-cake” model for
the organization of geographical data discussed previously and the popularization of the geographical data matrix by Brian Berry. Originally, the data matrix was organized with the columns representing places and the rows representing their attributes. When Berry’s model was incorporated into early GIS software this arrangement was transposed to make the geographical matrix more compatible with standard database technology. Waters (1998) discusses contributions from the field of operations research, where work on decision support systems by IBM researchers was being incorporated into planning-based software.

During the 1960s the first fully functional vector-based GIS, the Canada Geographic Information System (CGIS), was developed. The CGIS, initially a collaboration between Roger Tomlinson’s company, Spartan Air Services of Ottawa, and the Canadian Government’s Canada Land Inventory, produced a series of innovations, including hardware for laser scanning technology and software for vectorizing the resulting images (Waters 1998) and for storing raster layers efficiently, with such developments as Morton ordering. Because of Roger Tomlinson’s seminal contribution to the origins and development of GIS he has often being credited with being the “father of GIS”. In these early years, those working in the field of GIS were not simply taking advantage of developments in the field of computer science, as computer science did not offer all that was needed for the development of GIS. As the field matured, GIS would indeed take advantage of computer hardware developments and the move away from mainframe computing. External developments in database technology also proved beneficial to the development of GIS.

During this seminal period the Harvard Laboratory for Computer Graphics and Spatial Analysis, established in 1965 by Howard Fisher, laid the foundations for subsequent developments. Thus, the Harvard Laboratory made major algorithmic contributions and produced widely adopted computer mapping packages, such as SYMAP, CALFORM, SYMVU, GRID, POLYVRT, and ODYSSEY. The first three packages for producing line printer maps and 2-D and 3-D plots, respectively, were adopted throughout North American universities. William Warntz became the Director of the Harvard Laboratory in 1969 and made further conceptual contributions, including a recognition that the critical features of surfaces could be used to produce triangulated irregular network (TIN) models to provide more compact storage of surface features. Associated with the Harvard Laboratory at various times was Jack Dangermond, founder (in 1969) and co-owner of the world’s leading GIS company, Esri, which now produces the industry-dominant ArcGIS software. For a complete history of the early days of the Harvard Laboratory see Chrisman (2006). In the United Kingdom, the experimental cartography unit (ECU) was founded in 1967 by David Bickmore, head of the cartography unit at the Clarendon Press. Like the Harvard Laboratory, the ECU stimulated and championed the possibilities of computer-based mapping, providing the incentive for the British Ordnance Survey to move into automated, computer-based mapping.

In 1970 the US Census Bureau produced the first geocoded census. The topological structure of street segments was coded by identifying the IDs of right and left blocks and “from” and “to” nodes. Also recorded, using X,Y coordinates, were the address ranges of street segments. These files were known as DIME (dual independent map encoding) files and were the forerunner of the US Census Bureau’s more sophisticated TIGER (topologically integrated geographic encoding and referencing) files (Mark et al. 1997).
GIS: HISTORY

One of the primary ways in which new knowledge about GIS has been disseminated is through the organizations that have catered to academia, government, and industry. The Urban and Regional Information Systems Association (URISA) is one of the oldest such organizations. URISA held its first conference in 1963 and has continued to hold annual conferences up to the present. Over the decades the proceedings of the URISA annual conferences have been a major source of information concerning new developments in the evolution of GIS.

The government-funded experimental research period: the mid-1970s to the early 1980s

Conceptual and software developments during this period were taking place within academia, government agencies, and industry. For example, algorithms to solve location-allocation problems that had been developed in the mid-1960s were now available in stand-alone programs and were also being integrated into software systems, such as GADS (geodata analysis and software display system) developed by IBM’s research division (Waters 1998). In Europe, government-sponsored research led to the development of the Swedish road data bank and other computerized spatial databases.

Developments in GIS reflected advances in the field of computer science. During this period, mainframe systems had given way to minicomputers based on time sharing and, eventually, to desktop microcomputers, enabling the gradual movement of GIS software to these new computing platforms. One of the most prominent and earliest of the government-supported, mainframe GIS of this period was the Minnesota land management information system (MLMIS). This was a raster-based (as opposed to the vector-based CGIS) resource inventory, where the pixel cells had a resolution of 40 acres. By the end of this period, such mainframe systems were gradually becoming obsolete, due to high maintenance costs, the problem of data currency, access issues, and nonuser-friendly command line interfaces. The introduction of powerful workstations in the early 1980s led to the gradual demise of large mainframe systems.

In 1974 the first Auto-Carto conference was held. These conferences, although not held annually, are still held on a regular basis and are now sponsored by the Cartography and Geographic Information Society. Similarly, in Europe, a series of fourteen EuroCarto meetings were held from 1981 to 1997 (every year except for 1982, 1988, and 1996). In 2015, these conferences re-emerged under the sponsorship of the International Cartographic Association (ICA) as the 1st ICA European Symposium on Cartography (EuroCarto 2015).

The commercial period: the early 1980s to the late 1980s

Tomlinson (1987), writing in the first volume of what was to become a flagship journal of GIS, provided a state-of-the-art review of this newly emerging subdiscipline of geography. He noted that significant progress had been made in adopting GIS software in government and commercial organizations, including in the transport and facility planning and management, cadastral systems, agriculture and the environment, and the forestry and civil engineering sectors. He argued that in the future new innovations would come from academia and from government rather than the commercial sector. This was only to be partially true for, in 1982, Esri released ARC/INFO, the first commercial GIS. ARC/INFO adapted the CGIS model of handling the spatial and attribute data separately. The former used Esri’s topological
ARClstructure while the latter were stored in the INFO relational database. In 1986, Esri released PC ARClINFO due to the popularity of the IBM PC desktop computer. By 1988, Esri had become a $40 million a year company with clients in forestry applications and other government departments.

Tomlinson (1987) had been correct in arguing that the expansion of commercial GIS was being curtailed by the lack of educational opportunities to produce personnel who could run and maintain GIS facilities, conduct basic research, stimulate new innovations, and staff university departments. In 1988, to motivate fundamental research into the development of GIS, the US National Science Foundation (NSF) made a grant to a consortium of universities that included the departments of geography at the University of Santa Barbara (the lead institution where Mike Goodchild was the Executive Director), the State University of New York at Buffalo, and the surveying engineering department at the University of Maine. This consortium is now funded with a grant from the NSF of $5 million annually. In addition to its primary focus on research, which manifested itself in a series of research initiatives, the NCGIA (National Center for Geographic Information and Analysis) also developed a core curriculum in GIS comprised of 75 lectures, grouped into three semesters each of 25 lectures. The lectures were initially written by 35 different authors and contained additional laboratory material. They were remarkably successful and by January 1995 over 1300 copies had been distributed to over 70 countries. Eventually, the original core curriculum was made available in Chinese, French, Hungarian, Japanese, Korean, Polish, Portuguese, and Russian. The core curriculum was intended to provide a core set of knowledge that would allow faculty teaching GIS courses to cover a broad set of topics to students new to the discipline.

In February 1987, the UK’s Economic and Social Research Council established four regional research laboratories (RRLs), in London, Edinburgh, Cardiff, and Newcastle. Their mandate involved four primary functions: data management (the provision of a spatial data archive); software development; spatial analysis; and research training together with professional development. Concurrent with the development of the RRLs, the UK’s Lord Roger Chorley chaired the Committee of Inquiry into the Handling of Geographic Information. The Committee’s Report was made public in 1987 (Waters 1998) and made recommendations (subsequently acted upon) that the British Ordnance Survey, the primary supplier of maps to the British public, should move to a fully digital environment.

The period of user dominance: the end of the 1980s to the mid-1990s

Coppock and Rhind state that during the last of their four periods there was intense competition among GIS software manufacturing companies due to “user dominance” and an associated thinning out of the market to a small number of major vendors. This competition was fostered by the numerous GIS conferences and by the publication of the annual GIS World Sourcebooks (Waters 1998). These volumes were noteworthy for their annual survey of GIS companies and their software, which included detailed tables assessing the capabilities and attributes of the listed GIS software. This ongoing competition resulted in the emergence of a few dominant companies among the GIS software vendors, including Intergraph and Esri. During this period, vendors moved away from the complexity of command line interfaces to
graphical user interfaces (GUIs), once again tracking ongoing developments in computer hardware and commercial operating systems (the so-called WIMP interface of windows, icons, menus, and pointers). It was in 1990 that the US Census Bureau introduced its TIGER file system: this, together with the fact that Census Bureau data was freely available, further boosted the US geodemographics industry. Other countries including Canada and the United Kingdom made census data only available on a so-called “cost recovery” basis, arguably imposing a continuing chill on what might have been a more robust market for GIS data. In recent years many countries have permitted more open access to geospatial data under the Aarhus Convention, which became law in October 2001. However, the only states that signed the agreement were from Europe and Asia.

A number of companies supplied GIS software that specialized in niche markets. For example, Caliper Corporation produced TransCAD, a software package focused on transportation planning and transportation GIS (GIS-T). Others, such as Idrisi, developed by Clark University in Worcester, MA, successfully catered to the academic market, providing detailed tutorials and accompanying datasets. It was during this period that the movement to introduce GIS instruction into the K-12 curriculum in the United States gathered momentum. These efforts were summarized and resource materials and advice for teaching GIS in primary and secondary schools were provided at the first national conference on the educational application of geographic information systems held in 1995 and sponsored by Technical Educational Research Centers (TERC). TERC has continued to provide educational resources to schools for all grade levels (and for university GIS courses as well) and now maintains an active website.

The era of geographic information science (GIScience)

The mid-1990s saw a sea-change in the development of the academic discipline of GIS. In 1992, Goodchild published a major theoretical contribution when he argued that the discipline should move from a concern with the technology of geographic information systems to developing answers to questions that might more properly be considered to be part of a geographic information science (Goodchild 1992). In the opening arguments of his paper, Goodchild stated that much of the early history of GIS was technology driven. It was concerned with how to get geographical data into an information system and with new technologies that were developed largely within government agencies, such as the CGIS and the US Census Bureau, and by remote sensing companies that were developing new technologies to acquire satellite imagery. Now, he argued, it was more appropriate to concentrate on the task of how to “handle” and exploit the data held in these GIS databases. The way forward was prepared by research that was being reported at a newly developed series of conferences, the International Geographical Union’s spatial data handling symposia (the first of these conferences was held in Zurich in 1984 and the 17th of these biennial meetings in Beijing in 2016). Goodchild presented a review of the nascent discipline of GIScience, including a synopsis of three decades of algorithmic research, into a series of topics: spatial data handling; data collection and management; data capture; spatial statistics; data modeling and theories of spatial data; data structures, algorithms and processes; data display (visualization); analytical tools; and, finally, institutional, managerial, and ethical issues. While some of these developments were to benefit from progress in computing (e.g., data display from a new emphasis on scientific
GIS: HISTORY

visualization, often referred to as the second revolution in computer science), most launched new subdisciplines in geography (e.g., spatial statistics, which now produced new stand-alone software packages such as GeoDa, and new functionality in commercial software, such as Esri’s ArcGIS ToolBox, Spatial Analysis and GeoStatistical Analysis modules). Some of these new fields were now located in other academic departments such as information science and geomatics engineering, mirroring developments that had occurred decades before when fields such as geomorphology and climatology moved out of academic geography.

Within a few years a number of journals had changed their names to reflect this new emphasis on science as opposed to systems. For example, in 1997 the International Journal of Geographic Information Systems had replaced the word Systems in its name with Science. The new name was explained in the introduction to that volume by then editor, Peter Fisher, who acknowledged the debt to Goodchild’s seminal article in providing a rationale for the new focus to the journal and the discipline. The American Cartographer, which had been launched in 1974, had changed its name in 1990 to Cartography and Geographic Information Systems. This lasted until 1999, when it also changed the Systems in its title to Science. Other journals, such as Transactions in GIS, circumvented the problem by leaving the acronym in their title undefined. When the 2nd edition of Geographical Information Systems: Principles, Techniques, Applications and Management appeared in 1999, the word Systems was retained, but when the same four authors published the first edition of a textbook two years later, they included both terms, Geographic Information Systems and Science (Longley et al. 2001). The Annals of the Association of American Geographers requests submissions in four broad areas, one of which is Methods, Models and Geographic Information Sciences but its Table of Contents retains the now more ambiguous acronym, GIS, and its specialty group in the field prevaricates, as well, with the title Geographic Information Science and Systems. The new NCGIA core curriculum, which gathered lectures for its website until 2000, also used geographic information science in its title. The lectures and associated material were now all online and no print copies were created. A note posted on the website in August 2000 stated that there would be no further updates due to new educational resources becoming available, including the digital library of Earth system education, the NCGIA’s own center for spatially integrated social science, and Esri’s virtual campus (Waters 2013). A review of progress in the field of GIScience, twenty years after the initial discussions of the concept, has been given by Goodchild (2010).

New educational initiatives also characterized this period. In 1990, the NCGIA board of directors recommended that a new organization be developed to assist researchers in GIScience. The UCGIS (University Consortium for Geographic Information Science) website, in its brief history of the organization, states that an ad hoc steering committee was formed by the NCGIA in 1991 containing 16 members from seven different disciplines. Unfortunately, this brief historical note does not list either the members of the committee nor the seven disciplines represented. In 1994, a founding meeting was held in Boulder, CO, and in 1995 the UCGIS was formally incorporated. The UCGIS had two primary objectives listed on its website: “Advance research in the field of geographic information science” and to “Build scholarly communities and networks to foster multidisciplinary GIS research and education.” The membership of UCGIS has fluctuated over the years, reaching a high of perhaps 70 US universities in about 2005 but declining to 53 US universities at the time of writing. In
GIS: HISTORY

the initial meetings it was made quite clear that this was a US organization and non-US universities would only be granted affiliate status. No Canadian university has ever been a member and at present there are only two non-US universities that have been awarded and retained affiliate status, CentroGeo in Mexico and the University of Salzburg’s department of geoinformatics.

The UCGIS has promoted annual meetings and symposia and, in partnership with the Association of American Geographers, the development of a body of knowledge (BoK) for teaching GIS. This was seen as a natural successor to the core curricula developed by the NCGIA. However, in conceptualization the BoK was vastly different. Waters (2013) provides a critical review of the development process that led to the publication of the BoK in 2006. The BoK was structured into ten knowledge areas that were then divided into 73 units that, in turn, were further subdivided into 330 topics. Contributors to the BoK had suggested that one of the primary weaknesses of the core curricula had been the lack of an explicit structure for continuous updating. Unfortunately, this was equally true of the BoK and it was not until the UCGIS held a special workshop at its summer symposium in Pasadena in 2014 that a new BoK was proposed with a formal timeline. In the field of computer science there is a process for updating the curriculum approximately every six years. This has yet to be achieved by GIScience.

Nevertheless, by the end of the 1990s Mike Phoenix, former higher education specialist for Esri, was able to claim that their GIS software products were used in more than 60 different kinds of university academic and administrative departments (Waters 1998). By this date, GIS had influenced the teaching of many of the subdisciplines of geography and would, in the following decade, go on to influence the operations of many other disciplines that used spatial data.

Reactions to a formal geographic information science approach to GIS

Some academic geographers reacted with dismay to the new emphasis on geographic information science, seeing it as a reassertion of the aridity of the spatial paradigm of the so-called “quantitative revolution,” which had been disavowed by some members of the discipline in the 1970s. The most widely cited critique of the spatial paradigm within GIS came in the form of John Pickles’ edited volume, Ground Truth (Pickles 1995). Although some of the leading proponents of GIScience contributed essays to the book, most of the papers were written by academics unsympathetic to the achievements of those working in GIS.

Shortly after the publication of Ground Truth, the public participation in GIS (PPGIS) movement was launched at an NCGIA sponsored workshop held at the University of Maine. PPGIS may be defined as an approach to community planning that privileges the traditionally marginalized segments of society (the poor, the old, the young, the physically challenged, and members of ethnic minorities, among many others). It leverages GIS software to allow these individuals to participate in the planning of their communities and their environments. To achieve these goals PPGIS broadened traditional approaches to GIS by including a wide range of social science methodologies and theories. It is closely aligned with participatory GIS, a cognate set of methodologies and approaches and low-tech solutions, such as sketch maps, to the acquisition of geographic information. Typically PPGIS and PGIS involve the interaction and collaboration of academics with GIS expertise.
with members of the community wishing to participate in the planning of their communities. These approaches had antecedents, paradoxically in the later work of Bill Bunge, one of the pioneers of the quantitative revolution (Miller and Goodchild 2015). PPGIS has also produced new lines of research, such as the current concern with the design of age-friendly communities.

In the twenty-first century, stimulated by the popularity of PPGIS, which had spawned a series of conferences in conjunction with the annual URISA meetings, GIS began to embrace a host of traditionally nonscientific approaches to geography, including qualitative, feminist, and critical GIS to name a few. PPGIS itself had rarely spelled out whether it was concerned with geographic information systems or science, the latter being somewhat of an anathema to those practicing PPGIS. The more important of these new approaches to GIS included formal adoptions of critical GIS and feminist approaches to the use of the technology. The possibility of the former was introduced in an article by Nadine Schuurman (2000) who identified three waves of criticism of the GIS community. She argued that the first wave had lasted from 1990 to 1994 and the debate had centered on the merits of the positivist approach adopted by GIS practitioners. The second wave occurred in the mid-1990s and represented the beginning of a dialogue between GIS specialists and those concerned with both the social effects and implications of GIS technology. The catalyst for this discourse was the NCGIA’s “Research Initiative 19, GIS and Society: The Social Implications of How People, Space, and Environment Are Represented in GIS.” According to Schuurman, in the third wave, at the end of the 1990s, there was a greater commitment to the technology of GIS. This led to the rise of PPGIS in that decade and ever since. Quite separately, there was a call for a “critical GIS” or “GIS2” that would incorporate the various perspectives of social theorists (see Sheppard et al. (1999) for a discussion of the societal implications of the NCGIA’s Varenius Project, and also the papers in the special issue of Cartographica, 2009, 44(1)).

GIS developments since 2005: the world of volunteered GIS, web-based mapping and mobile GIS, and cloud computing and big data

Since 2005, developments in GIS have again mirrored the importance of progress in computing technology. Crowdsourcing and social networks have been hugely influential developments in the social application and individual use of computing technology, but these changes have been reflected in the move away from the use of authoritative data in GIS and the rise in influence and use of volunteered geographic information (VGI). The attractions of VGI are well described in Goodchild’s (2007) seminal paper on the topic: VGI is inexpensive, timely and available to all on the right side of the digital divide. Goodchild (2010), in reviewing progress in the field of GIScience, notes that the breaking down of the barriers between expert and nonexpert is also referred to as neogeography and that VGI itself has been called crowdsourced geographic information and community mapping, and thus has strong links to PPGIS. VGI has been aided by the move to web-based mapping and the availability of online GIS technology such as ArcGIS Online and the almost universal availability of map-based apps on smartphones and in-car GPS navigation systems (see Miller (2007) for a review of these technologies that have produced a time–space convergence and aided the processes of globalization). GIS and computing hardware are becoming invisible
technologies whose benefits can be leveraged and enjoyed seamlessly by wide sectors of the population in industrialized and developing countries.

Other software developments that have led to the almost universal use of geographic information and related technologies include Google Earth, OpenStreetMap, and software for finding directions, such as MapQuest. The familiarity of large sections of affluent populations with this type of software has led to the rise of location-based services and to new developments such as OpenImageMap and web mapping services.

Advances in computer technology, including cyberinfrastructure (leading to CyberGIS), cloud computing, and the rise in importance of “big data,” are almost immediately integrated into GIS software, with leading GIS companies such as Esri providing online guides to how big data may be used in such GIS applications as predictive modeling and social media. A review of the implications for the discipline of geography in general, and GIS in particular, specifically a move to a “data driven” geography, is provided by Miller and Goodchild (2015). Traditionally, big data was concerned with the three “Vs”: volume, velocity, and variety. The terms are self-explanatory and geographic data often qualify on all three counts. More recently, computer scientists have added additional “Vs” to the list, including veracity (relating to the provenance of the data: thus, for example, VGI might have lower veracity than authoritative data) (Miller and Goodchild 2015), value, validation (whether the data conforms to a priori model expectations), and voracity (the rate of ingestion, which is important in the use of virtual reality simulations with a GIS framework). Vagueness (or uncertainty) might also be added to the list as it is endemic to much GIS data.

GIS returns to its roots in geography and GIS

It can be argued that GIS has returned to its origins, from earlier concerns common to many geographers, at least on the human geography side of the discipline. Miller and Goodchild (2015) summarize the history of geography’s concerns with idiographic (description-seeking) and nomothetic (law-seeking) approaches. At various times over the centuries one approach has been dominant and the other subordinate, disparaged, or overlooked. Miller and Goodchild argue that Strabo and Ptolemy were concerned with both approaches, for they provided detailed descriptions of specific places as well as generalizations that applied to the Earth or large regions. However, Miller and Goodchild also state that such an integration has rarely been adopted by researchers in the two millennia since Strabo and Ptolemy wrote. GIS, with its emphasis on software and algorithms and its concern with creating spatial databases, is seen by Miller and Goodchild as an intellectual activity that permits a dialogue between the idiographic and nomothetic world views. Perhaps this is best demonstrated in the various spatial interpolation algorithms, some of which produce global models (trend surface analysis, for example) while others emphasize local differences (e.g., geographically weighted regression). Miller’s (2007) call for a people-based approach to GIS also emphasizes individual differences.

A recent trend in GIS has been the recognition of the importance of geodesign. This is now the focus of a new series of conferences being held annually in Redlands and also in Europe and China. It has led to new undergraduate and graduate degree programs. Geodesign has been championed by Esri cofounder, Jack Dangermond, and reflects his graduate education in landscape architecture. Dangermond (2014)
has defined geodesign as taking geographic information and linking “it to the design, decision-making, and planning process using collaboration … by building the power of GIS into the process, allowing alternative plans to be visualized, compared, and evaluated.” He credits his former Harvard University professor Carl Steinitz as introducing him to “this methodology” and so the history of GIS returns to its roots.

In 2007, the NSF began supporting research into “transformative science.” There is little doubt that over the past fifty years GIS has been a transformative science for both the academic discipline of geography and the world we inhabit. The impact of GIS on the discipline of geography has been compared often to the impact of the telescope on astronomy but, as with the telescope, people choose what they want to see through the GIS lens. The NSF is interested in how transformative science has changed the world. It would behoove the discipline of geography to do as Sheppard et al. (1999) suggested and study how GIS has transformed the world.

Glacial depositional processes and landforms

Paepin Goff
Texas State University, USA

Glacial landforms are primarily the result of erosion during glacial advances and deposition during glacial retreat. The glacial landforms that exist today are the product of both current glaciers and past glaciations. Climatic conditions allowing for the existence of glaciers are found in polar and alpine regions where low temperatures and high levels of precipitation prevail.

In polar and alpine regions, the amount of snow accumulation outpaces ablation, or snow loss from melting, evaporation, wind erosion, and calving (see Figure 1). The difference between accumulation and ablation is the mass balance of a glacier, which is used as a measurement of glacier health. According to the 2011 United Nations Educational, Scientific, and Cultural Organization (UNESCO) Glossary of Mass Balance and Related Terms, annual mass balance is monitored on more than 100 glaciers (UNESCO 2011), and monitoring efforts are expanding.

A glacier has a positive mass balance when it experiences more accumulation than ablation, which means the glacier will grow. In contrast, a glacier has a negative mass balance when it experiences less accumulation than ablation, meaning the glacier will recede (see Figure 2). A glacier that experiences equal amounts of accumulation and precipitation is said to be in equilibrium.

Glaciers with mass balances that average positive over time are said to be actively advancing. As net accumulation builds annually, the snow compresses under its own weight. Fluffy surface snow will compress into a dense layer of snow called firm, which has small air pockets. Increased compression creates an even denser snowpack layer called glacial ice, which forces air into tiny bubbles trapped in the ice.

The same mechanisms that allow for the creation of a glacier contribute to glacial flow, or movement, including:

- ice properties (weight, thickness, steepness, temperature, density),
- topographic relief,
- bedrock properties (yielding potential, temperature, mineral compositions),
- subglacial hydrology,
- terminal environment,
- mass balance.

These factors contribute to glacial flow at the internal, basal, and subglacial levels.

Glacial spreading is known as internal deformation, or creep, and is the result of ice crystal changes as a glacier compacts. Flow at the bottom of a glacier is called basal sliding, which occurs when water collects between the ice and the bedrock layer. Bedrock deformation contributes to flow at the subglacial level, which happens when soft sediments yield to glacial weight and movement. Subsurface hydrology also plays a role in glacial flow by weakening the bedrock.

Multiple types of glaciers contribute to glacial landforms including alpine, or mountain valley glaciers, and continental glaciers, or ice sheets. In general, features created by alpine glaciers are smaller and more distinct than those created by continental glaciers owing to differences in...
Figure 1 Columbia Glacier calving, Prince William Sound, AK, USA, 2005. A dramatic iceberg calving from Columbia Glacier in Prince William Sound, Alaska. The iceberg has just broken free from under the water and shot to the surface, spinning towards the ice face. The ice cliff here is about 70 m (229.7 feet) tall. Icebergs are calved as stress fractures in the glacier merge, eventually resulting in a piece of ice cracking off and falling into the water. The stress fractures are caused by the glacier flowing over uneven stretches of ground on its way to the water. Photo by Shad O’Neel, June 17, 2005. Reproduced from USGS.

glacial flow behaviors. Alpine glaciers, subject to the natural features of mountain regions, flow down valleys from high to low elevation. In contrast, continental glaciers flow outward from their centers and extend over large areas of flat land from the poles.

Depositional landforms

During periods of glacial retreat, when ablation outpaces snow accumulation, glacial drift is left behind, resulting in depositional landforms. Glacial deposition occurs when debris is released from a glacier during transport. The debris, called glacial drift, can range in size from fine sediment particles to large boulders and can be deposited during glacial advance or retreat and during periods of stagnation. Debris deposited directly by glacial ice is called glacial till, which ranges in size from particles of clay to large boulders.

Moraines are a distinctive landform made up of sediment deposited by a glacier. Several types of moraines exist in glaciated and previously
glaciated landscapes: terminal moraines, recessional moraines, lateral moraines, medial moraines, ground moraines, and supraglacial moraines.

At a glacier’s maximum extent, or terminus, are terminal moraines, which vary in size depending on how long a glacier stays in one place. These formations, also known as end moraines, are directly related to glacial speed and the surrounding environment. The longer a glacier remains at its furthest extent, the more sediment builds at the snout, resulting in larger moraines. If a glacier pauses during retreat, it creates recessional moraines, which are located behind the terminal moraine. If the glacier pauses several times, it will leave behind multiple recessional moraines.

On the sides of a glacier, lateral moraines form perpendicular to the terminus as debris is scraped away from the surrounding path and deposited on the margins. Glaciers typically have two lateral moraines parallel to one another, which are similar in size. When two lateral moraines are pushed together by glaciers, the debris combines to form one line between the two ice streams. This process creates a debris ridge between the two glaciers, called a medial moraine (see Figure 3). As the glacier progresses and joins to form one large glacier, the material that forms a medial moraine is carried to its eventual resting place at the terminus, where it is combined with the terminal moraine. If a medial moraine persists through the life span of a glacier, it will remain as a rocky ridge after the glacier melts.

Ground moraines, also known as till plains, are landscapes of glacial deposits that resemble anything from rolling hills to flat plains. In contrast to recessional moraines, which form as a glacier pauses during recession, these landforms are the product of a quickly retreating glacier that does not pause long enough to deposit organized ridges of material. Instead, a fast-moving glacier in retreat deposits material haphazardly across the ground. The resulting landscape is an unsorted mixture of unconsolidated sediments and rocks that covers the area where a glacier previously existed.

The nature of moraine creation lends itself to the scientific study of glacial history. Investigations of terminal moraines give clues about a glacier’s origin, path of movement, speed, and
Figure 3  Medial moraine, Alaska. In this photo, merging glaciers form a medial moraine between two ice streams. Lateral moraines can be seen on the outer sides of the glaciers. Photo by Don Becker, August 26, 2008. Reproduced from USGS.

life span. Multiple terminal moraines in the same location provide evidence for multiple glaciations, which plays a large role in paleoclimate reconstructions. Recessional moraines offer insight regarding environmental conditions, which is helpful in understanding the life span of a glacier and its retreat. Lateral moraines lend themselves to the study of an alpine glacier’s path from the high elevation of the valley head to the lower elevation below. Ground moraines, which often contain other features such as kettles and kames, illustrate processes that may have played a role in glacier flow and retreat. All of the combined information provides scientists with data that can be used to model past, present, and future glacier growth and recession.

Glacial retreat leaves behind another type of plain called a sandur, or outwash plain. These glaciofluvial features are the result of sediment overflow at the terminus of a glacier carried beyond the end moraine by meltwater. The drift in an outwash plain is typically stratified, or sorted by size, with the largest materials remaining close to the terminus of the glacier and the finest sediments deposited farther out. When outwash material is deposited in a ridge-like path, rather than a plain, it is called a valley train.

In the outwash plains, tributary meltwater streams break off into smaller branches, which then split and rejoin in weaving patterns called braided streams. These streams are the result of sediment overload combined with a steep stream
slope, variations in stream flow, erosional potential of substrate material, and lateral pressure gradients. Braided channels are the result of pressurized meltwater flow – pressurized flow and higher amounts of discharge result in a high braiding intensity (Catania and Paola 2001). Braided streams contribute to distinct features in an outwash plain called *outwash fans*, which are the poorly sorted outspreading of sediments.

As a glacier recedes, ice calves off the terminus and is left in the outwash plains. These blocks of ice remain frozen in the ground and are covered by outwash sediment. When the ice finally melts, it can leave behind one of two formations. The first likely formation is called a *kettle*, which is a pond-like hole in the outwash plain, often filled with water (see Figure 4). The second likely formation is called a *kame*, which is an irregular hill or mound of sediment left behind in an outwash plain.

When streams flow through glacial ice and deposit material in a lake or pond at the terminus of a glacier, the water flow creates a landform called a *kame delta*. Although this landform exists while a glacier is still active, glacial melt can act to either collapse the delta through melt or deposit additional material. The material in a kame delta is characterized by a distinct stratigraphy owing to the sorting action of the stream during transport.

While outwash material exists beyond the terminus of a glacier, similar features exist within and beneath the glacier itself. *Eskers*, or ridges of glaciofluvial sediment, form near the terminus. Some eskers form underneath a glacier from deposits in meltwater-carved tunnels. Other eskers form on glacial surfaces or in crevasses in the ice. The main esker channel is referred to as the *tributary esker*, which allows branching eskers to form in the direction of glacial movement. These landforms often wind across several kilometers, but some extend across hundreds of miles. In the United States, esker systems in Maine extend for over 160 km. In Canada, the Thelon Esker stretches across 800 km.

Beneath a glacier, meltwater also contributes to the creation of *tunnel valleys*, which resemble steep-sided U-shaped subglacial pathways running parallel to one another in the direction of glacial flow. These long subglacial drainage pathways near the margins of large ice sheets serve as drainage pathways for large meltwater streams, which have a large impact on glacial flow at the subglacial level.

At the supraglacial level, meltwater drains through the ice, creating waterfalls within a glacier called *moulins*. These channels transport water to the basal level, affecting subglacial
GLACIAL DEPOSITIONAL PROCESSES AND LANDFORMS

water pressure and velocity and thereby affecting glacial flow. On glaciers with moulins, meltwater is delivered to the basal level at discrete points, which increases the glacial sliding speed across a surface (Gulley et al. 2012). However, because access to the basal level of a glacier is naturally restricted by ice, a limited number of direct observations of subglacial water pressure leave much to be studied in the way of glacial hydrology.

If meltwater cannot drain, or if it accumulates faster than it drains, it will collect in pools. Surface water from ablation, or surface melt, will collect in crevasses and melt ponds, while subglacial streams will collect in basal lakes. If these pools of water overflow, the result will be a glacial outburst flood, also known as a jökulhlaup, an Icelandic term that translates to “glacier run.” These floods release large amounts of meltwater and debris across a large area of land. Given their potential for destruction, international monitoring efforts focus on the prevention of harm to people who live in communities where glacial outburst floods are possible.

Meltwater also deposits sedimentary material into tunnel valleys, which carry and store large amounts of meltwater, making them effective aquifers. Similar to U-shaped valleys, tunnel valleys are wide and steep with flat bottoms. The sediment layers of a tunnel valley are made up of glaciofluvial material deposited during the creation of the original formation and subsequent sedimentary infill. The geological composition of tunnel valleys allows for the study of glacial history through investigations of sediment, valley size, and terminal location.

During the life span of a glacier, debris can be transported across a large area. Alpine glaciers can transport plucked debris in addition to material delivered to the glacier’s surface through rockslides. Large boulders are often left behind as a glacier moves and melts. These rocks, known as erratics, are distinct from surrounding native rocks in size and type.

Drumlins, or streamlined teardrop-shaped till deposits, often exist in clusters following the direction of ice movement (see Figure 5). The origin of these landforms is the subject of scientific debate, but most research points to their formation as a result of subglacial meltwater transporting sediment into ice cavities. Erosional hypotheses suggest that meltwater and outwash from fast-moving glaciers carve away weak subglacial material, leaving behind strong sediment deposits in the form of drumlins. Depositional hypotheses, on the other hand, suggest that the increased deposition evidenced by drumlins occurs when changes in ice pressure

Figure 5  Drumlin field in Northern Canada, 2014. This image shows a drumlin field in the Nunavut Territory of Canada, about 27 km (17 miles) southwest from the Amundsen Gulf. build mounds under the ice, creating a positive feedback loop of deposition and ice deformation.

Today, there is only one active drumlin field in the world, which is the subject of multiple investigations. The Múlajökull glacier in central Ireland, which left behind over 100 drumlins, was the subject of geomorphological studies in 2014 using aerial photographs and remote sensing data (Jónsson et al. 2014). The researchers’ data suggested that the drumlins formed mostly by subglacial erosion and bed deformation, in alignment with depositional hypotheses.

Glacial erosional processes and landforms

Robin Blomdin
Stockholm University, Sweden

Jonathan Harbor
Purdue University, USA

Glaciers are one of the most effective agents of erosion in the Earth-surface system, and produce landforms spanning scales of millimeters to kilometers in size. Over geological time, glacial erosion wears down topography and plays an active role in the evolution of mountain ranges and continental landscapes in alpine and high-latitude settings. Glacial erosional landforms vary widely in both their size (Figure 1) and the time taken for their formation (Figure 2). On timescales of one or more glacial cycles (several hundred thousand years), erosion by glaciers in mountainous areas produces classic features of large-scale glacial relief, such as glacial valleys, troughs, fjords, overdeepenings, and cirques. On timescales of thousands of years a glacier can produce medium-scale features such as roches moutonnées and rock steps. Glaciers also erode a bedrock surface on a timescale of hours to days to produce small-scale landforms such as striations, grooves, and chatter marks.

Glacial erosion is the loosening of rock, sediment, or soil by glacial processes, and the entrainment and subsequent transportation of this material by ice or glacial meltwater. The spatial and temporal pattern of glacial erosion is complex and reflects both glaciological and topographical factors as well as characteristics of the bed material. Glaciological factors include the basal temperature (warm-based glaciers erode, cold-based ice is largely ineffective in erosion), meltwater drainage, and the amount of debris entrained in the ice, while topographic factors include glacier catchment morphology, existing slope angles, and bed roughness. Bed characteristics include lithology, rock resistance to erosion (hard beds (bedrock) and soft beds (unconsolidated sediment)), and the rheology of deformable bed materials.

Glacial erosional processes and rates

Abrasion

Abrasion is the general wearing down of rock material by clasts (rock particles) embedded in the basal layer of glacier ice. The effectiveness of abrasion is controlled by: (i) the relative hardness of the clast and bedrock, (ii) the force applied at the point of contact and the contact area, (iii) the relative velocity of the clast and bed, and (iv) the concentration of clasts in the basal ice. Clasts can both striate (scour/scratch) and polish bedrock surfaces, producing fine rock particles that are transported away with meltwater (glacial flour), and leaving behind erosional traces. Striations are formed as moving ice drags clasts across a bedrock surface. A concentration of transient stress below the point where the clast contacts the bedrock promotes crack growth and brittle failure. At the micro scale, striations are made up of multiple crescent-shaped cracks, each representing a failure event. Pervasive striation can produce glacial polish, which is a very smooth rock surface (Benn and Evans 2010; Figure 3a).
Several models have been proposed to describe abrasion, which is somewhat analogous to the action of sandpaper on wood. The harder you press down sandpaper against wood and the faster you move the sandpaper, the greater the sanding effect. Similarly, abrasion will be most effective where the force applied on a clast at the bed is large and the speed of the glacier at the bed is fast.

**Plucking**

Plucking (also called quarrying) includes both the fracturing of bedrock under a glacier and the subsequent entrainment (pulling away) of rock fragments at the bed. The rock fragments can be the result of glacial action or may have been isolated by pre-existing cracks and joints. In plucking, rock fragments first have to be...

Separated from the parent material. As glacier ice overrides a bedrock surface, clasts embedded in the ice cause temporary stress concentrations in the bedrock that enlarge pre-existing cracks and joints leading to isolation of rock fragments. The frequency of existing joints and cracks, and the effective pressure of the ice-bed contact (overburden and basal water pressure) control the efficiency of plucking. Bedrock lithology also plays a role since different rocks have different strengths, resistances, and weathering histories. This fracturing of bedrock can result in rock fragments ranging in size from rock flour to boulders. Once rock fragments have been isolated, weakened, and/or broken apart from the parent material, the primary mechanism controlling the removal and incorporation of these into the basal ice is freezing.

The bed topography underneath a glacier is not an even surface but consists of highs and lows (bumps and steps). When the ice is close to the pressure melting point, meltwater will flow around bumps and refreeze on the lee side of a bump or step, forming a frozen regelation layer on the down-glacier side. This refreezing meltwater incorporates fractured rock fragments into the ice, and the movement of the ice down-glacier then removes these fragments.
Meltwater erosion

Glacial meltwater can be produced in two ways: (i) as surface melt, resulting from ice contact with atmosphere and precipitation at temperatures above the freezing point, or (ii) by melting of basal ice due to geothermal heat and heat from friction and internal deformation of ice. Meltwater at the bed of a glacier erodes underlying bedrock both mechanically, by evacuating rock fragments produced by abrasion and plucking, and chemically, by dissolution, carbonation, and cation exchange. Mechanical meltwater erosion is most efficient in subglacial meltwater channels. The meltwater carries clasts in suspension and as bedload and as these clasts interact they cause fracturing and failure to both the bed and the clasts. The hydraulic potential of channelized subglacial...
meltwater is high enough to erode large bedrock gorges underneath glaciers and ice sheets (Jansen et al. 2014).

Erosion rates

Rates of glacial erosion have been assessed using a range of different approaches (summarized in Hallet, Hunter, and Bogen 1996) including measurements of contemporary basal processes as well as measurements of watershed averaged erosion rates using both volumes of glacial deposits and characteristics that vary with erosion rate such as concentrations of cosmogenic radionuclides in sediments. These approaches yield estimates ranging between $10^{-4}$ and $10^1$ mm year$^{-1}$, reflecting differences in types and scales of glaciation and in the measurement methods.

Glacial erosional landforms

Small-scale erosional landforms

Erosional landforms resulting from abrasion range in size from a few millimeters to a few tens of meters and include striations, chatter marks, and grooves (Figure 3a). Their location and appearance reflect pressure conditions and the availability of clasts at the base of a glacier. Striations are elongated scratches consisting of numerous accurate fracture surfaces. Grooves are deeper tracks that might be straight, curved, or winding in plan form, while chatter marks are sets of fracture marks that record the removal of rock flakes by plucking. The orientation of these features reflects the dominant ice flow direction at their time of formation and thus these forms are used to reconstruct former ice flow directions.

Bedrock depressions that look as if they have been sculpted from plastic (Figure 3b, c, and d) were first labelled “P-forms” and attributed solely to glacial erosion; however, the term “S-forms” (sculpted forms) was added later to reflect the involvement of both glacial and fluvial processes in the development of some forms. P and S forms occur in a wide variety of sizes and shapes, and three main groups: transverse forms (perpendicular to ice flow), longitudinal forms (parallel to ice flow), and nondirectional forms (Benn and Evans 2010; Figure 3b). P and S forms result from erosion by: (i) debris-rich basal ice, (ii) saturated till flowing between the basal ice and bedrock surface, (iii) subglacial meltwater under high pressure, and (iv) ice-water mixtures (Munro-Stasiuk, Fisher, and Nitzsche 2005).

Intermediate-scale erosional landforms

Intermediate-scale erosional landforms reflect complex interactions between bedrock, topography, and ice flow patterns. Roches moutonnées are a classic glacial landform first described by the Swiss naturalist de Saussure at the end of the eighteenth century. They are asymmetric bedrock humps or hills with abraded stoss (up-glacier) faces and plucked lee (down-glacier) faces (Figure 3e) that range in size from a meter to several hundred meters across. Striations are common on the abraded stoss side, while polished surfaces usually occur on the flanks and gently sloping surfaces of the lee side, and plucking dominates along joints and cracks occur on the lee side. The formation of roches moutonnées is controlled by (i) the distribution of stress underneath a sliding glacier as it moves over bedrock humps and (ii) the pattern of rock failures. A high stress on the stoss sides of pre-existing bedrock humps results in large forces where clasts embedded into the basal ice contact the bed surface, and thus high rates of abrasion. On the lee side, lower stresses encourage the formation of cavities and enhance crack
formation in bedrock, while refreezing increases the effectiveness of plucking.

Whalebacks (symmetrical in plan view) and rock drumlins (asymmetrical in plan view; Figure 4a) are elongated and smoothed bedrock bumps that have been streamlined by glacial action but lack the plucked lee side of roches moutonnées. For whaleback and rock drumlin formation to occur there must be no regions of low pressure (no cavity formation) along the bedrock hump so that there is no plucking on the lee side. This can happen underneath thick and fast-flowing ice where normal stresses over the lee side are high enough to inhibit cavity formation. Whalebacks and drumlins appear frequently as swarms in areas where basal stress conditions were suitable for their formation, such as south of Lake Ontario where drumlins were formed by ice draining the Laurentide Ice Sheet at the end of the Pleistocene (Figure 3f).

Crag and tails are streamlined, erosional features, consisting of a resistant bedrock crag at the up-ice end, and a tail of less resistant rocks or sediment extending in the down-ice direction (Figure 4b). They are commonly produced by ice streamlining around an obstacle and protecting the “tail” of the feature from erosion. The classic crag and tail example is in Edinburgh, Scotland, where a castle is built on the crag, which is volcanic intrusive rock, and the tail consist of sedimentary rocks (Figure 4c).

Meltwater channels and tunnel valleys result from meltwater erosion underneath, on the sides, or in front of glaciers and ice sheets. Ranging in length from meters to several hundreds of kilometers (Figure 5), they can be eroded either in bedrock or in consolidated or unconsolidated sediment and can have various degrees of infill. Meltwater erosion under ice is a function of the water pressure gradient, and so is controlled by patterns of high to low pressure under the ice; in some cases this results in water flow that goes down pressure but “uphill” on the underlying bed topography. The regional distribution of meltwater features is dominated by deglacial phases of glaciers and ice sheets. Meltwater channels formed at or close to former ice margins are especially important since they can be used to infer past ice margin geometries and slopes. Well-developed meltwater channels are found in southern Patagonia (Figure 5a), the interior plateau of the Coastal Mountains in British Columbia, and northeastern Quebec-Labrador.

Tunnel valleys are large overdeepened meltwater channels, sometimes forming channel networks hundreds of kilometers long and several kilometers wide (Figure 5b). Tunnel valleys have undulating bed-long profiles, overdeepened valley floors, hanging tributary valleys, and after deglaciation are often filled by thick sedimentary deposits (Benn and Evans 2010). The large size of tunnel valleys may reflect (i) progressive excavation of sediment by normal meltwater discharges, in combination with subglacial sediment deformation, and/or (ii) excavation by extreme meltwater discharges associated with catastrophic drainage events. Well-developed tunnel valleys occur along the margins of the former northern hemisphere ice sheets (e.g., Figure 5b).

Large-scale erosional landforms

Glacial valleys are large-scale erosional landforms, typically with U-shaped cross-sections and long-profile overdeepenings, which result from erosion by valley glaciers in alpine settings (Figure 6a and b and Figure 7; Li et al. 2005). Glacial troughs are generally larger than glacial valleys, with smoothed and steeper valley sides, asymmetric cross-sections, and lacking Spurs. Fjords are glacial troughs in coastal areas with part of the trough below sea level (Figure 6c). The characteristic cross-section shape of glacial valleys, troughs, and fjords, with flat valley floors
Figure 4  (a) Rock drumlin shown in profile and in plan view, (b) crag and tail shown in profile, and (c) Edinburgh Castle crag and tail in Scotland where the crag is a volcanic intrusion and the tail consists of sedimentary rocks. Map data: Google, Infoterra Ltd, and Bluesky.
and steep valley walls, occurs because glacial erosion rates increase with basal sliding velocities, and so erosion is small at the edges of a glacier and increases rapidly towards the center (Harbor 1992). Glacial valleys develop on timescales of one or more glacial cycles and are best developed in areas that have been glaciated multiple times (Li et al. 2005). Glacial valleys, troughs, and fjords range from several hundreds of meters to hundreds of kilometers in length. Glacial valleys and troughs exist in all glaciated alpine regions of the world.

Overdeepenings are deep erosional basins in glaciated areas, and the formation, size, and shape of these basins are controlled by glaciological variables such as thermal regimes at the bed (warm-based versus cold-based ice), stress conditions at the glacier bed, and characteristics of the substratum such as bedrock structure and lithology (Benn and Evans 2010). Basins can range in size from small hollows between roche moutonnées to trough-sized larger overdeepenings. Large overdeepened valleys and basins exist in most alpine and foreland settings.

Cirques are amphitheater-shaped valley heads that are common in alpine settings (Figure 7). They have been cut into mountainsides by smaller ice patches or glaciers. The typical cirque profile has a flat floor/overdeepened basin connected to a steep back wall by a concave slope. Cirques evolve from hollows by retreat of the back wall and flattening of the floor leading

Glacial erosional landscapes

The individual types of glacial erosional landforms described so far are organized into landscape-scale patterns of glacial erosion controlled primarily by the subglacial thermal conditions of a glacier system. The efficiency of a glacier system to erode depends primarily on basal sliding velocities. Warm-based glaciers have high sliding velocities and erosion rates because the ice-bed contact is at or below the pressure melting point. A cold-based glacier, on the other hand, has very low sliding velocities or is completely frozen to the bed, and has little or no erosion. Thus warm-based glaciers leave behind well-developed glacial landscapes, whereas cold-based glaciers in continental settings leave poorly developed glacial landforms. Underneath ice sheets and ice caps, variations in the bed topography cause differences in basal thermal regimes to occur across the bed. For example,
a patchwork of glacial and nonglacial landforms in northern Scandinavia has been used to infer complex patterns of warm-bed and cold-bed patches underneath the Fennoscandian Ice Sheet (Kleman, Stroeven, and Lundqvist 2008).

Ice flow patterns are linked to basal velocities and erosion rates, and thus also play a role in determining landscape types (Figure 1). There is little or no erosion under ice domes because of low sliding velocities, whereas under larger areas of ice sheets relatively uniform movement causes scouring over large areas (Figure 8). Areas of concentrated ice flow where ice converges (controlled by topography), as in ice streams or outlet glaciers, generally have high-velocity warm-based glacier ice and produce landscapes of selective linear erosion, which include glacial valleys, troughs, and fjord landscapes. Strong gradients in glacial erosion are created as the fast-flowing ice continues to carve the bed where ice flow is concentrated while rates of erosion in adjacent areas are much lower.

The effect of glacial erosion on the evolution of mountain landscapes has received a lot of attention because of interest in the links between tectonics, climate, and glacial activity (Spotila 2013). The observation that glaciers are capable of eroding more material than rivers and at rates that are faster than rock uplift has led to the idea that glacial erosion plays an important role in causing mountain uplift and can also limit the height of mountains.

Earth periodically experienced glacial conditions throughout the second half of its geological history. During a “glacial age” or “ice age” the mean global temperatures of the Earth’s surface and atmosphere are reduced for a significantly longer than usual time. As a result, existing continental and polar ice sheets and alpine glaciers extend, or new ones develop. The designation “ice age” requires the presence of extensive ice sheets in both the Northern and Southern Hemispheres. Hence, the Holocene or “Recent” Epoch (≈11,700 BP–present) is part of the present ice age, because ice sheets are covering the Arctic, Antarctica, and Greenland.

During an ice age, longer individual pulses of cooler and warmer climate alternate. A “glacial period” or “glacial” or “glaciation” is a stage that has cooler and drier climates over most of the Earth resulting in the formation of new or the growth of existing large land and sea ice masses extending outwards from the poles and of mountain glaciers often reaching into the forelands. Since significant amounts of ocean water were removed for building up the ice masses, sea levels are lower and ocean circulation patterns might have changed. Individual glacials within a specific ice age are separated by “interglacials,” which are periods of warmer and moister climates. The Holocene is such an interglacial of the present ice age.

Glacials are not uniformly cold and interglacials are not uniformly warm. In fact, glacials include “interstadials,” phases of warmer temperatures and minor ice retreat that are not long or intense enough to be considered interglacials, while interglacials include “stadials,” phases of lower temperatures and minor ice advance that are not long or intense enough to be considered glacials. The “Little Ice Age” (≈1250–1650) until the latter half of the nineteenth century or early in the twentieth century) was a stadial within the present Holocene interglacial.

Research results suggest that ice ages and glacials typically develop slowly, whereas they end more abruptly.

As explained above, while the term “glaciation” is a synonym for “glacial period” and “glacial,” it is commonly (and here) used to describe (i) the condition of being covered with glaciers or masses of ice, or (ii) the result of glacial action.

Research history

The documented history of research on glaciations starts in the eighteenth century; once the first ideas about former larger ice masses had been proposed, a chain of discoveries and theories evolved.
GLACIATIONS

1742 Daniel Tilas suggests that drifting sea ice brought erratic boulders to Scandinavia and the Baltic region.

1744 Pierre Martel, after he had visited the valley of Chamonix in the Alps of Savoy in 1742, reports in his publication that locals had explained to him the dispersal of erratic boulders with formerly larger glaciers that must have been receded.

1795 James Hutton describes that erratic boulders were transported from the Alps to the Jura Mountains by a great mass of ice.

1804 Erhard Wrede speculates that Earth’s axis had tilted, raising sea levels in the Baltic region and leading to floods that transported huge blocks of rock on ice floes to northern Germany.

1815 Jean-Pierre Perraudin proposes the idea of extensive glacier advances, and Johann Wolfgang von Goethe discusses similar explanations in his work.

1818 Goran Wahlenberg publishes his theory of a former regional glaciation of the Scandinavian peninsula.

1819 Leopold von Buch explains erratics as having been transported by violent floods or mudflows.

1821 Ignaz Venetz presents his idea of a former larger Alpine glaciation and a glaciation in the plain of northern Germany.

1824 Jens Esmarck argues that a sequence of global ice ages was caused by climate change, which itself was caused by Earth’s orbital changes.

1824 Jean de Charpentier supports Venetz’s idea of a former much-enlarged Alpine glaciation at the annual Helvetic Society meeting.

1832 Albrecht Bernhardi speculates that former polar ice caps reached as far as the temperate zone, and recognizes a former glaciation in Germany.

1833 Charles Lyell announces his “drift theory” that explained the existence of “diluvium” or “drift” deposits in Britain with a transport by icebergs.

1835/1836 Karl Schimper lectures about times of obliteration (German: “Verödungszeiten”) with cold climate and frozen water.

1837 Karl Schimper coins the term “ice age” (German: “Eiszeit”). Louis Agassiz announces the theory of a “great ice period.”

1839 Charles Lyell introduces the term “Pleistocene” (“Most New” or “Newest”) to describe strata in Sicily.

1840 Louis Agassiz publishes his Etudes sur les glaciers in which he describes a vast ice sheet that had extended from the North Pole to the Alps. He mentions neither de Charpentier nor Schimper, with whom he had developed the theory, in this book.

1841 Edward Hitchcock speculatively applies the glacial theory to “flood” features in North America.

1842 Roderick Murchinson points to the fact that “the greater numbers of practical geologists of Europe are opposed to the wide extension of a terrestrial glacial theory.”
Joseph Adhemar suggests that the primary instigator of ice ages might be Earth’s orbital path around the sun.

1846 Edward Forbes redefines the Pleistocene and refers to it as “Glacial Epoch.”

1847 Edward Collomb replaces the early mono-glacial hypothesis with a concept of two glaciations.

1853 Andrew Ramsay supports the concept of two glaciations.

1849/1950 Ernst von Bibra visits the Chilean Andes and learns that natives attributed fossil moraines to the former action of glaciers.

1864 James Croll presents his theory of the effects of variations of Earth’s orbit on climate cycles.

1870 Friedrich von Richthofen identifies loess as glacio-eolian sediment.

1875 James Croll publishes his *Climate and Time, in Their Geological Relations*, which led to international acceptance of the ice age theory.

1883 Rollin Chamberlin presents a “till” classification.

1906 Grove Gilbert publishes his major contribution on glacial erosion.

1909 Albrecht Penck and Eduard Bruckner present their Alpine glacial chronology in *Die Alpen im Eiszeitalter* [The Alps in the Ice Age].

1914 Ralph Tarr and Lawrence Martin recognize that glaciers surge.

1929 Motonori Matuyama discovers the polar reversals.

1930 Milutin Milankovich suggests three orbital causes for glaciations: eccentricity (100,000-year cycle), obliquity (41,000-year cycle), and precession (21,000-year cycle). These are later called “Milankovich cycles.”

1941 Milutin Milankovich suggests the effect of variable solar insolation on climate.

1947 Richard Flint publishes his *Glacial Geology and the Pleistocene Epoch*.

1957 J.K. Charlesworth publishes his *Quaternary Era*.

1964 W. Brian Harland argues for an ice age that was so extreme that it resulted in the deposition of marine glacial rocks in the tropics.

1969 The International Geological Correlation Programme – Project 38 on “Pre-Pleistocene Tillites” is initiated.

1970 Friedrich von Richthofen identifies loess as glacio-eolian sediment.

1987 V. Sibrava, D.Q. Bowen, and G.M. Richmond publish their *Quaternary Glaciations in the Northern Hemisphere*.

1992 Joseph Kirschvink proposes his “Snowball Earth” hypothesis that explains that Earth was nearly totally frozen more than 650 million years ago. His theory receives support from Paul Hoffman in 1998.

2004 Jürgen Ehlers and Philip Gibbard publish their *Quaternary Glaciations – Extent and Chronology*. Francis Macdonald and colleagues support the “Snowball Earth” theory by arguing that the Sturtian glaciation (720–660 Ma) during the Cryogenian (850–635 Ma) was global in extent.

GLACIATIONS

Evidence

Three main types of testimony help in the reconstruction of former glaciations: geological, chemical, and paleontological.

Geological evidence is given with numerous sediments, landforms, and landform features such as rock scouring and scratching, valley cutting, glacial moraines, drumlins, till or tillites, glacial erratics, loess, sand dunes, and glacial lakes. The two main problems in using these testimonies when reconstructing glaciations are their exact dating and that successive glaciations tend to distort and erase the geological evidence.

Chemical evidence exists in the form of variations in ratios of isotopes in fossils present in sediments and sedimentary rocks, particularly from the oceans. Furthermore, atmospheric gases trapped in bubbles of air in ice tell about the changes in the composition of the atmosphere through time. Hence, with the extraction and analysis of ocean sediment and ice cores from drilling projects, the understanding of glaciation chronologies radically improved.

Paleontological evidence is provided with the changes in the geographical distribution of fossils and with pollen data from lakes and bogs.

Causes

Several causes for the formation of glaciations have been identified: positions of the continents; supercontinental cycles; orogeny; and changes of ocean currents, astronomical conditions, and the atmospheric composition. While none of these causes alone can induce a glaciation, the occurrence of a multiple of them can.

The reconstruction of former patterns of Earth’s landmasses revealed that glaciations existed whenever specific configurations of the continents occurred that resulted in the reduction of energy exchange between lower and higher latitudes, and further to long-term variations in global climate at the scale of tens of millions of years. In the first case, a particular continent is located either directly on top of a pole such as Antarctica today or at high paleolatitudes. This repeatedly happened during the Paleozoic era (541–252 Ma) with glaciations ranging from Devonian (419–359 Ma) to Permo-Carboniferous (359–252 Ma) times, when glacial sediments were deposited across vast regions at high latitudes of southern Gondwana. However, paleomagnetic measurements of the very extensive glacial deposits from the earlier Neoproterozoic era (1.0 Ga–541 Ma) put several formerly glaciated areas at low latitudes. A possible explanation could be that Earth’s obliquity probably was much greater in these times, which allows for glaciated continents in low latitudes. A second scenario describes a configuration with an almost land-locked polar sea such as the Arctic Ocean today. In a third case, a supercontinent covers most of the equator such as Rodinia did during the Cryogenian period (850–635 Ma).

Earth’s history tells of the formation and disintegration of six supercontinents, an assembly of almost all of the cratons to form a single large landmass. The significant additions to the continental crust initiate a negative feedback mechanism. During periods of supercontinentiality, the continental lithosphere is elevated, which in combination with enhanced weathering on the now larger continents decreases the amount of carbon dioxide (CO₂) in the atmosphere. The reduced “greenhouse effect” results in significant cooling and, eventually, glaciation. In addition, changes in relative sea levels lead to supercycles of flooding and exposure of the continents, which produces either “greenhouse gas” or “icehouse” conditions at the scale of about 400 million years. However, at the same time the glaciation itself lowers weathering rates, which
in turn increases first CO₂ concentrations and then temperatures again and the ice masses melt.

During periods of extensive orogeny, global precipitation is increased resulting in a removal of CO₂ from the atmosphere and, eventually, cooling and glaciation. The formation of the Himalaya, for example, broadly matches the long-term decrease in mean global temperature in the last 40 million years.

The described tectonic activities result in constant modifications of ocean currents and long-term climate variations. For example, for most of geologic time, the Arctic Ocean was broad and open which allowed for an unabated circulation of the major ocean currents and, hence, a mixing of temperate and polar waters. As a result, climates were generally milder and more uniform reducing global ice cover. However, the Arctic Ocean was repeatedly partly enclosed by continents, which blocked the inflow of warmer waters leading to a cooling of the Arctic and glaciation.

While the described tectonic causes correlated to long-term (millions of years) climate changes, astronomical causes can affect global climate over shorter periods of between a few years to tens of thousands of years. The three “Milankovich cycles” summarize these effects: the eccentricity is a measure of the departure of Earth’s elliptic orbit from circularity and describes a cycle of about 100000 years. The obliquity is the variation between 22.1° and 24.4° of the Earth’s axial tilt against the plane of the Earth’s orbit and represents an approximately 41 000-year cycle. The precession is the trend in the direction of the Earth’s axis of rotation relative to the fixed stars, with a cycle of roughly 26 000 years. While all three cycles themselves and particularly in combination match periods of glaciation and deglaciation, some interpretative problems do exist: for example, while in theory the eccentricity should have the weakest impact on solar forcing, the strongest climate signal match the 100 000 year cycle, at least during the last one million years. Another problem is that the penultimate interglacial during marine isotopic stage 5 (MIS 5; 130–71 Ka) appears to have begun much earlier than hypothesized, that is, “out of cycle.” Milankovich also proposed the idea that the variable solar insolation affects climate. Indeed, short-term climate changes correlate to solar magnetic activity cycles (“solar cycles” or “sunspot cycles”) at the scale of about eleven years and to longer episodes such as the Maunder Minimum that describes the period from about 1645–1715 when sunspots became exceedingly rare; the latter coincided with the middle part of the Little Ice Age. Since the 1970s, the astronomical theory of paleoclimates is accepted as the major explanation for the occurrence of glacial and interglacial periods during the Late Cenozoic era.

Also, the variation of the atmospheric composition, particularly the concentration of greenhouse gases, can help explain climate changes. Records show that CO₂ and methane levels fell with the onset of glaciations and rose during deglaciations. However, it is not clear if these concentration variations are the cause or effect of climate changes. Without doubt, an increase in solar insolation increases the concentration of greenhouse gases. It is believed that the deforestation and farming practices during the Neolithic Revolution (about 10 000 years BCE) increased the greenhouse gas concentration and, hence, stopped following the periodic pattern of the Milankovich cycles with an expected onset of an already overdue glaciation.

Effects

Although glaciations are relatively rare and short phenomena in Earth’s geologic history, they had manifold effects on landscapes, sea levels, ocean
currents, weather patterns, tectonics, and even astronomical parameters.

While glacial landscapes were shaped in a relatively short time, they cover wide regions of the continents and include sediments, landforms, and landform features such as eskers, roche moutonnees, pluvial lakes, and fjords.

Besides this, the heavy ice masses also press parts of continental lithosphere into the asthenosphere with the result that with retreating ice sheets the landmasses rebound. Initially, this isostatic adjustment is a rapid elastic uplift as the ice is being unloaded, and, eventually, it is followed by slow viscous flow. The rebound can be as much as 1 cm per year near the center of the rebound such as in the cases of Scandinavia and the North Sea or the Great Lakes region, where it will continue for at least another 10,000 years.

During glaciations, the redistribution of ice and water and flow of mantle rocks might affect the gravitational field and the distribution of the moment of inertia of the Earth. As a result, changes in the angular velocity, axis, and wobble of the Earth are possible.

Glaciations also lower global sea levels, for example, during the Last Glacial Cold Stage (26,500–17,000 years) by up to 110 m. The retreat of the sea exposes continental shelves and might lead to the formation of land bridges such as the Bering Street between the North American and Asian continents. The availability of new land affects biogeographic patterns, for example, through changed animal migrations. At the end of the last glacial around 12,000 years ago, Mongoloid people from northeast Asia walked over the Bering Street into America.

The disintegration of ice sheets and the unloading during deglaciation can result in earthquakes near the ice margin, and the earthquakes themselves reinforce the ice breakup, which accelerates the calving of icebergs.

---

### Precambrian glaciations

While for much of Earth's history geologic records and datings of material are relatively rare, more data are available for the more recent past. In the last 2.5 Ga of the Earth's history, at least seven major ice ages occurred – four during the Precambrian Supereon (4.7 Ga–541 Ma) and three during the following Phanerozoic Eon (541 Ma–present) (see Table 1): Huronian, Sturtian–Varangian, Marinoan/Natuo, Gaskiers, Andean–Saharan, Karoo, and Quaternary. Since there is insecurity about its dating, it is not clear if the Kaigas can be identified as an individual (eighth) glaciation. (For explanations on glaciations of the following Phanerozoic Eon see Quaternary glaciations)

During the Hadean (4.7–4.0 Ga) and the Archean (4.0–2.5 Ga) eons, the total landmass is relatively small and atmospheric CO2 concentrations are high leading to much warmer global temperatures. Hence, evidence for glaciation in the stratigraphic record is nearly completely absent. However, smaller regional glaciations are documented for the Pongola Supergroup in Swaziland (Pongola Glaciation, 2.9 Ga), the Witwatersrand Succession in South Africa, and the Stillwater Complex of Montana, USA.

Several ice ages occur during the following Proterozoic Eon (2.5 Ga–541 Ma). Evidence for the Huronian ice age (2.4–2.1 Ga) during the Siderian period (2.5–2.3 Ga) and the Rhyacian period (2.3–2.05 Ga) of the Paleoproterozoic era (2.5–1.6 Ga) exist from the Huronian Supergroup of Ohio, Snowy Pass Supergroup of Wyoming, and other locations in North America, and from Australia, Finland, India, and South Africa. In contrast, from 2.0 Ga on until the end of the Paleoproterozoic era, no evidence for further glaciations is known.

The greatest proliferation of ice sheets ever happens during the Neoproterozoic

era (1.0 Ga–541 Ma), when widespread and long-ranging glaciations on all continents peak in the three ice ages Kaigas (750 Ma (?), Sturtian (720–660 Ma), and Marinoan (650–635 Ma) during the Cryogenian period (850–635 Ma; from Greek *cryos* “cold” and *genesis* “birth”), and in the Gaskiers ice age (582–580 Ma) of the Ediacaran period (635–541 Ma). Deposits are well documented from central and southwestern Africa, Australia, western North America, the North Atlantic Basin, and Brazil. One of the reasons for this “ice age era” is the greatly (>54°) increased obliquity of the Earth. However, it is not clear, if many glaciogenic rocks form in tropical latitudes, or if – during a second “Snowball Earth” – ice sheets reach from the poles down to the equator.

The future

Uncertainties exist about the future of the Holocene (11 700–present, “The Recent”), which is the current interstadial of the present Quaternary and follows the preceding Pleistocene. Depending on the chosen scenarios for the development of Earth’s climate and atmospheric greenhouse gas concentrations, predictions vary widely. The Holocene might last for another 50 000 years, if CO₂ levels increase to 750 parts per million (ppm), or it might end in 15 000 years, if CO₂ levels drop to 210 ppm. The reason for this uncertainty is that there is still an unsatisfying understanding of some individual input parameters of climate change scenarios, for example, the influence of the orbital forcing on Earth’s climate.

Further reading

Glaciers are important fresh water resources releasing the water mainly in the summer months when the water demand for irrigation is usually highest. Moreover, glacier meltwater contributes significantly to global sea level rise. Receding glaciers increase the risk of hazardous mass movements such as slope failures and glacial lake outburst floods. Glaciers react sensitively to climate and are therefore recognized as important climatic indicators in remote regions where information from weather stations is rare or nonexistent. Hence, glaciers are naturally subject to changes in line with the Earth’s climate variability. Glaciers develop at locations where mass gain (e.g., through snowfall and avalanches) exceeds mass loss (e.g., through melting and calving). Favorable climatic conditions (e.g., lower temperature, higher snowfall) will lead to a positive mass balance and typically advancing glaciers while unfavorable conditions (higher temperatures, less snowfall) will lead to negative mass balance and retreating glaciers. The position of the glacier snout depends primarily on the glacier flow and the mass loss at the tongue. Higher temperature can cause melt and hence, an immediate retreat of the snout. Increased accumulation, however, results in a much delayed signal at the terminus as the snow needs time to transform into ice and to flow through the entire glacier. The time the glacier needs to adjust to a different climatic signal ("response time") varies between years to decades and is related to the thermal conditions, size, and topography. Hence, the same climatic forcing does not need to result in the same reaction of the terminus. Thick debris cover on the snout can further delay the reaction while calving into a lake and the sea will increase the mass loss. In addition, sudden advances of glacier tongues ("surges") cannot be linked directly to climate but more a sign of dynamic instabilities. Consequently, glacier length and area changes are in general difficult to interpret as direct climatic signals. Increase and decrease of glacier surface height can be more directly linked to the mass balance and, hence, to the climate forcing.

Late Pleistocene and Holocene glacier fluctuations

Glacier sedimentation and deposition forms such as moraines allow the reconstruction of former glacier extents. Further indicators can be sediments in proglacial lakes or trees and shrubs grown since deglaciation. Various dating techniques such as dendrochronological analysis, radio carbon dating of organic material within moraines, or dating of morainic boulders using terrestrial cosmogenic nuclides allow temporal classification. About one-third of the terrestrial land was ice covered during the last ice age. This Last Glacial Maximum (LGM) is usually dated approximately 24 000 to 18 000 years ago (24–18ka). However, maximum extents of mountain glaciation were reported from earlier periods, for example, approximately 35 ka for central Chile and approximately 29 ka.
GLACIER CHANGES

for northern Alaska (Clark et al. 2009). A global warming led, on average, to a strong reduction of the ice cover which started on average at about 19 ka with the earliest date of about 24 ka for the tropical glaciers until the early Holocene (starting at 12–10 ka). Glacier extents in most mountain regions were more likely of comparable size at the beginning of the Holocene than at the end of the twentieth century. Information regarding early Holocene glacier advances is sparse but there is evidence for several periods with relatively synchronous advances throughout the Holocene (Koch 2011). The Little Ice Age (LIA) moraines indicate the maximum glacier coverage of the Holocene. These moraines are usually clearly visible in the landscape and can be identified from high resolution satellite images. The LIA began around 1100 AD and lasted until the early twentieth century. The maximum glacier extents occurred in central Europe in the mid-nineteenth century but in other regions around the globe this date varies between the seventeenth to the late nineteenth centuries (Zemp et al. 2008).

Glacier variations since Little Ice Age

Field measurements of glacier length changes starting in the late nineteenth century and increasingly length change measurements based on satellite data allows a comparatively good overview of glacier changes around the globe for this period. Glaciers retreated on average worldwide since the maximum extent of the LIA until now. This can be well correlated with the global temperature increase since the middle of the nineteenth century. The overall recession is in the order of some kilometers for the larger glaciers and hundreds of meters for smaller ones (Zemp et al. 2008). Advancing or stable conditions were especially common around 1920 and 1980, with strong recession measured in the 1920s and 1940s and especially after the mid-1980s until today in most other parts of the world. However, local variability exists: for example, many glacier advances occurred in Scandinavia in the 1990s. Small glaciers show typically stronger fluctuations while large glaciers with a long response time have continued to retreat unabatedly since their maximum extent at the LIA (Zemp et al. 2008). Measurements of glacier area changes became numerous due to the availability of suitable remote sensing data for free or at low cost. Former glacier extents can be derived from topographic maps, aerial imagery, or declassified reconnaissance satellite images. Hence the earlier period of many area change assessments date usually only back to the 1950s, 1960s, or 1970s. Glacier area loss occurred in almost all regions of the globe in line with the length reduction (Barry 2006). Typical values vary between −0.2% per year for continental glaciers, for example, in central Tien Shan, and 0.7% per year for temperate glaciers in the Alps. However, values reporting absolute changes have to be interpreted with care as the uncertainty may be high. One major problem is different snow conditions which frequently occur especially around the higher parts of the glacier. Debris-covered glaciers, for example, common in many parts of the Himalaya show low or no identifiable area loss despite significant mass loss, because such glaciers tend to thin and waste vertically downwards. Surging or pulsating glaciers which show regular rapid advances (and area gain) followed by a strong retreat (and area loss) can be found in many mountains of the globe but are especially common in Svalbard in the Arctic, and for the Karakoram and Pamir in the western High Asian Mountains. Glacier-wide field-based mass balance measurements which show a more direct climate signal started around the 1950s with the highest observation density in central Europe and Scandinavia (Zemp et al. 2008). Only
few and short-term data series exist for South America and the Himalaya. Available data show on average a strong mass loss at the beginning of the measurements followed by a slowdown around the 1960s and a moderate ice loss until the mid-1980s. An increased mass loss was measured since then until now. The cumulative ice loss since the beginning of the mass balance measurements is more than 20 m water equivalent (w.e.) or about 0.34 m w.e. per year (Zemp et al. 2008).

Variation in the first decade of the twenty-first century and future glacier changes

The availability of more precise remote sensing data with global coverage since the beginning of the twenty-first century, such as from the gravity mission GRACE and the ICESat GLAS laser altimetry data and a detailed glacier inventory, allows now relatively precise estimates of glacier mass changes for the entire Earth. In addition, several satellite missions offer stereo data to derive digital elevation models (DEMs) which can be utilized to calculate changes in glacier volume by differencing of multitemporal DEMs. A consensus estimate for the period 2003–2009 revealed that the glaciers lost on average mass in all regions while the largest absolute ice losses occurred in the most glacierized regions, such as from the local glaciers in Greenland, Alaska, Arctic Canada, high-mountain Asia, and the southern Andes (Gardner et al. 2013). However, the specific mass loss (the value per area unit) was highest for the tropical glaciers, the glaciers in the European Alps, in the Caucasus, in Western Canada and the United States, and in the southern Andes, with values around −1.0 m w.e. per year. The lowest specific mass losses were measured for the glaciers and ice caps in the Antarctic outside the ice sheet, several arctic regions such as Svalbard and the Russian Arctic and high-mountain Asia with values varying between approximately −0.05 and approximately 0.3 m w.e. per year. The mass of all glaciers outside the two ice sheets reduced by 259 ± 28 Gt per year or 0.71 ± 0.08 mm of sea level equivalent per year which would account for 29 ± 13% of the measured sea level rise over this period. However, not all glacier meltwater will contribute to sea level rise because a small portion will be stored in inland drainage basins without outflow or in new lakes developed due to glacier recession. Projections of the future indicate on average further glacier wastage throughout the twenty-first century. The expected contribution to sea level rise until 2100 based on the global glacier inventory varies between 0.12 and 0.23 m on average depending on the applied method and the utilized climate scenario (Church et al. 2013). Highest specific mass losses are projected for the tropical glaciers, western Canada and the United States, Svalbard, Scandinavia, central Europe, and New Zealand, where likely less than 30% of the glacier volume from the year 2000 will remain. The availability of satellite information with higher spatial and temporal resolution combined with field-based studies will allow more precise assessments of the current glacier changes and will help to improve model projections for the future.

GLACIER CHANGES

Glacier hydrology broadly concerns the storage and transit of liquid water associated with snow and glacier ice. This includes water present at the surface of, in the interior of, at the basal interface of, and emerging from bodies of snow and ice. Today, glacier ice covers around 11% of Earth’s surface area, accounts for approximately 70% of the planet’s freshwater resources, and underpins the water security of over a billion people. For millennia, glacier-fed rivers have been critical for irrigation and agriculture, but have always posed a threat of flooding. Meltwater runoff from glacierized catchments is an important resource for hydroelectric power, accounting for 50% or more of the electricity produced in mountainous countries such as New Zealand, Peru, Pakistan, Switzerland, and Norway. Recently, focus has turned to sporadic, catastrophic, and destructive releases of meltwater from glacierized terrain, the mechanisms for and prediction of which remain poorly constrained. Therefore, the hydrology of glaciers is an important, topical subject demanding continued investigation, particularly in the context of the recent trends observed in glacier extents and the Earth’s atmosphere–climate system.

Glaciers represent a frozen environmental asset: natural reservoirs storing freshwater over a wide range of timescales, from hours to millennia. Long-term freshwater storage, at timescales greater than a year, typically involves glacial ice; intermediate and shorter-term storage more usually involves seasonal snow and liquid water and are best exemplified by the seasonality of glacier runoff. The hydrology and runoff from glaciers is fundamentally controlled by the surface energy balance (Hock 2005). For the vast majority of Earth’s glaciers, outside the tropics, mass is accumulated as snow during the winter, when the energy balance is at a minimum due to low air temperatures and reduced solar radiation receipt. During summer months, increased air temperatures and solar irradiance provide a highly positive surface energy budget, resulting in the melting of snow and glacier ice (termed ablation). Thus, glaciers modulate streamflow by releasing the most runoff during the warmest, driest periods in the year when all other sources of water are minimal. The volume of meltwater runoff that a glacier provides is a function of its surface area and ablation rate. The melt process ensures runoff from glacierized catchments correlates positively with air temperature and exhibits a strong diurnal signal in the ablation season hydrograph. Consequently, glaciers exert a strong influence over a catchment’s runoff, even if glacier ice only occupies a small proportion of the catchment area.

Within a glacierized catchment, the drainage system that routes meltwater from the glacier surface to the ice margin can be conceptualized as a cascade (Figure 1). Meltwater can travel along flowpaths at the surface (supraglacial), within the glacier’s interior (englacial), and at the ice–substrate interface (subglacial). The structure, function, and interaction of these systems determines the efficiency and transit time by which meltwater travels from the point...
GLACIER HYDROLOGY AND RUNOFF

Figure 1 Conceptual model of glacier hydrology. Note the drainage takes an arborescent pattern in cross-profile, which is also apparent in plan view with a dendritic structure leading to the main subglacial conduit(s) or channel(s) at the glacier snout. Water-flow is represented by blue arrows whose size infer discharge. Source: Irvine-Fynn et al. (2011). Reproduced with permission from Reviews of Geophysics.

of melting to the glacier terminus. Accordingly, runoff from a glacier is controlled by the characteristics and hydraulic properties of these three drainage system components, which modulate both meltwater volumes and water quality through solute acquisition and sediment evacuation. Hydrological coupling between the supra-, en-, and subglacial environments is fundamental in mediating the manner in which a glacier responds to environmental variability, primarily due to the role water plays in controlling ice motion. Here, focus is on mid-latitude, temperate valley glaciers, but for details on the hydrology of nontemperate glaciers and ice sheets, see Irvine-Fynn et al. (2011) and Chu (2013), respectively.

Supraglacial hydrology

The character of the supraglacial environment can be categorized into three key states, each with its own distinctive hydrology: snowpack, firn, and bare ice.

The snowpack

The hydrology of snow in the supraglacial environment is generally the same as for other terrestrial snowpacks (DeWalle and Rango 2008). Snowpacks on glaciers are the result of multiple snowfall events; in mid and high latitudes, these typically happen during winter.
months when little or no melt occurs, while for tropical glaciers, snow accumulates during warmer summer months. Consequently, glacier snowpacks are highly heterogeneous, exhibiting variations in crystal grain size and density from each snowfall event, leading to a complex, layered stratigraphy. After deposition, the snow structure is transformed by the pressure of overlying snow, by wind redistribution and compaction, and by internal processes of melting, refreezing, sublimation, and condensation. Such snowpack metamorphosis is driven by temperature gradients and snowpack age, and typically enlarges the crystal size or joins grains together (sintering), further influencing snowpack density. Combined, these processes result in local variations in snow density, ranging from 50 to 400 kg m\(^{-3}\), and lead to contrasts in snowpack porosity and hydraulic conductivity, not only with depth but also over space.

As the melt season commences, snow surface meltwater begins to percolate into and warm the snowpack. The infiltration of liquid water and the latent heat released by refreezing begins to overcome the cold content of the snow, raising the snowpack temperature toward the melting point. Densification of the snowpack occurs as diurnal melt–freeze cycles cause the refreezing of percolating meltwater either within the pore spaces of the snow or as more massive ice lenses. Continued melt ripens the snowpack as gravity-driven percolation causes the wetting front to descend away from the surface into colder snow below. The percolation rate of meltwater can be approximated by Darcy’s Law, with velocities of \(10^{-4}–10^{-5}\) m s\(^{-1}\). Critically, due to the structure and density variations within the snowpack, the wetting front is neither uniform nor horizontal, and preferential flowpaths or flow fingers develop. The velocity of meltwater through a ripe snowpack is dependent on the physical structure of the snow and the water flux: greater volumes of melt travel more rapidly. As the snowpack becomes isothermal (at the melting point) the increased water content raises its homogeneity and hydraulic permeability. Meltwater content and flow will be highest (and most concentrated) where melt rates are greatest. Drainage through a saturated snowpack is driven by the local slope, and transport velocities can increase to \(10^{-2}\) m s\(^{-1}\).

Over the accumulation area of a glacier, at the peak of the summer melt cycle, the varied physical and thermal properties of the snowpack may be classified as three distinct snow facies. The first is dry snow, which is typically only found at very high elevations (or in the interior of ice sheets), where no melting occurs, the water content remains at 0%, and the snow makes no contribution to runoff. Second is; percolation snow, which occurs at intermediate elevations, where some summer melting occurs, meltwater (about 3% water content by volume) penetrates the snowpack or drains into the firn (see next section), but refreezing and storage occurs, ensuring melt does not contribute significantly to runoff. Third comes wet snow, which arises where summer seasonal melt raises the snowpack to 0°C and vertical percolation results in saturated snow (8–15% water content) and lateral flow occurs, particularly at the glacier ice interface, or where ice lenses or layers occur. In contrast to cold or polythermal glaciers, the summer melt season warms the entire snowpack on temperate glaciers and the dry and percolation snow facies are not observed.

At lower elevations, in the ablation zone, the increasingly thin and saturated snowpack may become slush (>15% water content). Slush flows themselves may contribute to the removal of snow from the glacier surface. These slush zones commonly follow the seasonal retreat of the transient snowline, and in this zone supraglacial lakes
GLACIER HYDROLOGY AND RUNOFF

may form where glacier surface gradients are low or topographic depressions exist. Undulations in glacier surfaces can be formed by ice flow itself and by the topography of the glacier bed. Meltwater may also pond in crevasses during the early part of the melt season. Lake volumes of $10^4$ m$^3$ have been described on valley glaciers, while on the Greenland ice sheet, supraglacial meltwater lake volumes of $10^7$ m$^3$, with extents of up to about 9 km$^2$, have been reported. Supraglacial lakes are transient features usually forming early in melt season as supraglacial drainage is initiated, when saturated snow- or slush-plugs prevent flow through supraglacial stream courses. However, on ice sheets, lakes may persist between melt seasons.

At the end of the summer, the snowline position broadly corresponds to the equilibrium line altitude (ELA), which is the average elevation contour at which accumulation equals ablation over a one-year period. At the ELA, slush and supraglacial lakes may persist during summer, but superimposed ice is also evident. Superimposed ice forms where meltwater refreezes at the glacier ice interface, most typically in early summer as meltwater percolates through the snowpack, but also in early autumn when residual melt draining from the accumulation area and precipitation refreeze as air temperature decreases. Although superimposed ice can form across the entire ablation zone, the high ablation rate at lower elevations removes evidence of its formation. Superimposed ice can reduce the permeability of surface glacier ice, so that accumulation of meltwater on the glacier surface is pronounced early in the ablation season.

The firn

Firn represents the transition between snow and glacier ice, and is formed through the processes of firnification. This process represents the compaction and reorganization of snow and ice crystalline structure, which in turn increases its density to >400 kg m$^{-3}$. Snow that survives over a full annual cycle becomes firn. The rate at which this snow transforms into firn (and ultimately into glacier ice) is dependent on the accumulation rate of snow, the temperature of the snow, and the presence of meltwater in the evolving snowpack. These controls impose a gradual reduction in the air or void space within the snowpack, and firn becomes glacier ice upon the occlusion of intercrystalline air passages to bubbles, at a density of about 830 kg m$^{-3}$. The density of firn increases with vertical distance from the snow surface and also with proximity to the ELA, where production and refreezing of meltwater is commonplace. These spatial trends toward an increasingly tight packed crystal structure result in a porosity gradient. Characteristically, firn is found above the ELA and its hydrology is important for runoff sourced in a glacier’s accumulation area.

Due to the presence of firn, the accumulation area of a glacier represents a confined aquifer. Meltwater derived from the surface snow can percolate through the snowpack and into the firn layers. This meltwater drains through the higher porosity, unsaturated firn to form a saturated firn layer at depth, where the reduced permeability impedes further drainage. This saturated firn layer progressively develops following the onset of the melt season; the volume of water retained in this aquifer is dependent on, among other things, the snow melt rate.

The saturated firn layer on valley glaciers has been reported at depths of up to 15 m below the firn surface, with thicknesses ranging from 1 to 7 m above the firn–ice transition. The meltwater transit velocities of $10^{-4}$–$10^{-5}$ m s$^{-1}$ in the saturated layer emphasize the firn’s ability to delay snowmelt runoff at timescales of days to weeks. The slowed transport of meltwater
in accumulation area firn reservoirs results in the damping of any diurnal melt signal during summer. However, as the melt season ends, the saturated firn drains down-glacier or meltwater refreezes in situ (aiding firmification), at least partially reducing the firn aquifer’s liquid water content.

The bare ice

During the melt season, the decrease in snowpack extent, and up-glacier recession of the transient snowline toward the ELA, results in the exposure of glacier ice and initiates rapid supraglacial runoff from the ablation area. If unimpeded, this meltwater flows across bare surface ice at much higher velocities (typically $10^{-1}$ m s$^{-1}$) than those seen in the snowpack or firn.

On all glaciers during the melt season, the ablation area represents a transient thermal layer: in winter, the glacier ice surface is cooled below the pressure melting point (PMP), while during spring and summer the increasingly positive energy balance driving ablation ensures the seasonally cold surface layer initially approaches and then remains at the PMP. Because glacier ice is not a pure medium, the energy balance that drives melt is not uniform over space. Preferential radiation absorption at crystal boundaries or the presence of dust and/or impurities on the ice surface generates micro- (micrometer) to small- (centimeter) scale topographic variations. Meltwater may percolate through or along these flowpaths and, by increasing flow volumes, create rills on the ice surface.

Incident solar radiation also penetrates the uppermost glacier ice, typically to a depth of about 2 m. Through melting at subsurface crystal boundaries, the surface ice density can be reduced to about 550 kg m$^{-3}$ creating a porous weathering crust through which water can be transported. Observations have suggested this shallow weathering crust zone behaves like a perched aquifer, with the capacity to store and release meltwater; however, this weathering crust aquifer is typically saturated, with its water table just a few centimeters below the ice surface. Local differences in ice structure (e.g., foliation) result in contrasts in hydraulic permeability in the ice, which may contribute to the formation of preferential flowpaths within the weathering crust ice. Transport rates in the weathering crust are typically between $10^{-4}$ and $10^{-6}$ m s$^{-1}$.

By following the steepest surface gradient, surface rills coalesce to form supraglacial stream channels. Akin to terrestrial river catchments, supraglacial stream channels commonly develop dendritic or arborescent drainage patterns, with drainage densities ranging from $<10$ to $>20$ km km$^{-2}$, which generally decrease up-glacier where ablation is reduced. Due to the convexity of glacier ablation areas, elongated, subparallel drainage patterns are often observed. Similarly, the structural control imposed by down-glacier longitudinal foliation and annealed crevasse traces can result in rectilinear surface drainage systems. Delays of between 1 and 11 hours have been observed between peak melt production and peak supraglacial stream discharge; these delays relate to catchment size and geometry, but also the hydraulic properties of the weathering crust. The form of supraglacial flowpaths and stream catchment areas varies glacier to glacier: drainage networks may be disrupted by crevasses (see next section) occurring in response to site-specific glacier motion and the associated stresses in the ice.

The geometry of supraglacial streams is controlled by, among other things, stream catchment area and ablation rate. To accommodate increasing meltwater discharge, supraglacial streamflow velocity and water depth increases while channel width remains relatively constant.
GLACIER HYDROLOGY AND RUNOFF

Here, flow velocities of $>1\text{ m s}^{-1}$ are common, even in small streams. Channel roughness is very low; the dimensionless Manning’s “$n$” for supraglacial channels is typically $<0.03$. As is seen in terrestrial river systems, both meandering and step-pool morphologies can develop in supraglacial streams. Meander wavelength relates to discharge and stream width, while the sinuosity of meanders (typically $1.0–2.5$) is inversely associated with reach-length channel slope. Step-pool sequences appear to develop where channel slope exceeds about $15\degree$.

The incision rate of supraglacial streams is principally related to channel slope and discharge. Viscous fluid friction within the turbulent flow can accentuate channel incision. Supraglacial stream water equilibrates to around $+0.1\degree\text{C}$, meaning there is also sufficient thermal energy available to induce downcutting of ice-walled channels at rates of about $2\text{ mm h}^{-1}$. On glaciers in temperate latitudes, typically the ice surface ablation broadly matches stream incision rates (about $0.1\text{ m day}^{-1}$), and streams reform each melt season. Conversely, in colder climates, stream incision may be an order of magnitude greater than glacier ablation, resulting in the development of progressively more deeply incised “canyons” $>2\text{ m}$ deep and persistent over many years. The process of meandering will continue at depth and the planform surface expression of a supraglacial stream may not reflect its active channel.

As a result of the low permeability of surface and near-surface ice, the ablation area of a glacier exhibits a rapid hydrological response to changing melt rates. Here, rapid transport of meltwater via supraglacial streams ensures that the diurnal melt signal is apparent in the bulk meltwater discharge. However, the configuration of drainage structure in the supraglacial environment is, in part, dependent on the occurrence of features that provide hydrological access to the englacial environment.

**Englacial hydrology**

Massive glacier ice is permeable, allowing englacial water to permeate through it slowly. With a density of $830–910\text{ kg m}^{-3}$, at the microscale, glacier ice crystals are surrounded by a film of liquid water; these films form a network of veins at the junction between three or more individual ice crystals. Typically $0.1–10\mu\text{m}$ in diameter, the size of the veins depends on the ice crystal size, meltwater solute content, pressure, and temperature. Ice crystals commonly range from $<1\text{ mm}$ to $\approx10\text{ cm}$ in diameter and the size of the vein junction correlates positively with crystal size. The process of ice crystal formation itself rejects solutes and impurities, resulting in solute-rich (or saline) water within the intercrystalline or interstitial vein network. The lower freezing point of saline water compared to that of pure water allows for the existence of larger veins. Increases in overburden pressure reduce the PMP of ice, potentially enlarging the vein network in ice nearer the glacier bed; the hydraulic permeability of the ice in the lowermost several tens of meters in a glacier increases. Englacial strain heating resulting from the flow of the ice can also contribute to interstitial meltwater production ($\approx0.01\%$ by volume). However, irrespective of crystal size and solute content, as ice temperatures decrease, the vein network contracts; the porosity and permeability of ice at the PMP is considerably higher than for cold ice. Liquid water can be present in ice substantially below the PMP, but usually $<0.1\%$ by volume, while the water content of glacier ice at the PMP may rise to several percent by volume. The flow in the vein network is small, however, with laboratory studies suggesting velocities of between $10^{-8}$ and $10^{-13}\text{ m s}^{-1}$. The presence of air bubbles and debris, capillary forces, the deformation and recrystallization of ice, and
high confining pressures, are all likely to impede this flow.

Despite the low rate of water transport, the interstitial vein network is prevalent throughout a glacier and water will generally flow toward the glacier bed. Assuming ice is a porous medium, water moves from high to low hydraulic potential (Φ). Hydraulic potential is the sum of the gravity–defined potential energy and the water pressure defined by the force imposed by the overlying ice. Theoretically, water flows perpendicular to the 3-D plane with equal hydraulic potential – the equipotential surface – and follows the steepest potential gradient. On valley glaciers, equipotentials typically dip up-glacier at 11 times the ice surface slope. Using calculations based on glacier geometry alone (e.g., ice extent, topography, and thickness) it is possible to calculate an informative overview of likely flow-paths in the englacial environment.

Water-flow, directed by the hydraulic potential, generates heat proportional to the water flux, further enlarging already large veins in the ice. As such a vein enlarges, its water pressure drops compared to smaller veins. Water-flow will be directed toward the larger evolving conduit and, consequently, large conduits develop and grow at the expense of smaller flow-paths. This results in the development of an arborescent drainage pattern following the gradient of equipotentials through the englacial environment. However, studies of flow-paths in the englacial environment from direct observations (glacier speleology), ice-penetrating radar, and video imagery from boreholes do not appear to fully support the theoretical englacial drainage system as driven by hydraulic potential. Englacial conduits following subhorizontal pathways, vertical descent depths of up to 60 m interrupted by small steps and horizontal galleries, or small (<0.1 m) englacial drainage structures with shallow dipping orientations have contributed to a growing realization that structural controls (foliations, fractures, variations in ice rheology, etc.) may provide a greater influence on the geometry of drainage features, and local hydraulic potential fields, than was previously appreciated.

Crucially, in view of the limited water transfer capable by the primary permeability of englacial ice itself, it is the larger-scale structures (e.g., crevasses, fractures, and moulins) that provide the pathways for the bulk of seasonal meltwater to access the englacial environment (Figure 2), even if hydraulic potential governs the general direction of water-flow. These macroscale flowpaths that represent secondary permeability may allow transit velocities of between 10^{-1} and 1 m s^{-1}. Most commonly, crevasses exist as direct pathways to the glacier interior. Such crevasses form in response to high tensile strain rates and have depths of up to about 30 m in temperate ice (ice at the PMP), and greater in colder, more brittle ice or where they can be kept open by water flow (see section below). Crevasses truncate any supraglacial streams they intersect and sequester water from them.

GLACIER HYDROLOGY AND RUNOFF

(a)

(b)

(c)

(d)
Energy dissipation by flowing water at the crevasse base may develop a vertically descending conduit at depth. The stress field within the ice causes a lateral deviation of such evolving conduits, with observations suggesting a down-glacier orientation of about 25° from vertical. Where ice flow causes crevasses to close, but supraglacial drainage continues to incise a notch into the up-glacier edge of the former crevasse, a vertical shaft (moulin) forms. Moulins from <1 m to 10 m in diameter may be long-lived features, persisting for multiple melt seasons.

Where crevasses or moulins become water-filled, the process of hydrofracture may arise. Here, the mass of meltwater promotes fracture extension at the base of the crevasse or moulin. The depth of the hydrofracture depends on the volume of stored water and/or the persistence of meltwater delivery to the fracture locus. In the absence of a continuous water flux to the fracture base, refreezing will reduce the likelihood of the fracture descending to greater depths. Under optimal circumstances, crevasse hydrofracture has been observed in glaciers and ice sheets to propagate to depths of $10^2$–$10^3$ m in short (hours, days) timescales. As with crevasse and moulin drainage path formation, the changes in effective stress field with increasing depth can result in the hydrofracture flowpath becoming inclined at progressively shallower angles. Hydrofracture is also not limited to a vertical orientation and appropriate water pressures or structural weaknesses can facilitate shallowly dipping drainage path formation.

It is possible for supraglacial streams themselves to develop into englacial conduits, especially where stream incision exceeds general ice ablation rates: snow bridges and metamorphosed and deforming ice can cover these incised flowpaths, resulting in enclosed, high-roofed englacial channels called cut-and-closure channels. The geometry of these channels resemble supraglacial streams, with flow generally being at atmospheric pressure. Processes of vertical incision and knick-point retreat rates of 0.1–0.5 m day$^{-1}$ in these channels can lead to the formation of moulin-like forms at the channel head. Similarly, subhorizontal channel forms have been suggested to arise from the entombment of conduits formed at the base of the saturated snow zone in the accumulation area of ice masses. Crevasses may also lead to subhorizontal drainage structures: water-flow in crevasse bottoms may initiate a drainage route, and subsequent crevasse closure can isolate the drainage structure from the supraglacial environment. Speleological investigations have also revealed that ice structures – such as refrozen or annealed crevasse and/or fracture traces, debris bands, thrust faults, and highly permeable ice – all provide locations of high hydraulic transmissivity, supporting conduit inception. Studies have reported that englacial fractures can be found throughout 96% of a glacier’s depth. Fractures in ice can also result from frictional drag at the glacier bed, with basal crevasses propagating vertically upwards into the englacial environment.

Current wisdom suggests englacial drainage flowpaths close up over winter months and reopen each summer, when water pressures decrease with channel enlargement. The closure rate of water-free ice-walled channels is a function of ice overburden pressure and viscosity, largely controlled by temperature. In cold ice, even small channels can persist for over a year. In contrast, temperate ice deforms rapidly and, once empty of water, conduits close rapidly: theoretically, at a depth of 100 m, a conduit’s diameter may halve in <20 days. However, englacial conduit closure rates are substantially reduced if they are water-filled, as the stored
GLACIER HYDROLOGY AND RUNOFF

water impedes ice deformation. The englacial system, therefore, can represent a reservoir with capacity to store considerable volumes of water, particularly over winter months. Empirical water balance studies have demonstrated disparities between input and output meltwater volumes that suggest such processes of storage and release occur within the englacial hydrological system.

Subglacial hydrology

Assuming the glacier bed is at the PMP, water reaching the ice–bed interface flows toward the glacier terminus, orthogonal to the equipotential contours formed by the intersection of the equipotential surfaces with the bed. Water can exist at the ice–bed interface beneath cold ice areas due to the hypersalinity of mineralized waters resulting from solute rejection during melting and refreezing. Meltwater at the glacier bed may also be sourced from basal and frictional heating in areas of temperate ice, although annually this rarely exceeds about $10^{-1}$ m of melt. Once present at the ice–bed interface, though, meltwater flow is complicated by variability in both supply and bed conditions.

Where ice is thin, channel enlargement by viscous heat dissipation may offset channel closure, and such channels would be open with meltwater flowing at atmospheric pressure. In this situation, bed geometry is the primary factor in defining the orientation of subglacial channels. However, observed channel locations have often appeared to mirror those reconstructed from hydraulic potential assuming water at ice-overburden pressures. To reconcile this dichotomy, it is quite possible that drainage pathways close by deformation in winter months and subsequently reopen each summer. Since conduits are water-filled, and therefore at (or temporally above) ice-overburden pressure during re-formation in the spring, their initial location is controlled by hydraulic equipotential pressures. Subsequently, and despite reduced water pressures, melt rate is insufficient to allow lateral migration to the location dictated by theoretical open-channel flow (i.e., the low point of the glacier bed). Nonetheless, there is a broad agreement that water-flow at the bed occurs in one or both of two qualitatively and hydraulically different conceptual flow systems: distributed or “slow” flow and discrete or “fast” flow.

Distributed (slow) subglacial drainage

Distributed subglacial drainage occurs through spatially extensive, nonarborescent (or anastomosing) flow pathways at relatively slow velocities of $<10^{-2}–10^{-3} \text{ m s}^{-1}$. For a glacier with a hard bedrock sole at the PMP, microscale pressure-driven melting and refreezing (regelation) occurs around bedrock protuberances up to about one meter in length. The meltwater generated by this process flows around bedrock bumps and clasts as a millimeter-thick film. Sedimentological analyses reasoned that the lack of particles $<0.2 \text{ mm}$ at the rock–ice interface demonstrated the presence of water films capable of eroding finer particles, while numerical analyses indicated an upper limit to film stability of about 4 mm. In reality, small-scale bed roughness probably reduces stable film thickness to substantially less than this. Raised viscous heat dissipation in thicker films, or local increases in water discharge due to supply or bedrock variability, result in the development of preferential drainage paths and protochannels. Where ice flow is sufficiently fast, ice may separate from the bed in the lee of a bedrock protuberance, leading to the development of cavities. Subglacial meltwater may collect in, and thermally enlarge, cavities. The initial cavity size is dependent on
bed topography, ice velocity, and basal shear stresses. Cavities may be either autonomous or interconnected by narrow channels (orifices) where water-flow is sufficient. A network of interlinked cavities forms an anabranching linked cavity system. For small discharges, ice melt is unimportant for maintenance of the cavity system, so small increases in water pressure lead to a greater carrying capacity of the system. However, if meltwater discharge through the inefficient linked cavity system increases further, preferential channel-like flowpaths can develop.

Many glaciers are not entirely in direct contact with consolidated bedrock. Instead, subglacial investigations and observations of recently deglaciated surfaces commonly indicate the presence of unconsolidated sedimentary deposits. With a hydraulic conductivity typically in the range $10^{-6}–10^{-12}$ m s$^{-1}$, Darcian porewater flow is likely through subglacial sediments, although extremely difficult to measure directly. However, macroporous or preferential flowpaths may develop in subglacial till, and porewater flow is likely to occur in conjunction with other more efficient drainage.

**Discrete (fast) subglacial drainage**

Discrete subglacial drainage occurs through channels or conduits, typically forming a stable arborescent network along which meltwater flows rapidly at velocities of $10^{-1}–10^{-2}$ m s$^{-1}$. The relative instability of distributed drainage systems to increased water flux means that they break down as water discharge accumulates either gradually down-flow or locally due to point inputs. Here, preferential drainage paths develop by melting the overlying ice to form semicircular subglacial channels, Röthlisberger- or R-channels, which follow the hydraulic gradient. However, water pressures measured in subglacial channels have been found to be higher than those calculated for ideal R-channels, indicating unusually rough or sinuous conduits, or a cross-sectional shape that is broad and low rather than semicircular. In these Hooke- or H-channels, melting is concentrated on the conduit walls, since channels are not continually water-filled and lateral closure is limited by friction with the bedrock. Where bedrock may be readily eroded or where major subglacial channels persist for sufficient time, such channels may incise into the rock rather than the ice, forming Nye- or N-channels.

In the case of a poorly consolidated sediment bed, due to the instability of films and porewater flow to externally driven variations in water flux, it is thought that shallow anabranching canals incise into the deformable bed material. Canals are enlarged by water-flow removing sediments, with sediment creep and failure of the canal wall counteracting the tendency for growth.

Given the spatially restricted nature of discrete subglacial drainage and the spatially extensive nature of distributed subglacial drainage, it is anticipated that the two systems likely coexist side by side. Discrete channels are likely to form at point sources, such as beneath moulin delivery points, and to extend down-flow of them, irrespective of their location. Channels will also generally increase in representation down-glacier, where accumulated subglacial meltwater flux is largest. In between these channels, distributed drainage will dominate. Indeed, at temperate glacier beds at the PMP, the distributed component will be ubiquitous between discrete channel pathways. Critically, evidence suggests not only that such a combination of subglacial drainage systems do coexist, but that they interact at a variety of scales. For example, coupling between porewater flow and channelized flow has been observed whereby high daytime water pressures within channels drives water from them into the surrounding distributed...
system. At night, when the channel water pressures are markedly lower, that water returns, transferring solute and suspended sediment from the surrounding locality to the channel.

**Temporal evolution of glacier hydrology and runoff**

Conceptually, spatial and temporal changes in temperate glacier hydrology are thought to involve, on an annual cycle, a glacial drainage system that closes over in winter and reopens during summer months.

The relatively rapid rate of ice creep in temperate glaciers, with ice at the PMP, makes it unlikely that englacial and/or subglacial conduits or fast drainage structures remain open once devoid of liquid phase meltwater during winter. However, once closed, meltwater can become trapped through the winter in cavities at the glacier bed. At the commencement of the melt season, the volume of water stored within the glacier initially increases due to poorly interconnected drainage structures (e.g., snowpack, isolated crevasses, and flooded moulins) and the presence of a slow drainage system at the glacier bed. As surface warming continues through the spring and early summer, the surface snowpack becomes isothermal, and snowmelt floods (spring events) occur, which flush a large volume of meltwater through the glacier drainage system, resulting in an early melt season peak in runoff volumes (and commensurate ice velocity). This spring event may also release previously stored meltwater. As the summer progresses, ablation is heightened across the glacier surface and increasing volumes of water are routed into the glacier interior. This increases water pressures and destabilizes slow drainage structures such that a channelized, fast flow network develops at the expense of distributed drainage (Figures 1 and 3).

The hydraulically efficient system then probably persists for the remainder of the melt season with sufficient water flux to maintain fast drainage structures. Once ablation and meltwater volumes decline, the discrete, fast flow drainage structures begin to close through ice deformation.

Importantly, these temporal changes do not occur uniformly across the entire glacier bed but have a systematic spatial expression that is driven by the up-glacier expansion of the area of intense surface melting. This area corresponds to the expanding area of bare ice exposed by the melting of the (hydraulically buffered) supraglacial snowpack. The retreat of the snowline toward the ELA progressively exposes moulins and crevasses that become hydraulically active, delivering melt to englacial or subglacial drainage flowpaths. Consequently, water pressures within and at the bed of a glacier are not spatially uniform, and the growth of a fast, discrete drainage system evolving from a slow system follows the retreat of the snowline up-glacier (Figure 3b). The growth in extent of an efficient drainage system is also likely to reduce storage within the glacier, with more direct coupling between melt processes and runoff volumes following the reduction in both the snow/firn aquifer and the impedance of subglacial flow. Meltwater discharge as the snowline retreats to higher elevations has been demonstrated to result in an increase in bulk meltwater runoff volumes as well as a reduction in the time lag between peak temperatures and peak runoff. As the season progresses, the diurnal runoff signal becomes increasingly peaked due to the loss of hydrological characteristics capable of damping the transport of meltwaters. Later in the melt season, with falling rates of ablation, the reduced supply of meltwater is insufficient to maintain the fast drainage structures, which begin to close and decrease in extent as they transition back

GLACIER HYDROLOGY AND RUNOFF

to, and integrate with, the distributed flow structures.

The temporal and spatial progression of a temperate glacier’s hydrological system imparts systematic changes in the runoff hydrograph. Runoff may flow from a glacier throughout the year, with a base flow associated with slowly draining water, volumes of which only change at longer (most typically seasonal to annual) timescales. From the onset of melt, and following any snowmelt flood events, a glacier’s runoff hydrograph typically exhibits rising discharge volumes and increases in the amplitude of diurnal discharge variations as the drainage system progressively becomes more evolved and efficient (Figure 3c). The time lag between peak melt and peak discharge at the glacier terminus is progressively reduced. If melt season snowfall occurs or synoptic conditions reduce melt rates, discharges (and diurnal variations thereof) are commonly diminished. As the melt season ends, the hydrograph typically shows a rapid decline in runoff volumes.

Quality of glacial runoff

For most glaciers, water emerges from the glacier terminus in a few discrete proglacial streams associated with the dominant fast subglacial flowpaths. The water quality in these streams is dependent on the flowpaths meltwater has followed; a glacier’s hydrological structure is critical to the acquisition of solutes (ions dissolved in water) and entrainment of suspended sediment by waters emerging at the ice margin.

Solute

The hydrochemistry of meltwaters within glacierized catchments has been studied since the 1970s. The primary hydrochemical constituents in glacial meltwaters are solutes derived from atmospheric deposition and the weathering of catchment bedrock and glacial sediments, predominantly in subglacial or ice-marginal environments. The complex system of solute acquisition by glacial meltwaters may be conveniently simplified by a two-component model whereby bulk meltwater is composed of “quick” and “delayed” flow. Conceptually, the former can be considered as rapid supraglacial and englacial flow, along with channelized subglacial flow, which is largely devoid of solutes, while the latter relates to slower subglacial transport pathways, enriched in solute. In practice, however, these components do not exist as discrete entities, and solutes are acquired to varying degrees by glacial meltwaters that follow composite pathways, seriously undermining mixing model approach to determine solute provenance. However, it is well ascertained that solute acquisition is influenced by the residence time of waters at the ice–bed interface. In response to the variation in meltwater production during the summer melt seasons, typically high solute concentrations are observed at times of low discharge, with low flux and long contact times, and low concentrations during times of elevated meltwater discharge, with high flux and shorter contact times, both at the diurnal and seasonal timescales.

Precipitation in glacierized catchments is the primary source of base levels of solutes observed in runoff. Seasonal snowfall and snowpacks are, therefore, important as sources and stores of solutes within glacierized catchments. As snow begins to melt, the percolation of meltwater results in changes in that snowpack’s chemical composition. Field and laboratory studies have shown that 80% of the snowpack solute load may be released within about the initial 25% of meltwater runoff. This leaching or elution of
solute may be complicated by snowpack heterogeneity. Seasonal elution has also been observed in runoff from firn. This removal of solutes from snowpack and firn, the sources of glacial ice, means the ice itself is relatively dilute. As the snowline retreats up-glacier during the ablation season, dilute ice-melt comes increasingly to dominate supraglacial runoff.

The relatively high solute concentrations measured in proglacial meltwaters must, therefore, be acquired by chemical weathering of sediments in ice-marginal or subglacial environments. It is now widely recognized that hydrolysis and carbonation reactions dominate rock–water interaction and chemical weathering within glacierized basins. Calcium ions (Ca\(^{2+}\)) are the dominant cation in glacial runoff, which reflects its relatively rapid rate of dissolution from silicate and carbonate rocks, although silica concentrations tend to be lower than in nonglacial runoff because silicate weathering is depressed in cold subglacial and ice-marginal environments. The acquisition of other base cations depends on a catchment’s specific geology and geochemical susceptibility. However, observations of persistently elevated sulfate ion (SO\(_4^{2-}\)) concentrations suggest alternative weathering reactions occur along subglacial flowpaths. Anaerobic nitrate-reducing or sulfate-reducing microbes and oxidizing chemotrophs have been shown (or inferred) to exist in a wide range of glacier environments, and subglacial chemical weathering can be increased up to eightfold through microbially catalyzed reactions.

Sediment

The runoff from glacierized catchments characteristically exhibits high suspended sediment loads that influence the use and management of that water. Consequently, substantial research attention has been devoted to glaciofluvial sediment transport, which is typically confined to a limited melt season. Analyses have shown that annual specific glaciofluvial sediment yields, which routinely exceed \(10^2 \text{ t km}^{-2}\) \text{ year}^{-1}, are substantially greater than global averages for other terrestrial catchments.

In view of the conceptual model of valley glacier hydrology during the ablation season (Figure 1), the critical distinction between the quick flowpaths of the largely debris-free supraglacial and englacial systems, with low or intermediate suspended sediment concentration (SSC), and the slower, delayed flow through the subglacial drainage system, exhibiting high SSC through entrainment of rock flour and subglacial debris, is important. The transfer of fine-grained rock flour in suspension dominates sediment evacuation from most glaciers, and particularly from temperate-based glaciers. The concentrations of sediment transported via supraglacial drainage paths, although typically <0.5 g l\(^{-1}\), are highly dependent on the nature and extent of debris at the glacier surface and within the ice body as well as delivery of sediment derived from extraglacial locations, such as lateral moraines, to the supraglacial environment. Debris may be released from englacial and basal ice through the melting and enlargement of conduits by viscous heat dissipation. However, where the glacier bed is composed of unconsolidated materials, the entrainment and removal of sedimentary products will be the dominant source of suspended sediment entrained in meltwaters passing through subglacial drainage paths, with SSC commonly ranging between 1 and 10\(^2\) g l\(^{-1}\). Entrained sediment may itself increase SSC through mechanical erosion (abrasion) of bedrock or basal sediments. However, the relationship between SSC and discharge is neither linear nor stable in proglacial rivers and
sediment yields can vary markedly at diurnal, seasonal, and annual timescales.

Changes in the rate of meltwater production at the glacier surface and the hydrological configuration within a glacier control the temporal variability in suspended sediment transport by influencing the processes of erosion, entrainment, and transfer. The volume of sediment evacuated by runoff is typically viewed as a function of the availability of debris at the subglacial ice–bed interface. At a seasonal timescale, the sediment yield relates to the evolution of the subglacial drainage system: SSC (sediment evacuation) can be high during the spring melt, when snowmelt flushes the glacier’s subglacial drainage network and destabilizes the slow drainage system. Subsequently, up-glacier retreat of the snowline and corresponding growth of the fast subglacial drainage system may cause short-term increases in sediment delivery as the basal area accessed by fast-flowing subglacial meltwater increases. As the melt season progresses and diurnal melt cycles become more pronounced, sediment concentrations may be elevated as subglacial sediments are eroded by enlarging fast drainage structures. However, decreases in suspended sediment concentration may arise on a seasonal basis, arising from the exhaustion of available fines, as the subglacial drainage system spatially stabilizes and then begins to close during the latter portion of the melt season.

Short-term variability in sediment transport by runoff is usually dominated by a marked diurnal cycle, typically characterized by a strongly positive relationship between discharge and SSC. However, the direct, positive association between SSC and meltwater discharge commonly breaks down. On the diurnal timescale, clockwise hysteresis is frequently observed, whereby the flushing and exhaustion of sediment on the rising limb of the diurnal hydrograph occurs, and there is significantly less sediment available for transport when discharge declines. Similarly, anticlockwise hysteresis may occur in cases where subglacial channel water pressures reduce on the falling hydrograph limb and return flow from the distributed system elevates the SSC entrained at lowered discharges. Shorter-term subdiurnal variations in SSC, so-called sediment pulses, have been related to sudden changes in drainage system connectivity over the glacier bed, to glacier dynamics that result in reconfiguration of the drainage system, and to snowmelt or rainfall events where the drainage system becomes inundated. Additional influences on glaciofluvial sediment yields from glacierized catchments may involve the reworking and erosion of typically unconsolidated materials associated with moraines, and braid plains, or sandurs that typify ice-marginal environments and contemporary proglacial areas.

Summary and conclusion

The nature and dynamics of glacier hydrology exert critical controls on the volume and quality of meltwater runoff. Such runoff may be of critical importance as a valuable resource but, occasionally, as an unwelcomed hazard. Our understanding of glacier hydrology has been progressively built up over recent decades; conceptually, the model of drainage pathways through mid-latitude, temperate valley glaciers remains dominant. Here, the principal controls over meltwater generation, routing, and delivery have been summarized, categorizing central flowpaths as supraglacial, englacial, or subglacial. Meltwater produced in the supraglacial environment drains impeded through the snowpack and/or firn, but more rapidly over bare glacier ice. While the interstitial, primary permeability of the englacial environment cannot transport
meltwater at velocities $>1 \text{ m year}^{-1}$, secondary macroscale drainage structures represent key flowpaths delivering meltwater to the glacier interior. Once meltwater reaches the bed, it follows either slow, distributed forms of drainage, or discrete, hydraulically efficient, fast channels, although these systems likely coexist and interact. Thermal and mechanical erosion can enlarge or restructure the englacial and subglacial flowpaths while ice deformation causes their contraction. Although traditionally viewed as a top-down cascade, the supraglacial, englacial, and subglacial components of a glacier’s hydrology are interconnected and meltwater can readily transition between these environments. Seasonally, the entire drainage system of a glacier opens, develops, becomes increasingly efficient, and then begins to close once meltwater production declines. Processes of liquid meltwater storage and release occur within these three subsystems, at subseasonal, seasonal, and annual timescales, and it is these processes that strongly influence the runoff volumes and water quality draining from a glacierized catchment as well as representing a strong influence on the basal motion of a glacier.

Despite the advances in research techniques that have provisioned our current knowledge of glacier hydrology, research challenges remain, particularly to forecast drainage system and hydrograph adjustments under predicted climatic forcing and environmental change scenarios. Research priorities include (i) refining spatial and temporal variations in the generation and routing of supraglacial meltwater and the associated role of the weathering crust; (ii) improving understanding of the architecture, function, spatial extent, and temporal development of englacial drainage systems, perhaps utilizing geophysical techniques; (iii) constraining the reciprocal relationship between seasonal (and longer-term) evolution of subglacial drainage and ice mass motion. In addition to these flow-path-specific research avenues, recent awareness of microbial interaction with meltwaters warrants investigation into the potential role microbes may have on hydrological processes, water quality, and ecological habitat modification throughout the glacier system. Crucially, these questions remain not only for temperate valley glaciers but also for polythermal and cold glaciers, where ice temperatures impose complexity on the manner by which meltwater is transferred through the ice body. For ice sheets, uncertainties remain over the transferability of the conceptual, temperate valley glacier hydrological model as well as the response time of hydrological structures to changes in meltwater provision in a changing climate.

Further reading

A glacier inventory is a cadastre of glaciers that is, in general, regionally restricted to a country. It contains for each glacier an identifier (ID), its name (if available), location (coordinates), size, and other data. The information is either collected from topographic maps or, more recently, directly derived from satellite data and a digital elevation model (DEM). While in the early days of compilation all data were stored in a tabular text format, advances in computer technology have allowed the storage of digitized glacier outlines in a vector format with the required inventory information being available in an attribute table. A key requirement for generating an accurate glacier inventory is data acquisition at the end of the ablation period, that is, when the glacier perimeter is free of seasonal snow. This might be difficult to achieve in regions with a maritime climate and/or in high mountains, both having snow cover throughout the year. Additionally, the map or satellite image must have a high geometric quality and a scale or spatial resolution that is good enough to identify glaciers. Otherwise the quality of the inventory would be degraded; for example, only the largest glaciers would be included and details would be missing. Hence, glacier inventories were first created in the nineteenth century in regions with good topographic maps, such as those available for Austria and Switzerland. However, despite the constantly increasing quality of topographic maps, glacier inventories were only created in a few countries at that time and not continued systematically.

This changed in the international hydrological decade (1965–1975) when a working group led by Fritz Müller was appointed by the International Commission on Snow and Ice (ICSI) to prepare a “guide to world inventory of perennial ice and snow masses on and beneath land surfaces” (Hoinkes 1968). “The necessity of a new world inventory of glaciers, based on recently surveyed maps” was also emphasized by Hoinkes (1968), arguing that there was a disturbing 20% difference in the best estimates of the regions covered by ice outside of the polar regions. In the following years, glacier inventories were compiled in many regions of the world according to standardized guidelines from UNESCO (see web links) and a status report was published by the World Glacier Monitoring Service in 1989 (WGMS 1989). This so-called World Glacier Inventory (WGI) contained only preliminary information for some countries but provided the first global overview of the perennial ice masses in a standardized tabular format (Figure 1). Although the WGI served a wide range of purposes and was used for several regional-to-global scale calculations, it became clear that tracking glacier changes through time would be very difficult with the point information stored in the WGI. The emerging technological capabilities of geographic information systems (GIS) in the 1980s along with satellite data having sufficient spatial resolution resulted in numerous activities for the compilation of a global glacier inventory in a vector format from satellite data.
Source data and methods

Creation of a glacier inventory requires that glacier boundaries are available for the intended sample of glaciers. Such boundaries can be drawn (e.g., on a map) once the physical and optical characteristics of a glacier are defined. It is then a matter of interpretation by the respective surveyor, cartographer, or remote sensing specialist where to place the boundaries. Unfortunately, there is no unique interpretation of glacier extents. Glaciers exhibit a wide range of surface characteristics that can be interpreted differently without being wrong. For example, assuming that there are no restrictions in regard to visibility (e.g., due to clouds, shadow, or seasonal snow), the change from debris-covered ice to a lateral moraine – that might still have an ice core but is not moving anymore – is continuous and a precise boundary is difficult to determine in such cases (Figure 2). There are also topographic features like couloirs and depressions that have snow cover throughout the year (and maybe some ice underneath) that might be considered as part of the glacier area or not. In all cases there is variability in the resulting glacier area with an impact on the reported data in the inventory. If only the data table is available and not the source information showing where the outline was drawn, there is no way to decide whether a different area at a later point in time is due to a different interpretation or a real change. Such differences in interpretation apply to all source data used, largely independent of their spatial resolution (Figure 2).

While the earliest maps of glaciers were compiled by topographic surveying, modern topographic maps are based on aerial photography and photogrammetric techniques. The particular challenges for glaciers are related to the variable elevation of the terrain in mountain regions – resulting in a panoramic distortion (that needs to be corrected) – and the poor contrast over snow-covered regions – resulting in a reduced quality of the derived elevation information. If seasonal snow and clouds are not a problem, glacier outlines can be directly transferred from the aerial photograph to the map using a distinct color to reveal them (e.g., white with blue or green outlines and elevation contours). For a glacier inventory these outlines have to be separated and extracted from the rest of the map. For the WGI this was generally performed using planimetric techniques. Using GIS technology, the outlines are either digitized directly from the map or from a scanned version using on-screen digitizing. With the vector information being digitally available, it was for the first time possible to perform change assessment for exactly the same glacier entities. As noted above,
not all countries with glaciers have high-quality and large-scale (e.g., 1:25,000) topographic maps available. With decreasing map scale (e.g., toward 1:100,000), glacier outlines become more generalized and their geographic location more uncertain. Glacier inventories derived from such data can still be useful for a first-order assessment of the overall area covered by glaciers, but tracking glacier changes might not be useful anymore.

Finally, satellite data with sufficient spatial resolution (e.g., the 30 m from Landsat) have become publicly and freely available (e.g., on http://glovis.usgs.gov), and simple multispectral classification methods (such as a ratio of two image bands) were developed and used for automated mapping of debris-free glaciers (Paul et al. 2002). The resulting grid of classified image pixels are converted to glacier outlines (vector format) that can be uploaded in a GIS for further manual corrections (e.g., adding the unmapped debris-covered glacier parts) (Figure 3). A set of guidelines for glacier mapping (see web links and Racoviteanu et al. 2009) and calculation of inventory data (Paul et al. 2009) was created for the community to support consistency of the analysis.

The already orthorectified (i.e., terrain effects being removed and the image being transformed into a map projection) satellite scenes have several advantages compared to the also used aerial photography, among others: the large regions covered at the same time, the coverage of regions not accessible for airborne surveys, and the possibility of an automated multispectral classification based on the spectral properties of ice and snow. While the first advantage allows mapping of an entire...
GLACIER INVENTORY

Figure 3  Glacier outlines from 2003 as derived from satellite data (yellow). While glaciers in shadow are included in the raw classification, the analyst has to add the missing debris cover (red) and remove misclassified lakes (white). The final outlines are composed of the outer yellow and red lines. The satellite image in the background is a false color composite from 2009 showing glaciers in light blue. Some of the meta-information available in the attribute table for Oberaar glacier is shown in the inset.

mountain range within a day, the last one allows for a quick update of inventory information and change assessment.

The disadvantage of satellite images is their lower spatial resolution (around 15–30 m) that results in more generalized outlines and maybe problems in correctly identifying parts belonging to a glacier (Figure 3). However, the latter can also be a problem for high-resolution data (1 m or better) as Figure 2 and several tests have shown (Paul et al. 2013). More recently, high-resolution satellite data and aerial photography have also become available for viewing in tools such as Google Earth. These sources might help in the interpretation of glacier boundaries derived from lower-resolution satellite data and have been used widely for this purpose.

Existing glacier inventories

As mentioned above, basically two types of inventories can be distinguished: (i) tabular listings and (ii) vector outlines with attribute data. A third type is (iii) gridded data that indicates on an aggregated level how much of a larger grid cell is covered by glaciers. The last type is particular useful for models working on a global scale that do not resolve individual glaciers. When information about individual glaciers can

be considered in a model, type (i) inventories are more useful. Direct use has been made of the vector information stored in inventories of type (ii) only recently on a global scale (Marzeion, Jarosch, and Hofer 2012; Radić et al. 2014). Overall, the datasets available differ in the above types, their accuracy or degree of generalization, global completeness, epoch, included metadata, and file format, among others (Table 1). The overlay depicted in Figure 4 illustrates some of these datasets for Disko Island in western Greenland.

The WGI and WGI-XF

The WGI was compiled during the 1970s and 1980s mostly from topographic maps following the UNESCO guidelines (see web links at the end of this entry). The entries were organized in a fixed machine readable syntax using number codes with look-up tables to convey descriptive information. The entries listed for each glacier include a unique code (based on the hydrologic basin), name, location (longitude, latitude, country), year of map/photo, size, length, aspect, various elevations (e.g., minimum, maximum, mean), a classification (type, front, profile, nourishment, activity, moraine), and others. In some regions only preliminary information was obtained and for others data were created but not forwarded to the data centers, resulting in detailed information being available only for about one-third of the world’s 200,000 glaciers. The WGI was later extended to the WGI-XF (see web links) with newly assimilated data that are now also part of the WGI dataset available at the National Snow and Ice Data Center (NSIDC) (see web links). The rich meta-information for each glacier has been and still is used for a wide range of applications,
but the information is only available for point locations (Figure 4).

**GGHydro**

The “GLAC” layer in the GGHydro dataset provides the percentage of glacier cover for each 1 x 1 degree grid cell of the Earth’s surface (Figure 4). It has been compiled manually from 1:1 000 000 scale topographic maps and is available online (see web links). Due to the sampling of the information and the large scale of the maps used, small glaciers are underrepresented and glacier outlines are generalized. A distinction
between the two ice sheets of Greenland and Antarctica and glaciers is not made in this vector layer but available from the CRYO layer. The dataset might not be considered as a glacier inventory (e.g., individual glaciers are not resolved, meta-information is missing), but due to its spatial completeness it has been applied in several global-scale studies (e.g., for calculating the contribution of glaciers to sea level change).

The Digital Chart of the World (DCW)

The DCW has been digitized from 1:1 000 000 scale, partly military topographic maps where hydrology-related polygons are available in a separate layer. The outlines of glaciers are regionally highly generalized and locally also incomplete. A distinction between glaciers and ice sheets is not made (Pfeffer et al. 2014). The dataset is also not really a glacier inventory as only outlines are provided (i.e., glacier complexes are not further separated into individual glaciers). The DCW has been used to show where glaciers are located (Figure 4) and also to define regions with glaciers for data acquisition with the Terra sensor ASTER. The dataset is available online in an improved version called vmap0 (see web links).

The GLIMS database

The GLIMS database is the first systematic attempt at compiling glacier inventory information in a vector format using mainly satellite data. Initiated in 1995, the idea was to use freely available images from the ASTER sensor to map glaciers and provide the outlines to the database. Due to the small area covered (1/9 of a Landsat full scene) and the missing orthorectification of the ASTER scenes, glacier inventory work was demanding and progress slow. This changed when orthorectified Landsat scenes were made publicly available by the Global Landcover Facility, allowing a much faster data processing. The glacier outlines in the GLIMS database are made available in the shapefile format (a de facto standard for vector data), and have a very flexible data model for storing attribute and meta-information (Raup et al. 2007). The database is designed to store multitemporal information and a wide range of additional data (e.g., hypsographies, snow lines, debris-covered sections, calving termini, velocity fields). Glacier complexes are generally intersected by drainage divides and each resulting glacier entity has a specific code (GLIMS ID).

The Randolph glacier inventory (RGI)

The RGI was compiled in a special effort for global-scale glacier studies excluding the two ice sheets in support of IPCC AR5 (Vaughan et al. 2013). Its main purpose was to achieve global completeness based on the best available vector datasets in each region (Pfeffer et al. 2014). The RGI is thus based on glacier outlines that had already been available in the GLIMS database and was extended by datasets that were provided by the community (Figure 4), partly prior to citable publications. In some of the still uncovered regions, outlines from the DCW and nominal outlines (circles of the correct size at the respective location) from the WGI were integrated also. The RGI has a more simple data model than the GLIMS database and a reduced number of attributes. It was and still is frequently updated with improved datasets by the community (e.g., replacing the DCW and nominal WGI outlines). Apart from this, a main future goal is to increase the temporal consistency of the dataset (i.e., the epoch covered), which currently ranges from the 1950s to 2014. The RGI dataset is currently integrated into the GLIMS database to allow extraction of an RGI-like dataset from there.
The global inventory

The currently best assessment of the area covered by glaciers globally is provided by the RGI. Although there are still local-to-regional scale quality issues that need to be corrected (e.g., too much seasonal snow has been mapped as glacier ice in South America), a wide range of global-scale applications could be performed for the first time with this dataset. Examples include calculation of glacier volume or projections of twenty-first-century glacier evolution and their contribution to sea level change (Radić et al. 2014). For practical purposes, the dataset was divided into 19 first-order regions (Figure 5), following the suggestion of an earlier study. In each of these regions different data sources have been used to create the outlines, but most of them were derived from satellite data acquired in the period 1999–2011 (Pfeffer et al. 2014). Some key numbers for each region (count, area, mean size, mass, mean thickness, tidewater fraction) are summarized in Table 2. The RGI includes all glaciers and ice caps peripheral to the Greenland ice sheet and on the islands surrounding Antarctica, but it excludes those on the Antarctic mainland. A note of caution has to be made for glacier count: the numbers are highly variable and strongly dependent on several factors (e.g., the smallest size considered, the way of separating glaciers, snow patches being included or not) and will thus be different in various publications as well as subject to change in future compilations.

Referring to the study by Pfeffer et al. (2014), there are about 200,000 glaciers globally covering 727,000 km², of which 39% (by area) are tidewater glaciers (which are in contact with the ocean). When excluding region 19 (islands surrounding Antarctica), the tidewater fraction is reduced to 25%. There is an approximately two orders of magnitude variability of glacier number and areas covered among the regions (Table 2).
Table 2  Summary of glacier inventory data for the 19 main regions. For uncertainties and further details on data sources see Pfeffer et al. (2014).

Source: Pfeffer et al. 2014. Adapted from the International Glaciological Society.

This can be broken down to three or four classes when dividing the area covered by the number of glaciers, that is, when looking at the mean size of the glaciers in each region. While eleven regions are dominated by comparatively small alpine glaciers (mean size around 1 km²), three regions have mean glacier sizes of around 5 km², three are in the 20 km² range, and two have a mean size of about 50 km². The five latter regions are dominated by large ice fields or ice caps that might have not been separated into individual glaciers, and RGI regions 1, 4, and 5 have many large valley glaciers and ice caps. About three-quarters of the total glacier mass is found in five regions (1, 3, 5, 9, and 19). If all glaciers were to melt, sea level would rise by approximately 0.4 m. The ice mass calculated for region 9 is three times larger than for region 15, although the area covered by glaciers is more than 10 000 km² larger for the latter region. This indicates the different types of glaciers in both regions (large ice caps versus valley glaciers) and their very different mean thickness.
A closer look at the size–class distribution reveals that in nearly all of the 19 regions most glaciers are found in the 0.1–1 km$^2$ class, that is, small glaciers are dominating by number nearly everywhere (Pfeffer et al. 2014). Due to their large number they have also some impact on mean glacier thickness in most regions, but often a few very large glaciers result in a bias toward larger mean thickness values. For the 19 regions in the RGI, glaciers thicker than about 200 m can be distinguished from regions with mean thickness values around 60 m (Table 2), the former being dominated by large ice caps and ice fields. When looking at the area–elevation distribution (hypsometry) of glaciers, the distribution is roughly bimodal (Pfeffer et al. 2014). Most of the ice is located between 500 and 1500 m above sea level (a.s.l.) for polar regions and around 5500 m a.s.l. for glaciers in equatorial regions and in High Mountain Asia (regions 13, 14, 15). The comparatively small glaciers in the Alps, Pyrenees, and Caucasus are an exception with mean elevations around 3000 m a.s.l. Hence, despite their limited areal coverage they are situated in a climatically unique location. When considering all glaciers individually, mean elevation is a continuum with decreasing elevations pole–wards (Pfeffer et al. 2014).

**Summary and conclusions**

With glaciers impacting on hydrology from local (runoff, hydroelectric power) to global (sea level rise) scales and being considered as key indicators of climate change, accurate assessment of these resources and their changes through time requires basic information about their characteristics. This information is provided by glacier inventories in the form of tabular data (e.g., the WGI) and more recently vector outlines with attribute information attached (e.g., the GLIMS database). Compiling this information for a larger region with often thousands of glaciers is tedious work, even when latest technologies and automated classification of satellite images are used. The workload further increases when data from high-resolution sensors or aerial photography are used, as these have to be digitized manually, sometimes without providing better evidence of where the glacier boundary is located (e.g., due to a lack of contrast). As interpretation of glacier boundaries can vary without being wrong, change assessment based on outlines provided by another source might result in wrong conclusions.

With the only recently established globally complete inventory (RGI) it became possible for the first time to provide global numbers on glacier coverage and volume estimates or to model past and future glacier development and contribution to sea level change. Results of these studies might need to be modified in the future as some still existing regions with low-quality outlines in the RGI need to be replaced with more accurate data. With data from the recently launched satellite missions (e.g., Landsat 8 and Sentinel 2) being made freely available at no cost in high geometric quality (orthorectified) and with shorter revisit intervals, update and improvement of existing inventories will be more straightforward in the future. However, with experts being required to obtain a high-quality product, creation of a glacier inventory will always be time-consuming work.

GLACIER INVENTORY

Glacier lake outburst floods

Holger Frey
University of Zurich, Switzerland

Glacier lakes: characteristics and processes

Occurrence of glacier lakes

The formation of glacier lakes in the course of continued glacier retreat is observed in all glacierized regions worldwide. Different processes can lead to the formation of glacier lakes, resulting in different lake types. Distinctions can be made according to the location of the lake relative to the glacier (proglacial, supraglacial, ice-marginal, periglacial, and en- or subglacial) and regarding the properties of the damming material. The latter can be rock, morainic material, ice (glacier ice, dead ice from glaciers of ground ice in permafrost zones, or highly fractured ice from ice avalanche deposits or glacier surges), or other mass movement deposits (rock avalanches, landslides, or rock glaciers).

Glacier retreat has a major influence on the landscape and people’s perception of it mostly conceived as a loss in beauty and attractiveness. Glacier lakes often can replace this loss in attraction to some degree, and constitute new attractive elements in a changing landscape. However, such lakes at the same time have a potential for rapid and catastrophic drainage, so-called glacier lake outburst floods (GLOFs). GLOFs are the most far-reaching glacial hazard and often interact in chain reactions with other hazardous processes.

Mechanisms and triggers of glacier lake outburst

Depending on the dam type, different outburst mechanisms of glacier lakes can be distinguished. Solid rock dams can be spilled over, but normally are not damaged and persist for a long time. Moraine dams can collapse in cases of high water level and the resulting low freeboard of the dam or extreme discharges. Related processes are retrogressive erosion and breach formation, slope failure, or progressive groundwater flow through the dam. The latter, also called piping, is usually caused by very large hydraulic gradients or when new cavities within the dam are formed, for instance in the case of melting dead ice or ice cores. Since all these processes result in the permanent damage of the dam, outbursts of moraine-dammed lakes are often unique events. A typical process in the outburst of lakes dammed by solid glacier ice (supra-, en-, subglacial, and glacier marginal lakes) is the progressive enlargement of subglacial drainage channels. In such cases, discharge increases continuously over hours to days or weeks, until the drainage channels are closed by ice deformation when the water pressure becomes low and falls below the ice pressure, and the outflow ceases suddenly. This process, sometimes also referred to as the Icelandic term jökulhlaup, is often reoccurring. Dams of fractured ice from ice avalanches or surging glaciers can collapse suddenly, leading to complete lake drainage in a short time and related extreme discharges.

Mass movements impacting a lake can cause very high discharges, irrespective of the dam material. In high mountain terrain potential lake outburst triggers involve mass movements like ice, rock, or combined avalanches, rockfalls,
GLACIER LAKE OUTBURST FLOODS

landsides, and debris flows or GLOFs from upstream lakes. By moving the entire water column, such impacts on lakes lead to tsunami-like impact waves, which can overtop the dam and produce a GLOF. These impact waves can swash back and forth in the lake, leading to several subsequent overtoppings with diminishing intensities. Depending on the dam material and properties, the spillover can initiate breaching or failure of the dam.

Properties of the outburst floods are strongly affected by the hydrograph at the lake outlet as well as by the down-valley topography and characteristics. Possible flow types range from debris flows, in the case of steep terrain with loose material available for transportation, mud flows and hyperconcentrated flows, to water floods. In many cases, flow transformations are observed, depending on the slope and availability of material. For instance, loose material from the dam is entrained, leading to a granular debris flow. Further down, when the terrain flattens, most of the material is deposited and the GLOF continues as a hyperconcentrated flow, which then might transform to a debris flow again, if loose material is incorporated in subsequent steeper terrain.

Hence, for an assessment of the hazard situation of a glacier lake, potential mass movements that can trigger displacement waves, lake and dam properties, and the down-valley topography and sediment availability need to be considered. This illustrates that glacier lake outbursts often are linked in process chains, starting from a mass movement impacting a lake, followed by a displacement wave and a resulting GLOF, which then in turn can act as a trigger of an outburst of a subjacent lake. Eventually, depositions from a GLOF (or any other mass movement) can dam a river in the main valley, causing the formation of a temporal lake with a potential for sudden rupture and extreme discharges. In such process chains, glacier lakes thus have the potential to multiply potential reaches of hazardous processes of glaciated regions.

Glacier lakes, GLOFs, and global warming

In a period of atmospheric warming, glaciated high mountain regions undergo changes on different spatial and temporal scales, several of them affecting the hazard posed by glacier lakes. A comprehensive assessment of the hazard situation should thus not only analyze the current situation, but also consider potential future changes of different processes, in order to anticipate potential future developments. In the following, several processes influencing the hazard of glacier lakes are described.

Glacier fluctuations change the disposition of potential starting zones of ice avalanches, that is, if a glacier tongue retreats into a steep part of the bedrock, the potential for ice avalanches increases. If the tongue then recedes from this terrain step (or re-advances back into flatter terrain below), the susceptibility for avalanches decreases again. On a longer timescale, stress fields within steep rock parts or moraines can be modified due to de-buttressing caused by glacier retreat and thinning since the Little Ice Age, thus enhancing the susceptibility for failure. Furthermore, new terrain exposed after glacier retreat often consists of unconsolidated material that, if situated in steep terrain, constitutes starting zones of debris flows and landslides.

Changes in the thermal conditions of the underground influence the hazard disposition of ice and rock avalanches in different ways. Transitions from cold to polythermal or temperate beds of hanging glaciers and the occurrence of liquid water at the ice–rock interface reduces the basal friction and can thus destabilize hanging glaciers.
that are known to be stable. Permafrost degradation and related deep and long-term warming of perenni-ally frozen rock walls can increase the probability of rockfall. Finally, degradation of ground or dead ice in moraines can reduce the stability of moraine dams and increase the probability of piping within the dam (see above).

Glaciers in all mountain regions have experienced retreat since the Little Ice Age and today in most cases have an extent that is smaller than ever before in historic times. Not only are new lakes forming at locations that have been covered by glacier ice before, but also the disposition of potential triggers for lake outbursts are different than in the past. This implies that the situation of glacier lakes and potential triggers for lake outbursts are beyond historical experience and require assessment methods other than consulting known events from the past.

Hazard assessment and prevention

Assessments of high mountain hazard include gaining an overview of the situation, involved processes, and potential interactions (cf. Huggel et al. 2004). Based on these findings, a monitoring system should be established, the acceptable risk defined, responsibilities clarified, and further steps prioritized. After gaining a first overview of involved processes, potential magnitudes and probabilities need to be estimated. This can be achieved by applying rules of thumb developed empirically from past events, by consulting simple models that use such empirical relations, or by modeling potential processes with physically based models.

GLOF modeling

A large variety of models to simulate or estimate mass movements exist, having different complexities and different input requirements. They can be distinguished as either flow routing models or physically based models. The latter are able to simulate, for instance, kinetic energy and temporal evolutions of the flow, whereas the former are used to determine the direction and extension of the mass movement. Such approaches can be applied to large regions and normally meet the requirements for a first-order hazard assessment.

Physically based models typically are applied to more specific case studies, since they require more computational resources and also diverse input and calibration data that often are not available. Most such models require the initial volume of the mass movement that is being simulated, and there can be high uncertainties in cases of high mountain mass movements. The flow propagation is then modeled by solving equations of mass conservation and momentum, integrated over flow depth, for discrete time steps. Flow rheology is often approximated by using frictional parameters. Recent developments aim at integrating the entrainment of material along the flow trajectory, a process that is particularly important for GLOFs. Worni et al. (2012) were able to realistically simulate the discharge hydrograph, breach formation, sediment depositions, and hence also flow-type transformations of an outburst of a moraine-dammed lake in Patagonia.

Estimating values of input parameters for complex models is even more problematic for potential future events. Concepts from other natural hazards, such as flash floods for instance, are not applicable to glacier hazards, since for the latter typically no records exist, as these are new, unknown situations and related events often are unique. For mass movements, this shortcoming is often circumvented by using magnitude–frequency relations. However, data are typically scarce for establishing such relations,
GLACIER LAKE OUTBURST FLOODS

also because small events often are not recorded. Schneider et al. (2014) presented a remarkable work on modeling different outburst scenarios for Laguna 513, a glacier lake in the Cordillera Blanca, Peru. They used a chain of interacting, physical models to simulate different rock/ice avalanche scenarios, the development of the subsequent displacement wave in the lake and the overtopping of the dam, and finally the resulting GLOF, including different flow types. A reconstruction of a real event from 2010 was used for model calibration, and they had a high-quality digital elevation model, lake bathymetry, and records of the wave height available, conditions that are normally not fulfilled for most remote glacier lakes. Nevertheless, this study demonstrates the potential of linking such physically based models for providing reliable and reproducible information on potential future events.

Structural risk prevention measures

If the risk posed by a glacier lake is considered to be unacceptably high, the probability of a potential outburst can be lowered by either lowering the hazard or lowering the vulnerability of potentially affected people. The most rapid way to lower the hazard potential of a glacier lake is to lower the lake level. This is sometimes done as an urgent measure by constructing siphons that can lower the lake level rapidly. Another, more sustainable way to lower the lake level constantly is the excavation of tunnels through bedrock dams. For moraine dams a typical method is to make a cut into the freeboard of the dam and reinforce the dam and the outlet, or to place a culvert and to restore the freeboard. Such works have been successfully applied in different mountain regions, namely the Andes (mainly in the Cordillera Blanca, Peru), the Himalayas (Nepal), and the Alps. Carey et al. (2012) give an overview of such mitigation measures performed at Laguna 513 (see also above). Other mitigation measures involve construction works not at the lake but related to protective measures for potentially threatened infrastructure. Examples are diversion dams to protect exposed infrastructure or constructions with the potential to retain certain amounts of potential outburst floods. Such constructions have the potential for multipurpose use, for instance in combination with hydropower production.

Nonstructural risk prevention measures

Measures to increase the preparedness of the population provide an alternative to physical mitigation measures. Exact forecasting of the moment of a lake outburst or a potential lake outburst trigger remains problematic, but systematic monitoring of critical situations, using both on-site observations and remote sensing, offers the possibility to establish different alert levels and to alarm and evacuate the population in case of an event. Such monitoring can be either limited in time or permanent in the form of an early warning system (EWS). Only a few EWSs exist so far for glacier lakes, but they have a large potential for complementing or replacing mitigation measures. Understanding of the entire system of involved processes and a well-designed monitoring and warning service, including redundancy, are fundamental for EWSs. It is, however, important to recognize that such systems are highly complex and that, besides technical aspects, they include institutional and social components: responsibilities need to be clarified with authorities, ways of communication need to be established and standardized, and permanent contact with the population is necessary to achieve the required response.
Future perspectives

In the future, the formation of numerous new glacier lakes is expected in all glacierized mountain ranges. Such lakes will compensate the loss in landscape attractiveness caused by the vanishing glaciers to some degree, but they need to be carefully and repeatedly observed since they hold the potential for catastrophic drainage, in particular with the increased potential of mass movements associated with atmospheric warming. Conditions in high mountain regions will undergo constant and rapid changes beyond historical precedence, and hence will require innovative approaches to assessing complex and interacting processes influencing the hazard potential of glacier lakes. Establishing standardized assessment procedures will help in defining monitoring strategies and setting priorities for mitigation and adaptation measures. Socioeconomic developments such as changing settlement densities in high mountain valleys will also influence the risk posed by glacier lakes.

Glacier mass balance

J. Graham Cogley
Trent University, Canada

Glacier mass balance is the sum over the extent of the glacier and over a stated span of time of mass gains, treated as positive, and mass losses, treated as negative (Figure 1). Mass gain is referred to generically as accumulation and mass loss as ablation. Most accumulation is by snowfall, but avalanching of snow from valley walls can be significant. On most glaciers ablation is mainly by runoff of meltwater, but ice discharge – the calving of icebergs or, equivalently, the flow of ice across a grounding line – is significant on many.

Of the global glacier area of 726,800 km², 39% is tributary to tidewater termini (Pfeffer et al. 2014). This area excludes the Greenland ice sheet (1.7 million km²) and the Antarctic ice sheet (12.3 million km²). Thus the ice sheets dwarf the other glaciers, of which there are 200,000 or more.

The word “glacier” has a deep history, traceable to an Indo-European root with the general sense of “cold, freezing,” but its first appearance in English was in 1744, when William Windham reported from Chamonix in Savoy that “the whole Glaciere has a kind of Motion … it slides continually towards the Outlets into the Valley.” This observation influenced later thinking. For example, the Oxford English Dictionary’s definition of “glacier” begins as “A large accumulation or river of ice.”

However, in mass-balance studies the volume under study must be demarcated so that horizontal mass transfer can be quantified. The glacier is separated from its neighbors, if any, at ice divides where this transfer is zero. At grounding lines or calving fronts, the balance must include the outward transfer. Within the boundary there is an accumulation zone at higher elevations where low temperature favors accumulation and an ablation zone at lower elevations where warmth favors melting. The two zones are separated by the equilibrium line at which the local mass balance is zero. It follows from this definition and elementary physics that Windham was right: the ice must flow. If accumulation exceeds ablation the glacier grows, if the converse is true it shrinks, and if the two are equal, and remain so, it attains steady state.

The concept of mass balance had to await the development of this modern definition of the glacier. The first recognizably modern measurement was published in 1935, but the term itself did not become current until the 1960s, when measurements became widespread.

Mass balance has the dimension [M], mass, and the gigatonne (Gt) is often a convenient unit for calculations. The specific mass balance, which is the mass balance per unit area, has the dimension [ML⁻²]; common units are kg m⁻² or mm water equivalent, the two units being numerically identical. The meter of sea level equivalent (m SLE) is the total mass balance (kg) divided by the product of the density of water (1000 kg m⁻³) and the area of the ocean (362.5 × 10¹² m²), such that 1 mm SLE = 362.5 Gt. When regarded as a rate, the mass balance has dimension [MT⁻¹] or [ML⁻² T⁻¹]. Over periods of a year or longer the natural unit of time is the year.
Measurement of mass balance

Measurements of mass balance and other glacier changes are archived at the World Glacier Monitoring Service (UNEP/WGMS 2008).

Glaciological method

In the glaciological method stakes are inserted into the surface in a spatially representative network. The local change of mass is the change of surface elevation, relative to the top of the stake, multiplied by the density of the matter gained or lost. In the accumulation zone the density is measured in snow pits, while in the ablation zone it is usually assumed to be 900 kg m$^{-3}$, near the density of pure ice. The glacier-wide mass balance is extrapolated from the stake network, often by assuming that the local balance depends only on elevation. With this assumption, the glacier’s hypsometry must be known so that each stake can be given its appropriate weight, multiplying its specific balance by the area it represents and summing the products.

Measurements at stakes yield only the surface mass balance. There are also internal and basal components, which can often be assumed to be small. More often they are estimated indirectly or even neglected, possibly leading to large biases. Meltwater that percolates to depth instead of running off, for example, may reduce mass loss significantly.
The frontal mass balance, due to ice discharge or frontal melting, is never positive and may be known confidently to be zero, but if not it must not be neglected. This is particularly true of the Antarctic ice sheet, whose mass loss is overwhelmingly by frontal ablation. Here the ice discharge is measured by measuring its components, ice thickness multiplied by velocity, near the grounding line, with accumulation up-glacier usually obtained from regional-scale climate modeling.

On most glaciers there is a seasonal as well as a spatial separation between accumulation, typical of winter, and ablation, typical of summer. Winter and summer may be defined by fixed calendar dates, but when the glacier cannot be reached on those dates the field survey must be corrected somehow for unmeasured changes before or after the survey date. Alternatively the seasons can be defined in terms of the epochs of annual minimum (end-of-summer) and maximum (end-of-winter) glacier mass, in which case the durations of the seasons will vary and may be unknown.

Geodetic method

Geodetic methods, which have long been used as checks on the accuracy of glaciological measurements, record the mean change of the glacier’s surface elevation relative to a fixed external datum. The resulting volume balance is converted to a mass balance by assuming a density. In the absence of in situ measurements, this assumption introduces uncertainty. It often takes the form of Sorge’s Law, which asserts that the glacier has an unchanging profile of density as a function of depth beneath the surface, with the corollary that the matter gained or lost has the density of ice. Departures from Sorge’s Law become less serious as the relative extent of the accumulation zone becomes smaller.

Terrestrial and airborne surveys have largely been replaced by orbital surveys, greatly increasing the number and coverage of geodetic measurements, which now, when reckoned in mass-balance years, far outnumber glaciological measurements (Figure 2). However, the time between surveys is typically years or decades, so that geodetic methods contribute little to our understanding of year-to-year variability.

Gravimetric method

The GRACE satellite mission, launched in 2002, tracks changes in the Earth’s gravitational field with high temporal resolution (1 month.
or shorter) and coarse spatial resolution (of the order of 350 km). These changes are due to movements of water in the near-surface environment and of rock in the deep interior. For glaciological purposes the tectonic, oceanographic, and purely hydrological mass changes are biases and must be removed. Where the residual mass-balance signal is weak, as in mountain ranges with few glaciers or with regional mass balance near zero, GRACE has little to offer. Nevertheless gravimetry has become a standard tool for measurement of the mass balance of the ice sheets and of heavily glacierized mountainous regions and has contributed to assessments of the mass balance of all glaciers other than the ice sheets (Gardner et al. 2013).

Modeling of mass balance

Models of the surface mass balance rely on precipitation and temperature information, sometimes from in situ or nearby measurements, but more often from climate models of global or regional scope. The climate model cannot resolve the size of most glaciers and its topography is smooth, so it cannot simulate the strong but poorly quantified tendencies for precipitation to increase with elevation and to be greater on the windward than the leeward sides of mountains. The vertical gradient of temperature is better understood, but even so the correction of climate-model temperatures to those responsible for surface melting over the elevation range of the glacier is an uncertain procedure.

Some models estimate surface melting by solving the surface energy balance, but they are more demanding of input information, and therefore less versatile, than temperature-index models. The latter rely on field measurements to calibrate the conversion of climate-model temperatures to ablation, sometimes including additional forcing variables when they are available. The temperature index is usually the positive degree-day sum, which is the mean temperature excess above the freezing point multiplied by the duration of the excess. All temperature-index models acknowledge the difference in reflectivity between snow and exposed ice, the latter being darker and therefore yielding significantly more melt per positive degree-day.

For completeness mass-balance models must also treat the internal and basal balances, requiring knowledge of the subsurface temperature and hydraulic conductivity.

Models of frontal ablation are less advanced than models of surface ablation. Progress has been made in understanding the physics of how crevasses propagate through the entire thickness of ice, so as to detach the iceberg from the parent glacier, but individual calving events remain unpredictable. Measurements of ice discharge have little or no predictive power. Progress has also been made in simulating the behavior of grounding lines, but this remains a difficult subject.

For simulations over more than a few years, the slow dynamic response of the glacier to climatic forcing must be modeled. The glacier always seeks equilibrium with the climate, and both advance and retreat are stabilizing feedbacks. However, the rate of response is limited by flow speed, which is typically only tens of meters per year while the glacier is typically thousands of meters long.

History and future of mass balance

Dated terminal moraines document a maximum in glacier extent as the response of glaciers to the cooling known as the Little Ice Age. The implied dates of maximum mass lie between the late seventeenth and early twentieth centuries.
in different regions, with the global average near to 1850 according to analysis of long time series of glacier length changes calibrated against mass-balance observations made during 1950–2005. This analysis, updated in Vaughan et al. (2014), yields an estimate of approximately 80 mm SLE of loss since 1850. Estimates of total glacier mass in the early twenty-first century range from 350 to 470 mm SLE (Pfeffer et al. 2014), so the length changes suggest a loss to the present of perhaps 15–20% of the uncertain total mass in 1850.

The loss has not been steady. For example, loss rates were greater than average during the 1920s. A twentieth-century mass-balance simulation, driven by reconstructions of temperature and precipitation, exhibits even larger rates during the 1930s which can be localized to glaciers peripheral to the Greenland ice sheet (Vaughan et al. 2014). Without mass-balance measurements at these early times it is not possible to decide whether the increased losses are observational or modeling artifacts, or whether they represent real historical events. There is, however, indirect evidence of accelerated losses in Greenland between 1920 and 1940.

In mass-balance measurements made since the 1940s there is evidence of a minimum in the rate of loss centered near the 1960s (Figure 3), consistent with slight cooling from the 1940s to the 1970s followed by warming. (Northern Hemisphere temperatures are shown because most of the measurements of both temperature and balance are from there.) The first decades of the twenty-first century have seen the most negative balances ever measured.

The agreement in Figure 3 between mass balance and temperature is good to fair, partly reflecting measurement errors in and undersampling of both variables. However, it is also consistent with the well-established finding that over the past 70 years trends have been much clearer and more globally coherent in temperature than in precipitation.

There is substantial year-to-year variability in mass balance and also hints (via the height of the confidence envelope) of strong spatial variability within each year. More importantly, a correction for the spatial bias of the measurements affects the estimate of the global mean noticeably. The corrected red “staircase” is not always close to the center of the blue confidence envelope, suggesting that the glaciological bias toward well-studied mountain ranges is significant. There is a doubt about the reliability of the spatial correction, however. In regions with few or no glaciological measurements, recent gravimetric and geodetic measurements show noticeably less loss than the spatially corrected estimates. Moreover, longer-term variability in the corrected estimate appears less than in the uncorrected annual averages, due in part to the inclusion of geodetic measurements of which most are several to many years long.

Measurements of ice-sheet mass balance have been made only since the 1990s. Most mass loss from the Antarctic ice sheet is by ice discharge, while on the Greenland ice sheet the contributions of melting and ice discharge to ablation are roughly equal. There remain major gaps in understanding of such matters as the role of meltwater in promoting basal sliding (accelerating the delivery of ice to the grounding line), the stability of the grounding line (especially when the bed of the outlet glacier slopes downwards inland), the contribution of subaqueous frontal melting to the balance (water being much more effective than air at transferring heat to the ice), and the role of floating ice in buttressing the grounded ice (thus retarding ice discharge).

Nevertheless all glaciers have shown accelerating losses since the early 1990s (Figure 4). The acceleration has been more marked for the ice sheets (as shown by the upward concavity of their
Figure 3  (a) 90% confidence region of annual-mean Northern Hemisphere near-surface air temperatures, expressed as deviations from the 1961–1990 mean (http://www.cru.uea.ac.uk/cru/data/temperature/CRUTEM4-nh.dat). (b) Blue: global mass-balance rate from the dataset of Figure 2, shown as a 90% confidence region centered on the annual means (not shown) of measurements by glaciological methods; red: global pentadal-mean mass-balance rate (thick line with thin lines demarcating the 90% confidence region), including geodetic measurements and with the spatially biased sample corrected by an interpolation algorithm; measurements are too few before 1950 for reliable interpolation. (c) Number of measurements annually by glaciological methods.

curves) than for the smaller glaciers (Table 1). In the first decade of the twenty-first century, these three contributions to sea level rise have been of the same order, and their sum, about 1.6 mm SLE a\(^{-1}\), is slightly greater than the other leading contribution, 0.8–1.4 mm SLE a\(^{-1}\) from thermal expansion of ocean water.

The sizes of glacier accumulation zones are well correlated with their mass balances, accounting for a varying fraction of the total area. The average fraction is approximately 0.44 on glaciers with balance measurements during 1997–2006 (Bahr, Dyurgerov, and Meier 2009), but a reasonable estimate for glaciers when they are at equilibrium is 0.57. That is, the glaciers are too large for the present-day climate. The mass loss needed for all glaciers to reach the equilibrium fraction, and therefore the right size, for the climate of 2000–2010 is 184 ± 33 mm SLE. Adding the loss from 1850 to present, this represents a loss of 50–60% of the ice mass at the culmination of the Little Ice Age.

It also represents committed change. That is, the glaciers would continue shedding mass even if warming were to stop immediately. Thus the glaciers are insensitive indicators of climatic change, integrating the impact of one to many past decades of forcing.

More detailed projections relying on glacier–climate models all show continued mass loss, but the choice of climate scenario influences results strongly, as in Figure 5. Aggressive reduction of human emissions of greenhouse gases (RCP26) limits glacier mass loss up to 2100 to approximately 40% of the late twentieth-century total, while if society remains on the current high-emission pathway (RCP85) the loss is approximately 60%. The average loss by 2300 for RCP26 is more than 60% and RCP85 yields losses nominally exceeding 100%. These averages conceal the largest uncertainty, which is due to the climate models. For example, the six simulations extending to 2300 have dates of complete disappearance under RCP85 between 2120 and 3000.

Figure 5 also illustrates the concept of “peak meltwater.” Total meltwater yield is expected to rise as radiative forcing increases, but then to diminish as more and more glaciers disappear. Peak meltwater is reached before 2050 with aggressive mitigation and late in the twenty-first century with continued high emissions.

For projecting the future of ice-sheet mass balance (Table 2), the scenarios of Figure 5 are of limited value because surface temperature over the Antarctic ice sheet will remain mostly below freezing. In a warmer world, increased Antarctic snowfall is likely to outweigh increased melting, although the balance of the Greenland ice sheet will become dominated by losses from the surface as tidewater outlets retreat onto land. The role of “rapid dynamics” is very difficult to predict given current understanding of the observed and possible phenomena, which include unchecked retreat of grounding lines, especially where outlet glaciers are grounded below sea level. Church et al. (2014) assign only a moderate role to rapid dynamics over the twenty-first century. They do not attempt to quantify the likelihood of rapid-dynamic losses reaching catastrophic proportions.

Glacier modeling

Daniel Farinotti
Swiss Federal Institute for Forest, Snow and Landscape Research, Switzerland

The term “glacier modeling” generically describes the activity of representing glacier processes through numerical simulations. Four main branches can be identified in glacier modeling activities, reflecting the interactions of glaciers with other compartments of the Earth system. These branches include the modeling of (i) the internal processes of a glacier, (ii) the interaction between glaciers and the atmosphere, (iii) the processes at the glacier base, and (iv) the interactions between glaciers and open water. The four branches are briefly discussed hereafter.

The most developed part in the modeling of glacier-internal processes is the description of glacier flow. The aim of these so-called ice flow models is to simulate glacier motion and the associated processes. Traditionally, glacier ice is considered as a heat-conducting viscous fluid, whose motion is due to the action of gravity. Only recently have individual models included considerations about elastic properties, especially when addressing ice deformation at short timescales (i.e., hours to days). Two main components contribute to glacier motion on seasonal to secular time scales: basal sliding, that is, the relative movement of the ice body over the subsurface topography supporting it, and creep deformation, that is, the ice deformation caused by mechanical stress. A widely used description of the relation between stresses and strain rates is given by Glen’s flow law for glacier ice, which is implemented in most numerical models.

In this respect, state-of-the-art models consider a three-dimensional full Stokes formulation of the flow and are capable of representing arbitrary evolutions of the glacier geometry. In comparison to creep deformation, the knowledge about the processes controlling basal motion is rather limited. Models often describe basal sliding through empirical parameterizations that include the computed basal shear stress. Another focus of ongoing research is the description of crevasse formation with continuum damage mechanics, which is of particular importance for calving glaciers (see below). Other internal processes sometimes included in models are the internal mass balance, that is, the difference between processes that increase glacier mass and processes that result in the opposite, and the modeling of internal water flow and storage through conduits, cracks, and lakes. Internal mass balance is often taken care of by models dealing with glacier–atmosphere interactions (see below), and well-established theoretical concepts exist for the growth, evolution, and collapse of englacial and subglacial water conduits. The mechanisms contributing to the formation of internal water bodies, so-called water pockets, are poorly understood and, thus, seldom represented in models. For a general introduction in the modeling of glacier ice dynamics, refer to Greve and Blatter (2009).

The modeling of glacier–atmosphere interactions focuses mainly on the description of the surface mass balance of a glacier. In this case, the aim is to model all processes that contribute to glacier mass gain (accumulation) and loss (ablation) at the surface. Processes that contribute to surface accumulation are mainly the deposition of meteoric or wind-drifted snow and
avalanching. Depending on the local climatic conditions, significant additional accumulation can be due to condensation (hoar deposition), freezing rain, hail, or refreezing liquid rain. Processes that induce surface ablation, on the other hand, include snow- and ice-melt, wind erosion, and sublimation. A wide range of models exist for the representation of the surface mass balance. The degree of complexity of the model used is mainly determined by the application context: while studies aimed at calculating the surface mass balance over a large (spatial or time-) scale are forced to use rather simple models because of computational cost and availability of input data, models that are designed for reproducing the mass balance at the small scale are aimed at representing the various processes individually and in detail. Among the simpler models, many are based on so-called temperature-index formulations for the ablation part, that is, an empirical relation between air temperature and melt, and a distinction between snow and rain based on a temperature criterion for the accumulation part. More complex models, on the other hand, are based on energy-balance formulations and compute the actual melt as the residual of the energy balance equation which considers the solar radiation (often divided into various components according to the spectra) and the sensible and latent heat fluxes, as well as the ground heat flux. Similarly, these more sophisticated models compute total accumulation from the sum of various components (solid precipitation, wind drift, avalanching, etc.) that are modeled individually. When snow- and ice-melt occur, part of the generated water will run off at the surface, part of it will infiltrate into the glacier, and part of it will evaporate. The ratio between these three components is mainly determined by the atmospheric conditions and the ice temperature, and the determination of these individual shares is a task usually taken care of by the same models as those considering surface mass balance. A currently open question in the modeling of glacier surface mass balance is the influence of the deposition of black carbon and other aerosols. While it is known that such deposition can significantly lower the albedo of the surface, the magnitude of the effect on surface mass balance has not yet been quantified. Similarly, current models are inadequate in representing the effect of supraglacial debris (i.e., sediments and rocks deposited on the glacier surface): it is known that thin (typically <5 cm) layers of debris enhance glacier melt through a lowering of the albedo, and that thick (typically >10 cm) layers decrease melt through an insulation effect, but correctly accounting for these effects within models is still an open challenge. For an overview of glacier–atmosphere interactions and their modeling, refer to Oerlemans (2009). For a complete definition of concepts related to the mass balance of glaciers, see Cogley et al. (2011).

The modeling of the processes at the glacier base, that is, at the interface between ice and lithosphere, includes the modeling of glacier sliding, which is an important component of glacier motion, the modeling of subglacial water flow, and the modeling of basal accumulation and melt. The last of the three mentioned processes, that is, basal mass balance, is generally considered to be of minor importance, especially when compared to the magnitude of the surface mass balance. The processes of pressure-induced melting, melting through friction or geothermal heat, and ice accretion are, thus, often neglected in models, or mimicked through empirical functions. Considerable effort is currently spent in the representation of subglacial water flow. Particular interest in the topic is given by the close connection of the process to basal sliding, which can significantly affect overall glacier motion. Only recently has the general understanding been moving away from the simplistic “more
subglacial water equals more sliding because of lubrication” to a more complex pattern of interactions. To this end, recent models have been aimed at representing the water flow in subglacial conduits and distributed drainage systems separately. Conduits melted into the base of the ice are known as Röthlisberberger channels (or R-channels), develop during periods of high surface melt (i.e., summer), and form a high-capacity, highly efficient discharge network. On the other hand, distributed drainage systems are typical for winter situations, and consist of a low-capacity, low-efficiency water sheet including flow between so-called linked cavities, thin uniform water sheets, or permeable subglacial till layers. Physically based theories for the evolution of R-channels were proposed early on, while the mechanisms steering the evolution of distributed drainage systems have been proposed more recently. Models that successfully account for both processes are emerging, but a large open question is their validation. The main reason that explains the limited knowledge of these processes and the uncertainties in the relative models is the obvious difficulty in monitoring and measuring any of the relevant variables and processes. Providing direct access to the glacier base is both laborious and costly, while the instrumentation of the glacier base itself can be an even more challenging task because of the equipment requirements. For a review of different subglacial processes and their modeling, refer to Clarke (2005).

Compared to the above-mentioned topics, the importance of modeling the interactions between glaciers and open water has been recognized only more recently. Traditionally, ice–water interactions have been a topic in oceanographic and climatologic sciences, and have focused on the interactions between sea ice and the oceans because of their fundamental role in both the climate and the oceanic system. More recently, studies have highlighted the importance of considering the interactions involving glacier ice as well. Important processes in this respect include so-called glacier calving, that is, the mechanism that induces the breakoff of large ice blocks at the front of a glacier that is in contact with a water body, as well as subaqueous mass balance components, and the dynamics of ice shelves. Both ice calving and subaqueous mass balance can substantially contribute to overall glacier ablation. The importance of these phenomena is given by the large fraction of water-terminating glaciers, especially when considering ice caps and the two ice sheets Antarctica and Greenland. Recent studies have, moreover, repeatedly shown the effect that the removal of ice shelves (that is the floating part of glaciers draining an ice cap or an ice sheet) has on the dynamics of inland glaciers: after the collapse of the so-called Larsen B Ice Shelf, Antarctic Peninsula, in 2002, for example, an increase in ice-flow speed by up to 600% has been observed for the adjacent inland glaciers. This is alarming since the additional ice discharge directly contributes to sea-level change, and according effort is currently promoted for correctly including such effects in modeling studies. In models, calving processes have traditionally been described through empirical relations, mainly based on parameterizations of readily available variables such as the water depth at the calving front. Only recently have approaches that allow an explicit representation of the mechanics involved in glacier calving been emerging. Such approaches are, however, computationally expensive, and are therefore seldom included in large-scale models that represent glacier–ocean interactions. Such kinds of models, on the other hand, increasingly make use of the knowledge available in ocean sciences, in particular to better represent the processes that steer subaqueous glacier melt. Recent studies, in fact, point to a
hitherto underestimated importance of subaqueous glacier mass balance driven by various ocean and marine currents, especially underneath ice shelves. Much as for the buttressing effect of ice shelves, correctly modeling such interactions is of paramount importance, especially in studies addressing long-term sea-level change. Concerning the correct representation of ice shelves as such, particular effort is currently spent in including the elastic properties of ice in the modeling framework. While the importance of considering the elastic components of ice deformation at short time scales had been acknowledged earlier, only recent studies have suggested that this behavior can explain the formation of a hydrological barrier near the grounding line of ice shelves that controls, among other processes, subglacial hydrology. For an introduction to the modeling of ice–ocean interactions, refer to McPhee (2008).

Glaciers and the global environment

In programs of global climate observation, glaciers are sometimes called “unique demonstration objects of climate change.” There are two basic reasons for this: (i) everybody can observe within years to decades, from field visits or publicly available satellite imagery, the often striking changes in glacier extent, and (ii) the melting of ice under the influence of warm conditions is an experience of common life for many and, hence, easily understandable.

The continued shrinkage of glaciers in most mountain ranges is indeed a key indication of ongoing global warming (Figure 1) and as such even part of political considerations at national to international levels. Exact numbers, deeper understanding of the processes involved, and model projections of their future development are provided by more than a century of scientific research and monitoring, which recently experienced rapid growth and made important profit from new technologies. Model projections also help to assess impacts from global warming and glacier vanishing on environmental conditions at various scales of space and time.

With the retreat and disappearance of glaciers, the landscape of cold mountain chains loses an element, which is seen by most people as a treasure and beauty. The corresponding reduction of cold-mountain landscape diversity is striking and profoundly changes the public perception of glaciers. The romantic enthusiasm of the eighteenth, nineteenth, and early twentieth centuries still saw the “pure” and “eternal” ice of glaciers as a strong symbol of an intact relation between humans and their environment (Figure 2). As a consequence, glacier pictures were intensively used as postcards and for touristic advertising, books about landscape fascination, and governmental brochures on environmental programs. During the past decades, accelerated loss of glacier ice in many icy mountain ranges and the strong effect on landscape appearance of the exposed bedrock and debris fields caused increasing concern. For many, retreating glaciers today have become strong symbols of a heavily disturbed human–environment relation, perhaps even the “writing on the wall” with respect to possible future environmental disturbances from global warming of even (much) larger dimensions.

As frozen bodies, glaciers play an important role in the water cycle. They store precipitation when it falls as snow during the cold or wet season and release it as meltwater during the warm or dry season. This is essential for livelihood and agriculture in large regions up to continental scales surrounding cold mountains as the glaciers guarantee water supply during the growth period of vegetation and/or dry periods, when no water comes from the sky. Probably more than a billion people, especially in parts of central Asia, South America, or the North American Prairies, to some degree depend on this effect. The meltwater from shrinking glaciers is also contributing to rising sea levels. The total volume of all glaciers in the world is estimated at only about 4 dm of sea level equivalent but will primarily affect
the rate of sea level rise in the coming decades. Together with the effects of thermal expansion of the ocean and mass loss from the large ice sheets, the glacier contribution to sea level rise represents a serious threat to humanity.

Local to regional hazards caused by glaciers in densely populated mountain ranges change with changes of climate and glaciers. While glacier advances destroying farmed land or damming dangerous lakes caused the main problems during the past colder centuries of the so-called Little Ice Age, shrinking ice since then alleviated these threats but now leads to new concerns. Increasing human activities related to traffic,
tourism, or hydropower production followed
the retreating ice, introducing new exposures
and risks. Numerous new lakes also started to
form and will continue to grow in deglaciat-
ing mountain landscapes. The probability of
far-reaching floods from impact waves caused by
large rock/ice avalanches is slowly but steadily
increasing with every new lake forming at the
foot of steep icy peaks.

**Definition and processes**

In simplest terms, glaciers are perennial masses
of ice, combined with layers of snow and firn,
originating on land and exhibiting evidence of
down-slope flow. Under equilibrium conditions,
glacier flow evacuates mass added by *accumulation*
(mainly snowfall) at higher/colder elevations
to lower/warmer areas, where *ablation* (mainly

Nr. 1915–1975). Photo H.J. Zumbühl. Reproduced with permission.
GLACIERS

melting) removes this added mass again and produces meltwater to leave the glacier. The *equilibrium line* represents points on a glacier where accumulation and ablation exactly balance each other. Changing climatic conditions – especially air temperature and precipitation – disturb this equilibrium and cause glaciers to grow or shrink.

The *mass balance* of a glacier is primarily determined by the relation between solid precipitation (snow accumulation) and the *energy balance* (ablation). Snow remaining at the surface during more than one year is called “fri.” Compression of fri under the weight of subsequently deposited snow and fri layers leads to gas exhaustion and densification until the air is trapped in closed bubbles when it reaches the close-off density (about 830–850 kg m$^{-3}$ in cold/dry fri and about 900 kg m$^{-3}$ in wet fri) at the transition to ice. Fri layers on mountain glaciers are usually a few tens of meters thick and the *snow-fri-ice metamorphosis* takes some decades to be completed.

The primary energy source for melting the ice is shortwave solar radiation. The amount of this energy absorbed by glaciers depends on the surface reflectivity (albedo), which is much higher for bright snow than for darker ice. Albedo reduction by shrinking snow cover or dust input from local to regional sources is a strong positive feedback of ongoing glacier vanishing trends. On the other hand, longwave radiation depends on the temperature of the emitting body and cannot change with a melting snow/ice surface at constant temperature. As a consequence, glaciers react to changes in incoming longwave radiation from a warming atmosphere by enhanced melting rather than by rising surface temperatures. Air temperature, with its strong vertical and temporal variability, plays a dominant role in the energy balance of snow and ice surfaces. As air temperature influences not only ablation but also accumulation through the solid/liquid precipitation limit, it has an overall dominant influence on glacier mass balance and is often used in a pragmatic/simplified form (positive degree days) in numerical glacier models (Ohmura 2001). The change of mass balance with altitude on a glacier, the mass balance gradient, determines the atmosphere/glacier coupling and drives long-term glacier movement.

*Glacier flow* involves internal ice deformation and basal sliding. Correspondingly, surface velocity ($u_s$) is composed of the basal sliding velocity ($u_b$) and the velocity due to internal ice deformation ($u_d$):

$$u_s = u_b + u_d$$

(1)

The ratio $u_b/u_s$ is called “velocity ratio.” For internal ice deformation, a power law is commonly applied:

$$\dot{e} = A\sigma^n$$

(2)

where $\dot{e} =$ deformation rate, $\sigma =$ applied stress, and $A$ and $n =$ flow law parameters.

The essential stress related to glacier flow is the shear stress at the glacier bed ($\tau_b$):

$$\tau_b = f\rho gh\sin\alpha$$

(3)

where $f =$ shape factor accounting for friction at valley walls, $\rho =$ ice density, $g =$ acceleration due to gravity, $\alpha =$ surface inclination, and $h =$ ice thickness. Ice thickness is coupled via the basal shear stress to surface inclination, a fact which can be used for ice-depth estimates for unmeasured glaciers. Using digital terrain information and relations between basal shear stresses and surface mass turnover as governed by elevation ranges and mass balance gradients, local ice thicknesses and detailed glacier-bed topographies can now be rapidly calculated for entire mountain ranges (Clarke et al. 2013; Linsbauer et al. 2012).
GLACIERS

No generally accepted “sliding law” exists – a fundamental and still unsolved problem in glacier mechanics. Numerical model simulations often use approaches like:

\[ u_b = \frac{C\tau_b^m}{(P_i - P_w)^p} \]  

where \( P_i \) = ice overburden pressure, \( P_w \) = water pressure at the glacier bed, \( C \) = frictional parameter, and \( m \) and \( p \) = constants. This reflects that basal sliding increases with increasing water pressure, a well-documented effect, which can relate to striking flow instabilities.

A spectacular but still not fully understood flow instability is the phenomenon of glacier surges, sudden acceleration of flow velocity often by an order of magnitude or more and sometimes rapid advances over a distance of several kilometers and at rates up to many tens of meters per day. Why many glaciers in some mountain ranges (Karakoram, Alaska Range, etc.) show this behavior but not glaciers in other mountain chains and why surging glaciers tend to repeat their surges after an intermittent quiescent time interval remain open questions even today. A phenomenon sharply contrasting with the surge advances is the calving instability of glaciers with rapid retreat in deep water after a much slower advance phase on top of a frontal moraine. High water pressures in such cases are due to the calving front being submersed in the sea (or a deep lake) and, during rapid retreat through deep water, can even reach flotation conditions, inducing massive iceberg discharge.

Distribution and characteristics of glaciers

First attempts to compile a global inventory of glaciers were undertaken in the second half of the twentieth century. Detailed quantitative information, however, could only be provided where aerial photographs were available. High-resolution satellite images made it possible to complete a new glacier inventory (Pfeffer et al. 2014) for the Fifth Assessment Report (AR5) of the Intergovernmental Panel on Climate Change (IPCC) (IPCC 2014). In combination with the digital elevation models from the Shuttle Radar Topography Mission (SRTM)/Advanced Spaceborne Thermal Emission and Reflection Radiometer Global Digital Elevation Model (ASTER GDEM) and a model approach coupling ice depth with surface slope via mass flux and shear stress, detailed and realistic information on numbers, areas, thicknesses, and volumes of all glaciers worldwide were derived (Table 1; Huss and Farinotti 2012). The total number of glaciers depends to some degree on the definition of the lower size limit – small perennial ice patches or glacierets without clear features of flow are often considered separately – but can be estimated reasonably well at some 170,000. The total glacier area as documented by the new global inventory is about 735,000 km\(^2\) and the best estimate for the total volume about 170,000 km\(^3\) or around 40 cm of sea level equivalent. Roughly 10% of this ice volume is, however, already below sea level or below the level of lakes forming with continued glacier vanishing and will not contribute to sea level rise (Haeberli and Linsbauer 2013). The largest volumes of glacier ice are found in the periphery of the Antarctic and Greenland ice sheets, the Canadian Arctic, Alaska, central Asia, and Arctic Russia. Glacier volumes in low-latitude high-mountain chains are generally smaller but can be especially important for people living there and in surrounding lowlands. Behind overall numbers of areas and volumes there is a great variability of glacier characteristics.

Local topographic conditions determine the morphological types of glaciers (Figures 3 and 4).

Glacier ice can cover flat terrain as ice caps, occupy small cirques as cirque glaciers, cover slopes as mountain glaciers, or fill valleys as valley glaciers. Small hanging glaciers can be frozen onto slopes steeper than about 45°, in strong contrast to sometimes very large and flat glaciers reaching the ocean as tidewater glaciers.

Thermal glacier types are a function of average air temperature conditions at the surface, but temperatures within glaciers can be heavily influenced by ice flow (Wilson and Flowers 2013). Where mean annual air temperatures are below about −20°C, snow and firn of the accumulation area will remain cold and dry. With mean annual air temperatures increasing toward −10°C, firn will still remain cold, and small amounts of meltwater forming at the surface will refreeze and not leave the glaciers. Where mean annual air temperatures are higher than about −10°C, meltwater will completely warm up the firn to melting temperatures where solid, liquid, and gaseous phases are in equilibrium and can, therefore, leave the glaciers. The ice of ablation areas is more or less impermeable to
meltwater and therefore below melting temperature already with mean annual air temperatures around −3 to −4°C. As a consequence, the firn of accumulation areas may be warmer than the ice of ablation areas – a characteristic feature of many glaciers such as those on Svalbard. Glaciers with ice which remains everywhere below melting temperature are “cold glaciers,” glaciers with all ice at melting temperature are “temperate glaciers,” and glaciers containing both, cold as well as temperate firn/ice, are named “polythermal glaciers.”

In combination, regimes of mean annual air temperature and precipitation cause pronounced differences in the characteristics of maritime and continental-type glaciers. Where precipitation is abundant (meters per year), large amounts of snow must be melted. Mean annual air temperature at the equilibrium line of such maritime-type glaciers is therefore close to 0°C, and glaciers are mostly temperate, have a large mass turnover, and flow under relatively high shear stresses rapidly down to regions with seasonal frost only and rich vegetation, often
Figure 4  Glaciers in the Central Karakoram National Park, Pakistan. The almost 50-km-long, heavily debris-covered valley glacier in the center is Hispar Glacier which terminates (arrow) less than 2 km up-valley of the village of Hispar Nagar with its irrigated fields (see also similar irrigated fields at the village of Shimshal). forests. In regions of low precipitation (tenths of a meter per year), much less snow must melt, and the equilibrium line on such continental-type glaciers is therefore at altitudes with low mean annual air temperatures (< −5°C); glaciers are polythermal to cold, have small mass turnover, flow under lower shear stresses at lower speeds, and often end far above timberline in areas of widespread permafrost.

Glaciers at high latitudes are exposed to strong seasonal variations of atmospheric temperatures, causing distinct parts of the year with accumulation/freezing in winter and ablation/thawing in summer. Most of them are cold to polythermal and far away from human infrastructure. Extensive areas with high-latitude glaciers are in the Canadian and Russian Arctic. For mid-latitude glaciers, daily and seasonal temperature variations are both strong. Where precipitation falls during the entire year, as in the European or New Zealand Alps, accumulation mainly takes place in the cold season and ablation in the warm season. Under Monsoon influence, as, for instance, in the Tian Shan or Sikkim Himalaya mountains of central Asia, dry conditions coincide with the cold season, and accumulation and ablation both take place during the warm/wet time of the year. Large maritime-type glaciers exist in
Patagonia and Canada, while the dry regions of Tibet and the dry Chilean Andes contain smaller continental-type glaciers. Many high mountains in central Asia have transitional climatic conditions. Daily temperature variations predominate for glaciers in the central and outer tropics such as those on Kilimanjaro or in the Peruvian Cordilleras. There, ablation takes place during the entire year but accumulation only in the wet season; the equilibrium line is close to the \(0^\circ\text{C}\) air temperature isotherm and glaciers are temperate with the exception of the highest peaks with cold hanging glaciers frozen to steep permafrost rock walls.

**Internationally coordinated glacier observation**

In contrast to continental ice sheets, the enormous masses of which are *drivers in the climate system*, and in contrast to snow, sea ice, and permafrost, which, via their influence on surface albedo, ocean circulation, or greenhouse gases, are involved in multiple and important *feedback processes within the climate system*, glaciers and seasonal ice on lakes and rivers with their limited areas and volumes are *passive indicators of climate change*. They both primarily reflect atmospheric temperature changes but are complementary in that lake and river ice mostly relate to winter and lowland conditions while glaciers are more closely connected to summer and high-altitude effects. Striking traces left in the landscape by former glaciers such as moraines, polished rocks, or erratic boulders had indeed paved the way in the nineteenth century to the detection of past ice ages and to a modern understanding of natural climate changes. It was a logical step then to start monitoring fluctuations of existing glaciers in order to better understand past and possible future developments.

Following the example of the Swiss glacier-monitoring network initiated in 1893, *internationally coordinated glacier monitoring* formally started in 1894 with the foundation of the Commission Internationale des Glaciers (International Glacier Commission) and has built up since then one of the longest global environmental observation series. The early establishment of a systematic program of data collection and free dissemination is exemplary despite intermittent crises in the evolution over time. Two main scientific goals envisaged at the beginning of long-term observations were (i) to find physical causes for the dramatic climate excursion of the just detected Ice Age and (ii) to document whether climate and glacier changes were caused by terrestrial or extraterrestrial influences. A first phase of the activity was, therefore, characterized by the search for periodical oscillations (solar cycle) in the reported glacier length changes (advance and retreat; Figure 5). The two world wars and the economic crisis between them strongly reduced the program in a second phase of the 1930s and 1940s with the result that the scientific literature hardly noticed the drastic retreat of glaciers during these years. In a third phase beginning with the late 1940s, systematic glacier mass balance observations were begun in Scandinavia and soon also in other countries (Figure 6). These field measurements with ablation stakes and snow pits to determine annual or even seasonal mass gain/loss calibrated by precision mapping repeated at about 10-year intervals now captured the central element in the process chain linking changes in atmospheric conditions with the mass balance, thickness change, flow dynamics, and, finally, the easily observed advance/retreat of glacier margins (Figure 7). A fourth phase, starting in the 1970s, saw the compilation of the first worldwide glacier inventory and the foundation of the World Glacier Monitoring Service.
Figure 5  Cumulative length change of glaciers between high northern latitudes (Svalbard) and mid-latitudes of the Southern Hemisphere (Argentina) compiled by Leclercq and Oerlemans (2012) using long series of observations (mostly WGMS data) and reconstructions from various authors and data sources. The glacier retreat tendency since the end of the Little Ice Age around the mid-nineteenth century is strong and global. Reproduced under the CC-BY-NC license.

(WGMS). The fifth phase is characterized by the integration of glaciers as an Essential Climate Variable (ECV) within the Global Terrestrial Network for Glaciers (GTN-G) as part of the Global Terrestrial Observing System/Global Climate Observing System (GTOS/GCOS) in support of the United Nations Framework Convention on Climate Change (UNFCCC). This most recent phase of internationally coordinated long-term glacier monitoring was characterized by a rapid development of new technologies, especially high-resolution satellite measurements and digital terrain information.

A tiered observing strategy helps with bridging the gap between detailed local measurements and global coverage. On a small number of sites (about 10), detailed measurements about climate, mass/energy balance, flow, length change, and
Figure 6  Annual (a) and cumulative (b) mass balance of glaciers. The average rate of mass loss, expressed as thickness change in water equivalent, accelerated from 0.2 m per year for 1980–1990 to 0.4 m per year for 1990–2000 and to 0.8 m per year for 2000–2010. Reproduced from World Glacier Monitoring Service (WGMS), www.wgms.ch/.
Figure 7 Sketch illustrating characteristic features of mountain glaciers and the process chain linking climate and glacier response. C = accumulation area covered with snow and firn, A = ablation area (bare ice), EL = equilibrium line, LIA = moraines from glacier advances during the Holocene and the Little Ice Age, O = bed overdeepening beneath a flat, crevasse-free part of the glacier with compressing flow and possible site of a future new lake forming with continued glacier retreat.

runoff are carried out for process understanding and for the development of numerical models. Mass balance measurements at somewhat more than 100 glaciers provide a reference time series, primarily for the Northern Hemisphere. The question of how representative these measurements are at regional scales can be analyzed using length change measurements (especially concerning the past) and differences between digital terrain elevation models covering different times (especially for recent decades and the future). Glacier inventories repeated at time intervals of years to a few decades then enable coverage and change assessments at global scale.

Latest gravimetric and laser altimetry technologies such as the Gravity Recovery and Climate Experiment (GRACE) or the Ice, Cloud, and land Elevation Satellite (ICESat) make it possible to detect significant mass changes of great numbers of glaciers over time periods as short as a few years (Figure 8; Gardner et al. 2013). Automated image processing and glacier parameterization have the potential to provide millions of mass and length change data, requiring new formats for dimensions of data far beyond past requirements. However, long time series of mass balance have been carried out on logistically treatable small glaciers, which are shrinking or even disintegrating, may completely disappear within coming decades, and must be replaced in time by larger glaciers with a longer potential lifetime. Most glaciers are far out of equilibrium, and their length and area now reflect climatic conditions of the past decades.
Figure 8  Regional glacier mass budgets and areas 2003–2009 from satellite gravimetry and altimetry and from local glaciological records. Red circles show 2003–2009 regional glacier mass budgets, and pale blue/green circles show regional glacier areas with tidewater basin fractions (the extent of ice flowing to termini in the ocean) in blue shading. Peach-colored halos surrounding red circles show the 95% confidence intervals in mass change estimates, but can only be seen in regions that have large uncertainties. From Gardner et al. (2013). Reprinted by permission of AAAS.

rather than the present (Mernild et al. 2013). Besides such decoupling in time of glacier length change from changing atmospheric conditions, increasing debris cover, downwasting rather than retreat, lake formation, disintegration, and even collapse phenomena make definitions of ice margins difficult. The GTN-G not only combines field measurements (mainly WGMS), satellite observations (the Global Land Ice Measurement from Space (GLIMS) initiative), and data processing/management (the National Snow and Ice Data Center (NSIDC), Boulder, Colorado), but also continuously keeps scientific reflection with experts alive to deal with such challenges.

A future world without glaciers?

Since the beginning of coordinated worldwide observations at the end of the nineteenth century, strong overall glacier retreat and mass loss have been documented, providing strong evidence that climate change takes place at a rapid rate and at a global scale. The reduction in glacier length still remains key information concerning past developments. With few regional exceptions (Kääb et al. 2012), and despite small readvances around 1920 and 1960/70, glaciers worldwide retreated from extended positions reached during the Little Ice Age, which in many regions had come to an end around the middle of the nineteenth century (Figure 5). Rising
global temperatures are certainly the primary cause of this evolution. Accelerated warming and melting since about 1980 are reflected in the growing rates of glacier mass losses beyond historical precedents (Figure 6; Zemp et al. 2015). Glaciers in many mountain ranges may now be as small as, if not smaller than, during the warmest periods of the Holocene – the warm/high-energy limit of preindustrial climate variability since the end of the last ice age appears to have been reached or already passed.

Analysis by WGMS of glacier fluctuations and inventory data with a view to possible future glacier changes already in the 1990s showed that entire mountain ranges like the European Alps may lose most of their glacier volumes even in the case of moderate scenarios of global warming. More sophisticated approaches (Zemp et al. 2006 and various later studies) confirmed this and provided more detailed assessments. While some of the highest mountain peaks may keep their ice cover well into the future, many glaciers, especially the large, flat, and thick valley glaciers with their low-elevation beds, will disappear. With them, the largest glacier areas and volumes, and, hence, the most important ice storage part in the water cycle, are likely to vanish over the coming decades. Besides problems with the parameterization of surface effects (mass balance) and flow (deformation and sliding) of glaciers, uncertainties of corresponding numerical model simulations primarily relate to: (i) different possible climate scenarios, (ii) the still existing ice volumes, (iii) the evolution of the albedo under the influence of dust input, (iv) lake formation, and (v) a number of other minor effects. The results from simple as well as complex model calculations are nevertheless robust and show that presently existing glacier landscapes will rapidly turn into new landscapes of rocks, debris, sparse vegetation, and numerous lakes. The new lakes forming in characteristic overdendments of glacier beds (Cook and Swift 2012) are of special interest in view of their hazard potential but also for hydropower production, water supplies, and tourist attractions. A large number of lakes have indeed already formed and some of them have caused outbursts with severe damage to humans and infrastructure (Carey et al. 2012).

Fundamental changes have taken place in our perception of glaciers and their changes. Concern is growing that the ongoing trend of worldwide and fast, if not accelerating, glacier shrinkage at the century timescale is of noncyclic nature – clearly different from the originally envisaged periodical oscillations. Under the growing influence of human impacts on the climate system (enhanced greenhouse effect), dramatic scenarios of future developments – including complete deglaciation of entire mountain ranges – must be taken into consideration. A broad and worldwide public today recognizes glacier changes as a key indication of regional and global climate and environment change. Observational strategies established by expert groups within international monitoring programs build on advanced process understanding and include extreme perspectives. These strategies make use of the fast development of new technologies and relate them to traditional approaches in order to apply integrated, multilevel concepts (in situ measurements to remote sensing, local-process oriented to regional and global coverage), within which individual observational components (length, area, volume/mass change) fit together, enabling comprehensive views. Such comprehensive views are especially important with respect to future developments, which may lead far beyond the range of historical/Holocene variability and most likely introduce processes (extent and rate of glacier vanishing, distance to equilibrium conditions) without precedent in the Holocene.
Assessing the impacts of vanishing glaciers and preparing adaptation/mitigation strategies constitute increasingly urgent tasks in view of a world in which little remains of those glaciers that still exist.

Global cities

John Rennie Short
University of Maryland, Baltimore County, USA

In 1915 the Scottish polymath Patrick Geddes noted that much of the world's business is conducted in what he termed “world cities.” Rather than countries or regions, it was cities, he implied, that were the connecting points of a globalizing economy. His remarks did not inaugurate a body of work and the idea languished, to be resuscitated only in the 1960s by Peter Hall. He used the term “world cities” to describe London, Paris, Randstad, Rhine-Ruhr, Moscow, New York, and Tokyo (Hall 1966).

The idea of Geddes and Hall did not immediately become the basis for scholarly research because economic geography was concerned with regional complexes and national economies. The main emphasis of urban geography was on urban hierarchies at the regional and national level or on studies of individual cities. The connection between the global economy and the city was not made until the 1980s when the idea of globalization came to the fore. The terms “world cities” and “global cities” were used interchangeably although, more recently, the latter designation is more commonly employed. These were identified as cities that were important hubs in a global urban network and important command centers for the organization and management of a globalizing economy.

It was Friedmann and Wolff (1982) who first connected patterns of urbanization to the internationalization of capital. They identified a global urban hierarchy with world cities at the apex, characterizing them as the control centers of the global economy with a concentration of producer services, housing a highly mobile, transnational elite, and the sites of massive economic, social, and physical reorganization. They identified the following as world cities: Tokyo, Los Angeles, San Francisco, New York, London, Paris, Randstad, Frankfurt, Zurich, Cairo, Bangkok, Singapore, Hong Kong, Mexico City, and São Paulo. These world cities were asserted rather than demonstrated. In a later paper, Friedmann (1986) identified Tokyo, Los Angeles, Chicago, New York, London, Paris, Zurich, Rotterdam, Zurich, and São Paulo as the first-order centers of a global urban hierarchy, a similar but not identical list to their previous one. The authors drew attention to the global city as command center and to the global network of cities, but their loose definition of these cities, based on simple assertion rather than careful documentation, became a hallmark of many subsequent studies in what has been termed the “dirty little secret” of early global cities research.

Global urban networks

Waves of globalization are often associated with the creation of global urban networks. Merchant trading cities were nodes in an emerging global trade. We have a visual record of this network in the compilations of city maps and prospects in the first city atlas, Civitates Orbis Terrarum, by Georg Braun and Frans Hogenberg. One volume was published in 1572 but it became so popular that by 1617 the work consisted of six volumes with over 363 urban views. Collectively, the images indicate the increasingly global reach.
of mercantile capitalism and European colonization, forging a world economy in such urban centers as Aden, Peking, Cuzco, Goa, Mombasa, and Tangiers, as well as many other cities around the world. While the cities in the Civitates are depicted separately, the effect of the compilation is to reveal a global economy of urban nodes and a trading world of connected cities.

Today we can identify a global urban network connected by flows of goods, people, capital, and ideas. Some of the flows have been identified and measured. A substantial body of material has emerged from the work of Peter Taylor and his colleagues at the Globalization and World Cities (GaWC) research network. The website (http://www.lboro.ac.uk/gawc/) lists data sets as well as more than 450 research papers and is an indispensable guide to the metageography of urban networks. In 2000, they collected data on the distribution of 100 global advanced producer service firms, which includes accountancy, advertising, banking/finance, insurance, law, and management consultancy, across 315 cities. They analyzed the resultant data matrix to identify a global urban hierarchy. In 2012, they extended the analysis to 176 firms in 525 cities. The result was a fivefold hierarchy that identified cities as Alpha, Beta, Gamma, High sufficiency, and Sufficiency. New York (NY) and London (LON) dominate with a classification of Alpha ++ (Table 1). NYLON is an important pivot in the global networks, and its dominance reflects the historical legacy of London as the center of British Empire and the continuing importance of New York as the financial center of America’s more informal empire. Their data also hint at the rapid rise of new cities into the top tier as national economies make their way from periphery to core. In 2000, Shanghai was in the Alpha − category while Beijing was only a Beta city. In 2012, both Shanghai and Beijing were classified as Alpha +, only one step below NYLON. Both cities are moving into the top tier as China’s economic growth, both absolute and relative to the rest of the world, continues apace.

While the aggregate analyses are immensely useful, they also have their biases. The cities of the Global North tend to be privileged sites for investigation. Intensive fieldwork in less privileged cities reveals a different story, as in the detailed case study of Accra by Richard Grant (2009). As the capital of the West African nation of Ghana, Accra does not figure highly in the standard measures of globalization. On the GaWC classification it is listed Gamma −, well down the list. At first blush then, just another city in remote Africa, largely cut off from global flows. Grant presents a very different picture. Foreign companies now play an important role in the urban economy, constituting one third of all firms. The urban form itself was transformed. A new foreign-orientated central business district was established close to the airport. The city’s economy is fueled by remittances from Ghanaians abroad. Returning home, these repatriates often play key roles in transnational operations and flows. But even those stuck in the city also have global connections. Grant shows that shantytown dwellers are also connected to transnational nongovernmental organizations.

working with them to frame their demands and need. This detailed case study reveals the pervasive and multiple connections with the global space of flows of people, money, discourses, practices, and ideas. Accra is revealed as a networked city with globalization being imposed as well as embraced, transforming from above as well as changing from below. No African cities make the top tier of GaWC cities and yet, as the Grant study shows, Accra is a globalizing city firmly connected to global flows.

Lisa Benton-Short and colleagues also sought to identify a global network, but their work was based on flows of people. They looked at immigration into cities around the world and established an index based on the percentage of foreign-born, the total number of foreign-born, the percentage of foreign-born not from a neighboring country, and the diversity of immigrant home. The result was a threefold division into Alpha, Beta, and Gamma cities. The Alpha immigrant cities are New York, Toronto, Dubai, Los Angeles, London, Sydney, Miami, Melbourne, Amsterdam, and Vancouver. The Beta-ranked cities include Riyadh, Geneva, Paris, Tel Aviv, Montreal, Washington, DC, The Hague, Kiev, San Francisco, and Perth in Australia. They identify established gateway cities, unrecognized gateway cities, accidental gateway cities, and bypassed gateway cities. Examples of different types are listed in Table 2. Unrecognized gateways are particular strong in the former Eastern Bloc, and bypassed gateways, globalized cities with relatively low levels of foreign immigration, are common in Asian cities. There are similarities and differences between the GaWC and the Benton-Short et al. results. Confining comments to the top level and looking first at similarities, some cities appear in the same category in both analyses. New York and London are Alpha cities and sit atop the apex of both hierarchies. Other Alpha cities in both studies include Toronto, Los Angeles, Sydney, and Amsterdam. Looking at differences, while Miami, Melbourne, Vancouver, and Dubai are considered pivotal points of global migration reaching Alpha status, in the advanced producer service category they only make it to Beta status.

Some of the differences relate to issues of data and data availability, but they also refer to the nature of the global urban network. Networks vary according to the flow. Some flows “pool” in some cities rather than others. The flow of people, while matching the connections in command functions, also has slight differences. National regulations concerning immigration, the demand for labor, and the relative openness of societies to foreign migrants all play a part. The sheer need for labor, whether the global talent pool of specialized knowledge experts or cheap unskilled labor, varies throughout the urban network. The result is a similar but not
There is no one fixed global urban hierarchy but more of a “space of transformative flows.” Money, people, ideas, goods, and practices do not just flow through the global urban network; they are transformed in the process. Consider flows of people. The movement through the urban network is not a simple geographical movement; it involves cultural exchanges. These can refer to the new work habits and job practices of the temporary worker as well as the complex cultural transformations of long-term migrants as they adapt to new milieu and in turn transform their surroundings. Rather than mere transfers, flows along the urban networks are transformative experiences, even in the flows of inanimate things such as money, goods, and services. A small amount of money in London or New York when remitted back to Ghana or El Salvador can become the source for land and house purchase, enabling a new business, or paying for better schooling. Flows through the global urban network change the medium and the networks; as people adapt, ideas are tweaked, practices mutate, money is reimagined, and commodities are reappropriated.

To show the complexity of global city networks we can consider briefly three other types of flows. First, there is the general movement of knowledges and expertise. Contemporary urban polices such as neoliberalism, for example, move quickly as they are transferred around the cities of the world, recreated as they move, adapting to and undermining national and local practices. Urban policies are shaped and shifted as they travel and mutate through the global urban network of policy adoption and adoptions. Second, there is the burgeoning interurban circuit of contemporary art, comprising transnational biennial exhibitions and art fairs. Cities barely recognized as major urban, much less art, centers a decade ago – Luanda, Sharjha, Guangzhou, for example – ring increasingly familiar as sites of contemporary art display and debate (and art-making), gaining degrees of cosmopolitanism in the process. Now major exhibitions of contemporary art (biennials and triennials geometrically increase every year) similarly function as dazzling vehicles for global aspirations. Third, there is the franchising of culture and education through the global urban network. The Guggenheim Museum now has “branch” museums in Abu Dhabi, Bilbao, and Venice. Higher education institutes are selling their name and creating linkages and feeder institutions across the globe. Yale has established a branch campus in Singapore while New York University (NYU) has perhaps the most ambitious global presence with degree-granting institutions such as NYU Shanghai and NYU Abu Dhabi and centers in Accra, Berlin, Buenos Aires, Florence, London, Madrid, Paris, Prague, Sydney, and Tel Aviv. The liberal values of a traditional US university have to be tweaked to operate in such places as Abu Dhabi, Shanghai, and Singapore. Ideas and practices mutate rather than simply diffuse through the global urban networks.

While most studies concentrate on identifying the central hubs of global urban networks, a few have begun to consider the idea of black holes and loose connections in the global urban network. One study, by Short (2004), identified black holes, 11 cities which met three criteria: they had a population of over 3 million, were not identified by GaWC as a world city, and did not share their national territory with a world city (Table 3). They ranged from Tehran, with a population of 10.7 million, to Chittagong, with a population of 3.1 million. There are a number of reasons behind these very large cities’ non-world city status. Some cities, despite their size, are so poor that they do not represent a market for advanced producer services. They are the
black holes of advanced global capitalism, with many people but not enough affluent consumers or complex industries to support sophisticated producer services. There are not only cases of endemic poverty, but also cases of catastrophic decline where there has been an almost complete collapse of civil society. In recent years, Khartoum and Kinshasa, for example, have witnessed the decline of the rule of law and descent into social anarchy. War and social unrest have been the norm rather than the exception. Sustained social disruption reinforces the global disconnect. Cities are bypassed as forms of risk aversion by capital investors. The perception of risk can be self-fulfilling. High risk puts corporations off from establishing connections, which in turn increases the risk rating.

Command centers

Global cities are centers for coordination and control, sites of production of specialized services, especially producer services such as accountancy, financial services, and consultancies. A central reason for the concentration of command functions in selected global cities is the need for social interaction in global financial business deals. Trust, contact networks, and social relations play pivotal roles in the smooth functioning of global business. Spatial propinquity allows these relations to be easily maintained, lubricated, and sustained. Global cities are the sites of dense networks of interpersonal contact and centers of the important business/social capital vital to the successful operation of international finance. Global service corporations are adept at producing their own commodities, including new financial products, new advertising packages, and new forms of multijurisdictional law. All of these depend upon specialized knowledge. The coalescence of a range of expertise produces state-of-the-art commodities to meet the specific needs of clients. In order to be able to put together such packages, firms need to be in knowledge-rich environments. Face-to-face contacts between experts are facilitated by the clustering of knowledge-rich individuals in cities like New York and London. Cities at the apex of this particular network are “privileged sites” housing the “knowledge elite” that enact the economic reflexivity crucial for economic success. Reflexivity and networking are at the heart of understanding global cities as places where people, institutions, and epistemic communities work to establish and maintain contacts. More importantly, these communities act as crucial mediators and translators of the flows of knowledge, capital, people, and goods that circulate in the world.

The globalizing economy creates lots of information, narrative uncertainty, and economic risk that must be produced, managed, narrated, explained, and acted upon. Global cities are epistemic communities of surveillance, knowledge production, and storytelling. Studies of cities as

economic command centers identify a number of key characteristics: they have articulated infrastructures of market trading involving an agglomeration of demand and supply, an environment of innovation, business support services, pools of highly skilled labor, a proximity of business organizations allowing information to be generated, analyzed, and disseminated, and deals to be struck, all set within shared cultures of expertise and of contacts set within an even broader context of a disciplined market, multicurrency trading, and a responsive central bank and governmental system of economic regulation.

Global cities operate as major nodes of reflexivity in global networks through the migration of business elites. As the contemporary international service economy requires specialist professionals to be globally mobile to deliver intelligence, skills, and knowledge to the point of demand, the development of a cross-border transnational migrant elite contributes to the production and consumption of the global city. In the world of high finance and international corporate law it is essential for international companies providing these services to maintain a tailored personal relationship, built on mutual trust, with clients around the world. And this requires global firms to maintain offices in cities around the world staffed with highly skilled professionals. These elite workers move through the distribution of corporate offices to pass on the corporate culture, to gain knowledge of local markets and work with specific clients; their career paths trace routeways through the global urban hierarchy.

A large proportion of command functions are still concentrated in just a few cities, but rather than a model of competition between global cities for global dominance, it is more accurate to consider a network of global cities with economic control concentrated in only a few cities but with the operation of this power dispersed in the second and third tiers of the global city hierarchy through branch plants and back offices. The global urban hierarchy is a network of flows that transmits global command functions across the world.

**Polarization**

Increasing social and spatial polarization is a feature of the large global city. Chris Paris (2013) describes the process of decoupling where the housing markets of global cities, because they attract the rich and superrich, are more linked to prime real estate neighborhoods in other global cities than to the national housing market. The result is a decoupling of housing prices from national markets effect. Lower-income households are squeezed out by rising house prices and gentrification is common. Rising inequality is a by-product of a globalizing city. Social and spatial polarization is not accidental but integral to the making of the global city as they house both the super-rich and the wealthy elites, as well as the marginal and the poor.

**Becoming a global city**

One important feature of global city research has been the search for global cityness. Many studies have been devoted to identifying whether this or that city is a global city. While the work is interesting up to a point, it tends to focus on a narrow range of cities at the top end of the urban hierarchy. This focus tends to ignore how globalization is acting in and through all cities. A more useful term is “globalizing city” to refer to the fact that almost all cities can act as a gateway for the transmission of economic, political, and cultural globalization.

The focus on globalizing city as opposed to global city shifts the attention away from the
question of which cities dominate the global urban network to show all cities in the network are affected by globalization. It also focuses attention on the making of global cities and the promotion of global city status.

Global city status requires the attributes of a global city. Such prerequisites include an international airport, signature buildings of big name architects, impressive buildings (the most recently constructed tallest buildings in the world are in Kuala Lumpur, Shanghai, Hong Kong, and Taipei), and cultural complexes such as art spaces and symphony halls. Combining these elements is always a useful strategy: hiring a famous architect to design a cultural complex, as in James Stirling’s Neue Staatsgalerie in Stuttgart, Isozaki’s Museum of Contemporary Art in Los Angeles, Pei’s glass pyramid in front of the Louvre in Paris, or, one of the oldest yet still impressive, Jorn Utzon’s Opera House in Sydney. The construction of these complexes involves urban redevelopment schemes through which local developers, landowners, and politicians amass substantial fortunes. Chang, Huang, and Savage (2004) consider the case of Singapore’s attempts to create urban landscapes that project the city-state’s global aspirations. The Singapore River Development Zone Project is intended to project global city status and successfully connect with global flows of capital movement and tourist flows. Both global and local forces are at work and the nature of the development is a negotiated outcome between the perceived need to make global connections with local empowerment and community rights all mediated through debates about national identity.

The city of Shanghai, for example, has embarked on an ambitious goal of projecting global city status. Since the early 1990s, improvements have been made to the physical infrastructure, including the building of a shiny new downtown of high-rise towers and the construction of a new international airport, land-use planning measures have been introduced to encourage the dispersal of industry from central sites and the development of mixed commercial and residential use of prime land, and organizational streamlining has been inaugurated to improve urban management. The project is to make a global city that sits alongside New York, London, and Tokyo. A self-consciously global city is being created and represented.

An important part of seeking and maintaining global city status is the hosting of global events such as the Olympics, World Cup, or other high-profile event that involves an opportunity not only to remake the city as a global city but to represent it as a global city. Hosting these events is not just an opportunity to be the site of a global spectacle, and hence to receive international name recognition, but also an opportunity for business and real estate deals, acting as giant urban redevelopment projects. Hosting the Summer Olympics, for example, involves a massive urban transformation including the provision of venues and major infrastructural investment. And it allows urban makeovers designed to create a modern global city defined in terms of a firmer insertion into international circuits of capital flows and the construction of modern urban forms. Hosting the Games provides an opportunity for city reimaginings as well as remakings. The changes often come with increased costs for city residents unless there is a specific commitment to redistributional outcomes.

The globalizing project varies in detail by individual city but overall there are recurring features across the world, including the reimagining of the city, the rewriting of the city for both internal and external audiences, the construction of new spaces, and the hosting of new events. A cosmopolitan lifestyle is also promoted as part of the project, complete with settings and performance that synergize the four c’s of culture,
GLOBAL CITIES

consumption, cool, and cosmopolitan. The globalizing project also involves a spatial reorientation of the city, the spectacularization of settings, the creation of specifically global sites, and the encouragement of transnational locations.

Global imagineering

In a globalizing world, the marketing of a city as a global city is now an important strategy. Because of the growing competition, there is a constant need to upgrade and improve a city’s image. From 1997 to 2007, Hong Kong was specifically marketed as “Asia’s World City,” a response in part to growing competition from Shanghai. Darel Paul (2004, 2005) explores the politics of “global imagineering” in Montreal, Canada, where business interests triumphed and Minneapolis–St Paul, USA, where similar interests were trumped by populist politics. In St Petersburg, Russia, not only was the old Soviet name of Leningrad dropped, but the city was actively promoted as an international hub of circulatory capital, host to corporate power, and stage for globalist megaprojects. St Petersburg was rebranded as an entrepreneurial, economically competitive, globally connected city (Golubchikov 2010). Kim and Short (2008) note that the rhetoric of global city branding is often associated with attempts to justify controversial and costly urban redevelopment projects, to justify tax incentives and business-friendly economic policies, and to heighten multiculturalism and cosmopolitanism in the city.

Cosmopolitan global cities

Global cities tend to have more foreign-born than their national territory. Table 4 lists the number of foreign-born in selected cities from the Benton et al. study that highlights the reliance of Arab cities on foreign labor, the lack of foreign-born in Asian cities, and the important immigration role of Canadian cities. The cozy and reassuring notion that immigration leads to greater cosmopolitanism, for example, is undermined by the experience of many cities in the Middle East where very high rates of immigration into cities are marked sometimes by cultural xenophobia and religious fundamentalism (not cosmopolitanism). There is no one-to-one relationship between foreign-born in the city and the cosmopolitanism of the city, and the disparity is especially marked even in cities such as Singapore where there are high levels of foreign-born female domestic workers.

Global cities with large numbers of foreign-born are hubs of diasporic convergence held together by shared identity but separated by thousands of miles. These new diasporic communities can enrich and enliven global city cultures. Some global cities are emerging as both points of cosmopolitanism where new hybrid identities and cultures are emerging and

as places of resistant local diasporic identities. These diasporic communities are also conduits of foreign trade as family connections merge into business connections, and small import/export companies arise from family and ethnic ties. Foreign trade is not just between giant multinational corporations; it also takes the form of smaller-scale linkages between communities. Immigrants play a key role in the economic development of the city in circulating money from rich to poor places and in identifying possibilities for international trade and exchange.

Global climate change

David F. Porinchu
University of Georgia, USA

Global climate change, which is driven by human activity and natural variability, refers to the change in the mean state and/or variability of the climate system at decadal timescales and includes changes in temperature, precipitation, and atmospheric circulation patterns (IPCC 2013). Observations of recent global-scale changes in the climate system can be placed into a broader temporal context through comparison with the geologic record, which in turn can provide insight into sensitivity of the climate system to various natural and anthropogenic forcings and serve to provide baselines against which projections of future climates can be compared. Knowledge of global climate change requires consideration and associated impacts. Documenting the causes and consequences of global climate change requires knowledge of the spatial and temporal patterns and the biophysical processes responsible for driving past, present, and potential future climate change and climate change-related impacts.

Observed changes in the global climate system

Global-scale observations of the climate system, based on instrumental records and remote sensing, provide detailed records of changes in the climate system that extend from the mid-nineteenth century to the present. These direct measurements document the response of the atmosphere, oceans, sea level, cryosphere, and land surface to recent climate change at seasonal, annual, and decadal timescales. The observed globally averaged combined land surface and ocean surface temperature anomaly for the interval between 1880 CE and 2012 is 0.85 °C, with nearly the entire surface of the Earth experiencing warming during the twentieth and early twenty-first centuries. Fourteen of the fifteen warmest years on record have occurred during the twenty-first century (see Figure 1), with a strong likelihood that 2014 is the warmest year since 1880 CE. In addition, the diurnal temperature range (defined as the difference between daily maximum and daily minimum temperatures) has decreased during the latter half of the twentieth century and the incidence of extreme weather events (heatwaves, heavy precipitation, droughts) has increased for the majority of Earth’s surface during recent decades. Approximately 60% of the net energy increase in the climate system between 1971 and 2010 CE has been stored in the upper 700 m of the ocean, resulting in the temperature of the upper 75 m of ocean increasing at a rate of 0.11 °C/decade during this interval. Ice sheets, alpine glaciers, and sea ice have experienced notable reductions in extent and/or volume since the 1970s. The average rate of ice loss from Greenland and Antarctic ice sheets has increased from 34 to 215 gigatons (Gt) year⁻¹ and from 30 to 147 Gt year⁻¹, respectively, between 1992 and 2001 CE and 2002 and 2011 CE. The extent of the summer sea ice minimum in the Arctic Ocean decreased at a rate of between 9.4% and 13.6% per decade between 1979 and 2012 CE. Satellite, tide gauge, and documentary data
Figure 1 The annual trend in average global air temperature through December 2013. For each year, the red vertical bars indicate the range of uncertainty. The blue line tracks the changes in the trend over time (NOAA 2014).

indicate that the mean rate of globally average sea level rise was 1.7 mm year\(^{-1}\) between 1901 and 2010 CE. The rate of sea level rise has been increasing in recent decades, with the rate nearly doubling to 3.2 mm year\(^{-1}\) between 1993 and 2010 CE. The observed rise in sea level is largely attributable to glacier mass loss and the thermal expansion of ocean water. Other components of the Earth’s biophysical environment that have been influenced by global climate change include river discharge, permafrost temperature, and biogeochemical cycles. Some of these changes have the potential to further amplify warming. For example, elevated temperatures in high northern latitudes have accelerated rates of thaw and aerobic and anaerobic decomposition in permafrost, facilitating the increased release of carbon dioxide and methane, which in turn acts to further augment radiative forcing (RF) (Hodgkins et al. 2014). It is important to note that methane is approximately 20 times more potent than CO\(_2\) in terms of radiative forcing over a 100-year period, and therefore has the potential to greatly accelerate warming.

Drivers and attribution of recent climate change

Changes in the concentrations of greenhouse gases, aerosols, land cover, and solar radiation influence the Earth’s energy balance and are considered to be the major drivers of observed climate change. Total anthropogenic radiative forcing in 2011 CE is 2.29 W m\(^{-2}\) relative to preindustrial (1750 CE) conditions. Currently, the most significant driver of recent climate change, in terms of radiative forcing, is the increase in the concentration of greenhouse gases, the most important of which is carbon dioxide (CO\(_2\)). The concentration of CO\(_2\), which at the end of 2014 CE stood at 396 parts per million (ppm),
is approximately 40% greater than its preindustrial concentration of 280 ppm. The current concentrations of the other major greenhouse gases, methane (CH₄) and nitrous oxide (N₂O), are 1893 parts per billion (ppb) and 326 ppb, and 150% and 20% greater than preindustrial levels, respectively. The well-mixed greenhouse gases (CO₂, CH₄, N₂O, and halocarbons) are responsible for an increase in radiative forcing of 2.83 W m⁻² relative to 1750 CE (see Figure 2). It is important to note that ice core records indicate that the current concentrations of CO₂, CH₄, and N₂O are higher than at any time during the last 800,000 years, and exceed natural variability. The rate of increase in these greenhouse gases in recent decades is unmatched in the last 22 ka (IPCC 2013). An increase in planetary albedo, due to altered land use, increased emission of aerosols, and aerosol–cloud interactions, which act to counteract the influence of greenhouse gases on global mean radiative forcing, have limited the rate and magnitude of recent
GLOBAL CLIMATE CHANGE

warming. Attribution studies have identified that anthropogenic activities are responsible for more than 50% of the observed increase in global mean surface temperature and have substantially contributed to the observed increase in global mean sea level, ocean acidification, and a reduction in Arctic sea-ice extent since the 1970s.

Past climates: placing recent climate change in context

The instrumental record (<150 years) is too short to adequately document the full range of climatic behavior and variability. Extending the observed record further back in time through the use of natural archives such as ice cores, marine and lake sediments, corals, tree rings, speleothems, and glacial deposits places observed changes in the global climate system during the twentieth and twenty-first centuries into a broader temporal context and provides evidence of longer-term climate change and variability at centennial to millennial scales. In doing so, the paleoclimate record enables an assessment of how unusual the rate of recent warming is. For example, analyses of multiple proxies extracted from marine sediment and ice core records indicate that the past 2.6 million years of Earth’s climate history have been characterized by repeated cycles of glacial advance and retreat. These cycles, which are driven by changes in Earth’s orbital elements, result in the spread of continental ice sheets in the Northern Hemisphere, the expansion of alpine glaciers and sea ice globally, and significant changes in sea level. During the Last Glacial Maximum (LGM), which occurred at 21 ka BP, global sea level and mean temperature were approximately 120 m and 4 °C lower than at present, respectively. The geologic record can also be used to document rates of change associated with past climate change events. For example, the Paleocene–Eocene Thermal Maximum (PETM) involved an initial increase in global temperature of 5 °C that occurred over approximately 10,000 years (Diffenbaugh and Field 2013); this rate of warming is 1–2 orders of magnitude slower than the rate of warming projected to occur this coming century. Rates of change associated with the most recent glacial–interglacial transition, the Medieval Climate Anomaly and the Little Ice Age are all lower than the current and projected rates of change. Increasingly, climate scientists are concerned about the potential of abrupt climate change, which occurs when the climate system crosses a threshold or “tipping point,” and responds in a nonlinear fashion at rates that exceed the initial forcing (NRC 2013). Importantly, the paleoclimate record documents the existence of abrupt changes in global climate during the most recent glacial–interglacial transition. These events, the largest of which is the Younger Dryas, a millennial-length cold period that resulted from an abrupt change in Atlantic Meridional Overturning Circulation, led to a return to near-glacial conditions between 12.9 ka and 11.6 ka through much of the high latitudes of the Northern Hemisphere. Proxy–based paleoclimate data can also be used to test and verify the output of coupled ocean–atmosphere global climate models, simulating the response of the climate system to large changes in boundary conditions and forcings. Proxy and model-based studies documenting the expression of these abrupt climate change events provide valuable insight into the response of ocean and atmospheric circulation to climate forcing, and the resulting impacts of these changes on the structure, function, and composition of terrestrial and aquatic ecosystems. Other areas of concern related to abrupt change include the behavior of the ocean (acidification, oxygen concentration); atmospheric circulation (El Niño Southern
GLOBAL CLIMATE CHANGE

Impacts of climate change are widespread and include changes in the biophysical environment, phenology, species distribution and abundance, habitat availability, agricultural productivity, and the spread of infectious disease. Reductions in the volume and extent of alpine glaciers have influenced downstream freshwater availability, especially in mid- and low latitude regions, where the need for fresh water is increasing. Populations in mid- and low latitude regions are highly dependent on glacier meltwater for consumption, irrigation, and hydropower generation during the dry season, and as a result are susceptible to global climate change induced alterations of mountain hydroclimate. Earlier snowmelt also leads to reduced late summer stream flow, which negatively affects aquatic ecosystems, lowers the groundwater tables, and lengthens the fire season. However, it is important to recognize that the societal impacts associated with climate change are expressed differentially due to the varying exposure and vulnerabilities of populations to climatic and nonclimatic factors. For example, multidimensional inequalities in socioeconomic status and income, resulting from uneven development, influence the magnitude, risk, exposure, and vulnerability of various groups to current and future climate change (Richardson, Steffen, and Liverman 2011). The increase in the atmospheric concentration of CO₂ has resulted in ocean acidification. The decrease of ocean surface water pH of 0.1, which has occurred since the Industrial Revolution, negatively influences calcifying marine organisms. Changes in phenology, or the timing of life-history events, have been attributed to recent climate change. For example, in response to elevated temperatures, the growing season has lengthened by approximately two weeks in the mid- to high northern latitudes during the late twentieth and early twenty-first centuries. A lengthening of the growing season can influence trophic relations and result in trophic mismatches, such as the timing of migration, breeding, and/or food availability. Shifts in regional climate and the varying velocity of these climate shifts can also influence biotic interactions, species distribution, and community structure through competitive displacement, increased predation, or altered predator–prey relationships (Blois et al. 2013). Global climate change also influences the provision of ecosystem services (Nelson et al. 2013), with the provision, timing, and location of ecosystem services such as nutrient cycling, wildfire regulation, fisheries productivity, coastal flood protection, and water supply altered both negatively and positively by global climate change. Agriculture will be heavily affected by global climate change, with crop growth and quality, livestock health, and pests all potentially influenced by changing climate (temperature and precipitation) and extreme weather events, which in turn may threaten global food security. For example, increases in growing season temperatures may lead to decreases in crop and livestock production and yields through increasing pressures from pests, weeds, and pathogens. Changes in precipitation patterns may lead to periodic crop failures and contribute to long-lasting declines in crop yields, requiring shifts in the crops and livestock raised in particular regions (Thornton et al. 2014). Changes in climate and the resultant shifts in ecological conditions may facilitate the spread
of pathogens, parasites, and food-, water-, and animal-borne diseases. For example, the spread of vector-borne infectious disease as a result of the direct and indirect effects of climate change is an area of increasing concern. As temperature increases, the latitudinal and elevational range of the vectors responsible for transmitting malaria (Anopheles mosquito) and Dengue fever (Aedes aegypti mosquito) will expand and increase the human population exposed to the parasites responsible for these diseases. It is also expected that the incidence of waterborne infections, such as cholera, that result in diarrheal distress will increase as untreated runoff and/or sewage, associated with extreme precipitation events, enters the water supply (Altizer et al. 2013).

Projections of future climate

Coupled ocean–atmosphere global climate models are used to simulate the Earth’s climate system, investigate the sensitivity of the climate system to various forcings, and project changes in temperature and precipitation regimes in the future under various scenarios. The scenarios used to guide the climate models that form the basis for the global and regional climate projections presented in the most recent Intergovernmental Panel on Climate Change assessment report (IPCC 2013) are referred to as representative concentration pathways (RCPs). The four RCPs (RCP2.6, RCP4.5, RCP6.0, and RCP8.5) which reflect the radiative forcings (in W/m²) associated with four potential greenhouse gas concentration trajectories consistent with physical, demographic, and socioeconomic constraints, describe four possible climate futures. The RCP2.6 scenario characterizes a climate future in which strong reductions in greenhouse gas emissions occur and radiative forcing peaks in the mid-twenty-first century and declines by 2100 CE. The RCP8.5 scenario, which is most similar to the trajectory we are currently following, characterizes a climate future where greenhouse gas emissions continue to increase throughout the twenty-first century. It is important to note that the choice of RCP scenario greatly influences the magnitude of the projected changes in global temperature as early as the middle of the twenty-first century. By the end of the twenty-first century, global mean surface temperatures are projected to exceed 1.5 ºC relative to the 1850–1900 CE mean global surface temperature for all RCP scenarios except RCP2.6. Under all scenarios high latitude and high elevation regions are expected to warm at a considerably faster rate than low latitude regions (see Figure 3). For example, the RCP8.5 climate model simulations indicate that the warming experienced at high northern latitudes will exceed 4 ºC relative to the 1985–2005 CE midway through the twenty-first century, and that the warming in these same regions will exceed 6 ºC by 2100 CE (Diffenbaugh and Field 2013). Precipitation patterns are expected to show greater spatial variability relative to temperature, with the contrast between wet and dry regions and wet and dry seasons increasing during the twenty-first century. Ocean circulation and acidity will be influenced by the increase in ocean heat content and the partial pressure of atmospheric CO₂, respectively. Continued reductions in global glacial ice volume, sea ice, and snow cover, together with the thermal expansion of ocean water, will contribute to a projected sea level rise of between 28 cm and 98 cm by 2100 CE. The occurrence, duration, and timing of extreme weather and climate events and variability in weather patterns are all projected to increase as the planet warms. For example, most land areas will experience notable increases in the frequency of extreme hot seasons for over 80% of years, with mean summer temperatures above
Figure 3  Map of CMIP5 multimodel mean results for the scenarios RCP2.6 and RCP8.5 in 2081–2100 of annual mean surface temperature (IPCC 2013).
the late-twentieth-century maximum by 2100 CE (Diffenbaugh and Field 2013). It is expected that improvements in the parameterization of clouds, ground hydrology, ocean–atmosphere interactions, and the inclusion of models that incorporate the dynamic behavior of ice sheets, and refinements to ocean and terrestrial biogeochemical cycles, will serve to better constrain climate projections in the future.

Defining a climate model

Climate model basics

A climate model is a mathematical representation of the global climate system and its interacting components (Figure 1). The climate system is a complex entity, encompassing the atmosphere, the ocean, ocean sediments, sea ice, the land surface, land vegetation, and continental ice sheets. All of these components of the climate system interact with each other, exchanging energy, water, and atmospheric gases such as carbon dioxide (CO₂). In addition, all of the components of the climate system have the capacity to change over time in response to changes in the flows of energy entering or leaving the system.

The aim of a global climate model is to simulate the most important components of the climate system, how they interact with each other, and how they change over time. The basic foundation of climate models is the physical laws that govern the motion of air and water in the atmosphere and ocean and the transfer of energy by radiation and convection. Other mathematical equations are used to represent key processes such as the formation of clouds, as well as key interactions such as the transformation of atmospheric CO₂ into organic carbon by photosynthesis.

Climate models vary widely in character and complexity, from a few equations to hundreds of thousands of lines of programming code. State-of-the-art global climate models are based around what are called general circulation models (GCMs) of the atmosphere and ocean. GCMs are three-dimensional models of atmospheric and oceanic circulation, where the atmosphere and ocean are divided into thousands of grid boxes. Within each of these discrete grid boxes, the model solves the three-dimensional equations of motion to simulate the horizontal and vertical motion of air in the atmosphere or water in the ocean. Energy and water are allowed to move between grid boxes, as determined by equations representing the transfer of energy by radiation, and the transfer of both water and energy by convection, advection, and diffusion.

Evolution of climate models

Climate modeling is a relatively young scientific discipline, and climate models have developed enormously in scope and complexity over the past few decades. The earliest climate models, developed in the 1970s, grew out of weather prediction models, and were very much focused on the atmospheric component of the climate system. Additional components were added to models over time, beginning with the land surface, clouds, and ice in the 1980s. In the early 1990s, climate models began to include a simplified representation of ocean processes, and by the mid-1990s had grown to include three-dimensional representations of both atmospheric and oceanic circulation. These were the first generation of atmosphere–ocean general circulation models (AOGCMs).

The 1990s also saw the recognition of the importance of aerosols (both natural and...
Figure 1 Model representation of the components of the global climate system, showing the basic components of the climate system, as well as the primary exchanges of energy (red arrows), water (blue arrows), and carbon (green arrows).

anthropogenic) as drivers of climate change, which led to an expansion of the representation of human climate forcings in global models. The turn of the century was marked by the first introduction of the carbon cycle as a dynamic component of climate models, as well as a continued focus on aerosols in the atmosphere and deep ocean circulation. The current generation of global climate models includes interactive chemistry in the atmosphere, as well as dynamic vegetation distributions that are able to change in response to changing climate patterns.

This increase in the complexity of models over time has represented an increase in the number of processes and interactions included within models. As a result, components of the climate system have shifted over time from being variables prescribed as inputs to climate models, to being included as interactive components simulated by the models themselves.

Accompanying this growth over time in the complexity of climate models was an increase in the spatial resolution of models. The resolution of a climate model refers to the size of grid boxes, or, correspondingly, the number of grid boxes within a given area. Over time, the resolution of models has increased, which has resulted in more and more smaller grid boxes. This, as much as the increase in complexity described above, has resulted in a large increase in the computer power required to run global climate models.

Modeling observed climate change

Before a model can be used for future projections, it is important to establish the model’s ability to simulate climate changes that have already occurred. The ability to hindcast (or reproduce observed climate changes) is an
important test of a model’s ability to simulate the climate response to human greenhouse gas emissions, and builds confidence in the model’s ability to project these changes into the future.

Model validation

Hindcasting is an example of model validation, in which a climate model simulation is compared to observed climate data to establish the model’s accuracy and validity. For example, a model simulation of present-day temperatures can be compared to temperature data to establish how well the model is able to simulate current climate conditions. The left panel in Figure 2 shows the spatial pattern of temperature, as simulated by a global climate model, and the right panel shows the observed spatial pattern of temperature according to the data provided by the Climate Research Unit (CRU) of the University of East Anglia. This side-by-side comparison shows that, in general, the model simulation is true to the temperature data, though close inspection does also reveal some regional differences. Given that all climate models are a simplification of the real world, it follows that any model validation will reveal differences between the model simulation and the real-world data, so-called model biases. There is no objective rule for what constitutes an acceptable difference; deciding which model biases are tolerably small, and which need to be the subject of further model development and improvement, is part of the art of climate modeling.

A key benchmark that is often used for model validation is the global temperature record since 1850, the period of time over which thermometer temperature measurements are widespread enough to estimate changes in globally averaged temperature. Over this time period, we also have good records for the factors that have driven climate since industrialization. If these climate drivers (which can be expressed as changes in radiative forcing over time) are provided as input to a model simulation, the climate model should be able to simulate the observed pattern of temperature change over the past century and a half.

An example of this comparison of model-simulated temperature change to historical temperature data is shown in Figure 3. The model used for the simulation is in a class of climate model known as an Earth model of intermediate

![Model surface air temperature](image)

**Figure 2**  Comparison of model-simulated temperatures (left) to observed temperature data (right) provided by the Climatic Research Unit of the University of East Anglia.
complexity (EMIC), which is a global climate model in which some aspects of the climate system are simplified in the model to decrease the amount of computer processing time required to run the simulations. This particular model has a simplified atmospheric component, with the result that year-to-year (interannual) temperature variability of the model (red line) is greatly reduced in comparison with the temperature data (gray line). This known limitation does not prevent comparison of the longer-term trend. As can be seen in the figure, the model captures the warming that was observed in the early part of the twentieth century, followed by a slowdown of the warming trend in the 1950s and 1960s, and finally a rapid warming between 1960 and 2010. Overall, the model is able to simulate the approximately 0.8 °C of global warming that has been observed since 1860.

Sensitivity studies

We can also use climate models to understand why temperatures have increased in the manner that has been observed. We can use models simulations, driven by a range of different input simulations, to construct any number of different time series of temperature changes over the past 150 years, and in so doing determine which factors contributed to the observed change and how.

This process of repeat simulations of the same interval of time is an example of a sensitivity study. In general, a sensitivity study is a series of simulations that are performed to determine a model’s sensitivity to either variations in internal model parameters, or variations in external input data. In either case, the aim of a sensitivity study is to determine why a model gives the results it does.

In the case of the simulation of global temperatures over the past century and a half, a sensitivity study can be performed to determine how much of the model-simulated warming is the result of human climate drivers (CO₂ and other greenhouse gas emissions, aerosol emissions, and land-use change), and how much can be attributed to naturally driven climate change (solar insolation changes and volcanic eruptions). This requires two additional simulations: one where the model is given information only about natural climate drivers, and a second where the model is given information only about anthropogenic climate drivers (Figure 4). The blue line (natural only) shows that some of the warming prior to 1960 can be attributed to natural variation in solar and volcanic activity, but that since 1960, natural climate variability by itself would have caused global temperatures to decrease. By contrast, the green line (anthropogenic only) shows that human greenhouse gas and aerosol emissions caused some amount of warming in the early part of the twentieth century, and are responsible for all of the warming that has been observed over the past half-decade.
Projecting future climate change

When using a climate model to simulate future climate change in response to a scenario of future emissions, it is very difficult to establish the actual likelihood of the results given by the particular simulation that is performed. The future climate changes produced by the model will always be contingent on the choice of emissions scenario and on the choice of the climate model that is used. Climate modelers often prefer to use the term “projection,” rather than “prediction,” to describe the scenario of future climate change generated by a particular model in response to a particular future emissions scenario.

Emissions scenarios

Efforts to forecast future emissions generally fall into the category of emissions scenarios, which are projections based on plausible storylines that reflect a range of different possible future societal decisions with respect to energy technologies, globalization, and environmental concern.

The first widely used set of emissions scenarios was produced by the Intergovernmental Panel on Climate Change (IPCC) in association with its First Assessment Report in 1990 (IPCC 1990). These were the so-called IS92 scenarios, which included the widely used IS92a business-as-usual emissions scenario (a scenario that assumes continued economic growth and no climate policy aimed at emissions reduction) with continually increasing greenhouse gas emissions throughout the twenty-first century. The next major round of greenhouse gas emissions scenarios came in the year 2000 with the publication of the IPCC Special Report on Emissions Scenarios (SRES) (IPCC 2000). This report contained details of a total of 40 different business-as-usual emissions scenarios, each reflecting different storylines of economic development, technological change, and population growth. None of the SRES scenarios included explicit climate policies to decrease emissions, and therefore they represent a range of possible futures that human societies could follow in the absence of specific efforts to decrease our impact on the global climate system.

In contrast to business-as-usual emissions scenarios, stabilization scenarios do include climate mitigation efforts, whereby future emissions are projected to decrease to a level that is consistent with the stabilization of atmospheric concentrations of greenhouse gases. Stabilization scenarios are typically not based on projections of economic growth, but are rather set based on a desired target for atmospheric CO₂ concentrations, such as 550 ppm.

The most recent development of future scenarios are the “Representative Concentration Pathway” (RCP) scenarios, which include some scenarios with storylines that assume business-as-usual emissions (similar to the SRES scenarios) in addition to other scenarios with storylines that assume plausible policy efforts to
GLOBAL CLIMATE MODELS

curb global greenhouse gas emissions (stabilization scenarios). There are four categories of RCP scenarios, named according to the target level of radiative forcing – the amount by which greenhouse gases in the atmosphere change the balance of incoming and outgoing radiation at the top of the atmosphere – at the year 2100. At the high end, the RCP 8.5 is a scenario of increasing emissions throughout most of this century, resulting in a radiative forcing of 8.5 W m\(^{-2}\) in the year 2100 (representing atmospheric CO\(_2\) levels of about 800 ppm). At the low end, the RCP 2.6 scenario has radiative forcing increasing until mid-century and then decreasing to 2.6 W m\(^{-2}\) at the end of the century. This change in forcing results from emissions that start to decrease at the year 2020, and reach zero by the last quarter of this century. In this scenario, net human greenhouse gas emissions actually become negative (implying intentional human greenhouse gas sequestration) by the end of the century. The RCP 4.5 and RCP 6 scenarios represent intermediate scenarios with emissions that increase for the next several decades and then decrease in the latter half of this century.

Climate forcing and response

To illustrate the process of generating a climate projection, consider the following example. Figure 5 shows a time series of radiative forcing which results from future emissions given in the RCP 4.5 scenario. In this figure, radiative forcing is broken down into its individual components, showing atmospheric CO\(_2\) concentrations increasing considerably throughout the twenty-first century in response to continued CO\(_2\) emissions. Nitrous oxide concentrations (and hence forcing) also increase somewhat, though the forcing due to methane and halocarbon both decrease slightly in the latter part of the century. Finally, the negative radiative forcing from aerosols also becomes smaller over time, reflecting a decrease in aerosol emissions between now and the year 2100.

This time series of radiative forcing can be provided as input to a global climate model. The model will then simulate the temperature changes that would be expected to occur if future generations produce emissions that are similar to the RCP 4.5 emissions scenario. According to one model simulation, global temperature would increase by about 1.5 °C in response to the overall increase in radiative forcing (which is mostly driven by CO\(_2\) emissions) shown in Figure 6; therefore, the RCP 4.5 scenario would result in 1.5 °C of warming by 2100 (left panel of Figure 6).

The right panel of Figure 6 shows the spatial pattern of warming over this same time period. As can be seen here, the entire globe does not warm at the same rate. Warming over high-latitude northern continents is about double the global average warming, whereas the tropical oceans warm somewhat less than the global average. This regional pattern is partly

![Figure 5 Radiative forcing from 2005 to 2100 associated with the RCP 4.5 emissions scenario.](image-url)
because land warms faster than oceans, and partly because of a powerful positive climate feedback that amplifies warming at high latitudes: the ice–albedo feedback. As temperatures over snow-covered regions increase, this leads to fast melting (or less accumulation) of snow and ice. This in turn leads to a less reflective surface, since snow has a much higher albedo than either soil or vegetated land surfaces. Consequently, more solar radiation is absorbed, and the warming in these regions is amplified.

**Sources of uncertainty in model projections**

The projection of future climate warming shown above is contingent on both the particular climate model that was used for the simulation, and the particular emissions scenario that was chosen as input to the model. Clearly, a different scenario of future emissions (e.g., the RCP 2.6 or RCP 6 scenario) would result in a different amount of simulated future warming. However, using the *same* emissions scenario as input to a *different* climate model would also give a different amount of simulated warming. In fact, the range of simulated warming produced by different models could be as large as, or larger than, the range of simulated warming in a single model in response to different emissions scenarios.

This difference in the climate change projections produced by different models, or intermodel uncertainty, reflects fundamental uncertainties in our understanding of which components of the climate system are important to include in models, as well as how to model certain interactions and feedbacks which occur in the real world. For example, there is considerable uncertainty in our understanding of how the global carbon cycle might change in response to human CO₂ emissions. The choices that modelers make in building the carbon cycle component of a particular climate model will result in a range of representations of the carbon cycle and carbon sinks in different climate models. Consequently, there will be carbon cycle uncertainty in future warming simulations because different models will simulate different trajectories of atmospheric CO₂ increase in response to a given scenario of future emissions.

Similarly, there are many different climate feedbacks which affect how much global temperatures will respond to a given increase in atmospheric greenhouse gas concentrations. As in the case of carbon cycle processes, the
GLOBAL CLIMATE MODELS

atmosphere, ocean, and ice components of different climate models vary considerably in terms of which feedbacks are included in the model, and in how a particular feedback is represented. This is true of the ice-albedo feedback described above, which means that the projected pattern of high-latitude warming will vary from model to model.

Another particularly important (and uncertain) feedback is the cloud feedback. Climate warming will likely lead to changes in the distribution and amounts of different types of clouds, which would in turn affect both the amount of incoming solar radiation and the amount of longwave radiation that is absorbed by clouds and re-emitted back to the surface. The formation of clouds is a difficult process to model correctly, with the result that climate models vary widely in how clouds are represented. Furthermore, different types of clouds have different effects on radiation transfer in the atmosphere. An increase in high clouds due to warmer temperatures will tend to increase the strength of the greenhouse effect, resulting in a faster rate of warming (a positive feedback). By contrast, an increase in low clouds will lead to more reflected sunlight, which will slow the rate of warming (a negative feedback). Because of the widely varying representation of clouds in different models, some models will simulate a negative cloud feedback (and hence less warming), whereas some other models will simulate a positive cloud feedback (and hence more warming).

The net effect of all feedbacks in a climate model will determine its climate sensitivity: the amount by which the climate changes in response to a given change in radiative forcing. There are two specific measures of climate sensitivity that are commonly used to compare the performance of different climate models and to try to quantify some of the intermodel uncertainty associated with future climate change projections.

The transient climate response (TCR) measures the global temperature change in a model simulation at the time that atmospheric CO₂ concentrations reach 560 ppm, or double their preindustrial value. Equilibrium climate sensitivity, on the other hand, measures the long-term temperature change that would occur if atmospheric CO₂ concentrations were to be stabilized indefinitely at 560 ppm. Because of the slow response of the climate system to changes in forcing, climate will continue warming for several centuries after the time that CO₂ concentrations reach and are stabilized at 560 ppm. Consequently, the equilibrium climate sensitivity of a given model will always be higher than its TCR.

The progression of uncertainty, from future emissions scenarios, to changes in atmospheric concentrations of greenhouse gases, to changes in climate and associated impacts, is sometimes called the cascade of uncertainty (see Figure 7). Human choices are subject to uncertainty, given the wide range of future decisions we could make regarding energy sources and the resulting greenhouse gas emissions. But even given some scenario of future CO₂ emissions, predicting the eventual impact of climate change on human societies depends on uncertainty.

Figure 7 Progression from emissions to impacts, showing the increase in total uncertainty associated with climate change prediction.
associated with the carbon cycle response to emissions, followed by additional uncertainty surrounding the climate response to an increase in atmospheric CO₂ (climate sensitivity being one of the most important unknown quantities in climate science), followed by even more uncertainty associated with understanding how much a given amount of climate change will impact a given sector of human society.

Predicting the future is never easy, and predictions of future climate change are no exception. It is important to understand, however, that some things are more uncertain than others. For example, we are confident that continued greenhouse gas emissions will lead to additional climate warming. How much warming actually occurs, and how this warming will vary regionally across the globe, is ambiguous because of the many contributors to uncertainty discussed above. Nevertheless, even given uncertainty, we can draw some general conclusions, which represent common trends that emerge from the many different model projections that have been performed.

Global changes

Temperature

Model-simulated changes in global mean temperature for a given future year are often depicted as a range of modeled temperature deviations from some baseline (such as the average of 1986–2005 mean temperatures) for a range of scenarios of future greenhouse gas emissions and across different global climate models. Across all RCP scenarios and all models used in the IPCC’s Fifth Assessment Report (IPCC AR5), global temperatures are projected to increase throughout the twenty-first century, with a likely range (which excludes some model outliers) of 0.3–4.8 °C above 1986–2005 levels (Collins et al. 2013).

This large range of model-simulated warming is due mainly to different emissions scenarios; that is to say, human choices regarding future emissions are the largest single determinant of how much climate will change by the end of the century. There is also uncertainty within results associated with a given emissions scenario, however, which reflects differences between models (intermodel uncertainty). For example, for RCP 6, the simulated likely range of warming across all models is 1.4–3.1 °C above 1986–2005 levels by 2100 (Collins et al. 2013).

Global warming does not mean that the entire globe warms by the same amount. Figure 8 shows the average spatial pattern of warming simulated by a range of climate model projections, for each degree of globally averaged temperature increase. As already discussed, temperatures warm more over continental regions and at high northern latitudes. The figure shows that some regions of the Canadian Arctic will warm by as much as 2.5 or 3 °C per degree of global warming.

Precipitation

In general, precipitation is expected to increase in a warmer world as increased temperatures drive more evaporation from the oceans, and warmer air is able to hold more water vapor. However, the expected pattern of precipitation change is highly variable, with some areas seeing a decrease in precipitation, and other areas seeing an increase. Figure 9 shows the percentage change in precipitation associated with each degree of global temperature increase. The United States is an example of a nation that will experience a trend toward more precipitation in some of its regions and less precipitation in others. The most intense increase (with as much as 35% more precipitation per degree
Figure 8  Change in regional temperature per 1 °C change in global mean temperature, based on the range of model projections from current global climate models (Collins et al. 2013).

of global warming) is expected to occur over the Pacific equator, in a northern subtropical portion of the African continent, and over a portion of the Arabian Sea and coast. Other regions of the world will see significantly less precipitation, particularly subtropical areas such as the Mediterranean and the western tip of Australia. In these areas, precipitation is expected to decrease by as much as 10% for every degree of global temperature increase.

A common pattern that emerges from climate model simulations of precipitation changes is that regions that are already wet will tend to get wetter, and regions that are dry will get drier. This is consistent with an overall enhancement of the global hydrological cycle, which will tend to enhance precipitation at higher latitudes and along the equator, and decrease precipitation in dry subtropical regions. However, evidence also suggests that areas which are projected to receive more precipitation may receive that increased precipitation in the form of more intense individual precipitation events, rather than as a simple overall increase (Collins et al. 2013). This means that regions such as Canada or Russia, though expected to receive more precipitation in total, could also see an increase in periods of drought, especially in areas of the country that already experience dry weather conditions at certain times of the year.

Extreme events

Many extreme events are expected to change in frequency and duration in a warmer climate. As previously discussed, climate change will likely lead to an increase in precipitation extremes, which means that unusually intense storms will bring more precipitation as a result
of warmer air temperatures. There is also some evidence that tropical cyclones and hurricanes could increase in intensity (while decreasing or remaining unchanged in frequency) as tropical ocean temperatures increase and are able to provide more energy to fuel the development of these intense storms (Christensen et al. 2013). Tornados are another type of extreme weather event that derive their energy from high surface temperatures, and which could therefore increase in intensity in a warmer climate.

Perhaps the most intuitive change in extreme events that we might expect is in the frequency and severity of temperature extremes. As expected, a warmer climate, and warmer winter temperatures in particular, could lead to fewer very cold days and nights. Additionally, warmer temperatures will lead to an increase in very hot summers. This in turn would likely increase the frequency and intensity of heat waves, such as that seen in Europe in the summer of 2003. Recent projections indicate that for many regions, a 2°C increase in global temperatures will result in every summer exceeding the temperature of the hottest summer of the past 20 years (National Research Council 2011).

Glaciers and ice sheets

Some of the most striking manifestations of climate change are occurring in the cryosphere: the frozen glaciers and ice sheets of the planet. The Canadian Arctic has warmed more than almost any other location on the planet, and this pattern of warming is expected to continue into the future. Mountain glaciers and ice caps the world over are receding in response to warmer temperatures, and this trend is expected to
GLOBAL CLIMATE MODELS

continue with additional warming. By the end of the century, glaciers around the world could decrease in volume by more than 75%, which would mean the disappearance of many individual mountain glaciers in the latter part of this century. With every degree Celsius increase in global temperatures, glacial volume will reduce by 0.32–0.40 m per year (Meehl et al. 2007).

Equally striking are the changes occurring in the world’s two major continental ice sheets: Antarctica and Greenland. Many Antarctic glaciers have accelerated the rate at which they discharge ice to the Southern Ocean, particularly along the margins of the Antarctic Peninsula (the portion of Antarctica that juts out northward toward South America). There is also concern among glaciologists that warming ocean temperatures could dramatically increase melting of the West Antarctic Ice Sheet adjacent to the Antarctic Peninsula, and could decrease the stability of this large mass of ice that is grounded below sea level.

In Greenland, the seasonal melt area has also increased dramatically in recent years, and is expected to continue to increase as arctic temperatures continue warming. As in the case of the West Antarctic Ice Sheet, scientists are increasingly concerned about the stability of the Greenland ice sheet. While simple melting of the Greenland ice sheet is a relatively slow process (it would take close to 2000 years to fully melt Greenland, even if CO₂ levels rise to more than 1000 ppm (Meehl et al. 2007)), there is the potential for dramatic increases in the flow of Greenland’s outlet glaciers, which could accelerate the decrease in ice volume that is expected in the coming decades.

Sea level rise

Many factors contribute to the potential for climate change to lead to rising sea levels. As discussed above, mountain glaciers, ice caps, and continental glaciers are all decreasing in volume, which is resulting in the transfer of this volume of water to the ocean. If all of the mountain glaciers and ice caps on the planet were to melt completely, this would increase global sea levels by about 70 cm.

The major concern for rising sea levels, however, comes from the potential melting of continental ice sheets. Greenland alone contains enough frozen water to raise sea levels by 6.6 m, were it to melt completely (Allison et al. 2009). An additional potential for sea level rise of 3.3 m comes from the volume of water stored in the vulnerable parts of the West Antarctic Ice Sheet.

In addition to these potential increases in the total amount of water in the ocean, the volume of ocean water will increase simply by virtue of increased temperatures. Similar to the increase in volume which occurs when air is heated, warmer water also increases slightly in volume. When applied to the entire volume of the ocean, this thermal expansion has a notable contribution to global sea level rise; an estimated 75% of observed sea level rise is attributed to thermal expansion (Church et al. 2013).

There is a huge amount of uncertainty associated with future sea level rise projections, particularly in regard to the contribution of Greenland and Antarctic melting to global sea levels. The Copenhagen Diagnosis report (Allison et al. 2009) summarizes some of the recent estimates of future sea level rise, showing continued greenhouse gas emissions will likely increase global sea level by between 50 and 150 cm by the year 2100. As with other climate changes, however, the regional pattern of sea level rise will not be the same everywhere; both local ocean temperatures and the patterns of ocean circulation will lead to regional differences in sea level relative to the global average. For example, sea levels along the arctic and eastern coasts of Canada will likely increase by 2–12 cm.
more than the global average by the year 2100. In addition, sea level rise will continue long after the year 2100, potentially increasing by as much as 1–3 m by the year 2300 (Church et al. 2013). The uncertainty associated with such longer-term estimates is even larger than for near-term sea level rise, and sea level increases beyond the year 2100 will also depend strongly on how quickly human societies are able to decrease our emissions of greenhouse gases and slow the rate of climate warming.

Global commodity/value chains

Deborah Leslie
_University of Toronto, Canada_

A global commodity chain is composed of all of the processes associated with the production of one good or service, including manufacturing, consumption, design, retailing, marketing, advertising, and disposal. Global commodity chain analyses trace these activities, analyzing the distribution of power across a chain and the flow of material resources, value, money, knowledge, and symbols between sites. A key concern is to investigate the way in which the production and distribution of goods and services reflects but also tends to perpetuate patterns of uneven development in the global economy.

There has been a growing interest in tracing the linkages between sites in a chain, partly because an increasing number of products consumed are produced in other countries (and often multiple countries), and yet consumers often know very little about how or where they are made. Commodity fetishism means that consumers are focused on the price of a product, as well as its physical and symbolic characteristics. This emphasis masks the underlying relations of production and distribution associated with goods. Commodity chain analyses allow us to trace different moments in the life of a commodity to uncover these meanings.

A variety of different commodities have been studied using a commodity chain approach, including clothing, footwear, furniture, gold, diamonds, electronics, flowers, coffee, tropical fruits, and vegetables. Recent research also explores shifts in the commodity chains associated with energy and many services, including call centers, accounting, and research and development. While there are a number of related concepts (such as supply chain, commodity circuit, actor network, _filière_, system of provision and global production network), this entry will focus on the global commodity chain (GCC) approach, and more recent versions of it known as global value chain (GVC) research. It will begin by tracing the development of these approaches and the main arguments in these literatures. Strengths and criticisms of the GCC and GVC frameworks will also be summarized.

The global commodity chain approach

The concept of the commodity chain originates in the work of world-systems theorists. Hopkins and Wallerstein (1977) first used the concept of the commodity chain to refer to the raw materials, transportation networks, and labor processes involved in the production of a commodity, as well as the food inputs into the labor involved in making it. They define a commodity chain as “a network of labour and production processes whose end result is a finished commodity” (Hopkins and Wallerstein 1986, 159). The concept of the commodity chain is thus meant to denote the transformation of raw materials into final products, but also the connections between production and the social reproduction of human labor at each site in the chain. A particular focus is on the historical globalization of capitalist commodity chains, and how this internationalization is tied to patterns of uneven development.
Another key figure in articulating a commodity chain approach is Gary Gereffi. Along with a number of colleagues, Gereffi (1996) uses the term “global commodity chain” to refer to the more recent interfirm relationships that constitute global production networks. Gereffi argues that, in the current period, commodity chains are characterized by increasing geographical complexity and international scope. Unlike the more macro-level and holistic approach of world-systems theory, which examines the logic and structure of world capitalism, emphasis is placed on the microscale. In particular, the focus is on the linkages between firms involved in the production and distribution of a product. The aim is to identify how, where, and who is adding value to the product, and the implications of these patterns for economic development.

Global commodity chains have four important characteristics, according to Gereffi (1996). The first is an input–output structure, which refers to a group of products and services linked together in a sequence of value-adding activities. Second, each chain has a distinct geography. Some chains are spatially concentrated, while others are more globally dispersed. High value-added activities are typically located in key cities in the Global North, while manufacturing takes place in a range of geographical locations that are subject to constant change. The third characteristic is that individual GCCs have unique forms of power relations or governance. This refers to how chains are organized and controlled by “lead” firms. Fourth is the institutional framework: how local, national, and international conditions and policies shape chain dynamics. For example, trade and tax policies, labor and environmental certification schemes, health and safety rules, environmental regulations, and government policies relating to employment and minimum wages all impact commodity chains. Commodity chains also often span several institutional contexts, raising considerable challenges for firms that must navigate different rules and regulations.

A number of themes animate contemporary GCC research. One issue receiving a lot of attention is the expanding geography of chains, partly as a result of innovations in transportation and communication technologies that make it easier to communicate at a distance and to move commodities around the world rapidly. The international division of labor shifted during the mid- to late twentieth century, with developing countries becoming important sites of manufacturing. This is especially the case with labor-intensive industries that have low barriers to entry. In contrast, more capital-intensive industries remain clustered in developed economies. A central preoccupation in GCC analysis has been to map and explain these patterns.

As one example of the growing role of developing countries in manufacturing, China now accounts for 67% of the world’s processing exports (WTO and IDE-JETRO 2011, cited in Gereffi and Lee 2012, 26). Manufacturing is concentrated in a number of large contract manufacturing companies such as Hon Hai/Foxconn, Flextronics, and Quanta. While China has benefited tremendously from this production, it does not create or capture a high level of value in the commodity chain. As Gereffi and Lee (2012) point out, there is often a discrepancy between where final goods are produced and where value is created and captured. They use the example of the Apple iPhone, manufactured in China by a Taiwan-based company, Foxconn, and then exported to the United States. China has a trade deficit with the United States, however, because it is charged for the inputs that it imports from the United States. In addition, most of the value for the iPhone is generated
in Korea, which produces the display panel and the memory chips – the most expensive parts of the phone (Gereffi and Lee 2012). This example illuminates the importance of tracing where value is being added in chains stretching across global space.

As is evident in the case of the iPhone, the current era is also associated with changing patterns of ownership. Globalization no longer encompasses transnational corporations setting up branch offices abroad. In many countries in the Global South, manufacturing supply firms are domestically owned, or owned by companies from other developing countries. GCCs also increasingly involve trade in components and subassemblies rather than finished goods. The growing international trade in intermediate goods is referred to as a shift from a trade in goods to a trade in “value added” or “tasks” (OECD 2011, cited in Gereffi and Lee 2012, 25).

Of the four features of global commodity chains identified by Gereffi (1996) governance structures have received the most attention in the literature. A particular focus has been on factors internal to a chain, rather than external governance. GCC scholarship examines the power relationships between firms, identifying powerful or lead firms, known as “chain drivers.” The early literature on GCCs identified two main ideal types of governance. First are the producer-driven chains. Here, transnational manufacturing firms play a pivotal role in coordinating the chain, including backward and forward linkages. Producer-driven chains are common in capital-intensive industries such as aerospace, computers, and automobiles, where suppliers make components rather than the final product. Producer-driven chains tend to be characterized by high wages and highly skilled labor. Profits stem from advantages related to scale and technological innovation. The second type of governance structure is the buyer-driven chain, where retailers and brand name marketers play the central role in coordinating production networks and dictating conditions along the chain. Buyer-driven chains are typical in labor-intensive industries, such as garments, footwear, toys, and electronics. Production involves multiple tiers of subcontractors, with suppliers making products according to the detailed specifications of buyers. In these industries, subcontractors make the finished product rather than components; labor tends to be unskilled and low wage, and profits derive from design and marketing.

Over time, there has been a shift from producer-driven to buyer-driven chains in a number of sectors, including food, footwear, and clothing. Powerful retailers such as Walmart, and brand name companies such as Nike and Apple, are increasingly able to exert pressure on their suppliers to conform to their rigid specifications. They dictate how chains operate and require suppliers to conform to their exacting standards. The role played by these powerful buyers has been augmented by concentration in the retail sector. For example, Walmart now operates 11,000 retail stores, under 71 banners in 27 countries. It is China’s seventh largest trading partner, larger than the United Kingdom (Gereffi and Lee 2012, 28).

While this conceptualization of producer-driven and buyer-driven chains is useful, there is also an acknowledgment that different governance structures may coexist within an industry, particularly within different segments (such as mass market vs specialty products, or organic vs conventional agriculture). Governance may change over time and across space. Others argue that the growing import-driven chains, such as automobiles and computers, are now outsourcing not only the production of parts but also final assembly. Researchers also increasingly
GLOBAL COMMODITY/VALUE CHAINS

recognize that different types of power may exist at different sites in the chain, and that chains may be controlled by actors other than manufacturers or retailers, such as trading and distribution companies or online intermediaries. The role of external actors, such as nongovernmental organizations (NGOs), certification bodies, and other experts, is also significant. These shortcomings have led to the search for alternative conceptualizations of governance within commodity chains.

The transition from global commodity chains to global value chains

In the 2000s Gereffi and colleagues shifted to a new terminology of “global value chain.” Beyond the conceptual weaknesses identified in GCC approaches to governance, researchers were using a variety of terms to refer to a similar concept, and there was a desire for a common vocabulary. Another motivation for developing the concept of the global value chain was that the notion of “commodity” was perceived to refer narrowly to agricultural staples.

As Gereffi and Lee (2012) note, the GVC concept is now widely accepted as a label for the literature on commodity chains. The notion of a global value chain has been widely adopted not only in academic discourse but also within international organizations interested in economic development and poverty alleviation, such as the World Bank, World Trade Organization (WTO), Organisation for Economic Co-operation and Development (OECD), and International Labour Organization (ILO).

While it is similar to the global commodity chain concept, which emerged in sociology, the GVC approach is more heavily influenced by international business school literatures. Less emphasis is placed on chain drivers and greater importance is attached to the coordination of chains. There is a strong focus in GVC approaches on the technical and organizational dynamics of chains and on transactions costs. There is also more of a focus on the relationship between a lead firm and its first-tier suppliers. As Gibbon, Bair and Ponte (2008, 323) point out, in GVC analysis the analytical scope is narrowed from the entire length of the chain to one specific site. This takes away from one of the main advantages of a global commodity chain analysis, which is examining the effects that governance structures have across the chain. There is considerable debate about whether GCC and GVC approaches are complementary or competing (see Bair 2005; Gibbon, Bair and Ponte 2008). For many external analysts, GVC approaches mark a distinct break with the theoretical traditions that informed GCC research. In this view, GCC/GVC analysis is better conceived of as a methodology for studying globalization rather than as a coherent theoretical framework seeking to explain it.

Moving beyond the binary of producer- versus buyer-driven chains, Gereffi, Humphrey and Sturgeon (2005) present a more complicated map of commodity chain governance based on the complexity of information involved in a transaction, the extent to which knowledge can be codified, and the technical capabilities of suppliers. These three variables are rated as either high or low. Using these criteria, they create a matrix identifying five ideal types of governance in global value chains. Each form of governance involves different levels of outsourcing, different relationships between buyers and suppliers, and contrasting forms of power. Market governance refers to situations where the complexity of information is low and knowledge is easily codified. Product specifications are usually straightforward and transactions can be completed with little coordination. Relationships are at arm’s
length and price is the central factor in negotiated price. Modular governance describes cases where technical standards are typically high: product specifications are complex but also uniform and easy to codify, which simplifies the process of interaction and reduces the need for monitoring suppliers. Buyers and suppliers lower coordination costs by exchanging information. Relational governance refers to situations where exchanges rely on tacit knowledge, which is not easy to codify. Exchange of tacit knowledge requires frequent face-to-face interactions. Relations of mutual dependence thus develop between buyers and suppliers, so there is a high cost associated with switching partners. Captive governance refers to situations where suppliers are dependent on a small number of buyers. There is a high level of product specification and control by the lead firm. As a result, supplier capabilities are low, with firms often completing a narrow range of tasks. Under these conditions, suppliers face considerable switching costs and are thus “captive.” The final type of governance is hierarchical governance, which occurs when there is a high level of vertical integration. Manufacturers make products in-house because capable suppliers cannot be found. Products are complex and knowledge cannot be codified. Lead firms often seek to control the resources, the exchange of tacit knowledge and intellectual property. Each of these forms of governance involves different degrees of power asymmetry, ranging from low in the case of market governance to high in the case of hierarchical governance.

A key theme in both the GCC and GVC literatures concerns possibilities for industrial upgrading among firms in developing countries. Upgrading can be defined as the ability of a firm or group of firms to improve their position within a chain. It refers to the increasing competitiveness of a firm and its ability to capture greater value added in the production process (Bair 2005, 165). The potential for upgrading is related to the degree to which buyers transfer knowledge to their suppliers.

Four types of upgrading have been identified: product; process; function; and intersectoral upgrading (Humphrey and Schmitz 2001). Product upgrading refers to making more sophisticated products with higher unit prices. Process upgrading refers to enhancing efficiency, either through restructuring the production process or by implementing new technologies. Functional upgrading refers to the ability to take on new roles or functions, such as making the product rather than the components, or carrying out logistics management, distribution, or design functions. Intersectoral (or interchain) upgrading signals an ability to take knowledge learned from one sector (e.g., clothing) and expand into another sector (such as housewares). A key argument in the GVC literature is that chains organized along more hierarchical lines lend themselves to product and process upgrading, but are unlikely to allow firms to expand into marketing or design.

In general, the literature suggests that there are increasing barriers to upgrading in developing countries. Marketing, branding, and design are increasingly important in all commodity chains, especially in buyer-driven chains, and developed countries have significant advantages in these capabilities. As these “intangible” aspects become critical, it is increasingly difficult for developing countries to engage in upgrading (Gereffi 2001).

Another theme in the literature on GCCs and GVCs concerns the shifting geography of end markets. With a slow recovery from the economic crisis of 2008–2009 in developed nations, emerging economies such as China, India, and Brazil have become increasingly important markets. This has led to the development of regional South–South supply chains that
GLOBAL COMMODITY/VALUE CHAINS

alter the conditions of possibility for upgrading (Gereffi and Lee 2012). The demand for lower quality and less sophisticated products in developing countries presents opportunities for developing country firms to produce products for these markets. These firms can engage in higher value-added functions, such as product development and design, roles they have less opportunity to play in global supply chains. This enables them to develop innovations suited to the local context. However, focusing on low-income developing country consumers has the disadvantage that it could restrict developing country suppliers to more competitive and cut-throat markets with slim profit margins. Nonetheless, the growth of markets in the Global South points to the growing complexity of global value chains, and the variety of upgrading opportunities within these networks.

Contributions of a GCC/GVC approach

In her review of the literature on global commodity chains, Bair (2005) identifies a number of important contributions of the GCC/GVC literature. Tracing spatially diffuse and complex production networks allows researchers to “explore globalization in situ,” analyzing particular locales while also illuminating how these places are connected through global commodity chains (Bair 2005, 159). A GCC (and GVC) approach thus facilitates an understanding of an abstract concept, globalization, in a concrete way. GCC/GVC studies also illuminate how power is exercised in global industries, which has important policy implications for developing countries. Understanding how chains are organized is useful for countries in determining how to gain access to the skills, technologies, and know-how necessary to function in global value chains (Bair 2005).

GCC research in particular has also influenced ethical campaigns surrounding global production. The ability to trace complex supply chains has led to antisweatshop campaigns targeting large retailers, holding them accountable for labor conditions in the factories of their suppliers and subcontractors. This has led to a number of initiatives designed to alter the organization of global commodity chains, such as fairtrade movements, corporate codes of conduct, and a variety of certification schemes targeting human rights, labor, and environmental practices.

Criticisms of the GCC/GVC approach

While many valuable insights have been gained through the focus on GCCs and GVCs, a number of criticisms have been made of both approaches. These can be divided into six main categories.

The first, and perhaps the most common, critique of the GCC/GVC approach centers on its linear conceptualization of the chain. It is presumed that there is a sequence of activities—a chain, starting with raw materials and proceeding through the stages of design, production, marketing, distribution, and retailing. In this conception, consumption is viewed as the end point of the chain. Alternative approaches draw on the less linear vocabulary of “circuits,” “actor networks,” or “global production networks.” Rather than searching for a singular or determining logic of a chain, and tracing relationships of causality (or identifying chain drivers), these accounts explore the multiple webs of interdependence between sites and the multistranded relationships between nodes in the chain, and between firms, states, organizations, and raw materials.

In actor-network theory, for example, power is conceptualized as an effect of relations between actors in the chain. Agency is generated through
a network of heterogeneous, interacting materials, including not only retailers, suppliers, designers, and other human actors but also technologies, material natures, and the commodity itself. The value of an actor-network approach stems from its more fluid conception of networks, and its open conception of spatiality. While production and other activities are localized, they are constituted by influences from different time periods and locations. Practices are therefore both local and nonlocal. This topological conceptualization allows for a consideration of overlapping spaces.

In economic geography, the concept of global production networks (GPN) has also been forwarded as an alternative to GCC/GVC approaches (see, e.g., Coe, Dicken, and Hess 2008). Like circuits and actor networks, the GPN approach is a more open, relational framework that includes a range of actors and relationships, and is more sensitive to the role of geography. Avoiding an emphasis on one site or scale, it also examines how relationships stretch across space.

Bair and Werner (2011) raise a second criticism of the literature on global commodity and value chains. They argue that GCC/GVC approaches adopt a narrow firm-centered perspective and are not attentive enough to the historical and geographical context in which chains operate. Greater examination is needed of the “coupled processes of linking and delinking that underlie the shifting geography of global industries and condition the position of regions within transnational production arrangements” (Bair and Werner 2011, 1000). They propose the concept of disarticulation as a way to unravel the histories of dispossession, accumulation, and disinvestment that shape a region’s position in global commodity chains, and to examine how these histories are both constitutive of and constituted by networks of global production. The focus on lead firms also tends to distance GCC analysis from the way chains are embedded in particular places, histories, and ecologies.

In a similar vein, Bair (2005) argues that the GCC/GVC focus on individual firms and sectors leads to the neglect of a country or region’s position within the global economy. This firm-centered approach poses a dilemma of how one understands the implications of firm upgrading for larger units such as regions and nations. Bair (2005) suggests that there needs to be greater attention to who benefits from upgrading. Process upgrading, for example, does not necessarily translate into increased security and profits for subcontractors. In addition, larger producers within a country may be able to upgrade, but smaller players may be excluded from upgrading. Finally, an ability to upgrade may not necessarily benefit workers, who continue to struggle with low wages and job insecurity. Thus the global value chain literature needs to pay greater attention to the winners and losers in processes of upgrading and to historical and geographical context (Bair 2005).

A third criticism of GCC/GVC approaches centers on their economistic approach. Bair (2005) calls for greater attention to social reproduction (something foregrounded in earlier world-systems research), as well as the social, cultural, political, and institutional context in which chains operate. While the GCC/GVC approach has proven useful in understanding the internal power dynamics between firms and their suppliers, greater attention needs to be paid to factors external to chains, such as institutions, government policies, and other regulatory measures. GCC/GVC research emphasizes the processes of production and value-adding sequences, but the role of discourses could be given greater weight. Chains produce not only goods and services but also meanings and identities. GCC/GVC approaches neglect the mutually constitutive link between the material and the symbolic. Research
GLOBAL COMMODITY/VALUE CHAINS

needs to emphasize the way material qualities are transformed and culturally valued, and how this is related to the capture and realization of value.

A fourth criticism centers on the neglect of particular sites in the chain. Very little GCC/GVC work has examined the dynamics of consumption, the role of consumers in shaping chains, or consumer spaces such as the home (Coe, Dicken, and Hess 2008). Consumption can shape the nature of chains through ethical campaigning and the development of standards and codes of conduct. Research in geography on user-led innovation also illustrates the growing role that consumers play in driving innovation in some chains, especially sporting goods, medical equipment, and video games. Beyond consumption, there is also a lack of attention in the GCC/GVC literature to the disposal, recycling, and reuse of commodities, and on the natural environment, both as a source of raw materials and as a site of waste (Coe, Dicken, and Hess, 2008).

A fifth criticism is that GCC/GVC approaches neglect labor, which is often viewed as a passive victim of globalization. Labor needs to be integrated into the heart of a global commodity chain analysis because commodity chains are networks of embodied labor. Labor is also a key actor, engaging in struggles over outsourcing, restructuring, and other actions that influence the dynamics of commodity chains.

Echoing many of these criticisms, a final critique of the literature on global commodity and value chains surrounds its lack of engagement with the gendered and racialized nature of global commodity chains. Women constitute the majority of workers in many overseas subcontractors. Contemporary commodity chains often exploit differences in gender, race, ethnicity, nationality, religion, sexuality, age, and citizenship. They rely on superexploitation: exploitation that depends on so-called noneconomic factors, such as gender, race, ethnicity, and nationality (Tsing 2009). Despite the fact that the exploitation of women has been a key component of global commodity chains, Palpacuer (2008, 402) argues that “mainstream GCC/GVC research has barely ventured into the world of women workers.” Ramamurthy (2004, 741) similarly criticizes what she views as a strongly masculinist tone characterizing many GCC accounts that refer to chain “drivers.” She argues that a feminist commodity chain analysis would begin “with the possibility that global commodity chains – as connections across times and places – are neither linear nor unidirectional nor closed” (Ramamurthy 2004, 741). In parallel with earlier criticisms, she advocates an approach to commodity chains that recognizes their open-endedness, contingency, and rupture (Ramamurthy 2004, 743).

The future of GCC/GVC research and politics

The global commodity/value chain approach has proven tremendously useful in the last several decades as a vehicle for understanding processes of globalization and the growing international division of labor. Using this approach, researchers now have a better sense of the unique characteristics of different types of chains, and how power is exercised within them. GCC/GVC approaches have given us an understanding of what different types of governance mean for the possibilities of upgrading in developing economies, and provided valuable insights for policymakers and activists tackling the growing problems of inequality. Despite the many criticisms that have been advanced, there are important contributions in GCC/GVC analysis that can be built on and enriched. Greater
attention to culture, regulation, institutions, and the structural dynamics of capitalism, combined with a more fluid, open-ended approach to power and space, can help to illuminate the complexity in global commodity chains.

Tsing (2009) reminds us that commodity chains are constantly contested and shifting. This makes them unpredictable. She suggests that this new form of capitalism – based on globally extensive supply chains – is not as all-powerful as it seems. Almost by definition, it is dispersed and disorganized. Although lead firms claim to be in control of the flow of products and profits through their complex logistics systems, “no one can fully keep track of the activities of every firm in the chain” (Tsing 2009, 172). Commodity chains are characterized by constant scandals which, while not destroying the chain, provide openings for critique and mobilization (Tsing 2009, 172). These opportunities need to be better exploited. As Tsing (2009) points out, this requires greater sensitivity to the diversity of practices within global commodity chains. It also requires attention to the intersecting dynamics of gender, race, nationality, and class through which commodity chain exploitation is possible.

Global dimming/brightening

Martin Wild  
*ETH Zurich, Institute for Atmospheric and Climate Science, Switzerland*

Solar radiation (sunlight) incident at the Earth’s surface is the ultimate energy source for life on the planet, and largely determines the climatic conditions of our habitats. The amount of solar energy reaching the surface is a major component of the surface energy balance and governs a large number of diverse surface processes, such as evaporation and the associated hydrological cycle, snow and glacier melt, plant photosynthesis, and terrestrial carbon uptake, as well as the evolution of surface temperatures on diurnal, seasonal, and decadal timescales. It has also major practical implications, for example, for the planning and management of the rapidly growing number of solar power plants in support of the world’s pressing demands on nuclear- and carbon-free energy sources, as well as for agricultural production. Changes in the amount of solar energy reaching the Earth’s surface can therefore have profound environmental, societal, and economic implications (Wild 2012).

Observational and modeling studies emerging in the past two decades indeed suggest that surface solar radiation (in the following referred to as SSR) is not necessarily constant on decadal timescales, as often assumed for simplicity and lack of better knowledge, but shows substantial decadal variations. Largely unnoticed over a decade or more, this evidence recently gained a rapid growth of attention under the popular expressions “global dimming” and “brightening,” which refer to a decadal decrease and increase in SSR, respectively.

Evidence and causes of dimming and brightening

Monitoring of SSR began in the early twentieth century at selected locations and since the mid-century on a more widespread basis. Many of these historic radiation measurements have been collected in the Global Energy Balance Archive (GEBA) at Eidgenössische Technische Hochschule Zurich (ETH Zurich) and in the World Radiation Data Centre (WRDC) of the Main Geophysical Observatory in St Petersburg. In addition, more recently, high-quality surface radiation measurements, such as those from the Baseline Surface Radiation Network (BSRN) and from the Atmospheric Radiation Measurement Program (ARM), have become available. These latter networks measure surface radiative fluxes at the highest possible accuracy with well-defined and calibrated state-of-the-art instrumentation at selected sites worldwide.

Changes in SSR from the beginning of widespread measurements in the 1950s up to the 1980s have been analyzed in numerous studies (see Wild 2009a for a review). These studies report a general decrease of SSR at widespread locations over land surfaces between the 1950s and 1980s. This phenomenon is now popularly known as “global dimming” (see Figure 1, left-hand panel, for a schematic illustration).

Increasing air pollution and an associated increase in aerosol concentrations are considered a major cause of the observed decline of SSR...
Changes in cloud amount and optical properties, which may or may not have been linked to the aerosol changes, have also been proposed to contribute to the dimming. An attempt has been made in Norris and Wild (2007) to differentiate between aerosol and cloud impacts on radiative changes over Europe. They show that changes in cloud amount cannot explain the changes in SSR, pointing to direct and indirect aerosol effects as potential major causes of these variations. Alpert et al. (2005) found that the decline in SSR in the period from the 1950s to the 1980s is particularly large in areas with dense population, which also suggests a significant anthropogenic influence through air pollution and aerosols. Several studies (Wild 2009a and references therein) also noted a dimming over the same period at remote sites, suggesting that the phenomenon is not of a purely local nature and that air pollution may have far-reaching effects (a concept on how SSR in remote areas may be modulated by subtle changes in background aerosol levels is introduced below).

More recent studies using SSR records updated to the year 2000 found, however, a trend reversal and partial recovery at many of the observation sites since the 1980s. The term “brightening” was thereby coined to emphasize that the decline in SSR and associated global dimming did not continue after the 1980s (Wild et al. 2005) (Figure 1, right). Particularly in industrialized areas, the majority of the sites showed some recovery from prior dimming, or at least a
leveling off, between the 1980s and 2000. The brightening has been somewhat less coherent than the preceding dimming, with trend reversals at widespread locations, but still some regions showed continued decrease, such as in India (see Wild 2009a, 2012 for an overview). Brightening is not just found under all sky conditions, but often also under clear skies, pointing once more to aerosols as important contributors to this trend reversal (e.g., Norris and Wild 2007; Wild et al. 2005). The transition from decreasing to increasing SSR is in line with a similar shift in atmospheric clear sky transmission determined from pyrheliometer measurements at a number of sites (Figure 2). This transition is also in line with changes in aerosol and aerosol precursor emissions derived from historic emission inventories, which also show a distinct trend reversal during the 1980s, particularly in the industrialized regions. The trend reversal in aerosol emission towards a reduction and the associated increasing atmospheric transmission since the mid-1980s may be related to air pollution regulations and the collapse of the economy in Eastern European countries. A reduction of aerosol optical depth over the world oceans since 1990, which may be indicative of the global background aerosol level, was inferred from satellite data by Mishchenko et al. (2007). This fits well with the general picture of a widespread transition from dimming to brightening seen in the surface radiation observations at the same time.

Updates on the SSR evolution beyond the year 2000 show mixed tendencies. Overall, observed brightening is less distinct after 2000 compared to the 1990s at many sites. Brightening continues beyond 2000 at sites in Europe and the United States, but levels off at Japanese sites, and shows some indications for a renewed dimming in China after a phase of stabilization during the 1990s, while dimming persists throughout in India (Wild et al. 2009). On the other hand, the longest observational records, which go back to the 1920s and 1930s at a few sites in Europe, further indicate some brightening tendencies during the first half of the twentieth century, known as “early brightening” (Ohmura 2009; Wild 2009a). This is illustrated in Figure 3 with the longest available record of SSR, from Stockholm.

Wild (2009a, 2012) proposed a conceptual framework for the explanation of dimming and brightening, suggesting that aerosol-induced dimming and brightening can be amplified or dampened by aerosol–cloud interactions, depending on the prevailing pollution levels. In pristine regions, small changes in cloud condensation nuclei (CCNs) can have a much bigger impact on cloud characteristics than in polluted environments, because clouds show a nonlinear

Figure 2  Time series of annual mean atmospheric transmission under cloud-free conditions determined from pyrheliometer measurements at various sites in Russia (Moscow), Estonia (Tartu-Toravere and Tiirikoja), Switzerland (Payerne), and Japan (average of 14 sites). Wild et al. 2005. Reprinted with permission from AAAS.
(logarithmic) sensitivity to CCNs. Additional CCNs due to air pollution in pristine regions may therefore be particularly effective in increasing the formation, lifetime, and albedo of clouds, which all act towards a reduction of SSR through enhanced cloud shading. Thus, aerosol–cloud interactions in pristine environments may cause a strong amplification of dimming (brightening) trends induced by small increases (decreases) in aerosols. This implies that dimming/brightening could be substantial even in areas far away from pollution sources, where small changes in background aerosol levels induced by long-range transports can effectively alter SSR through cloud modifications. This mechanism potentially could also be responsible for the brightening over oceans, with decreasing aerosol background levels (Mishchenko et al. 2007) between the mid-1980s and 2000 consistently seen in satellite-derived SSR records (Wild 2009a and references therein).

In polluted regions, on the other hand, cloud microphysics effects tend to saturate with the logarithmic sensitivity to CCNs, whereas the direct extinction of SSR by aerosols, which increases proportionally to the aerosol loadings, becomes more relevant. Absorbing pollution layers further heat and stabilize the atmosphere, and attenuate SSR and related surface evaporation. This generally leads to a suppression of convective cloud formation, and dissolves clouds in layers heated by absorbing aerosol (known as the semidirect aerosol effect). The associated reduced cloud shading may partly counteract the aerosol-induced reduction of SSR in heavily polluted areas. Thus, in contrast to pristine areas, aerosol–cloud interactions may tend to dampen...
dimming/brightening trends induced by direct aerosol effects (Wild 2009a, 2012).

Environmental implications of dimming and brightening

A growing number of studies provide evidence that the variations in SSR have a considerable impact on climate and environmental change (see Wild 2009a and 2012 for a review). Wild, Ohmura, and Makowski (2007) investigated the impact of dimming and brightening on global warming. They present evidence that SSR dimming was effective in masking and suppressing greenhouse warming, but only up to the mid-1980s, when dimming gradually transformed into brightening. Since then, the uncovered greenhouse effect has revealed its full dimension, as manifested in a rapid temperature rise (+0.38 °C/decade over land since the mid-1980s). Wild, Ohmura, and Makowski (2007) provided further evidence for a strong impact of dimming and brightening on global warming, based on analyses of decadal changes in observed daily maximum and minimum temperatures and related diurnal temperature range (DTR). They found a slight decrease in the daily maximum temperatures over the “dimming” period from the 1960s to the 1980s, which is in line with the reduction of SSR over this period. Daily minimum temperatures, on the other hand, have been increasing over the same period, as expected from an increasing greenhouse effect, causing a decline in DTR. In contrast, since the mid-1980s, observed minimum and maximum temperatures have increased at a very similar pace. This is indicative of a major change in the surface radiative forcing regime, where the maximum temperature rise was no longer suppressed as in the previous decades, due to the transition from dimming to brightening (Wild, Ohmura, and Makowski 2007).

The climate models used in recent assessments of the Intergovernmental Panel on Climate Change (IPCC) do not seem to fully account for the observed decadal modulations of global warming and DTR through solar dimming and brightening, even if all known forcings are included in the models (Wild 2009b). They underestimate the suppression of warming through dimming between the 1950s and 1980s over global land surfaces, and simulate a higher rate of temperature rise than observed during this period. On the other hand, for the more recent decades, the models underestimate the rate of global warming, indicative of a lack of brightening. Also, the trend reversal in DTR in the 1980s is not reproduced by the climate models (Wild 2009b). Indeed, numerous studies show that climate models seem to underestimate SSR dimming and brightening when compared to the direct surface observations. The potential explanations that have been put forward for these modeling issues include the large uncertainties in historic emission inventories and associated aerosol burdens in the atmosphere, which may not consider the full extent of decadal variations, the inadequate representation of the direct and indirect aerosol forcings, and a general underestimation of the unforced natural variability in the models.

More recently, Wild (2012) pointed out that the absence of global warming from the 1950s to 1980s, and the subsequent reversal into rapid warming, was most prominently seen in the Northern Hemisphere, while in the Southern Hemisphere a steady gradual warming was observed from the 1950s onward (Figure 4). This fits well with the asymmetric hemispheric evolution of anthropogenic air pollution, which strongly increased from the 1950s to the 1980s and declined thereafter in
the Northern Hemisphere with increasing air quality measures, while pollution levels in the Southern Hemisphere were an order of magnitude lower and steadily increased with no trend reversal (Wild 2012). This again points to a possible large-scale influence of aerosol-induced SSR dimming and brightening on global warming. Climate models, on the other hand, do not reproduce these characteristic differences in inter-hemispheric warming (Wild 2012). In the Northern Hemisphere, with considerable aerosol loadings, the average warming simulated by the models in twentieth-century “all forcings” experiments was too strong during dimming, and too weak during subsequent brightening as noted above for the global scale. This points again to an insufficient representation of the processes causing dimming and brightening in the models to dampen and enhance greenhouse warming, respectively. In contrast, in the Southern Hemisphere, where aerosol pollution is much smaller and greenhouse-gas forcing dominates, the models perform very well, with warming rates close to those observed (Wild 2012). This suggests that climate models simulate decadal warming trends adequately when greenhouse gases act as sole major anthropogenic forcing, as in the Southern Hemisphere, but may have difficulties when in addition strong decadal aerosol variations come into play, as in the Northern Hemisphere.

Interestingly enough, the observed suppression of warming during the dimming period in the Northern Hemisphere was even slightly stronger over ocean than over land areas (Figure 5), with a slight cooling of $-0.03\, ^\circ\text{C}$ per decade over oceans between 1958 and 1985, compared to a slight warming over land with $+0.04\, ^\circ\text{C}$ per decade over the same period, based on data from the Climate Research Unit, Norwich, and the Hadley Centre, Exeter, United Kingdom (Wild 2013). Even though anthropogenic air pollution sources are located over land, subtle changes in background aerosol levels over the relatively pristine oceans could have amplified SSR trends through effective cloud–aerosol interactions, as outlined.
Figure 5  Annual 2-m temperature anomalies observed over Northern Hemispheric oceans (left) and land surfaces (right). Observations from CRUTEM3 (land) and HADSST2 (oceans), anomalies with respect to 1960–1990. Linear trends over the dimming phase (1950s–1980s) in blue, over the brightening phase (1980s–2000) in red. Reproduced from Wild 2013 with the permission of AIP Publishing LLC.

in the conceptual framework above. This may explain the lack of warming particularly over oceans during this period (Wild 2012, 2013).

It is interesting to note that the indication for a slowdown of the brightening since 2000 noted earlier (Wild et al. 2009), and the possible reversal into a renewed dimming, coincides with a lack of warming since the turn of the millennium (“global warming hiatus”). Such a renewed reversal in SSR tendencies may be favored by factors such as the renewed increase in global sulfur emissions after 2000 (particularly originating from Asia) (Streets et al. 2009) or enhanced volcanic activities during this period (e.g., Santer et al. 2014).

SSR is also a major determinant of surface evaporation and thereby the main driver of the global water cycle. Wild et al. (2004) suggested that surface solar energy reductions outweighed the increasing thermal energy from the greenhouse effect from the 1960s to the 1980s, resulting in a reduction of surface net radiation and associated evaporation over land surfaces, causing an attenuation of the intensity of the associated water cycle (Figures 1 and 6). In contrast, for the more recent period of the 1980s to the 2000s, Wild, Grieser, and Schaer (2008) pointed out that SSR brightening adds to the increasing energy from the enhanced greenhouse effect, leading to higher evaporation and an intensification of the global terrestrial water cycle since the 1980s (Figures 1 and 6). Impacts of the transition from dimming to brightening can further be seen in the more rapid retreats of glaciers and snow cover, which became evident after the 1980s as soon as the dimming disappeared (Wild 2009a and references therein).

Modeling studies further suggest that SSR dimming/brightening may also impact the terrestrial carbon cycle and plant growth (Mercado et al. 2009). During dimming, plant photosynthesis and associated terrestrial carbon uptake might have been enhanced despite a reduction in SSR, since the stronger aerosol and cloud scattering enlarged the diffuse radiative fraction in this period. Diffuse light penetrates deeper into the vegetation canopies than direct sunbeams and can therefore be more effectively used by plants for photosynthesis.

Further research will be required to establish the full dimension of the impacts of SSR.
GLOBAL DIMMING/BRIGHTENING

Dimming and brightening on climate and environmental change. Research on the impacts of dimming and brightening may also provide additional insight into the potential consequences of geoengineering, as the proposed actions predominantly target the modulation of incoming solar radiation.

Global Dimming/Brightening

Global environmental change: human dimensions

Robin Leichenko
David C. Eisenhauer
Rutgers University, USA

Research on the human dimensions of global environmental change (HDGEC) encompasses a broad array of social science research on processes and outcomes of human-induced environmental changes. The changes include, for example, climate change resulting from rising levels of atmospheric greenhouse gases, stratospheric ozone depletion, urbanization and land-use change, and loss of biodiversity. Local-scale changes that occur on a worldwide scale, such as consumptive water usage and degradation of water quality, are also recognized as global environmental changes because of the scope and magnitude of their impact. The concept of the “Anthropocene,” which suggests that human activity has become a dominant factor changing natural, life-supporting processes, is also central to research on global environmental change.

As an interdisciplinary area of study, HDGEC research draws upon fields including climate change impacts, land-use change, natural hazards, political ecology, energy, and livelihoods, among many others, to explore societal causes, impacts, and responses to large-scale environmental changes. Human dimensions work has long found a home in major geography journals, such as the Annals of the Association of American Geographers, as well as in established interdisciplinary journals, such as Global Environmental Change, Mitigation and Adaptation Strategies for Global Change, Ambio, Environment, Climatic Change, Land Use Policy, and Natural Hazards. Over the past decade, a plethora of new journals with space devoted to the human and policy dimensions of global environmental change, often with a primary emphasis on the topic of climate change, have emerged. Some of the many examples of recently or newly established journals in this area include Weather Climate and Society, Climate and Development, Nature Climate Change, WIREs Climate Change, Urban Climate, Change and Adaptation in Socio-ecological Systems, Journal of Extreme Events, and The Anthropocene Review.

Along with a growing number of journal outlets for HDGEC research, numerous international research networks and programs have been formed in order to connect HDGEC researchers and to promote and carry out collaborative HDGEC projects. These networks take many forms and are sponsored or cosponsored by numerous international scientific organizations and research programs, such as the International Council for Science (ICSU) and the International Social Science Council (ISSC). Of particular importance for the establishment and promotion of HDGEC work over the past two decades has been the International Human Dimensions Research Programme (IHDP) (www.ihdp.unu.edu). Founded in 1996, IHDP was instrumental in the formation and establishment of an interdisciplinary HDGEC research community through hosting of international open meetings and through the many research projects that it sponsored. These projects were generally 10-year efforts designed by leading HDGEC scientists to facilitate and promote research on cutting-edge human dimensions.

DOI: 10.1002/9781118786352.wbieg0649
topics such as human security, urbanization, land-use change, governance, the carbon cycle, and water systems. IHDP closed in 2014 and all of its functions were incorporated into the newly formed Future Earth Initiative (www.futureearth.info). Future Earth also incorporated a number of other major international programs on global environmental change, including DIVERSITAS (www.diversitas-international.org), the International Geosphere-Biosphere Programme (IGBP) (www.igbp.net), and the World Climate Research Programme (WCRP) (wcrp-climate.org). While IHDP had an explicit focus on social science, Future Earth also includes research within the physical sciences, engineering, humanities, law, and other areas. This integration across many fields of science reflects wider acceptance of the value and prominence of the “human” in global environmental change.

One of the major goals of IHDP and other international scientific networks over the past two decades has been the diversification of the pool of scientists involved in HDGEC work. The Intergovernmental Panel on Climate Change (IPCC), for example, has worked to include scientists from all regions of the world. By incorporating a variety of voices across geographic regions, the generation of scientific knowledge reflects a broader array of cultural, political, and institutional viewpoints and includes more information gathered from disparate geographic locations.

The diversity of research outlets, networks, and participants that support human dimensions work is matched or perhaps exceeded by the theoretical and epistemological diversity of human dimensions research. As discussed next, the scope of the field can be broadly captured through examination of some of the major discourses that are implicit in the work. Following the discussion of HDGEC discourses, key issues and topics addressed in HDGEC work are discussed, including: (i) social, economic, political, and cultural drivers of global environmental change; (ii) impacts of and vulnerability to these changes within different sectors, regions, communities, and social groups; and (iii) societal responses, including adaptation, mitigation, and social transformation. In addition to shared discourses, research across these areas is also connected via a number of unifying and cross-cutting themes. Several of these themes are highlighted in the final section, including governance, equity and social justice, and the social production and communication of scientific information.

Discourses on global environmental change

Definitions and approaches to research on the human dimensions of global environmental change are embedded in a number of competing discourses. As described in Leichenko and O’Brien (2008), discourses entail underlying assumptions, values, and judgments, which provide the basic terms for analyses and debates, influencing both agreements and disagreements. Discourses also carry political weight such that proponents of some discourses exert a greater influence over how specific issues are framed and on which responses are prioritized (Liverman 2009). Discourses influence definitions of global environmental change and the approaches used to evaluate and address these changes. Leichenko and O’Brien (2008) organize the discourses on global environmental change into three broad and sometimes overlapping categories: biophysical discourses, human-environment discourses, and critical discourses. Recognition of these multiple and competing discourses helps to explain the breadth and diversity of HDGEC research approaches.
Biophysical approaches tend to frame global environmental changes as biophysically based processes that pose challenges for sustainability of human systems and need to be addressed through a combination of technological innovations and international commitments to reduce, limit, or suspend activities that contribute to these changes. Research within the biophysical discourse focuses on empirical documentation of physical changes that may influence biogeochemical cycles, atmosphere–biosphere–ocean interactions, and other natural and physical processes. Physical science–based mathematical models are often used to develop future projections of temperature change, sea level rise, acidification of precipitation, land-use change, and so forth. Within this discourse, better understanding of Earth system processes and how these processes are influenced by human activities, in combination with better communication of scientific findings, is seen as vital to addressing global environmental change. The biophysical discourse is based on an underlying belief that advancement of scientific knowledge about environmental processes will reduce technical uncertainties such that a social consensus on actions and responses will follow (Leichenko and O’Brien 2008).

Researchers working within human–environment discourses emphasize the integral connections between human and natural systems and stress the importance of connecting social and biophysical processes in order to understand drivers, impacts, and vulnerabilities. Research approaches emphasize the importance of integrating both biophysical and social processes in order to understand how outcomes of environmental change are distributed within society. Quantitative, qualitative, and mixed-method approaches are used in this research in order to explore topics such as social and economic vulnerabilities, livelihoods systems, resilience of coupled socioecological systems, adaptation, and social learning. Like the biophysical discourse, the human–environment discourse also subscribes to the idea that better scientific understanding of the drivers, processes, outcomes, and responses associated with global environmental change is needed (Leichenko and O’Brien 2008). However, the human–environment discourse increasingly emphasizes the importance of coproduction of scientific information about global environmental changes through collaborative engagement between scientists, governments, private sector actors, and members of civil society (Cornell et al. 2013).

Critical scholars often go further than the human–environment discourse by seeking to locate the root causes of environmental vulnerability and marginalization. A core tenet of this work is that both local and broader inequalities must be addressed in order to reduce environmental degradation (Peet, Robbins, and Watts 2011). Traditionally, critical researchers framed their work within “neo-Marxist” perspectives. In doing so, they sought to explicate causal chains of explanation located within structural forces, such as the global capitalist economy, coercive power relations, and unequal access to resources and institutions. Recently, critical approaches have broadened to include fields such as poststructuralism, third-wave feminism, and science and technology studies. This expansion has contributed to questioning of many of the causal assumptions of previous critical research and has opened up new avenues of research exploring the ways in which individuals change the way they see themselves (i.e., their subjectivity) in relation to environmental change and how the circulation of power contributes to this process. Critical environmental scholarship often unfolds within field research that seeks to detail the ways in which unequal power dynamics contribute to environmental change on the
ground. Through empirical case studies critical scholars highlight broad forces and the frequently technical framing of environmental change and they demonstrate how local capacity to manage resources can, under some circumstances, be more sustainable and equitable than reliance on centralized governments or market forces.

Societal drivers of global environmental change

Human actions are generally understood to be a driving force behind global environmental change, whether through population growth, resource extraction, energy consumption, urbanization, technological change, changes in consumer demands, or shifts in lifestyles, attitudes, and beliefs (Steffen et al. 2004).

Research on the drivers of global environmental change documents how human activities contribute to systemic changes that affect the entire Earth system, such as increasing atmospheric concentrations of greenhouse gases and stratospheric ozone depletion. Examples of systemic-focused research include studies of projected future carbon emissions associated with continued consumption of fossil fuels including oil, coal, and natural gas, and studies of the implementation of international regulations of chlorofluorocarbons and the consequences for stratospheric ozone levels. This work also entails study of the role of human activities in contributing to local-scale changes that cumulatively influence the global environment through the magnitude and distribution of their effects. Research that emphasizes the cumulative effects of local-scale changes draws attention to activities that are occurring on a worldwide basis, such as rising levels of meat consumption, rapid urban spatial expansion, and overfishing of large predatory species, and explores how these activities affect global land and water usage patterns, species survival rates, and so forth.

Biophysically based studies of the human drivers sometimes involve empirical documentation of global-scale changes based on remote sensing analysis of changing land-use patterns or statistical analysis of temperature records. The work may also entail development of future projections of environmental change based on social factors such as population growth, changing energy consumption, and growth of per capita income, as well as various policy responses. The economic or social causes of cumulative local environmental changes are also emphasized, such as the legal, policy, and economic causes of over-exploitation of groundwater for irrigated agriculture. Research also explores topics such as the influence of individual attitudes and beliefs on energy consumption and lifestyle choices, and the consequences of these decisions for energy use patterns. Critical work on this topic examines the connections between environmental change and longer-term expansion of the capitalist economic system. This work questions the implicit logic of continuous economic growth and capital accumulation and emphasizes the unequal political and economic power relations that produce environmental degradation.

Societal impacts of global environmental change

Human dimensions researchers also investigate the consequences of global environmental change for human and coupled social-ecological systems at a variety of scales. This work emphasizes topics including impacts, risks, vulnerability, and resilience. Impact and risk-based research typically focuses on how global environmental changes, such as higher temperatures, reduced precipitation or how more frequent extreme
events associated with climate change may affect specific sectors of an economy, such as real estate, agriculture, energy, transportation, health care, or tourism. Examples include documentation of populations and property at risk to sea level rise, impacts of water supply changes on crop production, effects of extreme events on infrastructure, costs of air pollution on asthma treatment, and impacts of coral bleaching on numbers of visitors to a tourist destination. Impact and risk research may also adopt a regional focus, looking at how a political, economic, or ecological region, such as a coastal city or agricultural area, may be affected by global environmental changes, again with an emphasis on the prediction and quantification of impacts and risks. In the case of a transportation system in an urban coastal region, for example, a study of climate change impacts and risks would identify key types of climatic impacts likely to affect the system, assign probabilities to these impacts (e.g., probability of a certain amount of sea level rise by 2050), and estimate potential economic costs.

Vulnerability and resilience studies explore factors that explain why some regions, systems, communities, and individuals are more likely than others to be harmed by global environmental change or are less able to recover and bounce back from associated shocks and stresses. Vulnerability studies, which developed partly from the hazards tradition in geography, explore underlying social, political, institutional, and biophysical factors that make some more likely than others to be harmed by climate and environmental change. The factors seen as most important typically depend upon the discourse that the researcher is working within (Leichenko and O’Brien 2008). For example, critical researchers will often point toward economic, political, and social inequalities that create susceptibility to harm; whereas, biophysical-oriented researchers will emphasize the degree of physical exposure to climatic or environmental change. Resilience work is more directly concerned with how communities and regions respond to shocks and stresses and the identification of actions that enhance the ability to recover. The concept of resilience developed separately within the fields of ecology, hazards studies, engineering, and psychology. While HDGEC works has drawn largely from ecological and hazard-based understandings of resiliency, these other fields are increasingly influencing research in this area.

A common point of departure for both vulnerability and resilience studies is emphasis on the importance of local and regional contextual factors in shaping options for response. These contextual factors include economic, social, cultural, political, and institutional conditions that either constrain or enable effective responses to various types of environmental stresses. Wealth, education levels, social capital, access to political power, and worldviews are among the many attributes that affect these responses. Both approaches focus on how society anticipates and plans for future changes including the factors that constrain or enable people to pursue outcomes that they value.

In addition to emphases on the capacity to respond to single processes of global environmental change, researchers also recognize that environmental stresses and shocks typically originate from multiple sources. Multiple stressor approaches recognize that individuals, communities, and regions are often subject to more than one ongoing process of global change. For a single region, the effects of climate change, rapid urbanization, globalization, and the spread of infectious disease may be felt simultaneously. Acknowledgment of multiple stressors is seen as key to understanding differential exposure, and multiple stressor approaches typically combine investigation of vulnerability to changing environmental conditions with examination of other
stressors such as migration, warfare or conflict, and economic recession. Expanding the analyses beyond “single stressor” approaches has also provided important insights into social processes that underlie the drivers of global environmental change and shape vulnerability and responses (Leichenko and O’Brien 2008). Multiple stressor frameworks are especially prevalent in research on global environmental change and human security (Sygna, O’Brien, and Wolf 2013). This work draws attention to ways in which environmental change acts as a threat multiplier for many factors that contribute to human insecurity including worsening poverty, unplanned migration, civil conflict, and loss of cultural identity.

Societal responses to global environmental change

Societal responses to global environmental change are also a major area of work for the HDGEC community. Adaptation research explores approaches and strategies to respond to stresses and hazards associated with global environmental change. The potential actors involved in adaptation include individuals, households, governments, organizations, and businesses. These actors operate at different political levels – ranging from local to international – and within a wide variety of contexts and geographic locations. The differences between and within these groups make adaptation a significant political challenge (Pelling 2011). Further, individuals and groups do not experience environmental change in isolation; rather, they experience the effects of global environmental change along with other changes in their social and economic lives. Efforts to adapt to environmental change are classified along a variety of dimensions. Adaptations can occur proactively to reduce foreseen vulnerability. Farmers can diversify their crops or purchase insurance to lessen their vulnerability to drought and/or flooding, for instance. Adaptation also can occur retroactively based on experience of past hazards. For example, city planners may build levees after a significant flood event. Central authorities or governments can plan adaptations or individuals and communities can autonomously develop them. Adaptation efforts can aim to spread or reduce risk to environmental change. Additionally, adaptation can aim to build resilience within a system so that it can maintain its structure and function, transition to a slightly different state in which the basic structure is maintained, or transform the system into a new form (Pelling 2011).

Researchers also recognize that adaptation requires resources and capabilities, which are often encompassed within the notion of adaptive capacity. Adaptive capacity refers to the store of material, social, and ecological capacities available to respond to climate change. This capacity is latent – meaning it is difficult to measure. Further, not all capacity is useful in every potential scenario. For this reason, HDGEC research distinguishes between specific adaptive capacity and generic adaptive capacity (Eakin, Lemos, and Nelson 2014). Individuals and groups can mobilize specific adaptive capacity to deal with a narrow range of hazards and stresses. For instance, investing in emergency centers can increase a community’s specific adaptive capacity to hurricanes or typhoons. Generic adaptive capacity is useful for a broader spectrum of situations. Economic development or education, for example, can aid people in adapting to many forms of environmental change. However, there are also recognized barriers and limits to each type of adaptation. A barrier to adaptation presents an obstacle that likely must be overcome. For example, laws, tax policies, insurance subsidies, and cultural preferences all contribute to building homes in risky coastal areas. While
legal and social barriers can potentially be overcome, limits to adaptation are more immutable. If sea levels increase too much, some coastal areas will become uninhabitable. Thus, sea level may act as a strict limit to adaptation in some cases.

Within the HDGEC research community, a “pathways” framing of adaptation action has become increasingly common. Across venues ranging from the IPCC to local governments to academic research centers, adaptation pathways are seen as flexible policy frameworks in the face of uncertain and rapid global environmental change. Broadly, pathways are alternative avenues to possible futures. Designing and implementing pathways can take a variety of forms. Back-casting involves describing desirable futures and designing pathways that could get society there. Alternatively, pathways can be designed to respond to potential environmental changes. That is, crossing a threshold or tipping point triggers a shift to a different pre-planned regime. Overall, pathways aim to be flexible, open to new information, and applicable within diverse contexts (Leach, Scoones, and Stirling 2010). Climate adaptation pathways entail designing alternative paths to maintaining a desirable state within a changing climate. Within this design process, it is necessary to define what is desirable and constantly monitor change and results. When the state of the system passes a threshold or moves into an undesirable condition, such as experiencing repeated damage from flooding, there is need for system transition to a new path. Knowing when and how to choose a new path depends on the social tolerance of risk and the ability to monitor changes in hazards and vulnerability (Pelling 2011).

Mitigation research emphasizes behavioral changes, policy measures, and technological responses that are intended to slow or halt processes of global environmental change. This differs from the usage of the term “mitigation” in hazards research where it is associated with local hazard and risk reduction. Mitigation work is often tied directly to the issue of sustainability with the notion that mitigation is needed in order to ensure that the activities of the present generation do not undermine the ability of future generations to meet their needs. Mitigation research typically focuses on ameliorating the causes of climate change through reduction of greenhouse gas emissions from energy production, transportation, buildings, construction, agriculture, and other sectors. Mitigation research is also directed to land-use issues that relate to climate change, particularly slowing the pace of tropical deforestation. Prominent topics for policy-focused mitigation research include carbon pricing, emissions trading, carbon taxes, and green development mechanisms. Mitigation research also investigates the feasibility of alternative energy technologies and the implications of shifts to alternative energy for job creation and destruction. Other types of technological solutions to climate change, including geo-engineering measures, are also considered in the HDGEC literature, though the primary emphasis of that work is more typically on political and ethical concerns surrounding deployment of such technologies. Mitigation research also explores local political organizing around global environmental issues such as urban-based efforts to reduce carbon emissions, which have been adopted by many hundreds of cities worldwide.

Mitigation pathways share many common features with adaptation pathways as they aim to describe alternative ways to reduce the impacts of climate and environmental change. However, they do so by seeking to preclude negative change from occurring by reducing greenhouse gas emissions. Mitigation pathways describe
possible carbon emission trajectories and usually are compared to a “business as usual” scenario, which assumes that no mitigation occurs. Targets, or future atmospheric greenhouse gas concentrations, typically seek to stabilize the global climate system at a state in which both the economic and social costs and benefits of decreasing emissions are balanced. Once targets are identified, pathways to achieve these goals are built. These pathways include a variety of mechanisms to achieve emissions reductions, such as energy efficiency, carbon trading, reforestation, and technology development. Mitigation pathways seek to be flexible so as to be able to change in light of new information.

Transformation is an emergent concept within HDGEC research. Though there is no universal definition, transformation generally refers to a significant change in a system that alters its basic functioning. In other words, transformation entails moving a system to a new state. Whereas coping, adaptation, and mitigation efforts tend to focus on dealing with the effects of environmental change, transformation aims to address the root causes of negative change and vulnerability found within social, political, economic, and ecological systems (Pelling 2011). By doing so, transformation incorporates aspects of both mitigation and adaptation. For a growing number of HDGEC researchers, the inevitability of and necessity for transformation is clear. Transformation is inevitable because society faces significant environmental changes. It is necessary because people will need to reconceptualize and alter the ways that they manage and plan in relation to the environment. Transformation ultimately requires challenging basic understandings of the state of the world and humans’ place within it. Transformation not only entails making significant alterations to the physical world but also includes fundamental, societal change (Pelling 2011).

Cross-cutting themes

There are many topics of cross-cutting interest that are relevant to all facets of HDGEC research. Some of the most prominent of these cross-cutting themes include governance, equity and social justice, and the social production and communication of scientific information.

Research on governance focuses on institutions, policies, and regulatory frameworks that influence how resources are managed. Within HDGEC research, much attention has been directed to examination of how neoliberal (i.e., free market) approaches, such as privatization of common lands, influence patterns and rates of environmental changes, such as deforestation and loss of biodiversity. This work also explores how different types of institutional arrangements affect the vulnerability and resilience of local communities and examines the potential of various governance mechanisms to promote adaptation. Human dimensions researchers explicitly recognize that efforts to both adapt and mitigate the causes of global environmental change may require new types of governance structures or new types of cooperative agreements. Some of the many characteristics of governing institutions that are identified as promoting effective responses to environmental change include: polycentricity, transparency, accountability, flexibility, and inclusiveness. But rather than prescribing a single, “best practice” arrangement, the environmental governance literature advocates a diversity of approaches, suggesting that effective institutional arrangements take many different forms (Ostrom 2010).

Issues of equity and justice are another prominent theme in HDGEC research. Questions of equity and justice frequently arise regarding mitigation of climate change, particularly with respect to who will pay the costs for efforts to
reduce emissions and who will bear the economic burdens associated with these reductions. Issues of temporal equity also come into play in these discussions. Most of the greenhouse gases above preindustrial levels that are currently present in the atmosphere are the result of energy usage and other economic activities that have occurred within developed countries, such as the United States, Australia, and the countries of the European Union. However, a subset of developing countries, including China and India, now account for a growing share of total global greenhouse emissions. While per capita energy usage within developed countries remains substantially higher than in most developing countries, per capita usage is rising within developing countries, as growing numbers of middle-class residents adopt energy consumptive lifestyles. Issues of intergenerational equity are also relevant, including obligations to maintain a wide range of options and ensure quality of life for future generations. HDGEC researchers have also long recognized that the effects of environmental change are highly uneven and create winners and losers (O’Brien and Leichenko 2003). Equity and justice issues arise, in part, because the differential effects of environmental changes and of adaptations to those changes often harm groups that are already politically and economically marginalized.

HDGEC research increasingly acknowledges that science is not removed from social relations. Scientists work within cultural, institutional, political, and interpersonal arrangements that influence their work and its dissemination. This is not to say that science cannot be objective, but rather that scientists always have a situated perspective. The norms and rules of science, such as measurement standards, replication, and peer review, aim to create universal knowledge valid in all contexts. The transformation of situated knowledge into universal knowledge has become a topic of interest within the HDGEC research community. Following from this interest, several subtopics have recently emerged in the literature: uncertainty and the limits of scientific knowledge; participation in science; and communication of scientific knowledge.

Uncertainty and ambiguity permeate many global environmental changes – this is especially true when predicting future changes (Hulme 2009). For example, many uncertainties exist within the study of climate change, including the sensitivity of the climate to increased emissions, how deep sea currents will respond to warmer temperatures, and the ways weather patterns will change. Additionally, there is uncertainty about how individual components of the complex and chaotic atmosphere, ocean, and terrestrial systems will interact as the climate changes. Finally, the role of society in mitigating, adapting, and further altering each system is uncertain. All of these uncertainties compound each other, limiting what scientists can definitively conclude about Earth systems and global environmental change (Hulme 2009). Scientists and society at large can, however, ameliorate some effects of this uncertainty through opening up the knowledge creation process and clearly communicating uncertainty.

HDGEC research is increasingly committed to productive engagement between scientists, policymakers, and the public in order to assess what these changes mean for society and to identify feasible solutions. Particular effort has been made to include nonscientists in the production of scientific knowledge (Whatmore 2013). This approach, known as the coproduction of knowledge, recognizes that the broader public has valuable insights into topics in which scientists are concerned. Within this model, all forms of knowledge are treated equally and a shared understanding of the problem is not assumed to exist. Rather, both scientists and the public
interact, debate, and collaborate to enrich each other’s knowledge about the world. This does not eliminate uncertainty. Rather, it treats uncertainty as fertile ground for exploring a problem. This approach is especially useful within controversial situations (Whatmore 2013). During and after a controversy, previous beliefs and assumptions regarding the world are challenged. For instance, a surprising flood might upset people’s beliefs in the behavior of the weather, settlement patterns, and flood control measures (Whatmore 2013), leading to a rapid increase in uncertainty. Coproducing a solution to an environmental controversy has the potential to combine both scientific knowledge and local knowledge in unique and unexpected ways that can be more effective than purely technical solutions.

Additionally, a great deal of recent effort has been spent on communicating both scientific knowledge and uncertainty of global environmental change (Boykoff 2011; Hulme 2009; Liverman 2009). This especially holds for climate change science. It is often assumed that scientists should communicate what they are certain about and couch their language within scientific models and terminology. On the one hand, this approach brings to the fore the valuable information scientists provide for understanding a problem and weakens skeptical claims of scientists’ biases. On the other hand, it also tends to decontextualize global environmental change and detach it from people’s experience and concerns (Boykoff 2011; Hulme 2009). Alternative and complementary approaches to communicating scientific knowledge seek to connect abstract science with local concerns and understandings. By using symbols and examples that the general public understands and relates to, scientists, scientific organizations, and others can contextualize global environmental change in ways that strengthen their ability to increase awareness of scientific knowledge (Boykoff 2011). Nevertheless, communicating what science does and does not know about global environmental change remains a challenging endeavor.

Beyond communicating the science and uncertainty, many researchers in the HDGEC have begun interrogating the persistent gap between knowledge about the dynamics of global environmental change and action by governments at all scales (Castree et al. 2014). Two emerging and related explanations for this gap are the limited conceptualization and integration of environmental social sciences and humanities within global environmental change science and knowledge and the overwhelming tendency to frame climate and environmental changes as physical, rather than social, problems (Castree et al. 2014; Hackmann, Moser, and St Clair 2014). Therefore, there have been increasing calls for giving the social sciences and humanities more prominence within the production of global environmental change science and knowledge. These scholars argue that the environmental social sciences and humanities can help elucidate the various and alternative values, technical and political means, and normative ends at stake – or what Castree et al. (2014, 766) call “values–means–ends’ packages.” By doing so, HDGEC research would redefine climate and environmental change as inherently social problems rather than physical ones (Hackmann, Moser, and St Clair 2014), thus shifting the dominant framing of global environmental change from biophysical to critical and/or human–environment discourses.

A brave new borderless world?

The global factory emerged as a significant phenomenon in the last decades of the twentieth century, corresponding to the resurgence of free-market ideologies and neoliberal approaches to economic development. Characterized by a post-Fordist, “flexible” form of production in an ostensibly borderless world, its rapid rise to prominence marked a critical conjuncture in the global political economy.

By the 1980s, rising wages and labor-protective legislation prompted many Northern corporations to relocate manufacturing units out of the United States and Europe to Asia and Central and Latin America in search of cheap labor. Around the same time, international financial institutions began to actively endorse structural adjustment policies, “free trade,” and export-oriented industrialization as pathways to economic development. Southern nations were compelled to liberalize trade policies in order to compete in the new regime of globalization. Most industrializing countries set up tax-exempt special economic zones, also shielded from national labor laws, in order to attract foreign capital investment. In nationalist and development narratives, export-based industrial employment signified progress for the nation as well as for the individual worker.

The production of labor-intensive low-end products such as apparel, electronics, and toys, which require minimal investment and allow for maximum capital mobility, flourished in the newly restructured global economy. “Fly-by-night” factories emerged and folded, moving to wherever labor costs were lowest. This relentless search for increasing returns effectively cheapened labor, as Southern economies vied with one another to attract multinational corporations in what has been called a race to the bottom. States desperate to retain foreign direct investment actively, often brutally, suppressed worker resistance and protest.

In line with global trends, labor precarity – high turnover, job insecurity, and casualization – marked work in export factories. The global factory also brought about major shifts in the international division of labor. A predominantly female, Southern migrant labor force characterized the new global assembly line. As such, the emergent proletariat was raced, classed, and gendered in ways that reflected older colonial and imperial divisions of consumption and production, as well as of wealth and inequality.

Transnational production and the “disposable” woman from the Global South

The long hours, low wages, and precarious working conditions typical of export factories prompted some commentators to classify the latter as sweatshops. Indeed, in popular and left academic circles, the “third-world” female factory worker became synonymous with
GLOBAL FACTORY

sweatshop labor and the depredations of global capital (Siddiqi 2009).

Women workers have figured centrally in debates around the sweatshop, an early version of which grappled with the relationship between capitalism and patriarchy, and whether insertion into the transnational chain of production liberated women or enchained them further. Anchored in the valorization of the export-led development model, one view embraced factory work as a harbinger of modernity and emancipation. The expectation was that industrial employment would undermine patriarchal structures as well as improve everyday living conditions.

Other feminist scholars, especially those working within a Marxist-historical tradition, were less sanguine. Several key anthologies in the 1980s set the tone for subsequent debates on the feminization of the international division of labor and the merits of multinational production (Ehrenreich and Fuentes 1983; Nash and Fernandez-Kelly 1984). These authors were unequivocal in their view of the hyperexploitation of women factory workers from the Global South in the service of capital.

This body of research carefully unpacked the tropes of “nimble fingers” and “docility” used by multinationals and others to justify hiring women at low wages for industrial work. An inherent capacity for agility, patience, diligence, and compliance, the argument went, made women naturally suited for repetitive monotonous assembly-line work. Considered to be culturally docile, “Oriental” women made especially desirable employees. Biological and cultural discourses were layered with a sociological one that positioned women as secondary earners, who worked either to supplement the wages of a male head of household or to satisfy their consumer desires (“working for lipstick”). Put differently, the naturalization of women’s labor through tropes of docility and agility simultaneously cheapened it, masking exploitative working conditions, low wages, and, ultimately, the suppression of organized labor movements.

By the 1990s feminist scholars, especially those working with postcolonial, poststructural, or transnational theories, moved away from the binary framing of exploitation versus emancipation. They also challenged the depiction of all workers as voiceless, passive victims of capital. Building on Ong’s now classic ethnography of Malaysian electronics workers, scholars foregrounded the contradictory and inconsistent outcomes of factory work, the messiness or complexity of everyday social relations, and unconventional modes of resistance on the shop floor (Ong 2010/1987).

Localized ethnographies often yielded contradictory insights. Fernandez-Kelly’s (1984) ethnography of Ciudad Juarez contends that factory employment increases women’s dependence on patriarchal family relations. In contrast, in a compilation of ethnographic work from a variety of localities (Rothstein and Blim 1991), Jaffee (1991) shows that mothers in South Africa may be able to delay childbirth and obtain a measure of autonomy. Kim (1991) documents the incorporation of young women into the militant labor movement following their entry into the factories of South Korea’s export processing zones. In short, despite the standardization of the global production chain, the “local” meanings of the global factory are not readily generalizable. The impact on women and on gender relations is intimately related to prevailing social and economic contexts.

A host of anthropological studies complicate received notions of culture in relation to political economy. Family and kinship ties, for instance, are critical not only to the survival of households in the new economy but also in the mobilization
GLOBAL FACTORY

of capital and the recruitment of workers (Rothstein and Blim 1991).

Working on the assumption that the material and ideological are co-constitutive rather than separate spheres, scholars have mapped the ways kinship and other social relations reconstitute the production process even as the structures of transnational production shape— in highly contingent ways—gendered meanings, processes, and subjectivities. Other ethnographies trace the close entanglements of localized regimes of sexuality and the regulation of labor, as well as young migrant workers’ negotiations of kinship ties, desires, and new practices of consumption and self-making.

Recent ethnographies also revisit questions of agency exercised in extremely constrained circumstances. Drawing on Michel Foucault’s work on technologies of the self, Pun Ngai (2005) explores “minor genres” of resistance among Chinese workers producing goods for Walmart. Ngai argues that the agency of workers effectively limits the domination of managers and creates spaces of mutual support and even hope.

The proliferation of maquiladoras (factories on the United States–Mexican border) following the ratification of the North American Free Trade Agreement, and the subsequent violence enacted on women’s bodies, have generated some of the most theoretically provocative work on transnational production. Drawing on fieldwork in China and Mexico, Melissa Wright (2006) unpacks the myth of the disposable “third-world” woman as it circulates across the globe. This myth, she argues, consolidates the present regime of transnational capital even as the myth itself is remade across different scales and registers. Wright powerfully connects the wearing out of workers’ bodies or gendered “waste in the making” within the maquiladora to the murder of women outside factory walls. She also highlights the significance of worker resistance in nontraditional registers. Her analysis echoes Pun Ngai’s (2005, 11) call to reactivate social struggle “by rooting it in class experience from below – that is, in the everyday infrapolitics of the Chinese workers themselves.”

The twenty-first century sweatshop

The collapse of Rana Plaza on April 24, 2013, in Savar, Bangladesh, in which over 1100 workers were killed, numerous others maimed for life, and the livelihoods of several thousand workers destroyed, catapulted the sweatshop into global headlines. The worst industrial disaster in the history of the global garment industry, Rana Plaza has reopened debates on the merits of sweatshop employment.

Some liberal commentators see the sweatshop as an inevitable stepping stone in the trajectory of economic development. Others have condemned it as hyperexploitation that benefits Northern capital at the expense of Southern labor and have compared the incident to the Triangle Shirtwaist Factory fire of 1911. The many layers of globalized subcontracting, the incorporation of local petty commodity production and home-based workers as well as factory workers across national boundaries, and new networks between producers and consumers, render such comparisons moot.

The Rana Plaza incident and its aftermath recalls and complicates Wright’s analysis of the essentially disposable nature of Southern women’s bodies. The stakes involved are enormous for the multibillion-dollar apparel industry, as well as for the workers whose bodies are rendered into “waste” in the process of contemporary capital accumulation.

Questions of accountability and transparency in the production chain are now at the forefront
GLOBAL FACTORY

of public debates. In the emergent discourse of ethical production and consumption, there is no place for visibly disposable and disposed-of bodies. Scholars must attend to the mediations, elisions, and accommodations at work to render invisible once more violence that was momentarily made hypervisible by the Rana Plaza collapse. It could be argued that this violence is foundational to the global apparel industry.

The global factory has become a rejuvenated site of transnational activism, alliances, and solidarity among groups as diverse as university students, fashion models, and consumers as well as workers’ rights organizations. The fraught nature of building solidarity in a multilayered globalized system is an urgent issue with which researchers and activists must engage (see Brooks 2007). Collaboration between activists and scholars is essential in this context. It may be time for researchers to take a step back and revisit the processes through which workers in places like Bangladesh have few alternative forms of livelihood and have been made desperate enough to choose work that is badly paid and often dangerous, sometimes even deadly.

Overview of GPS

The global positioning system (GPS) developed and maintained by the US Department of Defense (Xu 2007) was the first and is still the most utilized satellite navigation system. The first GPS satellite was launched in 1978 and the system became fully operational in 1995. The term global navigation satellite system (GNSS) refers to a constellation of Earth-orbiting satellites transmitting signals encoded with their positioning and timing data. A GNSS can provide autonomous geospatial positioning in all weather conditions with global coverage.

The GPS consists of three main components: the space segment, the control segment, and the user segment. The space segment is composed of 24 satellites in six orbital planes with approximately 55° inclination with respect to the Earth’s equator (Figure 1). In each plane, there are nominally four satellites orbiting at an altitude of approximately 20,200 km. Each satellite is in a nearly circular orbit with a period of about 12 hours so that the satellite passes over the same locations every day. For such a constellation design, at least six GPS satellites are visible almost everywhere on the Earth’s surface.

The control segment is composed of twelve monitor stations, a master control station (MCS, located at Schriever Air Force Base in Colorado), an alternate MCS (located at Vandenberg Air Force Base in California), four dedicated ground antennae (located at Kwajalein, Ascension Island, Diego Garcia, and Cape Canaveral), and six dedicated monitor stations (located at Hawai’i, Kwajalein Atoll, Ascension Island, Diego Garcia, Colorado Springs, and Cape Canaveral). All the monitor stations are equipped with GPS receivers to track all visible GPS satellites and collect observation data. The MCS then processes the data to determine broadcast GPS satellite ephemerides and to model the satellite clock errors. The ephemerides and clock error corrections are transmitted to each satellite via the ground antennae. The satellites, in turn, transmit the updated ephemerides and clock error corrections to GPS receivers.

The user segment consists of GPS receivers and the user community. In general, a GPS receiver refers to a combination of an antenna, receiver-processors, and a highly stable clock. These can process GPS signals and perform calculations to output the position, velocity, and time estimates referenced to the GPS antenna.

How GPS works

GPS satellites transmit three low-power radio signals (also called carriers), designated L1 (1575.42 MHz), L2 (1227.60 MHz), and L5 (1176.45 MHz, only available on Block IIF
satellites). Ranging codes (including L1 C/A, L1 P(Y), L1M, L1C, L2C, L2 P(Y), L2M) and navigation messages are modulated to the carriers under the control of onboard atomic clocks (Misra and Enge 2006). A GPS signal modulated to the carrier wave contains three different types of information: a pseudorandom code, ephemeris data, and almanac data. The pseudorandom code can be used to determine the range distance between the GPS satellite and GPS receiver, while both ephemeris and almanac data can be used to calculate the GPS satellite position and velocity in space. Compared to almanac data, ephemeris data are more accurate but have a shorter validity period. The US government’s current policy is to make GPS available in two services: precise positioning service (PPS) and standard positioning service (SPS). The PPS is available to the military and other authorized users only, while the SPS is available to any user worldwide. PPS users have access to the encrypted P(Y)-codes and M-codes (starting with Block IIR-M) on the L1 and L2 carriers, while the SPS users can observe the public codes L1 C/A, L1C, L2C, and L5. The encryption of the P-codes began on January 31, 1994 through the so-called anti-spoofing (AS) measures (Hofmann-Wellenhof, Lichtenegger, and Wasle 2008). Before May 1, 2000, the SPS users were affected by the GPS selective availability (SA) measures that degraded the GPS signal accuracy by intentionally introducing artificial errors to the GPS satellite clock and ephemeris data. The SA policy was formally implemented on March 25, 1990 and was turned off on May 1, 2000.

A GPS receiver calculates its position by a technique involving the intersection of at least three range measurements, as illustrated in Figure 2, Figure 3, and Figure 4. When one GPS receiver tracks signals from at least three GPS satellites, three ranges can be obtained. Each range measurement is actually calculated from the elapsed transmission time (the time GPS signals have taken to travel from satellite to receiver) multiplied by the speed of light.

Each GPS satellite has a unique pseudorandom noise (PRN) sequence, or Gold code. The good property of the PRN sequences is that the correlation coefficient has the maximum value 1 when two PRN sequences are exactly the same. The correlation coefficient is significantly low when the two PRN sequences are different. Each GPS receiver has the capability to generate PRN sequences for all the GPS satellites. GPS receivers generate PRN sequences to correlate with the incoming GPS satellite signals so that they can detect which GPS satellites are observed through the analysis of correlation coefficients, as shown in Figure 5.

Ideally, the GPS receiver clock is exactly synchronized with the atomic clock onboard the GPS satellite such that they generate the same
One measurement narrows down position to the surface of a sphere with a radius of 20,000 km.

**Figure 2** Spherical surface defined by a satellite position and a distance measurement.

digital code at the same time. When a GPS satellite transmits a ranging code (code 1) that arrives at the receiver after traveling the amount of time $\Delta t$, the receiver duplicates the same ranging code (code 2), as shown in Figure 5. Code 2 is a duplication of code 1, but it is delayed by $\Delta t$. The correlation coefficient between code 2 and code 1 is very low. The local duplication is shifted in order to get a higher correlation coefficient. The maximum correlation can be achieved when the shifted amount is exactly $\Delta t$, which is the time the GPS signal takes to travel from the GPS satellite to receiver. By multiplying $\Delta t$ by the speed of light, the receiver produces the pseudorange observations.

In addition to the pseudorange code measurements, the carrier wave can also be used as a GPS measurement. To generate carrier phase measurements, the receiver first reconstructs the carrier phase by removing the modulated ranging codes and navigation messages. The carrier phase measurement represents the range distance between a satellite and receiver expressed in units of cycles of the carrier frequency. Carrier phase measurements have very high precision (of the order of millimeters) but they also have unknown ambiguities, which are in the number of whole carrier cycles. The accuracy of carrier phase measurements is improved by resolving the carrier phase ambiguities, which is also known as ambiguity resolution. This is typically done by using multiple GPS satellites and taking advantage of the fact that the phase ambiguities are constant for a given satellite and time period. The accuracy of carrier phase measurements is further improved by using integer ambiguity resolution techniques, which involve solving for the integer carrier phase ambiguities.

Three measurements narrow down position to just two points.

**Figure 4** Three spherical surfaces intersect to generate two points. Usually the receiver can discard one of the two points because it is nowhere near the Earth. This leaves one point that is the location of the GPS receiver.

Two measurements narrow down position to the intersection of two spheres.

**Figure 3** Two spherical surfaces intersect to generate a circle.
phase measurements has a measuring accuracy of 1 mm or higher, but the ranging code has an accuracy of approximately $\pm 3$ m for C/A code and $\pm 0.3$ m for P code.

Once the receiver has the distance measurements, GPS positioning and navigation are now reduced to a problem of geometry. If the positions of GPS satellites in the space are known, it is possible to compute the GPS receiver location through trilateration. In theory, only three measurements from three GPS satellites are needed to determine the 3-D position of a GPS receiver. However, generation of GPS measurements closely depends on the GPS clock. For GPS measurements that contain a large clock error, the estimated 3-D positioning solution contains a large error too. If the GPS receiver clock error is estimated as an unknown parameter together with the 3-D coordinates of the receiver, the GPS positioning solution will become more accurate. Thus, in practice, at least four measurements from four satellites are needed in the GPS SPS.

The mathematical equations expressing the GPS distance measurements can be written as shown in equations 1 and 2.

\[
\rho_i = \sqrt{(X^i - X)^2 + (Y^i - Y)^2 + (Z^i - Z)^2} - \epsilon \cdot V_{Ri} + \epsilon \cdot V_{Si} + (V_{ion})_i + (V_{trop})_i + \epsilon_i \tag{1}
\]

\[
\phi_i \lambda = \sqrt{(X^i - X)^2 + (Y^i - Y)^2 + (Z^i - Z)^2} - N_i \lambda - \epsilon \cdot V_{Ri} + \epsilon \cdot V_{Si} - (V_{ion})_i + (V_{trop})_i + \epsilon_i \tag{2}
\]

where $\rho_i$ is the pseudorange measurement from satellite $i$ to the receiver; $(X_i, Y_i, Z_i)$ are the coordinates of satellite $i$; $(X, Y, Z)$ are the coordinates of the receiver; $\epsilon$ is the speed of light; $V_{Ri}$ is the receiver clock error; $V_{Si}$ is the clock error of satellite $i$; $V_{ion}$ is the ionospheric delay; $V_{trop}$ is the tropospheric delay; $\epsilon_i$ is the noise; $\phi_i$ is the carrier phase observation from satellite $i$ to the receiver; $\lambda$ is the wavelength of the signal; and $N_i$ is the integer ambiguity.

In pseudorange positioning mode, the tropospheric delay is usually corrected by models or eliminated by the combination of different frequency signals; the satellite clock error is corrected by using the clock correction information in the navigation message. The rest of the four parameters (three receiver coordinates parameters and one receiver clock delay parameter) need to be estimated by using at least four satellites’ pseudorange observations. In carrier phase positioning mode, the interambiguity should be estimated in addition to the coordinate parameters and the receiver clock error parameter. As the carrier phase measurements have a high accuracy, they are usually used for high-precision positioning. In addition, the satellite position error and satellite clock error, ionospheric delay, tropospheric delay, and other corrections should be carefully dealt with in high-precision GPS positioning.

GPS signals undergo two effects when they move through the atmosphere, bending and...
time delay, due to the atmospheric refraction. There are two major atmosphere layers: the troposphere and the ionosphere. The geometric bending of GPS signals with elevation angles above 5° is negligible. The delay in the ionosphere is dependent on signal frequency and, thus, can be eliminated by the combination of signals of different frequencies. The troposphere is essentially a nondispersive medium for frequencies below 30GHz (GPS signals frequency: below 2GHz). So, the tropospheric delay cannot be eliminated by frequency combinations; it is usually estimated in positioning models or predicted by tropospheric delay models.

In addition, errors in satellite orbits and clocks, relativistic effect, multipath, and receiver measuring noise also have an impact on the positioning accuracy. The receiver clock error is usually estimated as an unknown parameter in observation equations. The satellite orbit and clock errors can be reduced by using International GNSS Service (IGS) precise orbit and clock products. The relativistic effect can be calculated by physical equations. Multipath error can be weakened by using advanced receiver antennae or placing the antenna in an open-view environment or extending the observation time. The receiver measurement noise can be weakened by using advanced antennae and receivers.

During GPS positioning, geometrical dilution of the precision (GDOP) is usually used as an important index of evaluating satellites’ geometry. The wider separation among the satellites, the lower the GDOP value and the better positioning accuracy can be obtained.

In positioning and navigation, the accuracy of the GPS SPS is limited to a few meters. This is due to the large residual of atmospheric errors as well as satellite orbit and clock errors. To improve the SPS accuracy, a method called differential GPS (DGPS) has been developed. In DGPS, the differences in GPS observations from two receivers and two satellites can be used to eliminate common errors. Differential observations between two receiver stations can eliminate the satellite-related errors and significantly reduce spatially correlated errors (mainly tropospheric and ionospheric delays). With differential observations between two satellites, the station-related errors are eliminated and spatially correlated errors are reduced. Double differential observations eliminate the satellite-related and station-related errors at the same time and spatially correlated errors are further reduced. Because of this, DGPS is widely used around the world. In recent years, a new method called precise point positioning (PPP) has been developed, in which carrier phase measurements from a single GPS receiver are used to achieve positioning and navigation accuracy much higher than the SPS (to a few centimeters in static mode and to the decimeter level in kinematic mode). However, the PPP method requires the use of precise orbit and clock data from GPS satellites. Meanwhile, the GPS receiver takes tens of minutes to fix the carrier phase ambiguities in order to get the expected accuracy.

Global Navigation Satellite Systems

Integrated GPS and GIS systems: data collecting and mapping

GPS is an advanced tool for collecting accurate positions for point, line, and polygon features while the geographic information system (GIS) has developed to be a very useful cartographic tool for storing, manipulating, and visualizing all kinds of geographic data and attribute information with useful spatial analysis functions. By incorporating GPS and GIS, location data could be quickly and accurately collected and imported into GIS, which will be very helpful for creating, validating, updating, and maintaining GIS spatial information and attributes/features.
The progress in GPS/GIS integration in geography and geographic information science (GIScience) has led, during the past several decades, to the creation of real-time interactive (RTI) GPS/GIS systems. RTI GPS/GIS has created new possibilities to interact with, represent, and make decisions about the world in real time (Richardson 2013). It enables individuals to interact in real time with both their actual and digital environments simultaneously in daily life, and also allows researchers to better approximate and spatially model how individuals and populations interact with the world around them (Kwan 2009, McQuoid and Dijst 2012).

RTI GPS/GIS functionality has enabled the collection and use of geospatial data and attribute information to be achieved in a more detailed, timely, and accurate way than ever before, generating massive quantities of new, fused spatiotemporal data (including sensor data attributes). Location-based services (LBS) are among the many industries where RTI GPS/GIS technology plays an important role. In LBS, the GPS provides accurate location information while the GIS displays and updates in real time the street maps, attributes, and users’ locations. Besides the location service, LBS can also provide other location-related services that users are interested in, such as restaurants or shops nearby and how to get there. Miniaturized RTI GPS/GIS functionality has now been embedded also in consumer electronic devices such as cell phones and navigation devices, which further enriches the application of LBS and many other applications.

As technology advances, mobile devices become common in professional GIS and survey work. Mobile devices with embedded RTI GPS/GIS functionality, such as smartphones and tablets, have become an essential part of how people communicate and get their information. These devices usually have a position accuracy of 5–6 m under ideal conditions, which has long prevented them from being a viable solution for GIS survey work in the field. Modern professional-grade GNSS receivers are becoming smaller and more portable, and address the accuracy limitations of an older smartphone or tablet device. The small, compact professional-grade receiver provides submeter location data directly to the smart device via Bluetooth®. An example of a Trimble R1 GNSS receiver is shown in Figure 6. By simply pairing the device with their smartphone or tablet, GIS professionals can get the accuracy needed to quickly and reliably locate their asset, collect data, and move on to the next task. Other models of professional GNSS receivers for GIS applications have been placed on market, too. For instance, the Trimble R2 GNSS receiver is built for GIS professionals and surveyors alike and is capable of delivering between submeter and centimeter positioning accuracy in real time to a Trimble handheld or a smart device. Such high-accuracy handheld GNSS receivers are often combined with rugged cases for carrying out GIS field data collection and industrial or environmental inspection activities.

**Other GNSS systems**

**GLONASS**

The global orbiting navigation satellite system (GLONASS), maintained by the Ministry of Defense of the Russian Federation, is the second operational satellite navigation system with global coverage. The first GLONASS satellite was launched in 1982 and it became a fully functional navigation constellation in 1995. The GLONASS constellation consists of 24 satellites equally distributed on three orbital planes, with eight evenly spaced satellites on each plane (RISDE 2008). The three orbital planes are separated by 120° in the equatorial
Figure 6  The Trimble R1 receiver connects wirelessly to a smart device via Bluetooth connectivity.

plane. Satellite orbital altitude is about 19 130 km above the ground surface with an inclination of about 64.8° and a period of 11 hours and 15 minutes (RISDE 2008). The GLONASS orbit was designed especially to be suitable for use in high latitudes, where receiving a GPS signal can be problematic. Unlike the GPS that uses the code division multiple access (CDMA) technique to discriminate the signals of different satellites, GLONASS uses frequency division multiple access (FDMA) to distinguish between the satellites. All GLONASS satellites transmit the same C/A and P codes, but each satellite is allocated a slightly different frequency. Thus, users’ receivers can identify the satellite according to these different frequencies. However, modernized GLONASS satellites are gradually adopting the CDMA technique. The launch of the first GLONASS-K satellite in February 2011 marked the introduction of CDMA technique to the GLONASS signal broadcasting.

Galileo

Galileo is the European navigation satellite system currently under development by the European Union and European Space Agency. The first experimental satellite was launched on December 28, 2005 and sixteen satellites have been launched as of July 2016. Currently, nine satellites are in operation and four others are in the commissioning stage. The Galileo system aims to provide its initial operational capability (IOC) by 2017–2018 and reach full operational capability (FOC) in 2019. The constellation will consist of 30 medium Earth orbiting (MEO) satellites (24 in full service and 6 spare satellites), distributed evenly over three orbit planes (EU 2010). The orbital altitude is 23 222 km and the inclination is 56° with ascending nodes separated by 120° longitude (eight operational satellites and two active spares per orbital plane). The ground segment includes the Galileo control centers, telemetry tracking and control stations, uplink stations for transmitting navigation signals, and up to 40 Galileo sensor stations for receiving the navigation signals from the constellation and transmitting them to the Galileo control centers. The responsibility of the ground segment is to manage navigation of the satellite constellation and control the core functions of the navigation mission, such as satellite orbit determination and clock synchronization.

BeiDou

The BeiDou navigation satellite system (formerly known as COMPASS) is the Chinese version of a GNSS and is being developed rapidly. It began to offer services in China and neighboring areas in December 2011, with 10 satellites in use; a regional version including 16 satellites covering Asia and the Pacific area was completed by December 2012. As of December 2015, 24 satellites for the BeiDou system have been launched, 18 of which are in service. All the BeiDou satellites use the CDMA technique and share the same nominal frequency. The
BeiDou navigation satellite system is scheduled to become globally operational upon its completion in 2020. By then, the space segment of BeiDou system will consist of five geostationary Earth orbit (GEO) satellites, 27 MEO satellites, and three inclined geosynchronous satellite orbit (IGSO) satellites (CNSO 2013). The GEO satellites are operating in orbit at an altitude of 35,786 km and positioned at 58.75° E, 80.2° E, 110.6° E, 140° E, and 160° E, respectively. The orbital altitude of MEO satellites is 21,528 km with an inclination of 55° to the equatorial plane (CNSO 2013). The IGSO satellite orbit altitude is 35,786 km above ground surface and its inclination is 55°.

Regional augmentation systems

IRNSS: The Indian regional navigational satellite system (IRNSS) is an autonomous regional satellite navigation system being developed by the Indian Space Research Organization, with an aim to provide accurate positioning and timing services throughout India. The Indian government approved the project in May 2006 and completed the system in April 2016. On April 28, 2016, the IRNSS was officially renamed as Navigation with Indian Constellation (NAVIC) by the Indian Prime Minister. The constellation of seven NAVIC navigational satellites (orbital altitude is 36,000 km) includes three GEO satellites, four GSO satellites, and a support ground segment. The three GEO satellites are located at 32.5° E, 83° E, and 131.5° E. Two of the GSO satellites cross the equator at 55° E and two cross at 111.75° E. This orbit design means that all seven satellites are always visible to the Indian region.

QZSS: The Japanese quasi-zenith satellite system (QZSS) is a regional time transfer system and satellite-based augmentation system (SBAS) for the GPS. The first satellite was launched on September 11, 2010. The QZSS is expected to have four satellites by 2018 and up to seven satellites after 2018. The signals transmitted by QZSS satellites are compatible with the GPS L1 C/A signal, as well as the modernized GPS L1C, L2C, and L5 signals. The QZSS is designed primarily to increase the GPS availability in Japan, with the secondary function to increase the accuracy and reliability of GPS-derived positioning solutions.

WAAS: The wide area augmentation system (WAAS) is a satellite-based SBAS developed by the US Federal Aviation Administration with the goal to enhance the accuracy, integrity, and availability of the GPS. WAAS models the errors (mainly satellite orbit error, satellite clock error, and ionospheric error) in the GPS satellite signals using a network of ground-based reference stations in North America. Master stations process the measurements from the reference stations and send the correction messages to geosynchronous communication WAAS satellites. The satellites then broadcast the correction messages to users who are equipped with WAAS-enabled GPS receivers to compute their positions with improved accuracy.

EGNOS: The European geostationary navigation overlay service (EGNOS) is an air navigation aid developed by the European Space Agency, the European Commission, and EUROCONTROL to augment the GPS, GLONASS, and Galileo systems. Consisting of three geostationary satellites and a network of ground stations, the EGNOS system aims to improve the GPS positioning and navigation accuracy to within 3 m. The initial operations of the EGNOS system started in July 2005, with accuracy better than 2 m and availability above 99%. The EGNOS Open Service has been available since October 1, 2009; its Safety of Life service was officially declared available for aviation on March 2, 2011.
Other transformational applications

In addition to the traditional applications of global navigation satellite systems in navigation and positioning, the potential of global navigation satellite systems has been demonstrated in various applications, ranging from civilian to military, from general public to scientific research (Gleason and Gebre-Egziabher 2009; Someswar, Rao, and Chigurukota 2013).

**Precision agriculture:** In precision agriculture, global navigation satellite systems can be applied in farm planning, field mapping, tractor guidance, and crop scouting (Gleason and Gebre-Egziabher 2009). Global navigation satellite systems allow agricultural equipment to steer automatically. Farmers may use global navigation satellite systems to work during conditions such as rain, dust, fog, and darkness when low visibility occurs.

**Timing and synchronization:** The high precision of GNSS timing can be used for a variety of applications for timing and synchronization purposes. For time division multiple access (TDMA) communication networks, precise timing is often adopted to synchronize radio frequency generating equipment, network equipment, and multiplexers.

**Emergency services:** Emergency services can make use of GNSS functionality to locate the person in danger. The rescue coordination center can thus act quickly to get to the site.

**Weather prediction:** In the propagation from the satellite to ground receiver, GNSS signals will be delayed and bent by the atmosphere. Global navigation satellite systems can be adopted to determine atmospheric conditions, such as moisture, that can be used for weather prediction.

**Social networking:** Cell phones equipped with GNSS technology can provide geographic location for social networking functions (Someswar, Rao, and Chigurukota 2013). Based on the location information, many apps offer the ability to search friends or to pinpoint nearby facilities on custom-created maps.

**Transportation and logistics:** In many countries, traffic congestion and road safety have become serious social issues. Global navigation satellite systems can offer meter- to submeter-level service to land vehicle lane-level navigation, intelligent transportation, and management. Global navigation satellite systems can also be used for e-commerce or online shopping to improve the logistics and transportation of commodities for reaching clients. The instantaneous service of GNSS positioning could be used by clients to track their commodities online.

**Future trends**

Global navigation satellite systems are now widely used throughout our daily lives and this trend will continue in the foreseeable future. With the rapid development of GNSS technology during the past several decades, global navigation satellite systems have been applied in many scientific research and engineering applications, such as earthquake monitoring, meteorological weather service, ionosphere and space weather monitoring, geohazard monitoring, natural resource monitoring, LBS, and surveying and mapping, land, water, and air navigation systems. GNSS applications are also found in many fields of scientific study, including space weather, geophysics, geography, geology, ecology, and biology (Gleason and Gebre–Egziabher 2009). In the future, the development of global navigation satellite systems will be toward multisystem and multi-application, with goals to ultimately provide better performance and broader services for mankind. The majority of GNSS applications are currently based on GPS and GLONASS performances. Once the Galileo and the BeiDou systems are
fully operational, the ability to process signals from multiple systems will further improve availability and accuracy for users. At present, many countries and governments are concerned with substantial socioeconomic issues, including environmental pollution, transportation safety, extreme poverty, and natural disasters. Global navigation satellite systems are increasingly integrated with other technologies and systems to help address these problems. For example, applying a GNSS in emergency situations creates an efficient tool for numerous emergency services, such as the fire brigade, police, and sea and mountain rescue, allowing them to respond more rapidly to those in danger. The future of global navigation satellite systems is bright, with the progressively increasing number of constellations from multiple global navigation satellite systems, as well as new applications that will benefit from the increased robustness and availability of high-accuracy GNSS solutions.

Global production networks

Martin Hess
University of Manchester, UK

In the twenty-first century, the world economy has seen substantive challenges and changes, not least the global financial crisis, the ramifications of which are still being felt around the globe. Contemporary economic globalization can be characterized by the increased functional and geographical fragmentation and reconfiguration of production processes, deepening outsourcing and offshoring, changing geographies of production and consumption, and associated labor market dynamics including the ascent of temporary and migrant work. These dynamics have become increasingly prevalent with the rise of neoliberalism and the end of the Cold War, triggering new lines of social sciences inquiry into globalization and economic development. Moving beyond more state-centric approaches to economic development studies, approaches such as commodity chain research and global value chain analysis have been developed to better understand the social and developmental consequences of contemporary capitalism (Bair 2005). It is within this context, sharing such a research agenda, that the global production network (GPN) concept emerged as an analytical framework and heuristic tool to understand the changing nature and dynamics of economic globalization and regional development. The following discussion will first present the conceptual foundations of the GPN framework and its intellectual influences. Subsequent sections will focus in turn on power relations between actors and their impact on governance structures in and of GPNs; the increasing fragmentation of GPNs through outsourcing and offshoring, driven by, among other factors, corporate as well as other forms of financialization; the role of labor and labor agency in GPNs; and the dynamic relationships between GPNs and regional development. The entry will conclude with brief reflections on GPNs as politically contested fields and their “discovery” by policymakers and international organizations as arenas of international governance and developmental “tools.”

GPNs: conceptual cornerstones

As an analytical framework, the GPN concept has been developed since the late 1990s by a group of scholars in economic geography and international economic sociology, mostly based at the University of Manchester at the time. It emerged from a growing dissatisfaction with existing theories of economic development that operated either at macro-levels or micro-levels of abstraction and thus failed to capture the increasingly complex, networked nature of economic activities under neoliberal globalization and their impacts on uneven development at various scales. The construction of the GPN framework rests on a number of historical precursors. Hess and Yeung (2006) identified four strands of literature informing this approach: (i) the 1980s value chain literature associated with the work of Michael Porter; (ii) work on networks and the social embeddedness of economic activities as developed in economic

The International Encyclopedia of Geography.
sociology; (iii) actor-network theory (ANT), which emerged in the context of science and technology studies; and (iv) most notably, the literature on global commodity chains and global value chains, originating in world-systems theory and developed since the 1990s by Gary Gereffi and his colleagues.

Porter’s value chain analysis has been influential in both academic and policy circles, highlighting the various activities a firm performs and the resulting systems of inputs, transformations, and outputs making up the production process. Influential in economic geography for the analysis of industrial clustering, it has also informed the GPN framework with regard to the centrality of value creation and the spatial organization of production processes and service provision. To better understand how economic activities are organized within and between firms, the role of social networks and the embeddedness of economic action in ongoing social relations – in contrast to the methodological individualism of transaction cost economics – have to be integrated as crucial elements in GPN analysis. Economic sociology and an emerging literature on relational economic geography therefore had a major impact on the development of the GPN framework. This was complemented by insights from ANT and its emphasis on a nonessentialist approach to studying networks and actors. ANT reinforces a relational view, avoiding artificial dualisms like structure/agency and global/local, and thus opening up analytical space for investigating multiple actors and their heterogeneous relations in GPNs.

Finally, global commodity chains (GCCs) and global value chains (GVCs) have provided a major impetus for the GPN framework. GCC analysis addresses four different dimensions (Gereffi and Korzeniewicz 1994): an input–output structure describing the production process and associated activities along the chain, from raw materials to the final product; the territoriality of GCC, which represents its geographical configuration; the governance dimension, which denotes the power relations of actors (firms) along the commodity chain; and an institutional dimension, the background of state regulation and other institutional rule-setting against which firms in GCCs operate. The GVC framework built on this conceptualization with a view to refining the forms of governance found in inter-firm value chains, and – echoing some insights from Porter’s value chain approach – paying more attention to the local and regional dimension of clusters within GVCs.

Based on a critical engagement with these conceptual antecedents, and following Henderson et al. (2002), a GPN can be defined as the nexus of interconnected functions and operations through which goods and services are produced, distributed, and consumed. Over the years, GPNs have become organizationally and geographically more complex, increasingly blurring traditional organizational boundaries. They integrate regional and national economies, cutting through state boundaries in highly differentiated ways to create discontinuously territorial structures that are shaped by regulatory and nonregulatory barriers as well as variegated sociocultural conditions of the places connected by GPNs.

The GPN framework draws on three analytical registers: value, power, and embeddedness (Henderson et al. 2002). Two notions of value are important for GPN research. First, value is to be understood as surplus value created in transnational production systems through the labor process. This brings into focus issues of employment, working conditions, and productivity at various points in the network, with far-reaching consequences for socioeconomic development. Second, value refers to the notion of different forms of rents that firms can realize
within GPNs. These include technological rents, through access to advanced product and process technologies; brand rents, realized through a strong market presence and consumer preferences; organizational rents, achieved by optimizing managerial and organizational skills and production processes; and relational rents, through strategic links with other firms in the wider GPN. Other forms of rent may also occur. For example, in sectors where global trade is highly regulated or restricted, preferential access may generate "trade policy rents," as in the now defunct global trade regime in textiles and garments known as Multi Fibre Arrangement.

In relation to economic development, these two vectors of value creation are complemented by processes of value enhancement (increasing the value added at various stages of production) and, crucially, value capture: that is, the process of retaining economic benefits. The latter is of particular importance for both firms in GPNs and the places and societies they connect.

How and where value is created, enhanced, and captured depends on the power relations between the multiple actors in GPNs. Firms exercise corporate power based on their position within GPNs, their different capabilities, and the resources available to them. State and civil society organizations exercise power that influences firms’ operations; rather than forming an external environment within which firms act, these nonfirm actors are conceptualized as integral parts of GPNs. Thus state organizations assume power through authority as regulators and facilitators of economic activity, but also exercise buyer power as major consumers (public sector purchasing), and producer power (through state-owned enterprises). Civil society actors produce various forms of collective power, for instance through labor unions, nongovernmental organizations (NGOs), and consumer initiatives, which can also have considerable impact on GPNs by putting pressure on lead firms.

Finally, GPN analysis takes into account the embeddedness of economic activity, along three dimensions (Hess 2004). Societal embeddedness – a notion that draws on the work of Karl Polanyi – refers to the importance of an actor’s institutional and cultural background in shaping their actions, rather than deploying a universalistic notion of rational economic agency. Network embeddedness – from Mark Granovetter’s work in economic sociology – puts an emphasis on the relevance of social ties that shape the relations between actors in GPNs. Finally, territorial embeddedness takes into account the geographical dimension of GPNs and the varying degrees to which firms, nonfirm organizations, and institutions are “anchored” in particular places. Together, embeddedness, power, and value constitute the three analytical lenses of the GPN framework, guiding research into GPNs’ organizational, geographical, and developmental dynamics.

**Governing GPNs**

From early GCC analysis through to the GVC and GPN frameworks, a central concern has been with the governance of interfirm relations and the asymmetrical distribution of power between firms. The initial taxonomy developed in this context distinguishes between buyer-driven and producer-driven commodity chains. In industrial sectors where high capital requirements are the main barrier of entry for firms, as in the automotive and aircraft industries, the value chain is driven by large manufacturers (producers). Buyer-driven value chains are found in sectors that are labor-intensive and where entry barriers are primarily the design, marketing, and branding capabilities of lead
GLOBAL PRODUCTION NETWORKS

firms. Examples include the garment and light electronics industries (Gibbon, Bair, and Ponte 2008). While this taxonomy has proven useful to identify and analyze one important aspect of the distribution of power within GPNs, the increasing complexity of contemporary production systems does not always conform to this. Other forms of governance have subsequently been identified, such as technology-driven value chains characteristic of information and communication industries (particularly software), where entry barriers lie with the control of technological standards and related intellectual property rights.

While providing insight into some fundamental power configurations within GPNs, these types of chain-driving governance structures are quite crude, obscuring the multiplicity of power relations between firms (and nonfirm actors) within a GPN. To better capture the various power relations between firms, a typology of value chain coordination has been developed that describes the nature of exchange between firms as five possible forms of governance: market-based governance, where transactions are easily codified around simple products; modular value chains, where codification of transactions extends to complex products (e.g., between automotive manufacturers and first-tier module and component suppliers); relational value chains, where governance of complex products and exchange requires frequent communication; captive value chains, where suppliers are highly dependent on and monitored by their buyers; and hierarchical value chains, where exchange is internalized within the firm (in-house production).

Even this taxonomy, however, does not include an appreciation of power relations in GPNs extending beyond interfirm exchange, and actors which are also crucial for the configuration, dynamics, and governance of GPNs: state and nongovernmental organizations, civil society and consumers. Economic processes of production, distribution, and consumption are not simply driven by lead firms in GPNs and coordinated between firms along the value chain (Coe, Dicken, and Hess 2008). They are embedded in wider systems of sociospatial relations and shaped by nonfirm actors operating with their own spatial logic and according to their own specific goals and priorities. The GPN framework therefore explicitly recognizes nonfirm actors as integral parts of the production network. Consequently, state–capital–society relations in the places linked through GPNs are fundamental in shaping economic and social outcomes. Thus an explicitly geographical perspective is critical to understanding the ways in which GPNs are governed and different stakeholders struggle over the creation and capture of value.

This requires GPN research to conceptualize power more explicitly, rather than only in terms of the individual or collective actors exercising it. Following the work of John Allen (2003) on geographies of power, three different forms of power can be distinguished in investigating governance structures of/in GPNs (Hess 2008). The most commonly used view is a realist conceptualization of power as a capacity, something which individuals or organizations (firms, states) possess, enabling them to dominate others by virtue of social relationships. For firms, this potential to dominate derives from various resources and firm capabilities, and enables them to control or direct the actions of others, as in the case of lead firms driving value chains. Governments, at various scales, derive their power from the authority and sovereignty accorded to them as political institutions.

While conceiving of power as a capacity to influence others, whether or not it is exercised, is certainly important to understand the dynamics of GPNs, it is not sufficient. Actors can also
mobilize resources that are not all of their own making, through collective action and cooperative network relationships. In such a relational, networked view, shared resources become the medium through which power is exercised. This opens up possibilities for "powerless" actors (firms lacking individual resources, workers, consumers) to work together for mutual benefit and achieve their respective goals. Examples for this range from the labor union movement to consumer and NGO campaigning, from firms’ strategic alliances to state-negotiated trade agreements, none of which can be understood purely through power as a capacity.

Finally, and more recently, GVC and GPN analysis have both developed a third lens of power relations by drawing on Foucauldian notions of power as knowledge and practice, moving from a governance perspective to a governmentality approach. Of interest here is how power is mobilized and practiced, and the specific techniques and discourses used and “normalized” to direct the behavior of other actors and achieve specific outcomes. These practices and techniques, including supply chain management to orchestrate interfirm relations and corporate social responsibility codes of conduct, often become institutionalized in the form of standards as an important element of GPN governance. Some types of standards, for instance environmental or social, may be coproduced through the collaboration of various firm and nonfirm actors; others, like some proprietary technological standards such as Apple Inc.’s mobile phone operating system, are produced in the context of the competitive struggle for market control and value capture through brand rents (Coe, Dicken, and Hess 2008).

The variety of governance forms and power relations found in GPNs, within and across different territories, has become increasingly complex since the mid-1980s, as global production systems have continued to expand their global footprint and become increasingly fragmented in organizational terms. The following section examines this “new wave” of globalization (Milberg and Winkler 2013) in more detail.

GPNs, fragmented production, and financialization

The second half of the twentieth century has seen a growing tendency of transnational corporations (TNCs) from the Global North shifting production activities to the Global South, especially in labor-intensive industries. This process has been described in the literature as a new international division of labor (NIDL), taking advantage of a large and growing labor force in developing economies, the transfer of standardized production processes that require only low-skilled workers, and the reduction of transport and communication costs based on new technologies. While still relevant today, as in the garment and consumer electronics industries, the NIDL thesis does not fully capture the drivers for the reorganization of GPNs that have emerged since the 1980s. Contemporary capitalism is characterized by a global division of labor that has experienced major geographical restructuring among world regions, the growing interpenetration of global processes, regional dynamics and local conditions, and massive transfers of people through migration, a workforce that GPNs seek to attract. Another striking feature of these transformations is the increasing fragmentation and vertical disintegration of production, through outsourcing, subcontracting, and offshoring.

Outsourcing refers to a firm’s strategic decision to purchase goods or services from other companies, rather than producing them in-house. The reasons for outsourcing usually lie in attempts to
save cost and enhance profitability by focusing on what a firm sees as its core competences and where it has a competitive advantage. Interfirm divisions of labor and outsourcing are by no means new, described in such classic texts as Alfred Marshall’s account of the Sheffield cutlery industry in *The Economics of Industry* (Marshall and Paley Marshall 1881). Alfred Marshall’s work highlighted the role of spatial proximity for the organization and profitability of interfirm divisions of labor, and was drawn on in the emerging literature on geographical clusters of economic activity. He could not foresee, however, the wave of outsourcing across national borders that became increasingly global in nature, referred to as offshoring. This has become a central empirical and conceptual feature of GPN and value chain research.

The transnational relocation of manufacturing and service activities – whether through international outsourcing or offshoring in-house activities – is pursued for a variety of reasons, including the pursuit of greater flexibility, the avoidance of risks through location diversification, and of course reducing cost to maintain or increase profitability. The combined effects of outsourcing and offshoring are manifest not only in the complex geographies of contemporary GPNs, but also in substantial changes in international trade. The “slicing up” of value chains has led to a growing trade in intermediary goods and components, along with finished goods. Therefore, for firms in GPNs, supply chain management has become an important element of competitiveness and a crucial strategic asset. At the same time, the offshoring of service tasks (for instance, call centers, back-office functions) has further increased what is called “trade in tasks.” These developments provide economic opportunities for some firms in developing and emerging economies, but other players, failing to realize the potential of new global divisions of labor, have lost their competitiveness.

Financialization has become much more important for GPNs since the mid-1990s (Coe, Lai and Wójcik 2014; Milberg and Winkler 2013). In the context of GPN research, financialization can be analytically broken down into three interrelated forms. First, it denotes the increased significance of the financial sector vis-à-vis other economic sectors. Financial markets have always been important for the functioning of GPNs, but their powers have continually grown since the liberalization and deregulation of the sector from the 1980s onward. By the early twenty-first century, the value of global financial markets is estimated at about three times the global gross domestic product, with approximately US$15 trillion traded annually. Accelerated financial integration, with a growing propensity for financial decisions in one place to influence conditions in others, has substantial consequences for GPNs. The financial system incorporates all actors and territories in GPNs (states, firms, individuals, cities, regions, and nations) via investments and borrowing, but also through taxation and public expenditure. This leads to the second aspect of financialization, the formation of global financial networks. Such financial networks, global in nature but centered on a small number of global cities like New York and London, intersect with GPNs in various ways and are crucial for their working. Networked financial institutions over the last decades have designed, produced, and sold increasingly sophisticated financial products, with implications for the third form: corporate financialization.

Firms in GPNs have shifted their focus of profitability away from traditional sources like production and toward profits gained through financial activities. Corporate financialization is linked to the fragmentation of production
Laboring in GPNs

While emphasizing how transnational production systems are orchestrated by a variety of firm and nonfirm actors, arguably the role of labor and the agency of workers in shaping GPN have been undertheorized. This is problematic, not least because the process of value creation and enhancement under capitalism is not only a question of generating different forms of economic rent from the production process or of generating profit in financial markets, but is also reliant on the labor process by which labor power is transformed into surplus value. Labor therefore needs to be considered explicitly in GPN research. Such an analysis should recognize the outcomes for workers, for example in terms of wages, working conditions, and labor rights, but also the potential for workers to transform and shape GPNs based on their individual and collective power and agency. Much of the literature addressing labor has focused on public- and private-sector governance of labor relations and on developing labor standards, but it often conceptualizes workers as rather passive and at the receiving end of capital and state power. In order to eliminate this blind spot, GPN literature has started to engage with the work of labor geography and the industrial relations literature (Coe and Hess 2013).

Since the formation of the labor movement in Europe during the Industrial Revolution and the subsequent legalization of trade unions, collective labor agency in the form of labor unions has played an important role in ensuring labor rights and improving working conditions. Through collective bargaining, workers exercise power vis-à-vis capital to negotiate a fair share of the value created and generally improve their lot. As production in GPNs has extended in scale and scope, however, the global fragmentation of value chains has posed additional problems for organized labor, as it tries to match the capability of capital to organize across national and international space. Unlike capital, labor is socially and, to a large extent, territorially embedded, and therefore in danger of being played off against labor in other locations. Yet trade unions have developed strategies to upscale their activities, establishing their own global networks. Two forms can be distinguished: labor networks centered on a specific TNC, where bargaining takes place, for instance, through international framework agreements between unions and a single employer; and Global Union Federation-centered networks, which usually cover a specific industrial sector and negotiate with various firms in GPNs.

While collective agency through trade unionism clearly has empowering effects for labor in GPNs, this has been gradually eroded in this era of neoliberal globalization. Labor markets around the world have been increasingly deregulated, leading to growing numbers of “flexible,” casualized, and often precarious jobs in manufacturing as well as services. In the wake
of this, new labor market intermediaries such as temporary staffing industries have emerged to play an important part in many countries, fueling GPNs with domestic and migrant labor. Under these circumstances, traditional collective action by organized labor has a declining potential to galvanize workers’ power. Yet individuals and groups still have agency in shaping GPNs and the conditions of work within them. Following Cindy Katz (2004), worker agency can take the form of strategies of resilience, where people develop everyday coping mechanisms. It can result in reworking strategies, where individuals or communities work to actively improve the material conditions of their existence, and it can lead to strategies of resistance, through which the status quo of capitalist social relations is directly challenged. Thus labor is most certainly not a passive element in the formation of GPNs.

Yet working conditions and enabling rights in GPNs continue to be areas of serious concern. The collapse in 2013 of the Rana Plaza building in Dhaka, Bangladesh, in which more than 1100 garment workers died, was a horrendous incident that threw into sharp relief the dark side of fragmented production in GPNs in the pursuit of profits, and reopened academic and public debates about the responsibilities of governments, firms, and consumers in GPNs to safeguard workers’ lives and livelihoods, especially in labor-intensive industries in the Global South.

One way in which recent GPN research has taken up the challenge of conceptualizing labor, as socially embedded agents and human beings rather than simply factors of production, is the notion of social upgrading in GPNs (Barrientos, Gereffi, and Rossi 2011). Social upgrading can be defined as the process of improving the rights and entitlements of workers as human beings and social actors, enhancing the quality of their employment, and improving the living standards of workers, their families, and communities. In most of the literature, this is broken down into two components: (i) measurable labor standards, including wage levels, working hours, social protection entitlements, and type of employment – regular or irregular; and (ii) enabling rights, including freedom of association and the right to collective bargaining. The concept of social upgrading is usually deployed together with the notion of economic upgrading which describes improvements in technology, skills, and productivity that generate enhanced profits derived from participation in GPNs. It is often assumed that economic upgrading is positively associated with social upgrading, but empirical studies have shown that this is not necessarily the case. How the economic and social dimensions of labor in GPNs play out in specific places to generate positive outcomes for workers depends on how labor agency is shaped by the governance structures of particular GPNs (the vertical dimension) and by the local social and economic conditions of employment and work (the horizontal dimension). This returns us to wider questions of socioeconomic development at the global–local nexus.

**GPNs and regional development**

To understand regional development in an era of global, networked capitalism, it is clearly not enough to focus on local, endogenous factors alone. At the same time, economic globalization cannot be adequately explained without paying attention to the specific assets and socioeconomic conditions in different countries, regions, and localities. In a relational view, both the growth factors within a given region and the strategic priorities of transregional and transnational firms that orchestrate GPNs need to be taken into consideration in order to investigate and explain development outcomes. In the GPN
literature, this has been labeled the globalization of regional development, a process whose outcomes are far from certain, depending on the strategic coupling of regional assets with GPNs (Coe et al. 2004). Regional assets include the size and composition of the workforce (human capital), education and research facilities, and natural resource endowments, among others. Three aspects are characteristic for the strategic coupling process between regions and GPNs: first, it is time- and space-contingent, subject to change but also path-dependent; second, it is multiscalar and transcends territorial boundaries; third, it is strategic because the coupling process comes about through the intentional and active intervention of multiple actors.

Mediating the strategic coupling process is a range of institutions operating within and beyond the region, in particular government, labor, and business agencies, with the aim of generating beneficial outcomes in terms of value generation, enhancement, and capture, and hence economic development through the integration of regions into wider GPNs. Positive outcomes from globalizing regional development through strategic coupling are not guaranteed, however; insertion into GPNs may be detrimental in specific circumstances, depending on the power configurations and asymmetries in the relevant networks. Coe and Hess (2011) term this the “dark side” of development, which can manifest itself in the form of ruptures within regions (e.g., political exclusion, displacement or eviction of people) and between regions and GPNs (e.g., disinvestment, exit of foreign firms). It can also result in friction when such connections cause social and economic tension and conflict within and beyond the region, such as social and class conflict, struggles over uneven value capture, labor exploitation, or growing gender inequality. In such cases, institutions will often aim for strategic de- or recoupling (Horner 2014) to improve regional developmental outcomes.

GPNs are part of development as the geographically uneven and historically contingent expansion and extension of capitalist systems of production, exchange, and regulation. They are also an arena for organized intervention by private and public actors with different implicit and explicit goals (Hess 2009). As firms in GPNs develop their networks of capital accumulation, they are always operating in the context of (potential) societal and social resistance and protective social movements, a process that has been described by Karl Polanyi (1944) in his institutionalist view of development as the “double movement.” This process plays out through organizational networks and coalitions across different scales, and GPN research grounded in relational concepts of space needs to be conscious of this if it is to produce non-reductionist understandings of globalization and regional development, in both their material and discursive dimensions.

Arguably, GPN analysis has much to offer in terms of research into regional development and the experiences of different places enmeshed to various degrees in global networks, but of course it cannot claim to be fully adequate to capture all dimensions of development, let alone be the only heuristic to guide empirical research. In a sympathetic critique, Kelly (2013) argues that some crucial elements for fully understanding development in place are obscured by exclusively utilizing the GPN concept. For example, he highlights the importance of environmental and landscape changes that usually escape the gaze of GPN research unless they are immediately relevant for the transnational and regional firms being studied. A similar “blind spot,” in Kelly’s view, is the realm of households and families. He attributes these shortcomings to a tension between the network ontology underlying a
relational GPN framework and a place-based ontology found in other work on (regional) development that assumes localities and regions as “complete” – albeit not bounded – entities and spaces of lived experience. A dialogue and exchange between the GPN concept and cognate approaches, recognizing the possibilities and limitations of one another, needs to continue as part of a critical cultural political economy of GPNs and regional development.

GPNs: a politically contested field

To conclude, the GPN framework as developed since the turn of the century provides a heuristic device with which to analyze the complex realities of economic globalization and economic development. On the ground, GPNs are not only networked forms of organization and value creation in increasingly global markets, but also political in character – making them highly contested fields (Levy 2008). They connect multiple sites of struggle for the creation, enhancement, and capture of value, shot through with power relations that ultimately determine the implications of GPNs for territorial development. One of the antecedents to the GPN framework, global value chains, has recently gained much prominence in international policy circles, from the International Monetary Fund and the World Bank to the World Trade Organization and the International Labour Organization. Indeed, some are concerned that GVC analysis is running the danger of becoming another neoliberal tool, despite its rootedness in critical social science, as its central ideas are “translated” into the international development policy realm that, critics argue, still follows orthodox economic development ideas and practices (e.g., Fernández 2014; Neilson 2014). Thus it is imperative for global production network analysis and cognate approaches to maintain their critical focus, investigating GPNs as both economic and institutionalized, highly political, and discursive structures with far-reaching and often contradictory developmental outcomes.

Globalization and rural areas

Michael Woods  
Aberystwyth University, UK

Globalization is a major driver of change in rural areas around the world, impacting on economic activities, structures, and relations; migration patterns and the composition of rural populations; and cultural traditions and practices of environmental management. Globalization is a complex and multifaceted phenomenon, involving the multiplication, stretching, and intensification of social, economic, political, and cultural relations over space which leads to places becoming more tightly integrated in transnational networks of inter-dependence. As such, globalization challenges popular perceptions of rural areas as places that are isolated from mainstream economies and culture and that retain greater economic independence and cultural distinctiveness than cities. In practice, many rural areas have long been integrated into global networks of trade and migration, notably through colonialism. However, late twentieth-century and early twenty-first-century globalization is distinguished by the reach and intensity of transnational connections, and by the immediacy of communications and transactions between distant places.

In practice, many rural areas have long been integrated into global networks of trade and migration, notably through colonialism. However, late twentieth-century and early twenty-first-century globalization is distinguished by the reach and intensity of transnational connections, and by the immediacy of communications and transactions between distant places.

Research on globalization in geography has tended to focus on urban areas and particularly on the concept of the “global city,” to the relative neglect of rural areas. This tendency has contributed to the conflation of globalization and urbanization in analysis of rural change, with the erosion of rural cultural and economic distinctiveness attributed to integration into urban systems, which in turn have become increasingly interconnected through globalization. As such, rural experiences of globalization were positioned as mediated through the concentration of power in global cities. This analysis was particularly associated with research conducted from a political economy perspective, which focused primarily on structures, processes, and institutions rather than on communities, and thus emphasized dependency and convergence over local difference.

More recent rural research, however, has drawn on the relational approach to globalization developed by geographers including Ash Amin and Doreen Massey, which sees places as unique entanglements of social, economic, and political relations that are reconfigured in globalization. The relational approach has a number of implications for the analysis of globalization in a rural context. First, by highlighting the complexity and contingency of the relations that link places, and the uniqueness of their intersection in a specified place, it suggests that globalization produces cultural and economic hybridity, not homogeneity. Second, by revealing relations that can be rural-to-rural as well as rural-to-urban, it shows that globalization is not necessarily always mediated through global cities. Third, by arguing that globalization is reproduced through the reshaping and substitution of relations within place, it demonstrates that the outcomes of globalization are not inevitably positive or negative. And, fourth, by pointing to the diffusion of power in globalization, not its concentration, it indicates that rural actors have agency to affect the outcomes of globalization in their localities. These features are presented by Woods (2007)
as characteristics of an emergent “global countryside” in which rural places are changed by globalization but continue to be different from each other (see also Aguayo 2008).

**Rural areas and the global economy**

One of the most significant expressions of globalization in rural areas has been the incorporation of rural economies into longer and more complex commodity chains, linking sites of production and consumption. The development of global commodity chains (or global value chains) has been facilitated by technological advances, market deregulation, and trade liberalization affecting all economic sectors, but notably in a rural context in relation to agriculture and food (see, e.g., Challies and Murray 2011). Between 1970 and 2010, the value of global agri-food exports increased from less than US$100 billion to over US$1100 billion per year, with a greater share of food being produced for export, and the distance traveled by produce bought by consumers (known as “food miles”) increasing. The lengthening of these supply chains has been enabled by improvements in transport and preservation technologies that have changed the principles of agricultural geography by allowing perishable food to be sold over longer distances, and also by trade agreements that have dismantled controls on agri-food imports designed to protect domestic farmers. Free markets for agri-food products have been created within regional economic blocs such as the European Union and the North American Free Trade Agreement (NAFTA) area, while negotiations at the World Trade Organization (WTO) have attempted to remove trade barriers and abolish production subsidies in agriculture under pressure from the Cairns Group of agri-food-exporting nations.

Global agri-food commodity chains do not only connect sites of production and consumption in different countries, but can also involve commodities being sent for processing or packaging in third or fourth countries, as companies seek cost efficiencies. Accordingly, the spatial division of labor in agriculture has become increasingly fragmented, with impacts for rural localities. The weakening of local supply chains has altered social and cultural relations between farmers and local communities; food-processing industries that had located close to sites of production have closed down as their functions are concentrated in lower-cost locations; the incomes of individual small farmers have been squeezed by competition from cheaper imports, and their financial power reduced; and landscapes have been transformed as production has been switched to new commodities with higher market value or export potential. Globalization has consequently promoted increased regional concentration and specialization in agricultural production, including the relocation of industries such as intensive livestock farming to regions that offer not only lower production costs but also looser environmental and animal welfare regulations.

Footloose economics is evident in rural areas in respect to not only agriculture, but also other traditional industries including mining and forestry, with smaller mines and paper and lumber mills closed as production is concentrated in fewer, larger, sites. The search for new resources to supply global markets has led mining companies to increasingly remote locations (often staffed by “fly in, fly out” shift workers), and spurred both deforestation in regions such as the Amazon and new commercial forestry plantations in areas such as Australia. In manufacturing, some regions such as rural Ireland benefited in the late twentieth century from new branch plants attracted by land availability and low labor costs;
yet some of these factories have subsequently been closed – along with longer-established factories in industries such as textiles – as production has been relocated to more cost-effective locations in Central America and Southeast Asia. In some rural areas, the closure of a mine, mill, or factory has meant the loss of the dominant employer in a single-industry town, prompting community decline and depopulation.

Economic globalization is also associated with the increased influence of transnational corporations that dominate markets in traditional rural industries, having squeezed out or taken over local firms. Mining and forestry are dominated globally by a handful of companies that each operate on a transnational scale. In agriculture, while the majority of the world's farmers are still small-scale individual farmers, agribusiness accounts for an increasingly substantial share of global production, and key parts of agri-food commodity chains are controlled by limited numbers of transnational corporations. These include biotechnology firms with control over inputs such as seeds and fertilizers, and supermarkets, food-processing companies, and fast-food brands, which are the major purchasers of agricultural produce. In some cases, companies have formed strategic alliances to achieve “vertical integration,” with interests at each step of the commodity chain, from “seed to shelf” (Hendrickson and Heffernan 2002). In this way, relations between transnational corporations and individual farmers are unequally weighted. In India, for example, transnational biotechnology firms have been accused of pushing genetically modified seed that would make farmers dependent on their supplies and chemicals. Similarly, supermarkets and fast-food corporations can use their market power to depress prices paid to markets, standardize requirements for the appearance and variety of produce, and determine practices in animal welfare, pesticide use, and labor conditions.

Corporate power in the global agri-food system is exercised not only by agribusiness and supermarkets, but also by banks, pension funds, and traders, who supply the financial capital for investment and set the prices of agricultural commodities. Financial speculation has been an important part of capitalist agriculture since the nineteenth century, permitting farmers to off-load risk by selling future crops to speculators at guaranteed prices. However, deregulation of trading in food futures in 2000 sparked a surge in investment in food derivatives from US$3 billion in 2003 to US$126 billion in 2011, which has been accused of contributing to the sharp rise in global food prices in 2008, but which has had little effect on farm incomes. Over the same period, international investments in rural land have also increased, colloquially referred to as “land grabbing.” These have in part been driven by concerns about food security following the 2008 crisis, with sovereign wealth funds in affluent but land-poor countries such as Qatar, Saudi Arabia, and the United Arab Emirates, and corporations in Japan and South Korea, purchasing land in Africa, Central and South Asia, and Australia, in order to secure the supply of food for domestic markets. Yet, private investment brokers and funds have also purchased farmland in Africa and parts of the former Soviet Union as an opportunity for Western investors. Although some of these projects are presented as assisting agricultural development, international land investments have been criticized for replacing staple crops with cash crops, diverting resources such as water, extracting profit from poor rural communities, and in some cases displacing peasant farmers.

Indeed, across much of the Global South, and notably in South America, globalization is associated with depeasantization, as the
livelihoods of peasant farmers have been threatened by the opening of local markets to imported food and the diversion of resources to support export-oriented industrial agriculture. To survive, farmers have been forced to become migrant workers, or paid farmworkers on large corporate farms, in some cases selling their land to agribusinesses (see, e.g., Echánove 2005; Rigg 2006).

International migration and rural areas

Alongside economic globalization, rural areas have also been affected by the increasing global mobility of people as migrants and tourists, acting as both a source of and a destination for international migrants. As described, the impacts of economic globalization have contributed to a flow of labor migrants from disadvantaged rural areas, especially in the Global South, to more prosperous regions both nationally and internationally. In many cases, migrant workers leave families at home, at least initially, and remittances from labor migrants have become a major source of income in many rural areas. Furthermore, as labor migrants from the Global South tend to be young men, the demographic character of rural communities is changed, as are roles within the community, including the feminization of agricultural work in some parts of Africa and Asia.

Although most labor migrants head to cities, there has been a growth in the number of labor migrants living and working in rural areas of Europe, North America, and Australia, commonly employed in marginal jobs in agriculture and food processing, with limited pay and conditions. As such, migrant workers have filled a void created by efforts to achieve global competitiveness by minimizing labor costs that have deterred recruitment of local workers and made industries such as horticulture, meat-processing, and salad packing dependent on immigrant labor. Some of the highest growth rates in the Latino population in the United States since the mid-1990s have been in rural counties in the South and West, especially areas with large-scale poultry production, while migration from Eastern Europe to Britain since the enlargement of the European Union in 2004 has produced new concentrations of Polish residents in areas of intensive agriculture such as Lincolnshire. Many of these localities have little previous experience of large-scale immigration, and tensions can develop over cultural differences and competition for jobs and housing. Yet, Torres, Popke, and Hapke (2006) point to a “silent bargain” in which rural communities accept labor migrants for the economic contribution they make, and migrant workers accept low wages and poor employment conditions for the perceived safety and tranquility of living in a rural area.

Rural communities can also be transformed by international amenity migration, an extension of domestic counterurbanization with individuals moving to rural areas abroad for a combination of economic and lifestyle reasons. Amenity migration is associated with rural localities that offer recreational amenities (mountain and coastal resorts) or idyllic landscapes and historic villages, but also cheap, empty property left by depopulation or a low cost of living, and access by budget air travel, including parts of southern and Eastern Europe and Central America. In particular, amenity migrants are commonly attracted to areas that are already popular with international tourists, and there is a blurred line between amenity migration and residential tourism, with some migrants moving permanently but others occupying foreign properties only seasonally or for vacations. Both international tourism and amenity migration can boost rural economies and help revive declining villages, but they can also generate tensions around infrastructure.
Globalization and rural areas

developments, the inflation of property prices, and the commodification of local cultures for tourist consumption (see, e.g., Woods 2011).

Global consciousness and rural environments

In addition to the multiplication, stretching, and intensification of social and economic relations, some commentators also describe globalization as including the growth of global consciousness, as improved communications, increased travel, and the growth of the global media have made people better informed about other parts of the world and more likely to think in global terms. This has affected how people perceive rural areas, with understanding of rural life informed by globalized media representations that blur geographical differences. The growth of global consciousness has also involved a globalization of values, in which there is an expectation that universal standards apply across the world, regardless of historic cultural differences. The globalization of values is promoted by transnational nongovernmental organizations (NGOs) and campaign groups, which can elevate localized issues to international causes, and is encoded in international treaties and agreements. In rural areas, conflicts have arisen when globalized values clash with traditional cultural practices, such as seal hunting in Canada or bullfighting in Spain, or farming activities such as the live export of livestock. Similarly, the transnational conservation movement has promoted standardized approaches to environmental protection, including the designation of protected areas (such as national parks) on international models that introduce restrictions on the traditional use of natural resources by rural communities or, in some cases, the eviction of people from designated zones. There are estimated to be up to 136 million “conservation refugees” globally, who have been displaced from protected areas (see Brockington and Igoe 2006).

Rural responses to globalization

Globalization extends to all parts of the rural world, but different rural regions experience globalization in different ways. As globalization includes a multitude of different processes, some will have greater impact in some regions than others, and the balance of negative and positive impacts will also vary (Woods 2007). The impact and outcomes of globalization in a particular region are shaped by a number of factors including geographical location, economic structure, natural resources, transport infrastructure, and human capital, as well as by the policies and actions of governments and other local agents. In many regions, rural development strategies have attempted to engage proactively with globalization by seeking to attract foreign direct investment (FDI), encouraging international tourism, or supporting entrepreneurship to develop export markets for local products (see, e.g., Cheshire and Woods 2013). At the same time, revived interest in regional cultures and efforts to promote local food systems can also be seen as responses to globalization, as people react to a perceived loss of identity or economic independence.

Responses to globalization can also be more confrontational, as activists attempt to resist changes that are perceived to threaten local economies, cultures, and environments. Protests by farmers against food imports or the influence of transnational corporations have occurred in several countries, including Britain, France, Australia, India, and South Korea, with actions
including blockades of ports and attacks on symbols of globalization such as fast-food outlets. In Western countries such actions have not generally been coordinated internationally or been framed as antiglobalization protests. More direct links to the counterglobalization movement have been made, however, by rural movements in the Global South, especially in Latin America and Asia, and notably through the international farmers’ movement La Via Campesia (The Peasants’ Way). Rural activists have joined counterglobalization protests at major international summits, including WTO meetings, and regional concerns have been highlighted by transgressing space to reach international audiences, with, for example, Indian farmers mounting a series of demonstrations in Europe to protest against trade agreements and the introduction of genetically modified (GM) crops by transnational corporations (Featherstone 2003).

Globalization

Matthew Sparke
University of Washington, USA

A specter haunting the world with both promise and peril, globalization names a process of increasing but uneven global integration that is bringing market-mediated interdependency along with enormous inequality, asymmetry, and volatility to life across the globe (Sparke 2013). As a promotional and promissory Discourse, globalization has been increasingly politicized in ways that associate observations about global market integration with repeated calls for more market freedom. Thomas Friedman, for example, is a columnist for the New York Times who has made a name for himself globally by recommending pro-market reforms everywhere on the basis of arguing that the world is becoming flat, and that we must adapt or just get flattened. Globalization, he says, “involves the inexorable integration of markets, nation-states, and technologies to a degree never witnessed before – in a way that is enabling individuals, corporations and nation-states to reach around the world farther, faster, deeper and cheaper than ever before. The driving idea behind globalization is free-market capitalism – the more you let market forces rule and the more you open your economy to free trade and competition, the more efficient and flourishing your economy will be” (Friedman 1999, 7–8).

The sudden uptake in the use of the actual word “globalization” in the last two decades of the twentieth century has clearly been linked to such advocacy of market rule, or what critics call Neoliberalism (Harvey 2005). For the same reason, its emergence as a key term of political debate needs to be examined in relation to at least three intersecting global imperatives: first, the economic shifts of the post-Fordist era (from roughly the 1970s onwards) in which corporations shifted from the Fordist balancing of mass production and mass consumption nationally to pursue market opportunities globally; second, the ideational achievements of pro-market academics, advocates, and think-tanks in promulgating neoliberal orthodoxy as a “business-knows-best” consensus; and third, the global political and economic dominance of the United States, which has led to a series of complex associations between globalization, Americanization, and the ups and downs of US hegemony.

Between militarized shock therapy for some and the commercial advance of McDonaldization, CocaColanization, and Wal-Martization on others, the variegated triangulations of globalization-neoliberalization-Americanization have been best theorized as a form of informal, market-mediated Imperialism (Gindin and Panitch 2012). Some of the associations with more overt forms of US militarism in the Bush administration’s “global war on terror” may also at least partially account for the fall-off in the use of the non-US spelling “globalisation” (with an “s”) after 2003 (see Figure 1).

But these terminological tendencies noted, globalization should by no means simply be viewed as American, unidimensional, or unipolar, especially now that Asian economic growth, the new triangles of Asian investment in Africa and Latin America, and the emergent terms of “Asianization,” “Easternization,” and “ChIndia”
Moreover, as feminist scholarship further underlines, the ties and tensions of global integration are also embodied in intimate power relations that are as uneven and violent as they are intertwined with the asymmetries associated with changing configurations of global hegemony (Mountz and Hyndman 2006). Christa Wichterich, the author of *The Globalized Woman*, puts it like this: “For women around the world … globalization is not an abstract process unfolding on an elevated stage. It is concrete and actual. Female textile workers from … Eastern Germany are losing their jobs to women in Bangladesh; Filipinas clean vegetables and kitchens in Kuwait; Brazilian prostitutes offer their services around Frankfurt’s main railway station; and Polish women look after old people at rock-bottom prices in … Germany” (Wichterich 2000, 2).

It is amidst such embodied experiences of globalization, at once global and personal, that diverse articulations of precariousness are being critically reinterpreted as the basis for more emancipatory kinds of global consciousness and collaboration. Global precarity may in this sense inspire global solidarity (Butler and Athanasiou 2013). The globalization and adaptation of the *Indignados* and *Occupy* movements following the 2008 financial crises can certainly be interpreted this way. But, by the same token, the sad fate of the Arab Spring that co-inspired the *Indignados* and *Occupy*, indicates that cruel winters of precariousness can return with a vengeance, and, in Egypt at least, new rounds of neoliberalization too (Atia 2013).

Reimagined in terms of planetary precariousness, ideas about living in a fragile global ecumene may also create the basis of transnational communities that can globalize both human health rights and (more-than-human) environmental security in the face of market-induced insecurities. But for global precarity to inspire solidarity in this way, it clearly needs to be distinguished from the personalized, marketized, and, as such, increasingly neoliberalized practices of “resilient life” – practices that invoke the
inevitability of catastrophes of global finance, global health, and global climate change only to advocate for individualized and enclaved efforts at market-mediated adaptability. Against such apocalyptic-turned-adaptive accounts of enduring the “Anthropocene” (see Anthropocene and planetary boundaries), it is possible instead to explore how the interdependencies of the market and its degradation of the global commons nevertheless open opportunities for the active creation of the world as a common community beyond the market. Such alter-globalization efforts consciously politicize the political unconscious of the Anthropocene, rendering the inevitability invoked in pro-market globalization discourse open to resistance in the name of global climate justice, and thereby also opening globalized pathways out of the Kyoto–Copenhagen–Cancún–Durban dead end (Bond 2012).

Before contemporary climate justice struggles, the globalization of anti-neoliberal resistance in other areas has long been discussed by critical theorists. David Harvey’s revision of Marx’s notion of “primitive accumulation” (generally thought of as a pre-capitalist precursor moment of dispossession in which workers were deprived of their capacity for subsistence) as ongoing “accumulation by dispossession” (rethought as a form of ongoing destruction or removal or privatization of the commons and the personally shared) works well to further highlight how we have been witnessing a vast global accumulation of grievances against market-mediated dispossession (Harvey 2005). Conceptualizing all these responses as a singular global response to globalized capitalism, however, risks romanticizing resistance as well as obscuring how exactly ongoing value extraction and accumulation is tied to diverse forms of extra-economic domination. Most notably, for example, this is the danger in suggesting that a so-called Empire of networked global capitalism is co-creating its own nemesis in the form of a globalized and media-enabled “Multitude”: a multitude that is becoming interconnected and experimental enough to break out from within the matrix of atomized consumerism and contingent labor control. In order to be more materialist about such emancipatory possibilities, feminist geographers suggest that we need first to denaturalize the disabling “impact model” of globalization as an inevitable, unstoppable, and leveling juggernaut of market-led integration. And key to this denaturalization of dispossession is the challenge of replacing the flat world visions used by pro-market promoters to naturalize neoliberalism with more accurate geographies of the inequalities, asymmetries, and unsustainability in the actual real-world experience of uneven global integration.

The discipline of modern geography, with its origins in enabling early imperial rounds of globalized dispossession, is by no means a “natural” place from which to denaturalize dispossession. Indeed, as critically informed as the field of geography now is, the asymmetries in its globalized patterns of publication still point to Anglo-American dominance and the tendency towards exclusion of non-English accounts from publications – including this Encyclopaedia – that aspire to move to more inclusive and collaborative kinds of intellectual globalization. Reciprocally, some of the most powerful geographical critiques of flat-world globalization discourse have come from outside the Global North and outside the discipline. One of the best textbooks on globalization available, for example, is a brilliantly geo-graphic (as well as graphic) account by the Mexican cartoonist El Fisgón (Rafael Barajas Durán), published under the subversively subaltern title of How to Succeed at Globalization: A Primer for the Roadside Vendor. “Location, location, location,” is what El Fisgón’s main character – a roadside
vendor from Mexico City – is told when he asks how he might succeed at globalization; the point being that he really needed to have started out in another household, in another city, in another wealthier part of the world in order to benefit from the skewed arrangements of opportunity and exploitation that shape global integration (Fisgón 2004). This kind of geographical critique is also echoed in Vandana Shiva’s powerful retort to Thomas Friedman himself. “Friedman,” she writes in a scathing review of The World is Flat, “has reduced the world to the friends he visits, the CEOs he knows, and the golf courses he plays at. From this microcosm of privilege, exclusion, blindness, he shuts out both the beauty of diversity and the brutality of exploitation and inequality, he shuts out the social and ecological externalities of economic globalization and free trade, he shuts out the walls that globalization is building – walls of insecurity, hatred and fear – walls of ‘intellectual property’, walls of privatization” (Shiva 2005).

Overcoming the epistemic exclusions and blinders of its own imperial roots and routes, research within the formal discipline of geography is also now mapping the uneven political geographies of dominance, governance, and resistance shaping actually existing globalization. Attuned to the powerful presentism through which neoliberal globalization discourse asserts its own novelty, such work has further underlined how flat-world ontologies are inevitably ahistorical too, despite having historical-geographies. To be sure, some poststructuralist geographers (see Poststructuralism/poststructural geographies) further suggest that we need another kind of flat ontology in order to challenge fantasies about equalized access through market flattening. But, inspired by thinkers such as Badiou, Derrida, and Deleuze and Guattari, they do so deconstructively with a view to shaking off preconceived axioms about what sorts of spatial connection and hierarchy get to count as globalized in the first place. This in turn makes it possible to go from debunking globalization as discourse to examining its consequential framing effects in ways that include attention to the uneven economic developments that the dominant flat-world discourse itself tends to obscure.

One area where the assertive framing power of globalization discourse has been especially obvious (and obscuring) is in international relations and associated diplomatic, military, and foreign policy discussions that frame war, peace, and security in the terms of, on the one side, disconnection and geopolitical danger, and, on the other, global integration and geoeconomic opportunity. The actual term “geoeconomics” is still not widely used, and the work of the French economic geographer Jacques Boudeville, who first developed it, remains largely unknown. Nevertheless, as market-led globalization has intensified, geoeconomic arguments and visions have become increasingly popular and have even been formalized by Edward Luttwak as a new grammar for foreign policy. In place of orthodox geopolitics and its concerns for soldiers and citizens, this geoeconomic grammar tends to elevate the entrepreneurial interests of investors and customers; in contrast to a geopolitical focus on national borders and place, it privileges networks and pace; and instead of concentrating international politics on building alliances for “security” against supposed “evil empires,” geoeconomics is primarily concerned with building international partnerships that advance “growth,” “integration,” “harmonization,” and “efficiency” against the threats of “traditionalism,” “isolationism,” “anachronism,” and “anarchy.” In this dualistic discursive system, globalist claims about the “borderless world” and ideas about geoeconomics eclipsing Geopolitics have become influential scripts accompanying claims about globalization’s supposed historical novelty – even
though historical-geographical work documents that earlier rounds of global integration themselves came with similar talk of transnational capitalist expansion and opportunity.

While historical work points up the dangers of too quickly periodizing and separating a geopolitical past from a geoeconomic present, ongoing geographical research points in turn to the need to avoid partitioning the globe into geopolitical spaces defined by disconnection and geoeconomic spaces of globalized connection. Postcolonial geographies of the colonial present instead make clear that the supposedly “disconnected places” – places that are depicted by partisans of geoeconomics as mired in geopolitical strife because of a lack of globalization – have in fact long been connected through predatory forms of imperial connection and biopower. This point is also ironically confirmed by today’s apologists for empire who map the borderlands of intervention in terms of making the world safe for globalization and minorities at the very same time. In another way, political geographies of actual real-world borders have made clear that border regions are sites where, despite all the attempts to envision borderless geoeconomic futures, geopolitical ideas, affects, and imperatives keep coming back to shape practices of (b)ordering transnational flows on the ground. So rather than locate geopolitics in the past or in regions wrongly represented as disconnected, it seems far more useful to see geopolitics and geoeconomics as entangled, geostategic discourses that encode underlying tensions of global uneven development (Sparks 2013, Chapter 8). These tensions can in turn be at least partly explained in terms of the ongoing tensions between spatial fixity and spatial expansion in capitalism itself (Harvey 2005). And while all sorts of other imperatives ranging from the personal and emotional to the national and territorial to the global and ecological also overdetermine uneven development, much of the ongoing oscillation between geopolitical and geoeconomic discourses can thus be parsed in terms of the tensions between capitalist fixity and expansion that have made the long-term development of globalization so episodic, asymmetric, and geographically transformative.

GLOBALIZATION

Glocalization refers to the interaction of the spatial scales of global and local influences, with universalizing influences and models modified to fit local preferences and practices. In this regard, “glocalization” is less global and more a local response to perceptions of modernization requirements. Studies of glocalization appear in diverse fields. Originally a Japanese business concept for taking initially local products to a wider market, the term was later adopted by academics in the social sciences (Castree, Kitchin, and Rogers 2003). A popular jingo exhorts individuals to “think globally, act locally.” Glocalization is an issue for developing regions seeking to modernize by combining traditional systems with global practices for acceptance into or by a desired larger-scale group. Glocalization asserts the necessity for rejecting homogenization, given the need to retain some forms of locally specific traditional values or practices.

Concepts of time and distance are frequently involved when practices are intermixed from different locales and cultures, and the Western/developed becomes “global” versus the local “other” (Robertson 1996). Interaction between scales means that systems such as Japanese corporate-level “just-in-time” and “lean manufacturing” can permeate a global set of production practices that result in the subnational shaping the supranational (Sharma 2009). Rather than a polarity of opposite or differentiated parts, the term refers to a blend of complementary practices whose territorial identification occurs across political borders, interacting at a different cultural or intercommunication level. Transborder and within-border ethnicities with supra-border extensions also exemplify glocalization processes that display the effects of transboundary ties. Rather than referring to the border-transcending quality of the multi- or transnational, glocal emphasizes the incorporation of nonglobal specificities. The increase in physical and virtual mobility underlies the use of this term in a number of fields, signifying accelerating hybridity and an awareness that to understand this phenomenon requires a sensitivity to embedded values. Corporations selling products in varied countries and markets need to “glocalize” by adapting their portrayal to segmented market attitudes regarding cultural portrayals, for example.

Governance and development

University of Witwatersrand, South Africa
University of Johannesburg, South Africa

The origins and locus of governance

As a heuristic tool, governance draws attention to the fact that authority is plural and diffuse rather than singular and central. Governance is accumulated in many different spheres of authority (Rosenau 1997). Government itself is not a single site of authority but rather a kaleidoscope of intersecting political affiliations, ministries, jurisdictions, and scales. Authority occurs in many spheres beyond government, as can be seen in relationships between employers and employees, customers and suppliers, nongovernmental organizations (NGOs) and beneficiaries, donors and NGOs, leaders of a political party and members, and religious leaders and their followers. Furthermore, governance can occur in the absence of any authority insofar as processes of socialization guide everyday practices through informal rules and conventions.

These many spheres of authority are, in turn, shaped and contained by one another. Within a national context, the conduct of the government is itself governed by the law, the results of elections, oversight committees, and watchdog organizations. Meanwhile, national government is informed by the international context. For example, the way in which individual nations govern trade across their borders is shaped by agreements reached at the World Trade Organization. Therefore authorities do not govern in isolation but are themselves governed and circumscribed by superiors, peers, and citizens, and by intersecting and competing spheres of authority.

Governance is strongly defined by the legacy of systems established in the past. Contemporary authorities do not start from a blank slate but inherit an established bureaucracy which cannot easily be dismantled or changed. Authorities often commit themselves to incrementally improving existing systems or to introducing fixes for limitations. Major new bureaucratic capacities require enormous investment and political will. In 2011, for example, India began a process of registering hundreds of millions of people according to biometric information such as iris and fingerprint scans in order to enable direct welfare distribution (Szreter and Breckenridge 2012).

In addition to temporal considerations, governance has spatial qualities. Some authorities have spatially defined jurisdictions, as in national governments over a national territory, a province or state over a subnational region, or a municipal government over a city. This can have important material outcomes. For example, water delivery may be entirely different between two nearby cities as a result of the divergent approaches of the respective municipal governments. However, territorial boundaries do not always demarcate governance in a simple manner (Agnew 1994). Authorities do not have complete sovereignty over everything within their borders, and powerful influences can originate elsewhere. Furthermore, authorities govern their territories...
and populations in uneven ways. Chatterjee (2004) argues, for instance, that the way in which middle classes are governed in India is very different to the way in which poor populations are governed. Moreover, authorities do not simply “govern” people en masse by virtue of their happening to be within a particular territory, but relate to people through specific social interactions and diverse modalities (Allen 2003).

The scale at which populations and processes are, and should be, governed is an important strategic consideration. The foundational unit of governance in the modern period is the Westphalian nation-state which has enormous capacity to set and police legal parameters, and to acquire and allocate tax revenue. Yet nations may enter into cooperation in order to achieve social objectives that transcend their territories. For example, the efforts of one nation to reduce the emission of greenhouse gases are ultimately futile if emissions are not reduced globally, and so cooperative efforts have been underway to secure international governance systems on carbon emissions. Many more multilateral institutions such as the United Nations, the European Union, and the World Bank have resulted in governance parameters being defined beyond individual nation-states.

While the governance of some issues occurs at the supranational level, other responsibilities have been shifted toward local scales (Batterbury and Fernando 2006). Some advocates of reform have argued that some responsibilities should be devolved to subnational regional government units and local government in order to achieve greater efficiency and accountability.

These shifts in scale have enormous implications for the raising of revenue, enforceability, and the way in which different interests try to assert their own advantage by moving between places in order to find favorable governance environments. For example, the flight of wealth to tax havens presents an important governance challenge.

Shifts in scale are evident in other spheres of governance, such as the way manufacturers govern themselves. Under Fordist conditions, manufacturing was vertically integrated. The trend toward post-Fordism in the late twentieth century was characterized by the outsourcing of some, or even all, production processes to sometimes distant suppliers. Outsourcing has replaced one kind of governance, of employees by employers within a factory, with another kind, of suppliers by customers within a value chain. Suppliers comply with price, quality, and other pressures for fear of losing their contracts. Manufacturers stand to benefit from reducing the complexity of their direct responsibilities and the option of locating production in regions where labor is cheaper.

Steering people, processes, and organizations

As Antonio Gramsci (1971) argued, authorities use a combination of coercion and consent in order to attempt to bring about specific or general processes and outcomes. Coercion refers to the way in which authorities assume, or are granted, the ability to force people or organizations to conduct themselves against their inclinations. Disciplinary measures are a normalized feature of modern society. For example, traffic fines deter drivers from speeding, the threat of disconnection compels consumers of electricity and water to pay their bills, and the police may repress protests. In contexts where political rights are not recognized, authorities can resort to draconian methods. In the late 1800s, for example, colonial authorities in southern Africa attempted to force Africans to
enter the workforce by imposing taxes so that they would have to earn a wage.

While coercion is ubiquitous, and authorities at particular junctures try to dominate society, there are limits to this form of power. For example, many city governments in the Global South have attempted to ban street trading but eventually given up because people trade on the streets irrespective of the illegality of doing so. Neither can a goal such as gender equality be fully achieved through decrees and sanctions from above. Large social processes cannot be controlled through force in any absolute sense and there is a limit to coercion in the absence of popular buy-in.

Within liberal democratic contexts, authorities ostensibly relate to free citizens. Rather than micromanaging everyday life, liberal authorities regard citizens as free agents who make their own choices (Miller and Rose 2008). The role of authorities within liberal contexts is to establish governance frameworks which are akin to the rules of a game. This is not to say that authorities cannot direct people. Behavioral economists argue that people can be steered through incentives and disincentives. For example, taxes on alcohol and cigarettes are intended to discourage consumers from buying them without forbidding them from doing so. Meanwhile incentives can be provided to encourage certain behavior. In Brazil and Mexico, grants are awarded to poor families on condition that they keep their children in school.

The power of modern governments tends to derive from the alignments between those who govern with the majority of those who are governed. Where such alignment exists, most people and organizations conform to rules voluntarily, and authorities only need to police a defiant minority. Those in authority therefore govern with the consent of most subjects. As Michel Foucault (2008) has shown through his work on governmentality, this consent is itself manipulated. The “art of government,” he argues, is to shape subjects’ values, desires, and habits so that people internalize what is required of them, thereby largely negating the need for discipline.

The role of bureaucracy

Centralized bureaucratic authority has occupied an ambivalent position within development thinking. The decades following World War II were characterized by Weberian optimism that bureaucracies were the foundation of an ordered and modern society. Experts and professionals would solve social problems by collecting and scientifically analyzing data, and arriving at rational and impartial interventions.

Over time this optimism has given way to concerns that technocratic approaches are not necessarily benign. Top-down programs run the risk of prioritizing the vision of experts and technocrats over the welfare of vulnerable groups. The goal of slum-free cities is, at face value, a well-meaning ambition in that slums are poor living environments. Yet overzealous governments who remove people from slums in an attempt to create slum-free cities leave those evicted in a much worse off position (Huchzermeyer 2011). Also, Marxist approaches argue that in capitalist societies, states are not neutral arbitrators but tend to side with privileged interests and to support the process of capitalist accumulation (Glassman and Samatar 1997). Likewise, experts may present themselves as neutral, but sometimes represent elite economic interests over the needs of the poor (Ferguson 1990).

Technocratic approaches also necessarily flatten a complex world through their attempts to apprehend it through data and categorizations. These simplifications are made in order to render
complex society more “legible” (Scott 1998, 2),
but they result in a single bureaucratic response

to a great deal of individual variety. These
abstractions can, in turn, have disabling conse-
quences for those they classify. Cash transfers in
Mexico have been criticized for adding to the
burden of women by casting them in a maternal
role (Molyneux 2008). Furthermore, processes
of categorization can divide people, resulting in
fundamentally different treatment. The Chinese
*hukou* system of household registration was used
in the twentieth century to discourage urbaniza-
tion. However, large populations have migrated
to cities for work anyway but, as a result of their
rural registration, they are not covered by urban
social support systems.

Influential concerns about bureaucracies were
also raised by free-market, or *neoliberal*, thinkers
that the “ambitious and impatient reformer”
(Hayek 2011/1960, 376) does more harm than
good, and central authorities are not benevolent
(Lal 1985). These critics feared that bureau-
cracies became self-justifying, commandeering
ever more resources and imposing themselves
on parts of society that would be more likely to
succeed on their own. By the 1970s and 1980s,
various economic crises were attributed to
bureaucracies overreaching themselves, resulting
in price distortions and the crowding out of the
private sector.

More generally, the once positive image of
bureaucracy has unraveled as a result of the fact
that, in practice, it has not always been impartial,
rational, or progressive. Those in authority
might use their positions for their own finan-
cial or political interest. Rather than enabling
development, then, structures of authority have
the capacity to undermine it, not least because
vulnerable people in need of support may be
unable to access it unless they are able to posi-
tion themselves to benefit from favoritism or
to pay a bribe. Furthermore, funds intended
for the benefit of the public are lost to private
accumulation.

These growing doubts resulted in greater
amounts of development work being done
through NGOs and private corporations, and a
desire to diminish state intervention in order to
allow markets to meet needs and grow. How-
ever, by the 1990s, sentiment was shifting away
from “sterile debates about ‘how much’ states
intervene” toward an interest in how states do
intervene and the impacts of these interventions
(Evans 1995, 10). Evans argued that newly
industrializing countries were not explicable by
the free market alone but by states that were
sufficiently autonomous to act independently of
rent-seeking interests, yet sufficiently embed-
ded to facilitate development. The varieties
of capitalism literature explored the way in
which institutions have shaped the behavior of
firms and the long-term trajectory of economic
growth (Hall and Soskice 2001). Meanwhile,
new institutional economics has highlighted the
role that the state can play in reducing transaction
costs and encouraging investment by protecting
property.

From the 1990s, mainstream development
targeted the reform of bureaucracy under the
rubric of good governance to ensure that it was
enabling development and to reduce its coun-
terproductive tendencies. An entity is taken to
be well governed if it demonstrates good control
over its budgets and executes its functions in
an impartial, fair, transparent, procedural, and
accountable way. Performance management
systems have been widely introduced in order to
attempt to govern the effectiveness of officials.
Many definitions of good governance incorpo-
rate the need for democracy to ensure that vested
interests do not parasitically entrench themselves.

Another important outcome of the critique
of top-down bureaucratic governance has been
pressure to expose governance decisions
and systems to deliberation and participation. Experiments in institutionalized participatory democracy in Kerala (India) and Porto Alegre (Brazil) show that ordinary people can be incorporated into the operational aspects of governance. Radical democrats draw attention to the governing role of popular pressure through which ordinary people can assert their wishes through resistance, protests, and lobbying. Meanwhile, autonomists, anarchists, and those who subscribe to postdevelopment thinking, argue that greater social justice is fostered when people govern themselves without the interference of government, and when they are able to escape the free market through self-sufficiency.

**Governing production and social reproduction**

Marxist analysis argues that there is an important relationship between *production* – the way in which society produces goods and services – and *social reproduction* – or the way in which society invests in the welfare of people over time (Katz 2004). This is so, first, because systems of production generate the revenue that enable people to meet their needs, and, second, because economic systems require investments in people to create a labor force needed in the economy. Where there is a high demand for productive labor, capital and the state have reason to ensure that labor has good education, health-care, and living environments. Fordist social compacts associated with welfare states in the Global North were the quintessential example of improving access to the means of life through market (wages and occupational welfare), state (in-kind services and cash-based welfare), and family (the division of labor within families so that those not earning wages are materially supported). In the Global South, the focus of many development strategies has been to expand the productive base in order to increase the size of the economic “pie,” and therefore the possibility of improving welfare. These strategies have taken divergent forms.

In the decades following World War II, some nations allied themselves with the USSR (e.g., China, North Korea, Vietnam, Cuba) or pursued socialism independently (e.g., India, Ghana, Egypt, Tanzania, Argentina). Governance arrangements were based on state planning, direct state control of production, nationalization of key assets, communalization, price control, subsidies, and social spending. In some cases – given that industrial sectors were not developed – these incorporated experiments in agrarian socialism.

In the context of the Cold War, officials in the West were concerned about what they regarded as the threat of communism, and so promoted a governance strategy based on a virtuous cycle of industrial investment, improving productivity, improving wages, and improving savings. Expansions in the industrial sector would draw in populations who were “underemployed” in the agricultural sector, causing a general process of modernization. As countries developed their comparative advantage, they could engage in trade with others.

A great deal of the industrialization that did take place in the postwar period was inspired not by anticommunist neoclassical approaches but by a desire to reduce dependence on the industrial countries of the North. Structuralists and dependency theorists were concerned that periphery nations that traded with core nations would always be disadvantaged since, they believed, the primary goods they exported would buy them fewer secondary goods over time. Many nations, particularly in Latin America, deployed protectionist governance systems known as import substitution industrialization, through which
high import tariffs discouraged importation and encouraged local production.

This strategy was ultimately limited by the size of the domestic market. This, along with a wider crisis of inflation and debt, laid the ground for a radical shift in the 1980s toward trade liberalization. Economic growth was to be unleashed by enabling producers to supply to the global market. However, the concomitant reduction of protection devastated many industries oriented to domestic markets. Meanwhile East Asian nations were well placed to benefit from trade liberalization since industrialization efforts were export-oriented. The ensuing “East Asian Miracle” was initially touted as a vindication of neoclassical approaches to trade, but subsequent analysis has shown that interventionist states played a crucial role in this success.

Widespread debt crises in the early 1980s resulted in bailouts from the International Monetary Fund (IMF) and the World Bank. These structural adjustment programs carried the condition that states would restructure themselves to become market-friendly, not only by reducing import tariffs but also through other state interventions regarded as price distorting such as price controls and subsidies. They were urged to pursue various forms of deregulation, for example of financial controls. Further, states were enjoined to reduce responsibility for social expenditure and to privatize the provision of some services and public enterprises.

Proponents of liberalized economic growth argue that they have been proved correct by the dynamism of middle-income countries, the appearance of large middle classes in the Global South, and the improvement of workers’ conditions in places such as China. Critics argue that gains have been highly uneven and have very often benefited privileged groups at the expense of others (Smith 2008). Economic growth has, at times, been achieved, but at the same time labor supply increased dramatically as a result of the entry of women into the workforce and the introduction of previously unavailable labor pools from China and the USSR into global production (Harvey 2010). The result has been that large populations who would like to be employed cannot find work, or, given the competition for work, any available jobs are highly exploitative. Some development perspectives have valorized the informal economy, arguing that entrepreneurialism provides the livelihoods that are not provided by the labor market. One mechanism which has received a great deal of attention in this regard has been microfinance, through which loans or savings schemes are intended to support the establishment of small enterprises.

From the 1990s, there was widespread recognition of the need to more actively manage the fallout from liberalization strategies which both failed to absorb all those seeking labor and hobbled the ability of states to provide social support. Poverty alleviation and poverty reduction efforts from the 1990s culminated in the United Nations-led Millennium Development Goals, which set out to achieve a series of targets by 2015. One of the most striking interventions on poverty has been the introduction of small monthly cash transfers, often in the form of grants targeting children and pensioners. In some cases the coverage is extensive: a quarter of Brazil’s population was receiving the Bolsa Família grant within a decade of its introduction. This approach has been accommodated within neoliberal thinking because neoclassical economic theory has long acknowledged the possibility of market failure and the need for states to provide safety nets. Cash is easier and cheaper to distribute than “in kind” support such as food, and beneficiaries are often expected to “earn” their grants by meeting certain conditions like keeping their children in school. While
grants are undoubtedly used for consumption by poor households, there is also some expectation that grants will improve the capacity of households to earn their own money by helping them secure jobs or start enterprises. Advocates of market-based growth tend to support grants only on condition that they are not generous enough to remove the incentive to work.

Since the 2000s, some governments have announced a desire to move to a post-neoliberal governance regime. A radical few, notably Bolivia and Venezuela, are pursuing what they call “socialism in the twenty-first century.” Many others have not abandoned their liberalized economic orientation but are combining market growth strategies with increasingly comprehensive social protection. Rather than containing state support within deliberately minimal safety nets, the United Nations and International Labour Organization have proposed the introduction of a global social protection floor which will progressively increase the extent (coverage) and depth (value) of social protection. This protection would include services and supplementary incomes funded from taxes, as well as labor market regulation such as minimum wages.

Governmentality

Matthew G. Hannah

Universität Bayreuth, Germany

Definition

“Governmentality” is a term brought into circulation by the French philosopher Michel Foucault in 1978 to refer to a modern political problematic centered on the question of how to govern socioeconomic life as “economically” as possible. This entry first offers a detailed definition of the term, then turns to the context in which Foucault coined it and subsequent inflections in its use, and, finally, surveys geographical engagements with governmentality.

To govern “economically” means, roughly speaking, to impinge to a minimal extent on the free unfolding of all the social, economic, and demographic processes of social life, or on the individual choices and decisions that make up its fine grain. The techniques and programs of governmentality are thus often aimed, most clearly in wealthy liberal societies, at indirectly guiding, framing, or eliciting human activities, often on the basis of expert knowledge about social life. Direct regulation or coercion are to be avoided as much as possible, in this way of thinking. Some illustrative examples of governmental techniques in liberal contexts are the use of demographic data in infrastructure planning, training, and incentive systems to promote safe driving, or health insurance schemes.

It is important to note up front, however, that, although Western liberalism and neoliberalism afford the clearest historical instances of this economic logic, they do not in any way exhaust its possibilities: governing economically is not merely another term for liberalism. Governmentality can also embrace measures serving more clearly coercive or unjust aims, such as control of colonized populations or the perpetuation of patriarchal relations between men and women in domestic life. These last examples make clear that instances of governmentality must always be understood within their specific political and geohistorical contexts. For this reason many authors speak, in the plural, of “governmentalities.”

Even with reference to privileged sectors of liberal societies, governmentality should not be understood merely as the name for a set of “neutral” political tools. It is a critical concept. However neutral, harmless, or even beneficial they might seem, techniques of governmentality nevertheless always involve power relations, that is, they are potentially contestable projects of ordering. Governmental measures may be employed by state institutions but also by other actors in a range of social settings including families, workplaces, and so on. Across these different settings, governmental techniques operate alongside and in connection with other forms of power, most notably sovereignty and disciplinary power. In turn, these variably combined techniques often make up the inconspicuous substratum of practices that perpetuate patriarchy, racism, economic exploitation, and other forms of injustice. They may also be brought into play as “countergovernmentalities” to resist or subvert such projects.

This points to another important sense in which governmentality is best thought of as a “problematic.” Governmental programs and techniques are products and relays of ongoing
governmentality

struggles, and also often end up becoming problems themselves. This may be because they fail outright, because they create unanticipated difficulties that discredit them, because they don’t succeed in blocking competing approaches to a problem, or because the successes they do have are only short-lived (Rose and Miller 1992). In this sense, governmentality is a name for the shifting problematic of government through which the ongoing series of specific reforms in a given context are in turn problematized and subjected to further reform, both from within and from outside the state.

There are two related but distinct aims implicit in many governmental rationalities and practices: self-government and governability. Promoting self-government, whether of individuals, groups, organizations, regions, or local state entities, represents the ultimate in “economy of government.” The more actors freely and spontaneously behave in ways that promote social order and prosperity (however these are defined), the less effort need be expended by public or private regulatory authorities. Reforms or practices that promote self-government are often designated in the governmentality literature with the term “responsibilization.”

But, of course, promoting self-government is rarely if ever sufficient to maintain social order. Thus a second, supplementary aim of governmental techniques is to instill at least a minimal level of governability. If people and organizations cannot be counted on to live ordered and productive lives when left entirely undisturbed, a second-best outcome, from the perspective of governing authorities, is that the governed will still respond to incentives and disincentives (whether moral, financial, or penal). Thus education and training in the broadest sense can be seen as part of the sphere of governmentality, because they instill not only specific knowledge but also habits of responsiveness to systems of rewards, incentives, and punishments. This dual cultivation of self-government and governability is referred to in the governmentality literature, following Foucault’s formulation, as “the conduct of conduct” and lies at the heart of Mitchell Dean’s (2013, 215) very useful definition of governmentality: “Governmentality is . . . not simply orderability itself but the forms of making human beings and things orderable, [a project] . . . which always allows [for] multiplicity, polyvalence and resistance, for problematization and counter-problematization, conduct and counter-conduct.”

The ideals of self-government and governability also highlight a final, crucial characteristic of governmental measures: their effect is not merely to influence the behavior of fully formed “subjects” who exist outside of or previous to relations of government, but rather to shape the very formation and re-formation of subjectivities. In their dual orientation toward constructing subjects and thereby establishing or stabilizing larger social orders, techniques of governmentality are sometimes described as both “individualizing” and “totalizing.”

To review, then, the term “governmentality” designates a modern problematic, and associated governing programs and practices, that:

- aim at an economy of government, characterized by a minimum of direct intrusion into individual or collective activities and processes;
- are always context-specific;
- are not merely neutral tools but are always political, that is, understandable as contestable projects of ordering;
- are articulated with other forms and techniques of power (sovereignty, discipline);
- do not necessarily originate with the state, though they may come to invest and shape state activities, and in fact have increasingly done so over the past two centuries;
are often unsuccessful or only temporarily or locally effective, provoking further governmental reforms;

- are typically aimed at promoting self-government, governability, or both;

- construct and reconstruct subjectivities, rather than simply influencing the actions of fully formed subjects.

A genealogy of governmentality

The general definition given in the first section can serve as a basic sketch of what is meant by “governmentality.” However, to grasp the concept of governmentality adequately, it is also necessary to place it, as Foucault himself would have done, within its contexts of emergence and subsequent adoptions and transformations. Foucault’s major writings on governmentality were not books intended for publication, but rather transcripts of provisional lecture courses from 1977–1978 and 1978–1979. These quite accessible courses trace a broad arc through a number of key precursors and sources of modern economic government (Foucault 2007a), and then delve more deeply into the varieties of neoliberalism that have underpinned many governmental programs developed since the late 1970s (Foucault 2007b). One of his central historical claims is that governmentality has not always been the province of states, but rather has a wide array of institutional and discursive origins that long predate the “governmentalization of the state” which has taken place over the past two centuries. His second major historical assertion is that techniques of governmentality have to some extent come to assume a pre-eminent importance as against sovereignty or disciplinary power.

When Foucault first introduced the concept in a lecture in early 1978, it was a product of his thinking about two intersecting contexts: first, his ongoing academic project of understanding the specific forms taken by power relations in the modern era, and, second, his engagements with domestic political struggles and shifts taking place in a number of Western European countries in the narrower time frame of the late 1970s. Broadly speaking, the first context helps explain why Foucault’s initial definitions of the term distinguish it sharply from definitions of sovereignty and disciplinary power. By contrast, the more immediate geohistorical context of European domestic politics in the late 1970s helps explain why governmentality is so closely associated in his empirical explorations with the emergence of neoliberalism. Both contexts, but particularly the latter, led him to emphasize the independence of governmentality from the category of “the state.”

The 1977–1978 lecture course, and the one given the following year, were originally conceived by Foucault as comprising a detailed genealogy of “biopower,” an umbrella term for the modern government of social life. In his 1975–1976 course, and then in the first volume of his History of Sexuality, Foucault had broadly defined biopower as a power aimed not simply at dominating social life but at fostering and cultivating it. This set it off, in Foucault’s reading, against the older and more familiar political logic of sovereignty.

At the core of Foucault’s account of biopolitics and then also of governmentality is the conviction that the eighteenth-century “discovery” of the concept of the population as an entity with its own economic and demographic processes and self-regulating mechanisms marked a decisive watershed in the history of modern power relations. This was because the government of populations shifted the focus of state power from death or the threat of death to social life, and the ends of state power from self-maintenance to the
GOVERNMENTALITY

cultivation of an entity outside the state. Second, the fact that populations and economies were discovered to have their own animating laws and processes meant that the *means* of government could not remain centered, as they had been up to that point, on coercion.

Foucault’s introduction of the term “governmentality” signaled, on the one hand, a shift in his ongoing genealogy from a focus on the *ends* of biopolitics toward a focus on the appropriate *means* of achieving those biopolitical ends, and, concretely, a move away from analyses of regulation aimed at collectivities toward analyses of the construction and management of individual freedom. The resulting “detour,” as he called it, transformed the bulk of his 1977–1978 course, and the entirety of the subsequent course, into a genealogy of governmental techniques and rationalities stretching far back before the modern period. The topics covered, starting with the watershed fourth lecture range from early Christian pastoral techniques, through early modern critiques of Machiavellian discourses, the rise and decline of what was called in the eighteenth century “police,” through to German *Ordo-liberalism* of the mid-twentieth century and the self-help technologies of late twentieth-century American neoliberalism. The 1978–1979 lecture course, in particular, was largely centered on the exploration of the emergence of the neoliberal programs of government just then on the verge of gaining major influence in the United States, the United Kingdom, and other wealthy countries.

There is a good case to be made that Foucault’s shift of focus in early 1978 was also quite specifically linked to political events in France, West Germany, and other European democracies during the late 1970s. In Italy and in West Germany, violent domestic extremists were able to provoke quite repressive responses from state authorities, prompting many engaged left-wing intellectuals in these countries, in France and elsewhere, to reflect on the nature of “the security state.” A widely held thesis (shared by Deleuze and Guattari, for example) was that such repression exposed the fundamentally fascist character of so-called liberal democracies. The problem of fascism, as understood at the time, was that of explaining how populations could be led freely to choose their own subordination to patently unjust or even violent systems of government. For a number of reasons, Foucault found the notion of fascism deeply flawed and far too simple. The problematic of governmentality can be seen in part as his much more complex and historically sensitive response to the problem many of his contemporaries sought to explain with the blunt term “fascism.”

The academic discourses on governmentality that have emerged in the years since Foucault’s death span many different disciplines and an extremely wide array of concrete empirics. Probably the most interesting general development has been a searching reconsideration of the supposed pre-eminence of governmentality vis-à-vis sovereignty in modern political assemblages. This reconsideration was prompted in part by the seeming reassertion of sovereign power in the wake of September 11, 2001, and in part by the writings of the Italian philosopher Giorgio Agamben, who in an intriguing series of historical studies has sought to demonstrate primordial links between sovereign rule and the complex of biopolitics and governmentality that Foucault had long sought to distinguish from older forms of power.

Accompanying this shift has been a stronger focus on exceptional apparatuses and techniques of “security” capable of dealing with extraordinary risks, as well as the kind of everyday problems typical of liberal governance in the Global North. At the same time the notion of governmentality as economical has given way to
a more diffuse construction of governmentalities as variable “economies of government,” that is, intelligible orderings of techniques, positions, discourses, and practices.

Geographies of governmentality

Geographical studies have thus far sought to uncover the ways in which modern geographical imaginations and constructions of territory and place have played a role in programs and practices of governmentality, and how governmental measures have in turn had implications for constructions of spaces and places. Geographical research along these lines has proliferated so quickly in part because so many programs of societal reform aimed at economic government of populations and individuals have had an explicitly territorial or place-related component.

This might seem counterintuitive if one were to base one’s expectations on Foucault’s discussion of territory in his watershed governmentality lecture of 1978. There he argues that, with the historical shift to a concern for cultivating the life of populations, modern government to some extent turned away from the more clearly territorial projects he associates with traditional forms of sovereign rule, projects such as state control over territory and borders. However, as Stuart Elden argued in an important paper, territorial and geographical issues in fact necessarily remain central to programs of governmentality (Elden 2007). The dispositions of people, activities, and resources through which populations are governed are often in part pursued through explicitly spatial ordering projects.

A good deal of the early work done by geographers under the heading of governmentality can be seen as a corpus of fascinating elaborations on the link between spatial (re)orderings and the wellbeing or productive activity of populations. Only a highly incomplete sampling of themes, mostly taken from the anglophone literature, can be mentioned here. The work of Margo Huxley on reformist urban visions, of Reuben Rose-Redwood on the complex emergence of street address systems and city business directories, of Peter Merriman on the government of driving, and of Stephen Legg on urban design and reform in colonial India are all excellent illustrations of how to operationalize a governmentality perspective.

In general, the anglophone geographical engagement with governmentality has moved from the initial focus on the construction of “calculable territory” (Hannah 2009) animating the aforementioned works to embrace an ever wider set of additional issues having to do with place-based and corporeal enactments of subjectivity, as well as with the renewed issue of coercive sovereign power raised by Agamben and others. Stephen Legg provides a useful way of keeping an analytical handle on this proliferation of themes, distinguishing different types or manifestations of governmentality according to the dimensions of episteme, identities, visibility, techne, and ethos (Legg 2007, 12).

One important new direction in geographical research concerns ways of spatially framing human behavior that do not revolve around attempts to construct governability by relying on rationality but instead by seeking to govern, and to govern through, irrationality and affect. Indicative here is, for example, the research into “soft paternalism” or “nudge” by Mark Whitehead, Rhys Jones, and Jessica Pykett (Jones, Pykett, and Whitehead 2010). Here we see the basic problematic of governmentality, namely, how to promote efficient governability, addressed through new methods taking as their point of departure new evidence of the nonrational sources of human behavior.
Like governmental rationalities, academic geographical engagements with governmentality have varied across linguistic and national academic contexts. The reception and development of geographical aspects of Foucault’s analyses in France, for example, were for a long time much more attenuated (see Fall 2007). In Germany, as Füller and Michel (2012) explain, critical appropriations of governmentality have tended to focus strongly on discursive at the expense of material or nondiscursive constructions of spatial ordering projects. The German discourse is arguably also less strongly oriented around historical geographic studies than in the United Kingdom and North America, instead paying closer attention to current urban and immigration politics in a variety of settings.

Finally, it is worth singling out recent work on subaltern countergovernmentalities in the Global South by Ananya Roy, Arjun Appadurai, and others. This area is fascinating because it highlights bottom-up dynamics of activism for inclusion in and alteration of governmental systems. Focusing in many cases on South Asia, but also Africa and other parts of the Global South, this new strand of research explores the ways in which community groups have mobilized for projects such as self-enumeration and inventories of local infrastructure, particularly in the informal settlements surrounding megacities. Such studies open up interesting affinities with the long tradition of anarchist projects of local self-organization. Among other benefits, a countergovernmentality perspective could move scholarship beyond the lingering tendency to assume that governmental ordering projects (whether or not they originate with states) are essentially top-down affairs.

GPU computing

Wenwu Tang
University of North Carolina at Charlotte, USA

Graphics processing units (GPUs) are built using a many-core architecture to provide acceleration for general-purpose computation (see Owens et al. 2008; Kirk and Hwu 2010). The use of GPUs for accelerating computing can be traced back to the 1980s (Kirk and Hwu 2010). GPUs were originally designed and used exclusively for graphics operations (i.e., as a video accelerator). As modern computing evolved from single to multi and many cores, the use of programmable GPUs for general-purpose scientific computation has been extensively recognized. The development of GPU hardware in terms of its floating-point performance remains compliant with Moore’s law, that computing performance doubles about every 18 months (see Nickolls et al. 2008), even though this law has been claimed to be inapplicable to CPUs. For example, the latest NVIDIA Tesla K40 GPU, based on the Kepler architecture (see NVIDIA 2013) can deliver a peak double-precision floating point performance of 1.43 tera flops (floating-point operations per second), much higher than a current era CPU. GPUs are widely available on alternative computing devices, including smartphones, desktop computers, servers, and supercomputers. This widespread availability has stimulated the application of modern GPU technology for accelerating general-purpose computing in different scientific domains.

GPU computing falls within the paradigm of stream processing (Buck et al. 2004). A GPU is composed of a group of streaming multiprocessors (SM) each of which includes many (say, 32) streaming processors (SP). As an example, the latest NVIDIA Tesla K40 GPU has 2,880 computing cores (90 SM × 32 SP per SM). To efficiently employ this many-core stream-processing hardware, parallel programming standards and platforms have been developed and released, including CUDA (Compute Unique Device Architecture; see NVIDIA n.d.), OpenCL (Khronos Group 2013), and OpenACC (OpenACC n.d.). These standards and platforms allow users to harness the many-core supercomputing power in GPUs using an SIMD (single instruction multiple data; see Wilkinson and Allen 2004) parallel approach. GPUs provide support for massively parallel computing because of the large number of cores available (see Armstrong and Marciano 1995). Fundamentally, GPU computing uses fine-grained thread and shared-memory parallelism for data-intensive parallel computing (Kirk and Hwu 2010). Data of interest are split into a number of smaller sub-datasets that can be processed concurrently by the massive number of available threads.

The use of modern GPUs for general-purpose computing took off in 2006 when NVIDIA released CUDA to provide parallel computing support for GPU-accelerated general-purpose computation. In CUDA, a significant number (millions) of lightweight threads are launched to execute the same program for processing partitioned sub-datasets. These threads are organized into blocks and further grids to harness the many-core computing power in GPUs. A grid of threads corresponds to a kernel function, which encapsulates the algorithm to be executed by each thread in the grid (Kirk and Hwu 2010).
GPU COMPUTING

2010). The set of thread blocks is scheduled (automatically handled by CUDA) to streaming multiprocessors in the GPU. Thread blocks are executed independently to ensure the high throughput performance of GPUs. In CUDA, data can be maintained in GPU memories at different levels: global, shared, and register. The entire grid of threads can access data stored in the global memory, but with a relatively slow access speed. Each block of threads has fast access to shared memory, and each thread has its own (fast) register memory. Data should be maintained in the shared or register memory as much as possible because of the overhead latencies associated with access to the global memory. Thus, the combined use of thread and memory hierarchies enables the exploitation of supercomputing power in GPUs.

GPU coprocessors can be used to accelerate computation associated with spatial algorithms. Using GPUs to accelerate spatial algorithms normally requires support from a conventional CPU-based system which serves as a host. Generally, data associated with spatial algorithms must be read and maintained in memory within a CPU environment. Then these data are transferred and reconstructed in the GPU memory. Through the invocation of kernel functions, threads handle the computation associated with these data. Once the parallel computation of all threads is complete, the results are aggregated and transferred back to the CPU.

The acceleration performance of a spatial algorithm is mainly affected by the following aspects: its internal characteristics (e.g., data structures, procedures), characteristics of the data, parallel strategies (e.g., domain decomposition or synchronization; see Wilkinson and Allen 2004), CPU/GPU hardware features, and data transfer between CPU and GPU. The quantitative evaluation of GPU acceleration performance relies mainly on the use of the acceleration factor, a performance metric that is a ratio of the computing time of a CPU-based sequential algorithm in relation to a GPU-based parallel algorithm. The acceleration factor is similar to the speedup factor for CPU-based parallel algorithms (see Wilkinson and Allen 2004). Usually, a fast, modern CPU is chosen to support the derivation of acceleration factors. For instance, an acceleration factor of 100 means that the performance of the GPU of interest is equivalent to the simultaneous use of 100 CPUs. In practice, the acceleration performance of GPUs for spatial algorithms can be several orders of magnitude higher than that of a single CPU (Kirk and Hwu 2010; Nickolls et al. 2008). This level of performance acceleration often enables a single GPU to outperform a small CPU cluster, and a small multi-GPU cluster has a performance equivalent to a large CPU-based supercomputer cluster. Further, due to the cost-effective characteristics of GPUs, many supercomputers employ GPU acceleration (see www.top500.org).

Since the emergence of general-purpose GPU technologies in 2006, a series of spatial algorithms has been parallelized using GPUs (Zhang 2011; Zhao, Padmanabhan, and Wang 2012; Tang and Bennett 2011; Shi, Kindratenko, and Yang 2013; Tang 2013). The data-parallel nature of GPU programming makes GPUs most suited to data-intensive spatial algorithms (both vector- and raster-based). Conversely, the concurrent data characteristics of spatial algorithms (e.g., local, neighborhood, and global) make GPUs a suitable parallel computing platform for acceleration. In particular, as researchers are paying increased attention to big data analytics (Manyika et al. 2011), GPUs are now playing a pivotal role in the acceleration of spatial algorithms for big spatial data. The use of GPUs for acceleration, however, requires that data structures and spatial algorithms be transformed for accommodation in GPU environments (Tang 2013; Tang and
This represents a potential bottleneck because, without an appropriate transformation, the computing performance of a GPU-enabled parallel spatial algorithm may be even slower than its CPU-based sequential counterpart. As the development of GPU technologies continues, the barrier related to GPU-accelerated spatial algorithms may be lowered. In sum, GPUs, as an evolving technology in computational science and geocomputation (Armstrong 2000), hold enormous potential for accelerating computationally intensive spatial analysis and modeling.

Graph theory

César Ducruet
Centre National de la Recherche Scientifique (CNRS), France

The origins of graph theory are often attributed to the works of Leonhard Euler. In a classic study of the city of Koenigsberg in 1735, he designed a problem where a set of nodes (or vertices) connected by links (or edges) had to be traveled without using by the same road or bridge twice. Such an exercise proved to be mathematically impossible and motivated further efforts to define the topological properties of graphs during the subsequent decades and centuries. Today still, the application of graph theory to geography remains largely focused on technical networks, using traditional mathematical tools (Arlinghaus, Arlinghaus, and Harary 2002). This entry describes graph theory in general as well as its use by geographers, notwithstanding parallel evolutions of the field in other social and natural sciences, and their mutual influences.

Network types and structures

A wide and specific vocabulary describes various sorts of graphs having distinct internal structures, as well as subgraphs (subset of connected nodes) and individual nodes by the architecture of their mutual links. Graphs may be visualized either through matrices or by the node/link view, and many graph visualization software programs exist nowadays that are capable of applying numerous types of visualizations and measures, even on very large networks composed of thousands of links and nodes. Visualizing large graphs is often an exercise with limited outputs, due to poor readability, so that many different operations of network simplification should be applied prior to visualization, such as filtering links or nodes according to certain quantitative thresholds or qualities. Furthermore, visualizing a network on a map, such as in geography (although this has become so popular nowadays that any spatially embedded dataset made of nodes and links can be instantaneously projected on the screen regardless of its size, etc.), brings in additional issues of readability. The matrix itself (or adjacency matrix) is represented by a table where nodes are rows and columns, and links are, in their simplest understanding, represented in a binary fashion by the number 0 or 1 where lines and columns intersect. There are specific mathematical calculations based on matrices that are not detailed in this review. Visualizing graphs as sets of nodes connected by links proved to be more useful to illustrate the existence of various network morphologies, or fundamental components of networks, such as cycles, cliques, chains, motifs, and also various situations characterizing individual nodes, such as isthmus, bridge, ego network, star, and so on. Graph theory is based on a specific vocabulary to describe networks. Nodes and links are labeled vertices (vertex) and edges, respectively. Vertices may be junctions or end points in the graph, with edges between them. Connectedness refers to the property of a graph to have all its vertices interconnected, which otherwise contains isolates (i.e., vertices without edges) or at least two connected components. A complete graph is defined by the maximum number of edges.
among vertices. The graph is directed (digraph) when two edges exist between two same vertices, referring to two directions (AB vs BA). When both directions exist the graph is said to be symmetrical, otherwise it is asymmetrical. Other dimensions are also important, such as when vertices and edges have certain values, in a weighted graph (e.g., passenger flow, number of vehicles), when vertices are connected by only one type of edge (simple graph) or at least two types (multigraph, multiplex graph), such as in a social network, friendship, and professional ties. Finally, a bipartite graph exists when two or more types of vertices are connected, such as conferences and speakers, journals and scholars, and so on with the condition that vertices of the same nature are not connected with each other.

Numerous internal structures have also been identified within graphs at different levels of their organization. For instance, chains and cycles are both continuous alignment of edges, while the cycle starts and ends at the same vertex. A path between two nodes is a sequence of edges travelled in the same direction. Several paths may exist between the same two nodes, thus motivating the search for the shortest path and the minimum cost path, the latter being only possible in the case of a weighted graph where edges are valued by a distance, time, or other metric (e.g., days, hours, kilometers, monetary value). For the shortest path, topological distance refers to the number of edges to be crossed in order to reach the final destination of the path. Topological distance is often referred to as path (or edge) length but may also be depth. The clique is one fundamental structure of graph theory, defined as a maximal complete subgraph, that is, a subset of nodes being fully connected with each other, the smallest example being the triangle of “3-clique.” In social network analysis (SNA), the clique is an essential component of social organization and is often opposed to the “star” configuration, where several vertices are connected to only one vertex. The ego network comprises the connected neighbors of a given vertex as well as the edges among these neighbors. More complex internal structures have been the focus of several studies on graphs, such as the so-called “clusters” or “communities,” whose definition may vary according to several criteria. Overall, a cluster or community is defined either by a higher density of connections or by the similarity of their connections. In other words, tightly connected vertices may form a community with a high probability to be relatively close to each other in the graph. Vertices having similar connectivity to others, conversely, may be close to or far away from each other. Vertices and edges lying in between two or more communities are often labeled isthmuses or bridges, due to their high importance. In social network analysis, it is also called a weak tie or structural hole in the case of edges in-between different groups. Finally, a graph is said to be assortative when the number of edges of a given vertex is positively and significantly correlated with the average number of edges of its direct neighbors in the graph; otherwise it is said to be disassortative.

Based on the aforementioned characteristics, graphs may be labeled differently in terms of their overall structural properties. The regular graph (or k-regular) possesses exactly the same number of edges per vertex. The random graph exhibits a normal or Gaussian statistical distribution of the number of edges per vertex. Scale-free and small-world graphs are defined below when it comes to the more recent field of complex networks. The tree graph refers to a situation where no clique, cluster, or cycle can be found, as in the case of river networks for instance, which function as dendrograms. More conventional measures help reveal the overall structure
of the graph and define its main character. For instance, the diameter is the length of the longest of the shortest paths among all pairs of vertices in the graph, measured by the number of edges needed to be travelled. The average shortest path length is similar but refers to the average number of edges composing the shortest paths across the graph, while high values often imply more difficulty to circulate in the network. Planar graphs often have high values for both diameter and average shortest path length. The average clustering coefficient (or transitivity) measures on average the proportion of closed triangles in the maximum possible number of triangles in the graph. In that sense it is close to another classic measure of graph theory, the alpha index, which looks at the proportion of existing cycles in the maximum possible number of cycles, with the difference that a cycle can have a length of three edges (triangle, 3-clique) but also of four, five, and so on. High values of the average clustering coefficient mean that the graph is tightly connected, while tree graphs will always have zero.

Networks in geography and natural sciences

One of the first imports from mathematics into geography was made by Kansky (1963), incorporating previous studies on telecommunication flows and highway networks among US cities. Such works notably reviewed the various measures and indices applicable to mostly planar graphs, that is, graphs where two edges cannot cross without creating a vertex, as it is often the case for road, rail, and river networks; the main goal being to describe the morphology, connectivity, and density of various graphs (Haggett and Chorley 1969). Without reviewing them entirely, most common indices include the diameter (number of links between the two most distant nodes), the alpha (share of observed cycles in the total possible number of cycles – the cycle being a closed path of various length in terms of its number of links), beta (number of links per node, or density), and gamma (share of links in the total possible number of links, or completeness) indices. Three limitations of such general indices should be addressed, however. First, one major drawback is that two networks of identical size (number of nodes and links) but with drastically different topology (e.g., star-shaped network where one node connects all others versus chain-like network formed by an alignment of links) will be characterized by the same results. Second, and related to the first, general indices are not robust to network size, so that their level will vary according to the size of the network. Third, graph theory and its application to geography long remained binary (presence or absence of a link between two nodes), thereby completely ignoring the possible weight of links (e.g., traffic intensity or capacity, kilometric length) and their quality (e.g., links and nodes of different types).

Other measures include those at the local level, such as calculating, for each node, its distance from all other nodes by the number of links needed to connect the most distant node (Koenig number) or the total length of shortest paths connecting all other nodes (Shimbel accessibility index) (Figure 1). Such studies focusing on small, planar networks thus largely neglected the analysis of nonplanar networks (i.e., allowing edge crossings without creating nodes). Due to limited interactions with social network analysis (SNA) that developed from the 1920s onwards, no imports have been realized from sociology, although the latter had developed many tools for analyzing nonplanar networks. For instance, betweenness centrality (number of times a node lies on a shortest path in the graph) as well as transitivity (or clustering coefficient) came from
SNA, and later on were integrated in studies of complex networks. They consider that for each node, there is a share of observed triangles – or cliques – in the maximum possible number of triangles among its neighbors. Transitivity had no use for studying planar networks, as rectangles rather than triangles are often found in road or railway networks. It is only in the early 1990s that geographers started to analyze networks of a different nature, or nonplanar networks, such as those formed by multinational corporations, airlines, and shipping lines, thereby stepping out of classic graph theory (Ducruet and Beauguite 2014), and from a more urban perspective. Other important refinements of graph theory have been to consider the weight and spatial dimension of networks. The cited measures have been adapted to incorporate the weight of links and nodes so as to better reflect inequality in, for instance, traffic distribution, compared with the sole topological (binary) aspects. Thus, all measures can be weighted according to various metrics at global (whole network) and local (individual nodes) levels. When it comes to the spatial dimension of networks, physicists were keen to demonstrate the influence of spatial constraints on network growth and topology, whereas such aspects were often taken for granted by geographers, since all their studies focused on spatially embedded networks in contrast with studies of nonspatial networks such as social networks, collaborative and citations networks, the World Wide Web, and so on. Geographers focused more on detailed analyses of binary graphs in abstract spaces and of real networks using geographical information systems but often

Figure 1 Common measures of node centrality in complex networks.
without reference to graph theory. Physicists studying spatial networks notably underlined that preferential attachment occurs over shorter distances, as there is a cost of creating new links to overcome the friction of space, thus resulting in higher average clustering coefficients than in nonspatial networks (Barthelemy 2011).

Efforts made by geographers to improve their use of graph-theoretical methods occurred in relative isolation, though, from the rapid evolution that graph theory went through in the late 1990s and early 2000s. Natural scientists, such as physicists, have been eager to rejuvenate graph theory, and notably the aforementioned limitations as well as its approach to graph dynamics. They notably proposed to define a so-called “complex network” by nontrivial topological attributes, which are neither random nor regular, but are found in most real-world networks. Another dimension of complex networks is their large number of nodes and links, and their analysis clearly benefited from the growing availability of large datasets and computation power. New measures were proposed, although they were, in fact, a rediscovery of existing ones, such as transitivity (clustering coefficient) originating from SNA and the gamma index (density) proposed by Kansky (1963). Still, the merit of natural scientists has been to provide clearer definitions of network models and their evolutionary mechanisms, with new applications on real-world networks that were traditionally analyzed by social sciences in more limited ways. One of their major achievements has been to complement the random graph model, which was dominant until then (a random graph is characterized by a normal or Gaussian distribution of the nodes’ degree), by two new models: scale-free and small-world.

The small-world network is defined by a higher average clustering coefficient and smaller diameter than the random graph of equal size (Watts and Strogatz 1998). It means that small-world networks are more likely to contain cliques (subgroups of at least three connected neighbors forming a closed path) and to provide more efficient ways to circulate in the network, in terms of the length needed to connect its distant parts. Scale-free networks are similar to small-world networks but their distribution of degrees follows a power-law (the slope exponent ranging between two and three), which means that very few nodes have plentiful connections, and a vast majority of nodes have very few connections. Another dimension of scale-free networks is the process of preferential attachment by which newly added nodes primarily connect larger nodes, thereby reinforcing the hierarchical structure of the network (Barabasi and Albert 1999). Despite the spread of such models across almost all scientific disciplines, geography has remained somewhat reluctant in adopting and testing these innovations. In fact, geographers carrying out network analysis have continuously relied on the same indices and measures over the last five decades. Just like the innovative character of complex network research is questioned, the benefits of applying such methods to test geographic questions also remain unclear. Should this be indebted to the models or to the way they were applied? One part of the answer lies in the fact that geography as a whole went through a “behavioral” turn after the so-called quantitative revolution of the 1960s, graph theory and network analysis – and spatial analysis as a whole – remaining “somewhat of a backwater” since then (Waters 2006). Networks continued to be analyzed by regional scientists but not necessarily using graph theory, so in even more abstract spaces while focusing on costs, and engineers focusing on performance and optimization. Yet, a small number of geographers have promoted the rediscovery of graph theory through...
the adoption of certain methods and models rejuvenated by complex networks research.

Key directions of current and future research on networks

One primary and key issue raised by geographers has been the relationship between node centrality and socioeconomic features. As such, various centralities (i.e., degree, betweenness, and closeness) were statistically confronted with local urban/regional data (e.g., population or gross domestic product) for various kinds of network, such as Internet, airline, telecommunications, and scientific collaborations among cities (see Ducruet and Beauguitté 2014 for a synthesis).

The second dimension explored by geographers is the influence of distance on network topology as mentioned above, although this influence is often taken for granted by geographers. One original approach has been to apply space syntax to urban streets so as to consider the network from a more cognitive point of view. Space syntax notably proposed to consider crossroads as links between streets, the latter being defined by their name or number instead of as alignments of different segments (Hillier and Hanson 1984). Such an approach made it possible to have a completely different approach to centralities and topologies in a planar network, and to extract meaningful information on the small-world and scale-free dimension of many cities (i.e., dual graph). In the same vein, and as a third aspect of renewed graph theory applied in geography, several geographers have proposed a combination of methods rather than a strict, direct application of complex networks. It is interesting to mention that, for instance, spatial interaction models (SIM) such as the gravity model (Schintler et al. 2007), geographic information systems (GIS), multiplicative growth models, and social network analysis (SNA) tools such as structural equivalence and blockmodeling were applied, sometimes even jointly, to various networks, such as Internet backbone networks, commuting flows, road and railway networks, airline and shipping networks. This is mostly the case for regional science, which had already been using such methods for decades. It allowed, for instance, a better appreciation of the cost factor in network organization.

A fourth dimension is the existence of subgroups of densely connected nodes in the network, often referred to as clusters or communities of nodes. Geographers were keen to detect and define such subgroups with reference to the concept of region, sometimes also mentioning the multilevel organization of networks, whereby the different subgroups are linked to each other in various ways. Methods of partitioning (or clustering) were thus applied to a number of networks – such as the worldwide airline network of intercity passenger flows, container shipping networks, and mobile phone communication networks to verify the influence of geographic proximity in the emergence of clusters – and commuter flows between localities in order either to redefine functional urban regions or to identify secondary poles inside metropolitan areas. Such approaches were already far more advanced than the traditional single (or multiple) linkage analysis proposed in the 1960s by Nystuen and Dacey (1961) and further applied in numerous contexts afterwards. Other approaches also looked at the emergence of clusters within large cities based on the cartography of vehicle trajectories.

Fifth, geographers have attempted to go beyond the analysis of single (or simple) networks by proposing an analysis of coupled or interdependent networks of different nature, labeled multigraphs (or multiplex graphs) in the classic graph theory literature. Due to the
absence of a formal mathematical definition of multigraphs and, therefore, of a precise methodology to analyze them, scholars had to create innovative ways to extract meaningful information dedicated to such graphs. Sometimes the network is simply a combination of various networks (or network of networks) in which the nature of the links is ignored, but the analysis compares the effect of adding (or removing) one or more networks at the level of nodes or the entire network. This was applied to the analysis of world regions and global cities based on various types of links (e.g., trade, diplomatic, airlines, and shipping lines). Other examples include the combination of airline and Internet networks, airline and corporate (multinational) networks, and so on. Yet, geographers have poorly investigated to what extent certain places are more specialized than others in terms of combined centrality, how certain networks and nodes are more vulnerable than others according to their physical embedding and distribution across space. In particular, the local and global impacts of random or targeted attacks that are well investigated by physicists (e.g., cascading failures) have not yet received much attention from geographers so far. This is rather surprising given the fact that such approaches would well apply to the analysis of cities and urban systems, which are connected by a variety of networks (e.g., power grid, water, telecommunications, transport, etc.).

Finally, and as a sixth aspect of recent research based on graph theory, geographers have paid particular attention to network dynamics. Very few works have approached directly the dynamic evolution of real-world networks. Existing studies approach dynamics more through an analysis of successive static states of the network or phases, mostly due to a lack of continuity in available time series datasets of any kind. Other approaches to network dynamics are also those applying simulation methods to systems of cities, starting from an initial stage and testing the role of different parameters on the evolution of urban size in a relational perspective (Bretagnolle and Pumain 2010), but often without actual information on intercity linkages.

Graph theory has had an important influence on the way geographers studied spatial phenomena, but this influence was stronger in the early phase of its adoption, and has remained mostly true in the specific field of transportation networks. Natural scientists have been faster in adopting (and even fostering) innovations that appeared in the late 1990s through what is known as complex network research. While geographers became skeptical about the benefits of graph-theoretical methods applied to spatial issues, physicists and computer scientists had no doubt that their models, concepts, and methods would improve our understanding of the uneven distribution of flows and networks, especially across space. Nevertheless, one major limitation of the complex network research carried out by natural scientists is the absence of discussion about the link between their results and the wider social, economic, institutional, and political context in which networks evolve. Stronger interactions between natural and social sciences, among which is geography, are thus needed in order to better bridge abstract space and concrete space. In the past decades, geographers have been able to explain in detail the strategies of specific actors involved in building and expanding networks of all kinds, but without a firm engagement into renewed methods of network analysis. On the contrary, natural scientists keep on refining their models and tools to analyze graphs, but without questioning the possible link with existing geographical research. Issues of scales, borders, territories, urbanization, innovation, diffusion, globalization, regional planning, environmental, and socioeconomic impacts are still to be explored in relation to what graph theory may
provide to the concerned actors and institutions. Yet, an area well covered by geographers in the last decade, in collaboration with computer scientists, has been the search for better methods to visualize spatial networks and flows (Rozenblat and Melançon 2013). This constitutes, perhaps, the main contribution of geography so far to graph theory and network analysis as a whole.

Grassland ecosystems

Dwight A. Brown
University of Minnesota, USA

Grasses can thrive from tropical to arctic latitudes and in wet to dry environments. The major species have a common trait of a perennial growth habit. They often produce seeds the first year and, effectively use wind, water, and animal transport to disperse their seeds. Some species tolerate shallow burial by wind and water borne soil. As a result they can colonize large areas quickly and persist for centuries. However, the truly vast expanses of waving grasslands of two centuries ago are now substantially reduced. The areas dominated by grass species are naturally limited by competing vegetation types that rob grasses of sunlight, nutrients or soil water. Historically, the greatest cause of grassland loss has been the conversion of immense areas to cropland. High crop prices coupled with relatively low energy prices that enabled groundwater pumping or the river diversion have stimulated grain or fiber cropping even into relative dry environments.

We cannot treat the world grasslands as anything close to a homogenous unit. There are considerable variations in grass species and the fauna that use them. The details of the world grasslands information vary a great deal by continent and country as is evident in a recent FAO publication (Suttie, Reynolds, and Batello 2005). For most countries, only lists of species present are available. Rarely is species abundance information available. In the United States, where grazing of native ranges is still important, county soil publications often list species composition and abundance.

Grasslands occur on every continent except Antarctica, although hair grass (Deschampsia antarctica) is present. Extensive grasslands are confined between 55° north and south latitude (Figure 1). The species composition of the world’s grasslands differs by geographic location, landscape position, and soil traits. Some physiological traits help different species thrive under different environmental constraints. Most large areas of grasslands are dominated by relatively few species. They reflect episodes of dispersal that favored particular species from the nearby gene pool at times when disturbances created opportunities for new plants to establish. The dominant species or grasslands are generally tolerant of defoliation by grazers, drought, and fire. The lack of these tolerances by woody plants retards their invasion. The dominant grass species differ in their resource requirements and degree of tolerance. Genetics governs the ease with which seedlings become established plants. Photosynthetic chemistry differences give species different temperature tolerances and water use efficiency.

Grass photosynthetic chemistry falls into two broad types. On an evolutionary time scale, the oldest form among grasses involves three carbon atoms to convert atmospheric carbon dioxide into plant carbon. These are commonly known as C3 or cool-season grasses. Poa, Festuca, Agropyron, Pascopyrum, Elymus, Phleum, Dicanthelium, Hesperostipa, Bromus, Agrostis, Achnatherum, Puccinellia, and Nassella are major native grass genera of C3-dominated grasslands. The term cool-season grass comes from their early greening, maturity, and maximum
productivity at about 20°C (70°F). At higher temperatures productivity falls sharply. Common grain crops of wheat, oats, rye, and barley are C3 grasses, as are many lawn grasses.

A later evolution in grass physiology was the development of four-carbon photosynthesis in grasses (C4 or warm-season grasses). These grasses peak in productivity at about 35°C (85°F). This evolution probably occurred during distant geologic times when atmospheric carbon dioxide was much lower than the present. The C4 processes near the leaf surface enrich carbon dioxide fed to C3 processes deeper in the leaf structure. They are much more efficient water users and therefore more tolerant of arid conditions than C3 grasses. *Andropogon, Astrebla, Calamovilfa, Sorgastrum, Spartina, Schizachyrium, Panicum, Plectrachne, Triodia, and Bouteloua, Buchloe, and Bothriochloa* are major native grass genera of C4-dominated grasslands. Corn, sugarcane, and sorghum are common domestic grasses with C4 photosynthesis.

C3 grasses tend to dominate higher latitudes, but do occur in lower latitudes where winter rainfall enables them to mature before the high summer heat (Figure 2). They also are common at higher elevations or in high to mid-latitudes. Winter precipitation climates tend to favor C3 grasses because of their greater growth at cooler temperatures and their ability to germinate at lower soil temperatures than C4 grasses. They also grow in tropical grasslands, growing in the cooler winter season.

**Importance of photosynthetic differences**

C4 grasses occur in three primary variants, PCK, NADP, and NADP-ME in order of increasing photosynthetic productivity (Figure 3). Some species are transitional between two photosynthetic types. C4 grasses are more efficient water users than C3 grasses.
In Australia C3 grasses are dominant in the south and NADP-ME species are the most abundant variant of C4 grasses in the northern deserts and savannas (Figure 4). In North America, NAD-ME C4 species are abundant. In the southwestern plains and deserts, NADP-ME species dominate the eastern grasslands and C3 species dominate the northwestern grasslands (Figure 5). The Russian and Mongolian Steppes are dominated with many of the same genera of C3 grasses found in the United States and Canada although few of the species are the same.

Fauna of the grasslands

Grazers are a major element in maintenance of grasslands. The dominant grasses are tolerant of defoliation by grazers. Large hoofed mammals are the best known grazers, but burrowing rodents and insects are also important grazers. All grasslands support predators, carrion eaters, and decomposers to control populations of grazers and clean up the refuse.

Maintenance of grasslands

By far the greatest factor in the demise and continuing threat to grasslands is cultivation. High crop prices naturally result from a growing population’s demand for food, from wars that disrupt food and fiber production in some parts of the world, and from some government policies that stimulate farmers to grow more crops and bring grasslands under cultivation. Where natural rainfall is sufficient or irrigation water is readily available, grasslands have succumbed to the plow. When crop prices fall or irrigation is no longer economically viable, fields are left bare. The resulting buildup of salt and the isolation

Figure 2  World grass species abundance by photosynthetic types. Sources: Dwight Brown, data from Hartley 1957; Hartley 1958a, 1958b, 1973; Hartley and Slater 1960.
of these fields from seed sources of the previous grassland species limit grassland regeneration.

The almost complete annual fallout of plant material in grasslands, coupled with relative low decomposition rates allows a buildup of soil carbon that is great relative to forest environments where the plant carbon is maintained in standing trees and shrubs. As a result, the grassland soils can hold large stores of plant nutrients, which make them ideal for crop agriculture.

In some former grasslands with low rainfall, the chances of reestablishing grasslands to their previous composition are very low because the climatic conditions that enabled the previous grass species to be established no longer prevail. This is especially true for various warm-season species of grama grasses (Bouteloua) which have seedling root structures that require a period of surface soil moisture that has rarely occurred in the historic weather record. Some cool-season grasses are more easily established, but they are not as useful to grazers in late summer.

Erosion by running water, and to a lesser degree by wind, and animal burrowing have been major forces opening land for the dispersal of grass species into new spaces. Particularly with water erosion and subsequent deposition, there is often considerable connectivity of bare land, which provides a convenient corridor for nearby dispersing species that are able to colonize new sites.

The persistence of grasslands through tens of thousands of years is substantially due to their tolerance of defoliation. Most grasses have similar responses to grazing, fire, and drought. Because these defoliation agents are common throughout the world grasslands, the surviving and now dominant species are tolerant of these agents, except for a few species that are intolerant of defoliation early in the growing season. The intolerant species are normally lower in abundance and are not widely distributed.

The future of native grass populations will depend partly on the rising CO₂ levels in the atmosphere. C₃ grasses get a production boost from higher CO₂. C₄ grasses do not enjoy the same benefit because the C₄ process already enriches the CO₂ that is fed to the C₃ cells deeper in the leaf structure.

Grasslands of continents

North American grasslands

The American midcontinent is a converging ground for C₃ cool-season grasses that migrated from the northwest, short, warm-season grasses (C₄, NAD-ME) that spread from Sonora and Chihuahua in Mexico, and tallgrass warm-season species (C₄, NADP-ME) that probably found their way from Africa via the Caribbean (Figure 5). These tall grasses once dominated Indiana, Illinois, Iowa, parts of Minnesota and Missouri, and the eastern parts of Oklahoma, Kansas, Nebraska, and the Dakotas. Most of these grasslands have given way to the plow. Occasional tiny remnants of these native grasses can be found between cultivated fields. The species of these three major areas are listed in order of their abundance.

*Pascopyrum smithii* (Western wheatgrass), *Hesperostipa comata* (needle and thread), *Nassella viridula* (green needlegrass), *Sporobolus cryptandrus* (sand dropseed), *Elymus canadensis* (Canada wildrye), and *Koleriamacrantha* (Junegrass) are the most abundant C3 species of the northwestern plains and the Pacific northwest.

*Bouteloua gracilis* (blue grama), *Bouteloua curtipendula* (sideoats grama), *Buchlöedactyloides* (buffalograss), *Bouteloua eriopoda* (black grama), and *Bouteloua hirsute* (hairy grama) are the most abundant species of the southwestern plains. All are C4 NAD-ME species, except *Bouteloua curtipendula*, which is a PCK/NAD-ME intermediate.

The tallgrass prairies of the eastern plains are dominated by *Schizachyrium scoparium* (little bluestem), *Andropogon gerardii* + *hallii* (big + sand bluestem), *Panicum virgatum* (switchgrass), *Sorghastrum nutans* (Indiangrass), and...
GRASSLAND ECOSYSTEMS

Bothriochloa saccharoides (silver bluestem). All are C4 NADP-ME photosynthetic type.

North American grasslands were home to bison, mammoth (now extinct), deer, and antelope. Ten million years ago, now extinct camel, horse, and rhinos grazed grasslands of the midcontinent. Prairie dogs and ground squirrels also played important roles in disturbance and change in grass cover. Coyote, wolf, bear, and cougar were common predators before the rise of agriculture.

South American grasslands

Major grasslands of South America include the Llanos of Venezuela and the Pampas of east-central Argentina, Uruguay and southern Brazil. The Llanos of Venezuela are dominated by C4 NADP-ME grasses Andropogon spp., Axonopus spp., Elyonurus adustus, Leptocoryphium lanatum, Panicum olyroides, Paspalum spp., and Trachypogon spp. (Figure 2).

The natural grasslands of southern Brazil include some forests and herbaceous vegetation. Grasses dominate, with some legumes. Latitude, altitude and soil conditions enable the dominance of C4 grasses to grow in the warm season, and C3 species to grow in the winter. The area is species rich with more than 800 grass species. Major species on drier soils include Paspalum spp., Andropogon lateralis, Axonopus affinis, and Aristida filifolia (all C4, NADP-ME species).
