The practice of interviewing in geography has evolved in relation to broader philosophical changes in the discipline and together with a widening of the scope of geographic inquiry, reflecting changing scientific, sociopolitical, technical, and ethical issues. In the context of contemporary North American geography, some have connected early forms of interviewing to the Sauerian tradition of landscape and regional investigations of the early twentieth century. Sauer encouraged using questionnaires as a way to collect information on how “local people” lived and moved around an area, for example. Subsequent critiques of the landscape and regional traditions in human geography led some scholars to push for more refined and systematic forms of interviewing. With the rise of positivistic geography and spatial science in the 1950s and 1960s, geographers relied more on non-field and secondary data sources that could be analyzed through statistical methods. Those still involved in the collection of primary data through interviews placed more emphasis on ensuring that the contents of conversations with people remained independent of their social characteristics, suggesting a particular distanced or remote relationship to research subjects (McDowell 2010). The main attempt was to obtain objective data – to the extent possible. There was little attention paid to personal characteristics of the interviewees or the specificities of place, time, or topics under investigation. Interviews during this time were more similar to structured questionnaires that lend themselves more easily to data quantification or tabulation. This aim for objectivity was an attempt to introduce a more rigorous system for talking to people, but some have argued that such methodological choices further delayed the development and adoption of interviewing as a methodology for obtaining rich, in-depth accounts of the experiences of people in places.

Beginning in the 1970s, new interpretive and critical approaches made headway into the discipline and resulted in significant new developments in the area of qualitative methodologies, in particular in human geography. Key influences also came from other disciplines such as anthropology. The combined effect of these influences impacted the ways in which geographers conceptualized and conducted interviews. For example, with the advent of humanism and Marxism in geography, a participatory, interpretive, and political approach to collecting data began to play a more prominent role. More attention was being paid to the ways in which interviews were shaped by the social context within which they were conducted. Interviews were seen as a more appropriate way to understand how people assign meaning to the social relations and places that make up their lives. Humanists believed that in order to understand the world, researchers needed to understand how people perceive it in the first place. Marxists, on the other hand, saw talking to people not just as
More importantly, feminist geographers provided the discipline with a set of conceptual tools and ethical concerns that allowed for a complete rethinking of the procedures and goals for interviewing. In fact, feminism has proven to be one of the most important philosophies from which geographers have rethought the practice of interviewing. Feminist geographers emphasized the need to be critically aware of the conditions that enable the production of knowledge. In relation to interviews, this means paying attention to how gender relations and other differences such as race, ethnicity, and sexuality shape the interview process and how they are implicated in the research methodology itself. Equally important is paying attention to how gendered assumptions (or racialized, sexualized, and other difference-based assumptions) affect the type of information that is generated through interviews, as well as its interpretation (Herod 1993). Attention to the effects of gender and other differences as fluid, contextual, and dynamic in turn openly challenged notions of objectivity in the interview process, dispelling the belief that objective truths and data existed in the worlds and lives of the people being interviewed to be uncovered by designing more “scientific” interview procedures. Some feminist geographers saw more traditional or standard forms of interviewing as masculinist practices that kept a problematic hierarchy and distance between researchers and research subjects. Instead of searching for objectivity, feminists and other critical geographers emphasized that power dynamics were always present in the interview process and recognized that geographers conducting interviews were as much part of the construction of meanings as those being interviewed. Thus, geographers’ engagement with different philosophies changed the practice of interviewing, with the emphasis changing from objectivity to subjectivities and to paying more attention to the ways in which power relations and differences, place and social context, and emotions and affect mattered in the context of interviews. Today, the questions and issues that arise out of the uneven relations of power that exist between researchers and research subjects occupy a central place in the construction of knowledge that occurs through the interview process. Regardless of the way in which interviews are conducted or the perspective that guides the research, the majority of geographers today acknowledge that interviews are subjective and that it is not possible to collect unmediated, unbiased, or completely objective data. Recognizing issues of positionality, reflexivity, and situated knowledges and embracing (rather than avoiding or denying) the politics of interviewing have become crucial elements in contemporary practices of interviewing.

Types of interviews

In contemporary geographic research interviews can be grouped along a continuum ranging from collecting data based on predesigned research questionnaires and structured questions to uncovering information in more open-ended, interpretive, and intimate manners. Some in fact suggest distinguishing between questionnairing, a methodology more adequate for social surveys or extensive research strategies where the face-to-face interactions are more structured and consistent across the population being surveyed; and interviewing, more adequate in intensive research strategies where the goal is to have conversations to give a voice to research subjects (Cloke et al. 2004; see also Sayer 1993). All practices along this continuum involve asking people questions, so the lines between questionnaires and interviews are fuzzy.
INTERVIEWS

Questionnaires and more structured interviews given to particular populations still tend to be associated with the practices of quantitative and/or positivistic human geography, in particular when the goal is to collect information in a way in which it can be quantified or consistently coded into specific variables or nodes during the analysis phase. A good example of this type is the short answer interview typically conducted over the phone. This is a more detached approach to interviewing in which the researchers remain in control of the questions asked and where there are fewer opportunities for interaction and negotiation between the researchers and the people being interviewed. In-depth interviews with open-ended questions, on the other hand, resemble conversations among two or more people. In this type of interviewing, investigators do not shy away from engaging with participants and probing issues in-depth, sometimes even generating spirited discussions and debating or contesting some of the answers. This more participatory approach to interviewing places the researchers in intense contact with the research subjects and is typically associated with critical perspectives in human geography and with qualitative methodologies. In-depth interviews do not, in general, aim to be representative of a whole population; rather they often respond to a theoretically motivated research question that seeks to illustrate how people make sense of their own experiences (Valentine 2005). However, no philosophical tradition is necessarily linked to a particular way of conducting interviews since, for example, a feminist geographer could collect interview data in a fairly structured way and yet provide a feminist and critical interpretation of the data in the analysis. In general, however, there is a consensus that some forms of questioning or different types of interviewing are more adequate for certain types of research. It is true that questions of embodiment and power relations are now taken into account much more often. However, not all researchers pay the same amount of attention to the politics of interviewing. Interviews as a method could be better described as including a range of ways of asking questions that themselves reflect a range of different relationships to research subjects as well as a range of philosophical and theoretical concerns.

Geographers have produced significant scholarship explaining the importance of carefully thinking about interviews’ style, format, and context in relation to the different types of people involved in the interview process. For example, in the context of interviewing families, one might need to pay attention to the power relations between household members, in particular if interview questions are designed to uncover tensions or highlight differential power relations. In this context, a geographer might choose to conduct separate interviews with parents and children, or with husbands, wives, domestic partners, or other adults in a household, both for ethical reasons and to achieve fuller disclosure from participants (Aitken 2001). Variations from place to place are also important. Some advocate talking to people in their own territory because participants might feel more comfortable and more can be learned about their own place-specific contexts and spatial routines. Others advocate conducting interviews in neutral spaces. Regardless of the place chosen, the safety of the participants and the researchers should always be considered. Particular attention should be paid when interviewing people in different cultural contexts since linguistic and cultural misunderstanding can easily emerge, even if working with an interpreter.

Other forms of interviewing employed by geographers require a different style of engaging
with participants and careful attention to interview dynamics. A good example is life history interviews, a method that aims to capture an individual’s biography and life history in his or her own words. This method of interviewing is often utilized by geographers interested in the role that personal history, memory, and tradition play in the social construction of place and identities. Life history interviews share some commonalities with regular interviews; for example, power dynamics are always present and assumptions about gender and other differences are similarly embedded in interviews. Yet there are significant differences, including the intensity of personal relation between the interviewer and interviewee, which can lead to a deeper exploration of emotions and affect. In life history interviewing, different dynamics may develop over the course of the interview, thus reflexivity and interpretation may occur more than in a regular interview (Jackson and Russell 2010).

Geographers’ engagement with new philosophies, theoretical frameworks, and new spatial technologies has also helped produce new hybrid forms of interviewing, where different types of data can be obtained at once. The walking interview, for example, involves walking alongside participants while asking questions as a way to capture attitudes, emotions, and knowledge about the surrounding environment. This type of interview can provide a more intimate methodology for learning about both individuals and places. Qualitative data from the walking interview can be enriched by spatial quantitative data collected through a global positioning system (GPS) in the interview process, providing an additional layer of information that can contextualize qualitative data and generate new insights about the connections of the participants’ stories and meanings in place (Evans and Jones 2011).

**Conducting interviews and analyzing interview data**

There is significant scholarship that suggests what to consider when incorporating interviews in geographic research design and setting out to collect data. There is also voluminous scholarship providing advice on how to conduct interviews. Overall, there is general agreement that the interview process is similar to an exchange rather than an interrogation. While interviews are typically arranged with a specific research goal in mind, the focus of an interview sometimes identifies itself in the course of conducting the research. The context of the interview itself can alter such focus because interview participants lead complex lives and power relations and identities are negotiated in the process (McDowell 2010; Aitken 2001). Researchers have to consider the influences of all these variables when trying to establish contact and rapport with interview participants, keeping in mind that unforeseen ethical issues might surface as one becomes more involved in the process. Because of the fluidity of interviewing, it is not uncommon for research projects to deviate from carefully planned schedules. Gaining the trust of participants often depends on how researchers position themselves politically in relation to them. As several geographers with significant experience with this methodology have attested, persistence and open-mindedness are needed in order to conduct successful interviews (McDowell 2010; Aitken 2001).

Geographers pay increasing attention to the politics of representation in relation to the data collected through the interview process, acknowledging that researchers play a defining role in the act of recording, transcribing, interpreting, and representing interview data. Who sponsors the research and who is selected for the interview, for example, will likely affect the type
Interviews

of data obtained. Transcription is central to the process of analyzing interview data, but until recently that process had received little attention in methodological discussions. Transcription of verbal information collected through interviews used to be considered mostly a technical chore performed by the researchers themselves or by third parties, such as research assistants or others providing professional transcription services. More recently, some geographers have begun advocating including research participants in the transcription process as a way to further democratize the interview methodology. Presenting participants with transcripts of interviews to ascertain their own opinions about the geographers’ interpretations can work as a mechanism to achieve more clarity regarding the information collected as well as a way to find a more equitable balance of power between the researcher and participants. Through this practice, further opportunities for reflection on the data can emerge, though giving transcripts to research participants generates new and unexpected ethical dilemmas (Mero-Jaffe 2011). For example, some have found that interview participants can be embarrassed by verbatim extracts of their own words (Jackson and Russell 2010). Thus, geographers working with interviews grapple with complex decisions about representation at all stages of the process, indicating that interviewing is far from being an easy or simple methodological choice but rather one that has to be approached mindful of its methodological complexities and implications.

Geographers have also moved beyond only analyzing the verbal and textual output of interviews, and are now paying attention to the nonrepresentational dimensions of interviewing as a way to gain further insights into how knowledge is constructed during the interview process. Lessons from a range of approaches, such as nonrepresentational theory and psychoanalytic methodologies indicate that a critical and more comprehensive analysis of interview data should include attention to the influences of silences and other embodied experiences that take place during an interview, such as laughter, visceral reactions, and body movements and gestures. This is particularly useful in instances of less successful interviews, which tend to be perceived as failed instances of research. In these cases, a researcher’s first inclination might be to discard data that does not tell much or appears not to have enough content and thus is seen as less useful. However, a reconsideration of the nonrepresentational might provide useful insights into the embodied politics of interviewing and say something about fluid negotiations of identity in the interview process (Nairn, Munro, and Smith 2005). This in turn can help clarify why certain questions were answered or left unanswered and how the construction of knowledge and data took place over the course of the interview.

Intrametropolitan location

Anne Aguiléra
French Institute of Science and Technology for Transport, Development and Networks (IFSTTAR), France

Producer services are major players in today’s productive system. Over the last decades, these activities have expanded exponentially in industrialized countries and, more recently, in developing countries. Geographically speaking, producer services companies tend to be concentrated in large urban areas, where there is a wide variety of clients and where they have special access to transportation and communications networks.

At the intra-urban scale, producer services initially located downtown, that is, in the historic centers of European cities and the central business districts (CBD) of North American cities. This configuration was primarily explained using land rent theory (Alonso 1960 and Figure 1). This was originally used to account for the location of agricultural activities before it was widely adopted for analyzing the structure of activities and populations from the 1960s. Assuming a monocentric city, namely a city with only one center concentrating all the customers, according to land rent theory, the price of land and real estate decreases proportionally as the distance from the center of the city increases. The center is the most expensive location, because transportation costs there are minimized. According to this theory, only activities with a substantial need for accessibility and a need for limited space can bear the high costs of a central area location. Producer services usually meet both of these criteria. First, many are office-based activities which typically do not require extensive floor space. Second, they require frequent interactions with their clients, most of which involve complex information that necessitates the presence of all of the parties (Goe et al. 2000) and, therefore, requires that at least some of the participants will need to travel. Indeed, the producer service production process is characterized by the close interdependence between producer and user (client). Services, which are by definition intangible, require some degree (depending on the type of service) of client participation, not only during the definition of the content of the service (co-definition), but also during production (coproduction). Due to the often complex nature of the information exchanged with clients, face-to-face meetings are often preferred and the service provider will travel to the client, or vice versa. Geographic proximity to clients can simplify these interactions and reduce costs (Clapp, Pollakowski, and Lynford 1992). In addition to facilitating supplier/client interactions and reducing the costs of face-to-face interactions, clients see geographical proximity as a way of reducing uncertainties, particularly for service transactions that may be perceived to be risky. Thus, land rent theory explains the central location of producer services on the basis of their need for proximity to clients. This reasoning appears to be of universal importance for explaining the strategies used by producer service firms for identifying locations, especially in the early stages of firm formation and growth. Land rent theory overlooks two additional influences on the location
decisions of producer service firms: the prestige associated with an address in a central location, and the role of the property developers who create the supply of office buildings, many of them state-of-the-art, landmark structures, in downtown areas that command the highest rents and impart the prestige that retains the attraction of city centers for producer services.

The development of more polycentric urban spaces profoundly upset the conceptual frameworks for analyzing the intra-urban locations of economic activity, including producer services. Indeed, since the 1990s, first in industrialized countries and more recently in developing ones, the spatial structure of people and jobs location within metropolitan areas has undergone major transformations. The tendency is a shift towards more polycentric forms with the development of suburban centers concentrating jobs outside the CBD (McMillen and Smith 2003). Outlying employment suburban centers do not usually replicate all of the morphological or functional attributes of the primary center but do compete in the hosting of economic activities. Many of these suburban centers are, for example, located strategically along major highway routes into and around the center of metropolitan areas, like the New Towns in the Paris region or Orange County in the Los Angeles region. At the outset, this pattern of polycentric development was encouraged by the decentralization tendencies of industrial activities, and retail and household services escaping the high costs of a central city location. Relocating industrial activities were able to find new, larger, and less expensive sites that offered easier access and parking for freight services and employees. Furthermore, public authorities were anxious to move high-pollution industrial activities out of city centers. For their part, retailers and household services were following the dispersal of the population. The latter increasingly had access to personal automobiles and wanted to live in single-family housing at locations away from the center of the city where prices were lower and there was less crowding. Following this first wave of decentralization, activities that had traditionally continued to prefer the city center, such as producer services, also began to locate some or even all of their activities in outlying suburban centers (Coffey, Drolet, and Polèse 1996; Gong and Willer 2002; Halbert 2004; Han and Qin 2009; Shearmur and Alvergne 2002). This behavior stimulated new theoretical and empirical analyses of the spatial strategies at work. An important working hypothesis was that the decentralization of producer services heralded the decline of downtown areas as they lost their most dynamic, emblematic activities. In practice, this hypothesis has
not been corroborated: producer service firms have certainly relocated to suburban business centers but they have also continued to maintain a presence in city centers (Halbert 2004; Maoh and Kanaroglou 2009).

By shifting the conditions for intra-urban accessibility and the associated transportation costs, the rise of outlying suburban centers has modified intrametropolitan land price curves. Although central business districts have, in general, retained specific attributes, such as the high density and variety of service activities, the density of transit networks, and access to information and communication technologies (ICT), property rents no longer fall with increasing distance from the city center. Although downtown remains the most costly, it has been demonstrated empirically that there is an inverse relationship between costs/rents and distance from the city center or from a suburban center (Ahlfeldt 2011). This signifies demand for and the emergence of new intra-urban distribution of economic activities that includes producer services, their clients, their suppliers, and the workforce. In particular, when a company’s clients and employees are themselves located in suburban areas, it encourages relocation in order to reduce transaction and transportation costs (Aguiléra 2003). Lastly, polycentrism is accompanied by a multipolar demand for producer services accommodation that takes the form of a multipolar supply of office space. Developers, typically encouraged by the public authorities, have taken advantage of the demand from decentralizing economic activities by constructing new real estate, especially office buildings and retail centers (Cervero 2013). These are typically high quality facilities with rents considerably lower than downtown, combined with excellent intra- and inter-urban accessibility. Despite such advantages, in the majority of metropolitan areas these suburban business centers cannot replicate all of the functions and advantages of downtown (Gaschet 2002). They certainly do compete with downtown on the basis of lower cost office space, its quality and accessibility for clients and staff, and the relative absence of negative externalities such as traffic congestion. But the prestige and sheer diversity of national institutions and government functions as a whole range of related and often international services outweighs for many producer service firms the negative externalities.

Nonetheless, land rent theory has logically been completed by new models that reduce the influence of the monocentric assumption. They highlight two key parameters in order to explain the new intra-urban configurations of economic activities. Location decision-making by firms is now primarily dependent on economic sensitivities to workforce transportation costs, on the one hand, and to agglomeration economies, on the other. The latter are all of the benefits that each company derives from its proximity to other companies or to particular facilities (such as transportation infrastructure). Depending on the model, several types of agglomeration economies are considered, including access to transportation infrastructure, and sharing of a number of services like signage, cleaning, security, or informational externalities. These externalities include the formal, as well as informal or social, networks that are of benefit to companies, particularly with respect to innovation. Spatial proximity facilitates these interactions; information exchange is believed to increase in proportion to the number of nearby companies, and to decrease in proportion to the distance between them. Whether these circumstances result in economic activity organizing into monocentric or polycentric configurations depends upon the level of transportation costs and on the nature of the agglomeration economies. In particular, it has been shown that
the activities most sensitive to informational externalities tend to agglomerate downtown but that if they grow and can no longer fit their activities within that central area, they prefer to relocate in outlying suburban centers, rather than dispersing across the urban fabric. By selecting suburban centers, firms can continue to enjoy some informational externalities even if these are inferior to those offered downtown.

The decentralization of producer services, activities which are sensitive to informational externalities, will therefore only take place after the outer suburban centers have attained a certain level of maturity and are able to offer suitable positive externalities. Theoretical models also make it possible to consider the idea that the decentralization of producer services only involves, at least at the beginning, those activities that are the least sensitive to informational externalities. Producer services incorporate a wide range of activities, only some of which are considered “superior” (high value-added) services with a strong need for complex information and face-to-face contact with clients, like financial and insurance services or management consulting. Consequently, there are two possible scenarios with regard to the decentralization of producer services. The first is that only the more commonplace services, such as security services, cleaning services, rental services, or computer maintaining, will choose to operate from outlying suburban centers. The second scenario is that producer services firms will eventually be induced to subdivide their activities, in the interest of cutting their location costs, between the front office (design and decision-making) which is sensitive to transaction costs and client proximity, and the back office (fulfillment) which is essentially engaged in the exchange of codifiable (e.g., electronically transmissible) information with the front office or elsewhere. According to this scenario, the front office activities will remain downtown while back office functions will migrate outward to benefit from reduced real estate and other costs.

The empirical work conducted over the past 20 years in the United States and Europe, as well as in China and South Korea, generally upholds the outcomes predicted by the model. A sustained concentration of producer services in downtown areas or central business districts alongside them (such as La Défense (Paris) or Canary Wharf (London)) is shown to occur, but a broader distribution of such services in outlying suburban centers also occurs (such as Shanghai). However, producer services do not locate equally in all possible suburban centers but favor the most accessible location and also in general the ones that are not too far from the center. Moreover, geographic segmentation has been observed, based on the type of service provided: “superior” front office activities generally stay more central than their more commonplace, back office counterparts. For all this, downtown has maintained a strong appeal overall for producer services, particularly headquarters and high value-added services like finance and insurance services, advertising, or consulting. In other words, producer services are simultaneously characterized by strong centrality and tendencies to dispersal, but still remain more centralized than other economic sectors.

Amongst the other determining factors for the intrametropolitan location of producer services, empirical research has also confirmed the pre-eminent role of transportation costs, land and real estate costs, and agglomeration economies. It has been shown that some outlying suburban centers offer a viable alternative to the center, because they enjoy good access to highways while offering markedly lower property costs often of better quality (for example, in terms of energy consumption). A high value also tends
to be placed on parking facilities. Nevertheless, downtown maintains its high-value reputation for reasons of locational prestige, particularly in European cities. Surveys of the factors shaping locational decisions have also confirmed the influence of client locations: companies serving a primarily metropolitan catchment area often resolve the location choice between center and suburb on the basis of the (central or suburban) location of the clients with whom they need to interact most frequently (Aguiléra 2003). However, downtown is often preferred when clients are primarily located outside the urban area, because, in most cities, it remains far more accessible to national and international transport such as high speed rail or an airport than do outlying suburban centers. In the case of smaller producer service firms, the locational preferences (such as choice of residence) of the partners or senior employees of firms can also influence the choice of location. Finally, the most recent research has begun to explore the influence of the location of qualified manpower on the geography of producer services activities (Shearmur and Doloreux 2009). Processes such as gentrification, observed in many downtown areas, help to explain the enduring appeal of central business districts, because newly established producer service firms tend to be located near to central neighborhoods where their founders already live. In turn, the establishment of these services in central zones maintains the gentrification process which then reinforces the enduring attraction of downtown business locations.

Iran: Anjoman-e Geopolitic-e Iran (Iranian Association of Geopolitics)

Founded: 2002
Location of headquarters: Tehran
Website: www.iag.ir
Ireland: Geographical Society of Ireland (GSI)

Founded: 1934
Location of headquarters: Dublin
Website: www.geographicalsocietyireland.ie
Membership: 156 (as of November 2013)
President: Frances Fahy
Contact: frances.fahy@nuigalway.ie

Description and purpose

The purpose of the GSI is to promote the status and study of geography in Ireland. Drawing on both professionals and members of the public for its membership, the society is open to all those who have an academic interest in geography and the geography of Ireland.

Journals or major publication series

Irish Geography is the primary publication of the society. This premier peer-reviewed journal devoted to the geography of Ireland has been published since 1944. It has an international distribution and is read on all five continents. Its reputation for quality is long established and standards are maintained by an internationally based editorial advisory board.

GeoNews is the newsletter of the society, providing news and information about geography in Ireland and about the activities of the society. The newsletter acts as a forum for the discussion of matters of general geographical interest. Currently GeoNews is published twice a year (usually in May and December) and includes submissions of interest to the wider geographical community (in the form of articles, commentary pieces, field trip reports, details on events, etc.).

Current activities or projects

The society achieves its goals through its journal, its website and newsletter, outreach and educational programs, and the participation of its members in numerous national and international conferences, especially its annual meeting of the Conference of Irish Geographers (CIG). The CIG is hosted annually in May on a rotating basis between all the universities on the island of Ireland. In 2013 the CIG was hosted at NUI Galway and the conference theme was Transformative Geographies: Critical Reflections on Environment, Sustainability and Governmentality. The keynote speakers were Professor David Harvey and Professor Doug Sherman and over 300 delegates attended.

The GSI presents annual awards including Lifetime Contribution to the GSI, Postgraduate Fieldwork/Travel Awards, Book of the Year Award, and Geographer’s Contribution to Community Award. In addition, regular society activities include the organizing of Geographical Awareness Week and hosting a series of public lectures and fieldtrips including the Farrington Lecture.

Brief history

The Geographical Society of Ireland was founded in 1934 to promote the status and study of geography, drawing on both professionals and members of the public for its membership. The affairs of the society are managed by an elected committee. One of its early aims was the publication of a journal that would have a strong focus on the geography of Ireland.

Submitted by Frances Fahy
Irredentism refers to a claim made by a state or by an ethno-national grouping to territory currently lying within the borders of a neighboring state. The term derives from the Italian *irredento*, meaning “unredeemed,” and originally applied to territory regarded as Italian but lying outside the boundaries of the unified Italian state in the late nineteenth century. Irredentist territorial claims rest on the idea that the portion of geographical territory in question is rightfully part of another nation. Unlike secessionist nationalist claims, it is not independence that is sought but rather a transfer of sovereignty. Such claims rest on historical and cultural factors. It may be argued by a particular ethnic or national grouping that having lived for a long time in a place it rightfully belongs to them rather than to the power that technically has sovereignty over it. The desire to incorporate people who are part of the nation but living within another state may be driven by concerns over the treatment of those minorities. An alternative basis for such claims may be the symbolic importance of the territory due to historic events, and the preservation of places of memory such as battle sites. For political, cultural, and historical geographers, irredentist claims are of interest because of their assumptions of links between place, culture, and national identity, the questions they raise about political boundaries, and the utilization of cartography to bolster territorial arguments.

While many irredentist claims remain aspirational, others become sources of conflict. German annexation of Austria and other Germanic speaking regions in the late 1930s was justified on the grounds that these were Germanic territories. In much of central Europe the periodic redrawing of boundaries has produced many minorities that find themselves within the territory of another state. Similarly, the colonial construction of borders in parts of Africa and elsewhere has divided ethnic groupings. Colonial legacies persist in such cases as the Falkland Islands, over which Argentina maintains an irredentist claim, while Spain maintains a similar claim over Gibraltar. Many irredentist claims hark back to a time in which the nation’s territorial extent was much greater than it currently is. This fuels a desire to recapture territory lost and to reinvent a territorially expanded version of the state. Irredentist claims are often depicted on maps indicating territory occupied by ethno-national groupings that transcend state borders.

The case of Northern Ireland is a classic example of an irredentist claim in which the region (technically part of the United Kingdom) is seen by Irish nationalists as rightfully part of a united Irish state. While cross-border relations have evolved over time, the partition of Ireland in the 1920s was seen to rupture the territorial integrity of the nation (Coakley and O’Dowd 2007). The Balkans conflict in the 1990s reflects complex irredentist claims. Ethnic cleansing in Bosnia and elsewhere in the region was predicated on making the territory ethnically pure. The autonomous Republika Srpska within Bosnia is viewed by many nationalists as part of a “Greater Serbia” (Toal and Dahlman 2011).
Kosovo, which declared itself independent from Serbia in 2008, is still seen as an intrinsic part of Serb territory by nationalists who mobilize history to emphasize the Serb-ness of the region. For their part, many Albanian nationalists view Kosovo (along with parts of neighboring Macedonia and Montenegro) as belonging to the Albanian nation in a region where many ethnic Albanians live outside the borders of the Albanian state founded in 1912 (Malcolm 2002).

Irrigation

William E. Doolittle
The University of Texas at Austin, USA

Defined as the artificial application of water to land, irrigation is most commonly used in regard to agriculture, particularly the production of crops in arid and semiarid lands. Soils are pivotal to the process. All plants absorb water through their roots, and most cultivated plants need minimum amounts of soil moisture at specific times during their growth. This is not an issue in humid environments where rainfall is abundant but not excessive, and soils are of adequate fertility and temperatures moderate. In deserts and steppes, where rainfall is erratic in terms of amount, timing, and location, soil moisture can be problematic. Irrigation helps reduce this uncertainty.

There are several ways irrigation can be practiced. Some of these are simple; some are complex. Some are ancient; others are modern. Regardless of age and complexity, however, certain variable conditions underlie decisions about which form of irrigation is used. These are: the nature of the water source and distance to fields; available and appropriate technology; the size of the labor force; and the demand for irrigated products. The first of these conditions might best be described as geologic, the second cultural, the third sociological or demographic, and the fourth economic. In concert they are geographical.

All of these conditions must be considered to understand specific irrigation strategies. To illustrate, geologic and cultural conditions might be available for one type of irrigation in a certain locale, but demographic and economic conditions might be prohibitive. In another situation, it might be economically feasible to implement a given type of irrigation, but only if water is close at hand, technology is appropriate, and labor is available. Successful blending of these four factors underlies the currently fashionable concept of sustainability in terms of understanding the fluorescence and collapse of ancient civilizations, and in future development projects.

Water sources

If irrigation is deemed to be necessary in a given locale, the issue of where the water will come from is paramount. Sources of irrigation water are generally dichotomized as either surface water or groundwater (see entries elsewhere). This distinction, however, is not always clear.

Places at which the water table intersects the Earth’s surface are known as springs. This is where groundwater becomes surface water. The volume of water flowing from springs can vary considerably over time, and in times of drought when aquifer recharge is low, the water table can drop such that springs will dry up. An excellent example of a spring used for irrigation agriculture is near Balmorhea, Texas (30°56’40”N 103°47’18”W).

Also blurring the distinction between surface water and groundwater is subsurface flow. Many rivers in dry lands do not look like rivers at all, but appear as dry stream beds. In fact, however, water can be flowing just below the surface, through relatively thick permeable materials.
IRRIGATION

(e.g., gravel, sand) that form the stream channel itself, and above the impermeable underlying geology (e.g., shale, basalt). Subsurface flow typically provides only small amounts of water and hence is usually associated with small irrigation systems in near-subsistence situations.

Delivery methods

Getting irrigation water from a source to a field is at once simple and complicated. Perhaps the oldest and most basic of delivery devices is some type of handheld container, be it a gourd, animal skin, basket, jar, or, today, a plastic bucket. This is simple technology and is only feasible for watering very small plots, such as the “waffle gardens,” of the Zuni people of New Mexico ($35^\circ 4'2"N\ 108^\circ 51'5"W$). Other technology is clearly needed to irrigate larger tracts of land. Water naturally flows downhill under the force of gravity. If fields lie at an elevation lower than the source, then all that is needed is some type of conduit between the two. But again, nothing is as simple as it first seems, and it is here that technology becomes more complex.

Canals

A canal excavated into the earth from a water source to fields is a basic form of water conveyance. In a sense, irrigation canals are simply artificial stream channels. As straightforward as this may seem, however, it is not without complications. The canal has to be at such a gradient that it is neither too great (steep) nor too slight. If the gradient is too steep, the flow will be fast and may cause down-cutting and bank erosion. If it is too slight, the flow might be slow enough to result in the canal being filled with sediment (silt ing up), as irrigation water is rarely clean and clear. Given that gradient is a function of horizontal as well as vertical distance, canals with an ideal gradient usually appear somewhat sinuous or meandering when seen from above or on maps and aerial images. This is evident in the Lower Rio Grande Valley ($26^\circ 31’21”N\ 98^\circ 6’49”W$).

Unlined earthen canals are of great antiquity, and almost as soon as they came into use, problems arose, particularly with erosion. Lining the canal bottoms and sides with a hard plaster, especially at sharp turns, became a common solution. Today, of course, concrete is used to line canals, and some canals are actually made from prefabricated concrete segments that are linked together. A good example of some remnants of ancient canals, in this case those built by the Hohokam culture, paralleled by modern canals, can be found immediately east of the international airport in Phoenix, Arizona ($33^\circ 26’29”N\ 11^\circ 59’6”W$).

Excavating canals at proper gradients, and sometimes over long distances, can result in obstacles being encountered. Bedrock outcrops are not uncommon in dry lands where soils are typically thin and poorly developed. Chiseling through such materials is obviously labor intensive. Remarkably enough, in at least one case, China’s Red Flag Canal, workers bored 71 tunnels through the Taihang Mountains in order to convey water from the Zhang River on the west to farm land on the east around Linzhou ($36^\circ 21’47”N\ 133^\circ 13’4”E$).

Boring through bedrock is one problem, having to convey water from one side of a gorge to another or over low-lying ground is another. The proper gradient has to be maintained even above ground and through air. Narrow, shallow gorges that are obstacles for small irrigation systems pose a much smaller problem than huge gorges that affect the development of large systems. In the former situations it is not uncommon
for irrigators to use split and hollowed out tree trunks supported by a framework made of wood. Such devices have been used for centuries by Hispanic farmers in New Mexico where they are known in Spanish as *canos* (canoes) and in English as “flumes” (36°7′54″N 105°45′19″W). Spanning deep or broad valleys involves substantially greater structures, bridge aqueducts, typically referred to as simply aqueducts. Constructed of ashlar masonry blocks or concrete, the structures involve a series of arches that support a canal. Although aqueducts were built before and after them, the Romans are most commonly associated with their construction (41°50′40″N 12°33′47″E).

**Pipes and tubes**

Issues of gradients and obstacles can be mitigated in part and in certain situations by covering canals or using pipes. Some of the earliest recorded uses of pipe come from ancient Mesopotamia where slender ceramic funnels were fitted together to transport water. In a similar fashion, bamboo has long been used in China. Romans made pipes by rolling sheets of lead. Indeed, with the chemical symbol Pb from the Latin word *plumbum*, this is where the terms “plumbing” and “plumber” originated. In more recent times, pipes have been made of steel, and now polyvinyl chloride (PVC). Each of these materials has its advantages and disadvantages, but they all suffer from being relatively inflexible. Modern high carbon plastics are, in contrast, very flexible, with the latter being weather-resistant, malleable, and inexpensive. Whereas pipes can have inside diameters of several centimeters and carry reasonably large amounts of water, these new flexible tubes have small diameters and transport measured quantities of water.

**Extracting, lifting, and storage techniques**

Transporting irrigation water first involves tapping the source and then often lifting it from lower to higher elevations (e.g., from stream channels to adjacent field surfaces). In many cases, it also involves storage over periods of time. To compensate for rainfall deficiencies, irrigation water is often collected during periods of abundant precipitation and stored until it is needed.

**Dams and reservoirs**

The diversion of flow from springs and streams, including those with subsurface flow, is often aided by the use of dams (see entry elsewhere). Some dams are quite small, constructed diagonally across streams, and simply divert water out of channels and into canals. An excellent example exists near Villafranca del Bierza, Spain (42°36′34″N 6°48′40″W). Others are large, constructed in a distinctive arch-shape perpendicular to the river, and store huge amounts of water. A classic example is Hoover Dam on the Colorado River, which created Lake Mead – a reservoir – near Las Vegas, Nevada (36°0′57″N 114°44′15″W). Regardless of their size, the surface elevation of the water is higher behind dams (upstream) than it is below (downstream). As such dams result in canals much shorter than would have been required otherwise.

**Qanats, shadufs, and norias**

Innovative people in ancient Mesopotamia and Egypt developed some fascinating irrigation technologies that remain with us. Qanats are tunnels, much like near-horizontal mine shafts, extending from the water table to field surfaces...
sometimes several kilometers away. They were constructed by first digging a vertical shaft from the surface near the base of a mountain to the water table, and from there, digging a tunnel to the fields. Fearlessness and special skills were needed to work underground. Earth from the excavation of the tunnel was removed through a series of additional vertical shafts by means of a windlass (a hand-cranked horizontal shaft around which a rope is turned) and buckets, and deposited around the opening of each shaft. When viewed from above, the only evidence of qanats are rows of split bagel-like features extending from mountains to fields. One of the more conspicuous examples is at the Tafilalt Oasis in Morocco (31°20′54″N 4°5′14″W). Qanats terminate in canals that take water to the fields.

Two other ancient Middle Eastern water-lifting devices merit discussion because of their ingenuity, role in the evolution of technology, and applicability for local development projects. One is the shaduf, which consists of an upright frame across which lies a long pole with a bucket on one end and a rope on the other. It is operated by releasing the rope, allowing the bucket to pick up water, and then pulling the rope and swinging the pole such that water can be poured into a canal. Originating in Egypt 4000 years ago, shadufs remain in use in northern Africa and southwest Asia. The other ancient device is the noria, or Persian wheel. It consists in its most basic form as a vertical wheel with buckets attached to the rim. The bottom of the wheel is below water and as the wheel turns water is scooped up in the buckets and at the top of the wheel is poured out into a trough before flowing into a canal. In some cases norias are powered by stream flow as is the case of the most famous ones in Hama, Syria (35°8′6″N 36°45′10″E). In others, shafts are excavated from the surface to the water table, and rather than having the bottom of the wheel in the water, a chain of buckets is used. In these cases, a second wheel oriented horizontally and meshing with the vertical wheel like gears is powered by draft animals walking in circles.

Pumps

The vertical shafts used for norias, and those used for qanats, are in fact, wells. Indeed, the wheels used in norias are a development that evolved from the windlass. Today, we have perhaps two stereotypical images of wells, the proverbial “wishing well” with a roof over the windlass, and the windmill which is not actually a mill (grinding machine). Both devices lift groundwater to the surface. In the case of windmills, the vertical turbine powers a mechanical pump. Invented in ancient Greece, it is perhaps most identified with the Dutch who employed wooden wheels similar to those used with norias, but to drain low-lying areas (51°52′52″N 4°38′31″E). Settlements of the North American Great Plains, Argentina, Australia, and southern Africa in the nineteenth century were facilitated by the development of inexpensive steel windmills that used a gearbox and crankshaft to convert the rotary motion of the turbine into reciprocating strokes vertically through a rod to a piston-pump cylinder below. An excellent assortment of wind pumps can be found at the American Wind Power Center in Lubbock, Texas (33°34′45″N 101°49′26″W).

The mechanical wind pump was a precursor to the modern tube well. Each well of this type is constructed by boring a hole 10–20 cm in diameter from the Earth’s surface into an aquifer, often at a depth of more than 35 m. The hole is lined with a steel sleeve and water is pumped to the surface. At one time diesel was the preferred fuel, but electricity is becoming more common.
Field surface configuration

Regardless of its source, the type of lifting or storage device, and the method of delivery, water eventually must be applied to fields. Complicating matters, water has to be evenly distributed to every part of the field, in amounts that are neither excessive nor deficient. A number of methods have been developed to either reshape the land surface to accommodate watering or to account for topographical variations.

Wild flooding and border strip

The most basic and doubtless the oldest form of irrigation is wild flooding. Most commonly, this consists of opening sluice gates, or simply using a shovel to breach the banks of canals with parallel subtle surface contours, and allowing the water to wash down over cultivated surfaces. The gates are closed when the land is sufficiently wetted. Wild flooding is common on pastures of the Prairie Provinces of Canada. In locations where crops rather than pasture grasses are irrigated on slightly sloping land, parallel earthen ridges (10–30 cm wide and approximately 1 m wide and 5–10 m apart) are constructed perpendicular to the slope contours. These border strips help equalize distribution of water over the fields.

Contour ridging and terracing

Many areas are not slightly sloping, but rather consist of rolling hills or steep mountain slopes. Irrigating these lands has long required leveling, lest the water will flow off and not soak into the soil. On moderate slopes, this can be accomplished by building series of low parabolic earthen ridges (10–50 cm high and 2–15 m wide) parallel to the contours. Excellent examples can be found in central Texas (30°36′40″N 97°22′45″W). On steeper slopes a series of dry masonry rock walls, called risers, and varying in height from 1 to 4 m, are built along contours. The areas behind or upslope of the risers are filled with sediment that is either washed in through erosion or brought in and deposited by humans. The nearly level planting surfaces, called treads, can then be irrigated. Some of the best examples of past and present irrigated terraces are in Peru’s Colca Canyon (15°30′20″S 72°15′55″W).

Furrows and grids

Developing methods to keep water on slopes is one issue irrigators face; managing it with care is another. If farmers have access to plows and draft animals they most typically create a series of ridges and furrows. If they do not have this technology, they use hoes and shovels to build small rectangular ridges oriented parallel and perpendicular to each other that forms grids or micro water-retention basins. Fields to the east and south of the ancient earthen pyramid in Cholula, Mexico, for example, are in some years plowed into furrows and in other years shaped into grids, depending on the crop grown (19°3′18″N 98°18′07″W).

Sprinkle

Garden hoses and lawn sprinklers, be they oscillating, pulsating, or rotating, are common landscaping devices. Similarly, and increasing in popularity, are built-in lawn sprinkler systems that consist of buried tubes with a series of pop-up sprayers. Although involving small areas around residences or businesses and not farmland, these sprinkler systems are in fact irrigation. Using the same principles, agricultural sprinklers are much larger, each covering more than a hectare. And, because they involve
pressure, water is pumped from aquifers rather than flowing by gravity from surface sources.

Perforated pipe irrigation systems used to involve 4–5-m lengths of aluminum pipes, 10–20 cm in diameter, that one person could easily lift, clamp together, and be dismantled once an area was wetted and reassembled on a plot to be watered. As the name implies, the pipes have several holes drilled along their length. Increasingly, however, aluminum which corrodes is being replaced by PVC. Ranchers who irrigate pastures are the principal users of perforated pipes. Traveling sprinklers are an elaboration on perforated pipes. They consist of a horizontal pipe that doubles as a water conduit and an axle for multiple wheels that allow for the entire device to roll slowly over rectangular plots. The pipes are not perforated, but instead have sprinkler heads attached. The sprinklers are typically of the pulsating variety.

Without doubt center pivot systems are one of the most technologically advanced, and certainly the most conspicuous, form of irrigation. These systems consist of pipes supported by series of triangular-shaped wheeled devices. Several sprinkler heads are typically hung below the pipes. Rather than rolling over rectangular fields, one end of the pipe remains in place while the rest of the device rotates around it. The resulting landscape consists of a number of circular fields. These landscapes may look under-used as the corners between the circular fields are not cultivated. In many locations, however, such as the desert of central Saudi Arabia (23°46′35″N 49°6′6″E), lands would not otherwise be irrigated.

Trickle and subsurface drip

Farmers living in arid lands have always sought ways to use water more efficiently. The development of plastic tubing was a major step forward in this regard. Developed in Israel in the 1950s and 1960s, trickle irrigation involves hundreds of meters of small diameter tubing either laid directly on the ground or suspended on trellises, depending on the type of crop grown (e.g., on the ground for lettuce, above the ground for grapes). At various intervals along the tubing small spigots allow measured amounts of water to trickle onto the base of each plant. Excellent examples of trickle irrigation exist in the Champagne region of France (49°11′54″N 3°56′40″E).

A recently developed variation on trickle irrigation involves burying tubing a few centimeters below the ground surface. This allows for even smaller amounts of water to be applied directly to the roots of each plant.

Summary

As long as people have been farming dry lands – and the origins of agriculture can be traced to these very environments – they have been developing means to capture, transport, and apply water efficiently to their fields. Some ancient irrigation techniques remain in use today, and new techniques will doubtless be developed in the future.

Jamaica: Jamaican Geographical Society (JGS)

Founded: 1966
Location of headquarters: Kingston
Website: http://www.mona.uwi.edu/geoggeol/JGS/JGS.htm
Membership: under 100 (as of December 31, 2013)
President: Kevon Rhiney
Contact: kevon.rhiney@uwimona.edu.jm, jamaicangeographer@gmail.com

Description and purpose

The JGS was primarily established to advance the discipline of geography in Jamaica. The society is managed by an elected council and its members include scholars, educators, students, and employees in the public, private, and NGO sectors in Jamaica as well as members of the public with a general interest in geography. Since it was founded the society has been actively engaged in the dissemination of geographic research and knowledge through its newsletter and various outreach and sensitization activities including panel discussions, workshops, guest lectures, field trips, and occasional exhibitions.

Journals or major publication series

Current activities or projects

The JGS has embarked on a number of outreach activities in recent years ranging from panel discussions and guest lectures through to its various educational programs and workshops. Since 2010, the JGS has held four panel discussions on topical issues affecting the Jamaican society and economy. The society recently held a panel discussion looking at the state of the Jamaican housing market post the 2008 global economic recession. Previous panel discussions have focused more on the state of geography education in Jamaica, by (i) looking at the challenges Jamaican high school teachers face in preparing students for the Caribbean Secondary Education Certificate (CSEC) examinations and (ii) examining the reasons behind the decision of some high schools to replace geography with social studies. Over the past four years the JGS has been supporting the Dream Jamaica summer program by hosting whole-day workshops on GIS under the broad theme of “Why Geography Matters.” Dream Jamaica was formed in January 2008 to help high school students in Jamaica visualize and realize their dreams (for more details on the Dream Jamaica initiative go to www.dreamjamaica.org). The society has recently been awarded a Global Greengrants Fund grant to assist in raising awareness of climate change among Jamaican youth. The dissemination/exchange of geography research and knowledge is done through the society’s newsletter and Facebook page.

Japan: Jimbun Chiri Gakukai (The Human Geographical Society of Japan (HGSJ))

Founded: 1948
Location of headquarters: Kyoto
Website: http://hgsj.org
Membership: 1323 (as of September 30, 2013)
President: Masahiko Yamano
Contact: abeno-yamano@juno.ocn.ne.jp

Description and purpose

The society promotes the studying of human geography and promoting its advancement and development. It publishes Jimbun Chiri (Japanese Journal of Human Geography) every other month (English issue is published once a year). It organizes geographical meetings (annual meeting in November every year, regular meetings three times a year, and other specialty group meetings more than fifteen times a year). The society also makes contact with geographical and other academic institutions in Japan.

Journals or major publication series

Jimbun Chiri (Japanese Journal of Human Geography)

Current activities or projects

The society published Jimbun Chirigaku Jiten, The Dictionary of Human Geography on September 30, 2013 (Maruzen, Tokyo). The society supported the IGU Kyoto Regional Congress in August 2013. The society completed the registration as a general incorporated association for nonprofit legal entities in Japan in October 2014.

Brief history

The Human Geographical Society of Japan was founded in March 1948 in Kyoto as the academic association organizing most Japanese human geographers. It was originally established as The Geographical Society of Western Japan in October 1946 with some eminent geographers who lived in the Kinki district (western Japan). At present, this society has 1323 members and nearly all Japanese human geography researchers are members. The society publishes its official academic journal, Jimbun Chiri, the Japanese Journal of Human Geography (JJHG) in six issues a year. One issue in every volume of JJHG publishes a survey of geographical studies in Japan, an annual review of human geography. This geographical society also hosts the following five special study groups: (i) History of Geographical Thought, (ii) Historical Geography, (iii) Metropolitan Area Studies, (iv) Education of Geography, and (v) Political Geography. During 2000–2005 an Asian area studies group was also active. Each study group holds several research meetings a year. This society has published a total of 12 volumes of Bibliographies in Japanese Geographical Research between 1953 and 2009.

Japan: Nihon Chiri Gakkai (The Association of Japanese Geographers (AJG))

Founded: 1925
Location of headquarters: Bunkyo-ku, Tokyo
Website: www.ajg.or.jp
Membership: 3000 (as of January 1, 2014)
President: Noritaka Yagasaki
Contact: office@ajg.or.jp

Description and purpose

Since its inception in Tokyo in 1925, the Association of Japanese Geographers (AJG) has played a leading role in the advancement of geographic research and education in Japan. It now has some 3000 members who are geographers with diverse backgrounds, specialties, and interests. Given that the AJG attained the status of “Public Interest Incorporated Association” in Japan on April 1, 2012, it is expected to contribute further to the dissemination and application of geographical knowledge in society. The AJG publishes an online English journal, in addition to two Japanese journals. The AJG hosts two annual meetings in the spring and fall.

Journals or major publication series

Geographical Review of Japan Series A. www.jstage.jst.go.jp/browse/grj/-char/ja
Geographical Review of Japan Series B. www.jstage.jst.go.jp/browse/geogrevjapanb
E-journal GEO. www.jstage.jst.go.jp/browse/grj

Current activities or projects

The AJG hosts annual meetings in the spring and fall to promote scientific exchange and interaction. Thirty-one study groups are approved within the AJG, exploring various geographical subfields and topics. The AJG has started publishing a new English publication series entitled “International Perspectives in Geography: AJG Library.” The AJG provides two types of accreditation: the Certificate of GIS Skills/Advance GIS Skills and the Certificate of Regional Research/Advance Regional Research. In order to promote geography education, the AJG holds an open lecture series for the general public and supports the International Geography Olympiad.

Brief history

The AJG is the oldest and largest academic association of geographers in Japan. It was established by 49 geographers in Tokyo in 1925 as the Geographical Review of Japan. Membership has grown steadily over the years (272 in 1940; 612 in 1950; 1880 in 1960; 2810 in 1970; 3090 in 1980). Although AJG membership has been stable in the past three decades, geography in Japan has experienced substantial changes. The founding of the English language journal, the Geographical Review of Japan Series B in 1984 symbolized the effort of Japanese geographers to internationalize their academic activities. More recently, the English journal has become an open-access online journal and seeks to become a leading English geographical journal in Asia. The AJG, the leader among the geographical associations in Japan, obtained the status of “Public Interest Incorporated Association” as of April 1, 2012, marking the beginning of a new era of development.

Just-in-time production system

Neil Reid
University of Toledo, USA

Just-in-time (JIT) is a system of production that allows manufacturers to simultaneously reduce production costs, improve product quality, and quicken the pace of both product and process innovation (Reid 1995). It is a system developed by the Japanese automaker Toyota, beginning in the 1940s. A key characteristic of JIT is its emphasis on having component parts delivered to the point of production “just-in-time” to be incorporated into the manufacturing process. This permits manufacturers to reduce costs by minimizing the need to store component parts at or near the point of production. Under JIT, parts (or modules of parts) are delivered frequently (several times a day) and in small batches. In the 1960s, the Japanese introduced a process known as gaichu kanban, by which parts do not leave suppliers until an order for them arrives from the customer. Gaichu means “order” while kanban refers to the written instructions that provide the supplier with delivery details (quantity and delivery deadlines, frequency, and destination within the receiving factory). Under a JIT regime parts can be delivered as frequently as every two hours to the point of assembly (Kaneko and Nojiri 2008). Today the efficiency of the gaichu kanban process is greatly aided by the use of information technology (e.g., barcodes and laser scanners) and automation (e.g., automated storage and retrieval systems) (Fields 2006; Bowen 2008).

While there are many different aspects of JIT, geographers are primarily interested in understanding the spatial implications of the system. Interest in the geography of JIT began to emerge with the appearance of Japanese automobile assembly and component parts plants in the United States in the mid-1980s. Honda was the first Japanese automaker to open an assembly plant in the United States when they started producing automobiles in Marysville, Ohio, in 1982. They were quickly followed by other Japanese automakers such as Nissan (Smyrna, Tennessee, 1983) and Mazda (Flat Rock, Michigan, 1987). The Japanese automakers were quickly joined by Japanese auto component part makers who established production facilities in the United States in order to supply the assembly plants with component parts. Today there are 14 Japanese-owned automobile assembly plants in the United States and literally dozens of Japanese-owned component parts makers (Japan Automobile Manufacturers Association 2012). While JIT is utilized across a wide range of industries it is in the automobile industry where its use is perhaps most pervasive. The automobile industry, therefore, provides an excellent case study to highlight JIT’s spatial characteristics.

In an early study on the spatial implications of JIT, Kenney and Florida (1992) found its use to be widespread among Japanese automotive companies in the United States. Eighty percent of first-tier suppliers (who sell directly to the automakers) and 43% of second-tier suppliers (who sell parts to first-tier suppliers) deliver
parts according to a JIT schedule. Furthermore, they found that 41% of first-tier suppliers are located within a two-hour drive of their major customers. Indeed, proximity to automobile assembly plants was the most important site selection criteria for 90% of Japanese automobile component parts makers (Kenney and Florida, 1992). Reid (1990) found that 79.1% of Japanese automobile component parts makers in the United States were located in a state that also had a Japanese automobile assembly plant. The findings of Kenney and Florida are supported by Estall (1985), who suggested that JIT requires suppliers to be within 62 miles (100 km) of their customers. This need for spatial proximity between customer and supplier results in a geographically clustered customer-supplier network.

Later studies by Klier (1995, 1999, 2000) have challenged the whole notion that JIT necessitates spatial proximity and geographic clustering. Klier (2000) argues that the level of spatial clustering exhibited in the Japanese automotive industry is nowhere near as high as Kenney and Florida (1992) suggest. The most geographically clustered supplier network identified by Klier (2000) was Honda’s. Yet, only 29% of Honda’s suppliers are located within 100 miles of the assembly plant. Klier (2000) argues that JIT does not result in local-scale geographic clustering. Rather, clusters of suppliers are more regional in nature, extending over hundreds of miles. Thus, the median distance between Auto Alliance (a Ford/Mazda joint venture) and its Japanese suppliers is 286 miles (460 km). Klier (1995, 1999), however, notes that spatial clustering tendencies do seem to vary from automaker to automaker and according to whether the suppliers are domestic- or Japanese-owned. For example, Honda’s supply network is more geographically clustered than Diamond Star’s (a Mitsubishi/Chrysler joint venture). Twenty-six percent of Honda’s Japanese suppliers are located within 100 miles, compared to only 8% of Diamond Star’s Japanese suppliers. In a similar fashion, Japanese suppliers to Japanese assembly plants tend to be more geographically clustered than domestic suppliers to the Japanese assembly plants. For example, 19% of Toyota’s Japanese suppliers are located within 100 miles of the assembly plant. In contrast, only 5% of Toyota’s American suppliers are located within 100 miles of the assembly plant.

In Japan the distant delivery of component parts on a JIT basis is facilitated by the existence of third-party logistics providers who organize the delivery of various parts to distribution depots (cross-docks) that are located in close geographic proximity to the assembly facilities. Upon arrival the parts are sorted and delivered to the assembly plant on a JIT basis. Parts that are best suited for such long-distance delivery, consolidation, and sorting are those that are standardized and whose production can be planned well ahead of time (Kaneko and Nojiri 2008).

It is generally recognized that access to a well-networked and modern transportation system greatly facilitates the delivery of component parts on a JIT basis (Reid 1990). In contrast, an informative study of the Indian automobile industry demonstrated the impact that a poor and inefficient transportation infrastructure can have on JIT production systems (Gulyani 2001). Maruti, India’s largest auto assembler, has struggled to reduce inventories at its assembly plant. The relatively primitive highway system that exists in India increases unpredictability with regard to the length of time that component parts will be in transit. For example, a parts delivery that would take a predictable 1.5 days in Europe (2000 km) will take a highly unpredictable 6–9 days in India (2500 km). Maruti has found that suppliers who are within an 80-km radius are able to deliver parts with acceptable
frequency. Beyond that, the degree of unpredictability becomes problematic. Ford, which has an assembly plant in India, has addressed the transportation challenge in a number of ways – by encouraging its suppliers to locate in close proximity, by utilizing a distribution depot (cross-dock) system for more distant suppliers similar to that used in Japan, and by ensuring that hard-to-ship components (e.g., seats and fuel tanks) are manufactured nearby (Gulyani 2001).

In any discussion on the spatial impacts of JIT it is worth noting that the definition of what constitutes a JIT delivery schedule can vary widely. If choreographed perfectly a JIT system would eliminate all inventories at the point of production. Zero inventories is very difficult to achieve, however, with the result that different producers tolerate different inventory levels and hence can be said to be operating JIT more or less efficiently. In comparing Japanese and American automakers, for example, Delbridge and Oliver (1991) found that the latter, on average, had parts delivered on a significantly less-frequent basis (an average of 1.59 deliveries per day versus an average of 7.9 deliveries per day) with the result that they carried larger inventories at the point of production (an average of 8.1 days of inventory versus 1.52 days of inventory).

In summary, JIT is a production system that has at its heart inventory control. The studies cited here suggest that while geographic proximity between customer and supplier may be desirable it is not necessary for the smooth and efficient functioning of a JIT production system. The utilization of other methods such as distribution depots and cross-docking allows component parts to be delivered on a JIT basis from suppliers who are at great geographic distance.

JUST-IN-TIME PRODUCTION SYSTEM

Karst processes and landforms

Jo De Waele
University of Bologna, Italy

All landscapes of the Earth are formed by a combination of physical and chemical processes that have acted on the exposed rocks over long periods of time. The different lithologies are weathered and eroded away and leave erosional morphologies, while the resulting sediments are transported by various agents (rivers, ice, wind) and deposited elsewhere, sometimes thousands of kilometers away from their source, forming depositional landscapes on land or at the bottom of the ocean. These landscapes can take their name from the dominant processes that have shaped most of the surface features (e.g., glacial or volcanic landscape) or from the prevailing rocks (e.g., sandstone or granite landscape).

The karst landscape takes its name from a region between Italy and Slovenia dominated by outcrops of carbonate rocks. Karst is the German wording, adopted during the Austro-Hungarian period when the first studies on dissolution-related landforms were conducted. It derives from the old Indo-European term “karra,” meaning “stone” (Palmer 2007), known in Latin as “carusardius,” and still used in the form “kras” in Slovenia and Croatia. Karst landscapes are formed mainly by surface and subsurface rock dissolution and are best developed in tropical and mid-latitude regions where carbonates and evaporites are exposed. Karst dissolution is subdued or impossible in areas with no rain (e.g., deserts) or where temperatures are always below zero (polar regions, high mountain areas). When a karst area is buried by other rocks and dissolution stops, the voids are often filled with sediments or mineralizations. Some of these can become important mineral resources, such as the Mississippi Valley Type deposits. These ancient karsts are referred to as paleokarst (Bosak et al. 1989). By contrast with all other landscapes, in karst chemical dissolution largely overrules mechanical erosion. Most of the rock is carried away in solution by surface and underground flowing waters and physical sediment production is very low, restricted to insoluble material, mainly clays. Because of the dominant role of dissolution over erosion, karst areas are characterized by a very distinctive morphology and hydrology (Ford and Williams 2007).

Although karst typically refers to limestone terrains, mainly composed of the mineral calcite, dissolution can also be the dominant geomorphic process in other rocks. Extensive cave systems have also been discovered in dolostone, composed of the mineral dolomite which has slower dissolution kinetics than calcite. Good examples of such cave systems, mainly developed in tectonically complex areas, are found in the Dolomites in Italy (Sauro, Zampieri, and Filipponi 2013). Gypsum and anhydrite are around 100 times more soluble than calcite. Karst in these evaporite rocks has been described in all continents and in a wide range of different climatic settings (Klimchouk et al. 1996; Calaforra 1998). The most soluble rock on the Earth is rock salt (halite). In regions where rainfall is very low and/or rock salt is continuously brought to the surface by salt diapirism (e.g., Dead Sea area in Israel, Atacama desert in Chile, Zagros Mountains in Iran), surface dissolution can create the same
Karst processes and landforms

Karst morphologies encountered in limestones, but at a rate more than a thousand times faster (Frumkin 2013). Also, quartz-sandstone terrains, in tropical areas such as the tepuis in Venezuela and Brazil, can host typical karst morphologies such as solution rills, caves, and underground drainage (Wray 1997). Although referred to by some authors as “pseudokarst,” there is unmistakable evidence that dissolution is an essential morphogenetic process in these landscapes.

The chemical processes responsible for the dissolution of the rocks are various and depend on the mineralogy of the rock to be dissolved (Dreybrodt 1996). In gypsum and rock salt the dissolution is a simple two-phase (solid-liquid) dissociation. The solubility of gypsum in pure water is around 2500 mg/L at 20°C, roughly 140 times lower than that of rock salt (halite, NaCl, 360 000 mg/L) and three orders of magnitude greater than that of calcite (1.5 mg/L). Dissolution of any salt increases in the presence of other salts because of ion-pairing effects. Saturation is reached rapidly and dissolution rates are boosted in the presence of turbulent flow.

In quartz-sandstone terrains, quartz (SiO₂) is dissolved forming orthosilicic acid (H₄SiO₄), reaching saturation at 8.7 mg/L in pure water at nearly neutral pH and 20°C. Amorphous silica is slightly more soluble, reaching a solubility of around 100 mg/L. Both quartz solubility and rate of dissolution increase with temperature. The dissociation of orthosilicic acid, which also increases the solubility of quartz, starts at neutral to basic pH. In these conditions the orthosilicic acid undergoes up to four consecutive dissociations (Mecchia et al. 2014).

But the most intensively studied karst processes are those related to carbonate rocks such as limestones and dolostones. Solubility of both calcite and dolomite in pure water at 20°C is very low, similar to the solubility of quartz, but increases by two orders of magnitude in the presence of slightly acidic waters. In most natural systems on the Earth, acidity primarily derives from epigenic sources, mainly from carbon dioxide (CO₂) present in the atmosphere and in the soil. CO₂ slowly dissolves into meteoric waters forming carbonic acid (H₂CO₃), thus reducing pH and increasing the corrosion capability of the percolating waters. Besides carbon dioxide, acidity can also derive from organic acids (humic and fulvic acids) or oxidation processes occurring in aereate conditions. These aggressive waters penetrate into the bedrock through available permeable pathways (fractures, bedding planes) and flow down-gradient in the saturated (phreatic) zone towards the discharge points (i.e., springs). In carbonate karst areas, most of the dissolution occurs close to the surface, in the first tens of meters of rock, known as epikarst, and rapidly decreases downwards as the saturation degree increases.

Many factors influence the chemical reactions involved in the dissolution of carbonate rocks, the most important of which is mixing of different waters. In the mixing zone between two different waters, or at the interface between fresh and saline groundwater, typical in coastal karst areas, chemical dissolution is enhanced. Mixing of two solutions saturated with respect to calcite but at different partial carbon dioxide pressures results in an undersaturated solution capable of dissolving more limestone. This mixing effect, known in the literature as the “Bögli effect,” makes dissolution possible also deep in the aquifer. In young limestones close to the sea (e.g., small carbonate islands), enhanced dissolution at the interface between the freshwater body and the denser salt water gives rise to the so-called flank margin caves (Mylroie and Carew 1990).

The acidity of the solutions can also derive from deep (hypogenic) sources, in the form of CO₂- or H₂S-rich rising fluids. These sometimes highly aggressive rising waters lead to the formation of the so-called hypogenic cave...
systems (Klimchouk 2007), some of which are created by fluids enriched in carbonic acid (e.g., Black Hills, South Dakota), and others by solutions enriched in sulfuric acid (e.g., Guadalupe Mountains, New Mexico). Since the source of acidity derives from deep underground and is brought to the surface along major discontinuities (e.g., deep faults), these systems are often found in areas with thermal springs (e.g., Budapest). The dissolving power of the fluids diminishes moving upward, often leaving no geomorphic expression on the land surface. Hypogenic caves are also present in gypsum areas, where undersaturated waters enter the gypsum beds from below in an interstratal karst setting. These fluids dissolve the gypsum beds along every possible initial open fracture, leading to the formation of sometimes impressive regular maze caves (e.g., Ukraine) (Klimchouk 2007). Some of the largest cave systems in the world are actually hypogenic caves, such as Lechuguilla Cave in New Mexico (a 222-km-long sulfuric acid cave in limestone) or Optymistychna Cave in Ukraine (a 236-km-long gypsum maze).

In general the word “karst” refers to a landscape dominated by unique morphologies that form because of surface dissolution of the host rock. This process creates a wide variety of small-scale landforms typical of karst: these are called karren. They occur on all soluble rocks, especially limestone, gypsum, and rock salt, but also on quartz-arenites. They vary in form from small pits and grooves, to rills (rillen), to runnels (rinnenkarren), and flat-floored solution pans (kamenitze). These centimeter- to meter-sized rugged landforms are typical of high mountain karst (Figure 1) in the absence of soil and cover. Karren are also very well developed in coastal areas, where the corrosive, burrowing, and etching actions of organisms exacerbate their shape. In this environment bioerosion becomes dominant, and the landscape is often called biokarst or phytokarst.

Karst areas often have a drainage characterized by closed depressions and generally lack normal river networks. These closed depressions are probably the most distinctive landform of karst, and are known as dolines, from the Slavic word “dol,” meaning “valley.” In North America and in engineering language dolines are called sinkholes. The presence of dolines in an area is diagnostic of the dominance of dissolitional processes over erosional ones. Dolines can have many shapes, from shallow saucer-shaped depressions to large vertical shafts, depending on the dominant processes that formed them: dissolution, suffosion, collapse, or sagging. They can have diameters ranging from a couple of meters to over a kilometer and normally have a subcircular plan form. When numerous dolines coalesce they form complex depressions historically named uvalas, a term that is falling into disuse. Collapsed dolines that give access to the underlying aquifer are known as cenotes, typical in Central American coastal areas. Dolines occur both in carbonate and in evaporite rocks, with a greater frequency and dimension in the latter mainly because of their higher solubility (100 times more than the carbonate rocks), and their lower mechanical strength and higher ductility (Gutiérrez et al. 2014). Generally, dolines are classified as either solution dolines or subsidence dolines. The first develop because of focused dissolution in zones of higher permeability, resulting in the gradual and differential lowering of the ground surface. In general, this type of doline forms in areas with exposed or barely soil-covered soluble rocks. Subsidence dolines, on the other hand, form because of subsurface dissolution and gravitational downward movement of the overlying material. These are classified according to the type of material involved in the lowering (cover, bedrock, or caprock) and the main subsidence
process (collapse, suffosion, or sagging) (Gutiérrez et al. 2014). Cover refers to overlying material composed of unconsolidated deposits (e.g., soils, alluvium), bedrock is the soluble rock itself (e.g., limestone or gypsum), and caprock is a covering solid nonkarstic rock. The downward movement of the material can involve brittle deformation (collapse), slow washing away of loose deposits into underlying subsurface voids and settling of the overlying deposits (suffosion), or slow ductile bending of sediments (sagging). Cover collapse sinkholes (or dolines) are the most spectacular and dangerous ones. Sometimes more than one type of material and several processes can cause the formation of a complex doline, which will be classified using combinations of the above mentioned terms, putting the dominant material and/or process first, followed by the secondary one.

Dolines can occur as isolated individuals, in groups following the direction of fractured areas or the allogenic recharge boundary of the karst area, or can occupy all of the available surface area. This egg-box-shaped pattern of dolines is known as polygonal karst, and occurs in tropical and temperate areas characterized by high
values of rainfall (e.g., Papua New Guinea, New Zealand). The large density of dolines in these areas creates an extremely efficient autogenic drainage pattern, conveying surface waters very rapidly underground. The size of the dolines in these areas depends on a combination of lithological and structural factors, as well as climatic ones.

Another typical landform that derives mainly from dissolution of soluble rocks, in particular, limestones, is the karst plain, often referred to by the Slavic word “polje,” meaning “large plain.” These almost perfectly planed surfaces cut across the rock structure and their floor corresponds to the mean level of the water table. This means they flood during the rainy season, and remain dry for the rest of the year. Their floor is covered with a very thin cover of residual (insoluble) material with bedrock cropping out locally. Karst planation surfaces generally develop at the inflow and outflow boundaries and can be considered as the final stage of karst denudation in carbonate rocks. Often these large depressions are controlled by structural elements, such as grabens or large synclines. The soluble rock surface is lowered vertically until the water table is reached, after which dissolution enlarges these depressions laterally at the level of the water table. This produces a planation surface inclined parallel to the hydraulic gradient. Ford and Williams (2007) distinguish three main types of poljes: border poljes, structural poljes, and base-level poljes. The best examples of these poljes can be seen in the Dinaric karst.

Often the karst denudation is not complete, and some parts of the original bedrock are left standing out on the planation surfaces. Small hills like this are called hums in the Dinaric karst and are frequent in temperate areas. In a tropical climate, residual hills can instead be 200 m high and have steep to almost vertical sides. In China, isolated hills like this are called fenglin (peak forest), while clusters of residual hills sharing a common exposed bedrock base are known as fengcong (peak cluster). The first are formed close to the water table level (and thus erosional base level), while the latter are formed far above this level (and therefore lack the typical flat plain in between). The Spanish-derived term for the towers is “mogotes.” The intervening karst plains are formed in a similar way to the aforementioned poljes, as horizontal swamp notches at the base of the towers confirm. The presence of several of these notches along the tower walls reflects the changes in local water table level.

Surface rivers are absent in typical karst areas, and the drainage pattern is mainly characterized by dolines. Small allogenic rivers, for which the drainage basin is partially located outside of soluble rocks, normally disappear underground soon after they enter the karst area, forming blind valleys (valleys which end “blindly”). When allogenic streams are greater, water will flow on the karst surface forming a true valley, sinking along its path into more permeable areas (losing streams). When large amounts of water are conveyed underground through point sinks these are called swallow holes (also named swallets or ponors). The discharge carrying capacity of these swallow holes often does not allow all of the water to disappear, and the river continues downstream until all the water is absorbed by the karst rocks. Downstream of this last swallow the valley becomes dry for most of the year, and activates only during high discharge periods. Some rivers may maintain their flow throughout the entire karst area until flowing out of it. This may happen because the flow rate exceeds the capacity of the karst to absorb, or because the hydraulic gradient is very low, not allowing the water to penetrate underground rapidly enough. High hydraulic gradients in fact enhance the vertical percolation of surface waters. The river valleys in karst areas are generally characterized by steep walls, typically forming canyons (or gorges).
KARST PROCESSES AND LANDFORMS

Many of these canyons are formed gradually in a slowly uplifting region (antecedent valleys).

Since primary porosity in both limestones and evaporites is very low, surface waters in karst tend to penetrate underground through all available fractures. Passing through these variable pathways, dissolution continues and permeability gradually increases, resulting in an enhanced underground water flow and a consequent local groundwater lowering. Thus an aerate (or vadose) zone is created in the upper part of the karst aquifer, where water percolates downward or is held in place by capillary forces. This upper part of the vadose zone, extending immediately below the karst surface, is known as epikarst (or the subcutaneous zone), and can be regarded as the extension of the surface karren forms. This is where most dissolution of rock takes place in carbonates, since CO₂ concentrations are higher there. This network of fissures enlarged by dissolution often contains infillings of soil that can retain moisture over longer periods of time, gradually releasing their water downward by gravity. This subcutaneous habitat is also extremely interesting from a biological point of view. Epikarst usually ranges from a couple to some tens of meters deep. Below this epikarst, water flow is focused along a few larger voids that can extend very deep into the bedrock and give rise to cave systems, or are feeders of active caves below.

Dissolution processes, together with mechanical erosion along underground pathways, give rise to the formation of three-dimensional systems of conduits, and solutionally enlarged discontinuity planes (fractures, bedding planes), forming extremely complex three-component permeability aquifer systems. The direct connection between the surface and the karst aquifer causes underground waters to be extremely vulnerable to pollution. The high secondary permeability of karst enables waters and pollutants to be transported quickly and often without undergoing appreciable chemical and physical changes from their input points to the springs (Goldscheider and Drew 2007). Due to this rapid transfer, flow rates can also change by three orders of magnitude in a relatively short time span. During floods, pollutants stored underground during low flow conditions can be flushed out. Karst aquifers drain toward springs, which often have considerable flow rates. The largest springs in the world are most probably karstic ones, reaching flow rates of over 100 m³/s. The location of these springs is often controlled by the regional or local base level (e.g., sea level), or by a less permeable threshold (e.g., underlying or adjacent rocks, alluvium), sometimes caused by tectonic features (faults). Since sea level changed during the Quaternary, some springs can be located close to or even below sea level, giving access to underwater cave systems. These springs, typical of carbonate islands but also present in other geographical contexts, are known as blue holes. Headward retreat of the spring can produce a pocket valley with the spring at its upstream end, typically at the foot of a high limestone cliff. Base-level rise, due to valley aggradation, can cause vertical vadose passages to be flooded creating very deep springs, known as Vauclusian springs, named after the Fontaine de Vaucluse (France). Some springs become active only during floods, and are located above the regional water table. A special type of temporary springs is the so-called estavelles, which act as swallow holes during normal (low) flow, and become active as springs during floods.

Cave genesis (or speleogenesis) is a complex topic, involving different sciences, mainly geology, chemistry, and physics. Dissolution is an important process, but is generally not responsible for most of the created voids, since once mechanical erosion starts, this process largely overrules chemical dissolution. Dissolution,
however, is fundamental, especially in the initial phreatic phases of cave formation, when laminar flow is the only possible mechanism of water movement through the tiny little fractures and openings in the rock mass. This initiation phase in cave formation can last some thousands of years in limestone, and some decennia in gypsum. Once the width of the openings reaches a critical threshold, a little less than a centimeter, turbulent flow is established and flow rate increases. This allows the water present in these enlarged openings to remain chemically aggressive over longer pathways, enlarging this flowpath more than the neighboring ones. This causes, in the short term, the selection of this path as the main one, focusing most of the water flow through it, boosting its widening even more. This rapidly brings to the formation of a true cave passage, in a period similar to the initiation phase. These passages eventually will become air-filled and can accommodate sediments and speleothems, or continue growing through collapses. Complete infilling or surface dissection, with the creation of so-called unroofed caves, finally ends this cave’s cycle.

The overall cave pattern mainly depends on the origin of the dissolving waters, on the type of recharge, and on the nature of the guiding structures (Palmer 1991). In general, cave patterns depend on the local geological settings, including the distribution and type of soluble rocks, their structural setting, and the relative (and variable) position of recharge areas and points and the outlets (generally springs). Caves develop very rapidly (in a couple of years) in rock salt outcrops, in a matter of a hundred years in gypsum, and in some thousands of years in limestone and dolostone. The initial phases of speleogenesis will tend to favor the most permeable pathways, mainly consisting in fractures and bedding planes. The initial geological and structural conditions are often reflected in the morphology of the cave passage as a whole and on the cave wall sculpturing features. Differential corrosion-erosion creates typical cross-sections along more soluble beds, weaker bedding planes, and fractures.

As described above, the aggressiveness of the waters can have a surface origin (CO₂ in the soils and the atmosphere) or a deep origin. The first waters create so-called epigenic cave systems, the latter hypogenic caves. Recharge in epigenic caves can be allogenic (from outside the karst area) and autogenic (from inside). Allogenic input often is concentrated, while autogenic input can be either concentrated or diffuse. Recharge can also be indirect, through overlying nonkarstic aquifers. In general, epigenic caves form in unconfined conditions, with water flowing from a recharge area into the karst and then flowing by gravity following the hydraulic gradient to the outputs, in general important springs. Most of the upstream cave volume is produced in vadose settings, epiphreatic (flood-water) conditions prevail close to the water table, while in the downstream end phreatic conditions occur more frequently. Typical vadose passages are shafts and canyons, along which the waters tend to descend along the steepest available pathway, often represented by the dip of the beds. Once the water table is reached, the water no longer has a need to descend rapidly, and will follow the hydraulic gradient choosing the most efficient openings. Cave passages are often completely filled with water and tend to dissolve and erode the bedrock away in a homogeneous manner. This creates phreatic tubes that are roughly cylindrical in shape and, although they loop in both horizontal and vertical directions, they often more or less follow the strike.

The history of a cave can often be reconstructed based on the careful observation of the overall morphology of the system, but especially through the analysis of rock wall sculpturing
and its relation with the hosted sediments. Flow direction, for instance, can be inferred from the shape of scallops, erosional cusps left by turbulent flowing waters. Also the size of these scallops allows the flow velocity at the time of their formation to be estimated: the bigger they are, the slower the water was flowing. This ultimately allows flow rates in now abandoned conduits to be estimated based on scallop size and the passage's cross-section. Estimation of conduit cross-section size can be made difficult where sediments were present at the time of scallop formation. Underground rivers, in fact, can accumulate sediments on their floors, which shield the lower portion of the passage from corrosion-erosion. The water will thus be able to cut into the walls creating alluvial notches, slightly undulating subhorizontal lateral grooves on the walls. If alluviation fills the passage almost completely, phreatic conditions will be created and the water will corrode and erode the roof only. If sedimentation continues synchronously with this upward dissolution, ceiling channels or an anti-gravitative canyon can develop. Sediments can later be washed out from these passages leaving a canyon-like passage. This anti-gravitative erosional process is known as paragenesis, not to be confused with the minero-petrographical term. Para-
genesis in caves can be related to increased sediment input into the system, which can be induced by climate changes or can be caused by anthropogenic activities (e.g., deforestation).

The most common big epigenic caves are the typical underground rivers, and their genesis is strictly related to what happens at the surface. Developing over thousands of years, they reflect both climate and landscape changes, and their speleogenetic study can help unravel the paleo-geography and paleoclimatology of the area in which they have formed. Sinking points can shift upstream, creating new cave tributaries, while springs can move to lower elevations, following base-level lowering (e.g., valley entrenchment). This can create a set of cave “levels” that can be correlated with surface morphologies such as fluvial terraces.

In hypogenic caves, recharge comes from below and dissolves the rock upward. These cave systems are often located in regional ground-water systems where structural reasons cause fluids to rise (e.g., along major deep faults) and, when these waters come in contact with soluble rocks, create underground dissolution voids. In the typical intrastratal systems, the soluble bed is sandwiched between a lower-lying and an upper aquifer bed. Hypogenic caves in gypsum do not require acid waters, and caves can form as long as the rising fluids are undersaturated with respect to gypsum. This ascending speleogenesis acts along any available discontinuity and normally creates maze cave systems, some of which can reach kilometric development (e.g., Ukraine). Hypogenic caves in limestone, by contrast, need acidic waters able to dissolve the calcite (or dolomite). Since the waters often come from deep below the surface, the geothermal gradient causes them to be thermal. The decrease in pressure, due to rising, causes CO₂ to be released from the waters, while, conversely, part of this gas dissolves in the water again because of the decreasing temperatures, making these fluids become acid. Important thermal cave systems have been described in many parts of the world, such as in Budapest (Hungary) and the Black Hills (United States). In other cases the rising fluids can be enriched in H₂S, often deriving from the reduction of sulfates such as evaporitic rocks or hydrocarbon reservoirs. This gas, when arriving in an oxidizing environment, such as a cave or the shallow phreatic environment, turns into sulfuric acid that reacts with the limestone.
forming gypsum and releasing CO₂, which further enhances the dissolution of more limestone (Egemeier 1981).

Another peculiar type of cave is the flank margin cave, typically formed in relatively young carbonates close to the present or past sea level. In this zone freshwater-seawater mixing creates an area of enhanced dissolution forming a set of interconnected voids more or less parallel to the coastline and along a horizontal plane, corresponding to the sea level at the time of their formation (Mylroie and Carew 1990). Flank margin caves lack morphologies and sediments typical of underground streams. Cave passages tend to pinch out moving away from the mixing zone (and hence coastline). This type of cave is typical of carbonate islands, but has also been described in continental coastal limestone areas.

Once a cave has formed, it starts accumulating material, including clastic sediments, chemical precipitates, and organic debris. Cave entrances are often characterized by pitfalls, or sinks, and tend to collect surface material that falls in accidentally (animals) or is washed in by surface runoff. This creates preferential sedimentation sites of sometimes very valuable deposits that can be preserved over very long periods of time, while surface deposits are being stripped away by erosion. Caves can also be used by animals, including humans, as shelters or living places, or for ritual reasons. Caves have delivered some of the most important archeological sites for the reconstruction of the evolution of humans and their art (e.g., the Sterkfontein caves in South Africa with their Australopithecus finds, or the Lascaux cave in France for its wonderful Upper Paleolithic rock art).

Cave sediments can help to reveal at least part of the cave’s history, but because of extensive reworking and redeposition, they are often very difficult to study (Sasowsky and Mylroie 2004). Alternations of fine and coarse sediments in relatively undisturbed sedimentary sequences in caves reveal changes in flow in the underground stream. The mineralogical and petrographical composition of sediments can tell where they come from, and reveal possible changes in recharge areas. Sediments can sometimes be dated using paleomagnetism, in combination with U–Th dating of flowstone beds (Zupan Hajna et al. 2008). Allogenic quartz grains can be chronologically constrained using cosmogenic Al–Be dating techniques (Granger and Muzikar 2001). All these dating techniques deliver ages younger than the cave itself.

Inflowing and percolating waters introduce not only detrital particles but also dissolved species. Reactions between these fluids, the host rock, the sediments in the cave, and the atmosphere cause minerals to precipitate as single crystals or, more commonly, as aggregates known by the general name of speleothems. Over 330 different species of minerals have been described forming in caves (Onac and Forti 2011). Mechanisms of mineral formation include a variety of processes, such as CO₂ loss, evaporation, alteration of material already present in the cave, oxidation–reduction, cooling–heating, and changes in pH, just to mention the most important ones. The most frequent minerals are of course calcite and aragonite, followed by gypsum and other carbonates and sulfates. Where bat guano or bones are present, a variety of phosphates can be found. Some minerals are intimately related to the cave’s genesis, such as in the case of sulfuric acid speleogenesis, and their dating can give clues on cave formation (e.g., K–Ar and Ar/Ar dating of alunite) (Polyak et al. 1998).

But caves are especially appreciated for their hosted speleothems (Figure 2), such as the famous stalactites and stalagmites. These can be classified according to the nature of the water that deposited them (Hill and Forti 1997), or to the way single crystals and their aggregates
form the external shape of these cave formations (ontogeny, Self and Hill 2003). Most speleothems are formed of calcite or aragonite. Among the most common forms are: stalactites, stalagmites, columns, flowstones, soda straws, helictites, cave pearls, and rimstone dams. A review of most of these is given in Hill and Forti (1997).

Speleothems are important climate and environmental archives, characterized by annual layering of chemical origin, allowing the reconstruction of environmental and climatic changes at high temporal resolution (Fairchild and Baker 2012). The advantage of speleothems compared to other continental archives is the fact that they are datable with great precision with techniques based on the radioactive decay of uranium. Thanks to the introduction of MC-ICP-MS (Multicollector Inductively Coupled Plasma Mass Spectrometry) it is possible to date small (less than 0.2 g) samples of carbonate with high precision (2 sigma) of ±1% in the interval between 0 and 500,000 years BP. In recent years, the research on speleothems has focused on the isotopic composition (oxygen and carbon) of the carbonate of which they are composed and on their axial growth rates in order to reconstruct an annual and secular scale of climate variability, and to recognize the effect of internal and external climate forces on global climate changes. Recently, the study of the variability in speleothem trace element concentrations (Ba, Mg, Mn, P, Sr, U, etc.) through time has emerged as a useful hydrogeological marker that allows researchers to reconstruct rainfall, from seasonal scale to millennial scales, and to obtain information on the residence time of the water in the aquifer (often related to climate), with important consequences for the extension of phenomena of water-rock interaction. Speleothems have also been used for the reconstruction of Quaternary sea level changes, hydrological conditions in continental and marine environments, paleo-seismicity during early Quaternary, and relationships between climate change and archaeological events.

Many caves around the world have become tourist attractions because of their aesthetic value. A fee is charged to gain access to these caves, and normally visits are carried out following equipped pathways and under the surveillance of a cave guide. Although the first real show cave is Vilenica in Slovenia (where invited people have paid to visit the cave since 1633), most show caves developed in the second part of the twentieth century. The development of a show cave often requires modifications to be
made to the cave system, such as construction of pathways, opening of new or more easy access, installation of electric lighting systems, and a whole set of infrastructures both in the cave and above it or around its entrance. These operations often cause damage to the cave and the surrounding landscape, and environmental impact assessments should be carried out prior to show cave preparation to minimize these negative impacts (Cigna 2012). Special care should be taken in the selection of paths, lights and their position, and in the timing of the visits, in order not to exceed the so-called visitor carrying capacity, the maximum number of visitors that can enter the cave in a certain time frame without changing the environmental parameters irreversibly. In other words, modifications to the underground environment (e.g., temperature rise, CO2) should be recovered by the system at least over night, with return to natural conditions.

The protection of the cave and its environment is important to safeguard the mineral beauty of the cave (i.e., speleothems), but also to create as little disturbance as possible to the sometimes extremely fragile cave habitat. The underground voids, in fact, including not only caves but also the tiny fractures, are a habitat to an incredibly various and more or less specialized cave fauna (Culver and Pipan 2009). Some species are completely adapted to life underground: they have lost their pigments and eyes, have developed their other senses extremely well, and spend their entire life cycle in the dark and wet environment of a cave. These species, called troglobites, would not be able to survive outside and can be endemic to very small areas or even single caves. Troglophiles (cave-loving species) are species spending part of or their entire life cycle underground, being adapted to this environment, but can also be found outside (under rocks). Trogloxenes live close to the cave, and use caves as shelters (e.g., bats).

Even the slightest changes in cave environmental parameters can cause troglobites to migrate, and in the worst cases to succumb, resulting in loss of biodiversity. Modifications also include those that happen outside of the cave, at the surface or in the drainage area (water pollution, deforestation and soil loss, urbanization). While the extinction of a troglobite can pass unnoticed, the decrease in the population of large bat colonies in a cave can have a dramatic impact on the surrounding area, since bats are insectivores and therefore reduce the need for pesticides. Subterranean karst environments are also unique microbiological habitats. This biodiversity is worth protecting, and ongoing research on new cave-dwelling species and microbiological communities might allow the discovery of new substances useful for medical purposes (Barton and Northup 2007).

In the past decennia, public awareness of the unique character and the fragility of karst areas has increased enormously, especially in Europe and America, but still needs to be stressed in many countries. It is now understood that if we want to safeguard this fragile environment, and enjoy its multiple resources for centuries to come, we need to find a way of living on karst.

Description and purpose

KNGS is a public association founded in October 2013. KNGS unites the scientific and creative geographic community. Its goal is the development of geography and sciences of nature, society, and culture through the collaboration of the domestic scientific community and the development of cooperation with international associations of scientists.

KNGS concentrates on the following areas: geography and climate; environment and natural resources; biodiversity; tourism, travel and regional ethnography; and historical and cultural heritage, and ethnography.

Journals or major publication series

KNGS’s journals are under development.

Current activities or projects

As a young nonprofit organization, KNGS plans to expand its network nationwide and worldwide by opening eight branches in different regions of Kazakhstan and establishing ties with major international geographic societies. Scientific exchange and interaction occur through the KNGS’s annual conferences, joint research projects, and other collaborative activities. KNGS projects extend to a study of the Silk Road and different Kazakhstan regions, historical sites, nomad civilizations, national and international scientific expeditions, ecotourism and science tourism, restoration of fauna, study of migratory birds, and so on. KNGS also focuses on educational programs and popularization of geography.

Brief history

Before the establishment of KNGS there were a few geographic societies in Kazakhstan. KNGS was founded in 2013 by geographers of the Nazarbayev University, Kazakhstan, to unite the existing geographic societies under one umbrella.

KNGS’s mission is to promote research in the field of geography and related sciences, spread geographic knowledge among the population, and develop cooperation with international scientists, organizations, and geographic societies.
KAZAKHSTAN

KNGS is governed by a board of trustees and a managing council. The first conference of the KNGS, which gathered enthusiasts and experts in geography and related sciences, was held on October 8–9, 2013, at the Nazarbayev University. The conference was dedicated to the state of modern geography in Kazakhstan, its trends and perspectives, and the role of KNGS in solving problems at the national level with participation of academics, NGOs, and public organizations.

Among the first projects of KNGS are expeditions to Ulytau and Zhongar Alatau; restoration of Przewalski’s horse and the Turan tiger in Kazakhstan; a study of the snow leopard in Kazakhstan; the creation of a web museum of Kazakhstan that will list sites of historical, cultural, and natural heritage; the creation of short educational TV programs on historical sites of Kazakhstan; exploration works in south and west Kazakhstan; the development of infrastructure for local tourism; and many other projects.

Submitted by Vladimir Litvak
The term “knowledge-based economy” is used to characterize economies, national or regional, that are primarily driven by the “production, distribution and use of knowledge and information” (OECD 1996). The knowledge-based economy is thus different from economies that are mainly driven by other production factors such as capital, unskilled labor, or resource extraction.

The term began to appear in scientific literature in the 1990s, indicating that the development of the knowledge-based economy is a recent phenomenon (Foray and Lundvall 1996; Dunning 2000). Prior to the 1990s, capital and labor were usually regarded as the main drivers of economic development. With the shift toward stressing the importance of knowledge – or technology – as a production factor, a number of other related terms entered the academic discussion, for example “innovation.”

The knowledge-based economy has at least three important meanings. First, from the perspective of economic growth theory, it highlights the relative importance of different production factors. The standard production function in economics, developed in the 1950s and widely used in the field of regional studies/economic geography, highlighted the role of capital and labor. Economic growth was seen as a result of a balanced growth of both labor and capital, while fundamental changes in the way these two factors relate to each other, and changes in the effectiveness of their use, were attributed to technical progress, that is, new knowledge. The fact that knowledge was responsible for economic growth, and that it was more important than the growth of the production factors capital and labor, was empirically proven, and the focus of economic growth theory gradually shifted toward incorporating knowledge into the growth models (new growth theory; Romer 1990). It also resulted in a growing interest in basic innovation, technological paradigms, and their effects on economic growth and structural change.

With reference to growth processes in advanced economies, there is a broad consensus today that the creation and use of new knowledge is decisive, contrary to situations decades ago, during which economic growth was often fueled by an increase in labor (e.g., during times of rapid urban growth or mass immigration), the exploitation of natural resources, or a rapid growth in capital use (e.g., during the Industrial Revolution). Hence, the term “knowledge-based economy” denotes the attention paid to knowledge by economists.

Second, the knowledge-based economy acknowledges the fact that the industrialized countries, mainly the United States, Western European countries, Japan, and some other Asian countries, are investing heavily in the production of knowledge. Until the first half of the twentieth century, the production of new knowledge was usually not at the center of political and corporate decision-making. Technical progress was a result of trial-and-error processes in firms as corporate research and development activities were usually very limited. Public attention to knowledge creation meant providing schooling. Investment in basic science and tertiary education was limited to a few places, organizations, and individuals.
KNOWLEDGE-BASED ECONOMY

With the event of mass higher education in the 1960s and 1970s, and with a huge growth in the numbers and sizes of public research organizations, university research, and public research funding after World War II, the creation and dissemination of knowledge reached a new dimension. New knowledge was regarded as a tool for solving the great challenges of the modern world, ranging from providing cheap energy (or, today, clean energy), to fighting cancer, developing new means of communication, and achieving economic and military superiority. Hence, technical progress has accelerated and so has the dissemination of expertise with highly qualified engineers, scientists, and so on. The knowledge-based economy, and the growing importance of knowledge compared to other production factors, have thus been made possible by the expansion of science and education.

Third, the knowledge-based economy denotes changes at the corporate level that fundamentally affect the structures and dynamics of economies. The development of information-processing technologies (e.g., computers) and communication technologies (e.g., telephone, fax, the World Wide Web) has lowered the costs of interaction between firms. It has thus created opportunities for separating the activities necessary to produce a commodity (or a service), as independent firms that specialize in the different activities necessary for the production of one product can easily communicate with one another and bring together their contributions. Under these circumstances, companies have an incentive to concentrate on very few core activities that exactly match their core competence (Prahalad and Hamel 1990).

A concentration on core competencies and a specialization in related core activities require certain strategic actions. Companies then strive to be regarded as a producer of a distinct, special component or service. Technology leadership – or leadership regarding quality, customer orientation, and so on – is a necessary goal for a business strategy that is based on a narrow specialization. In order to be able to achieve such a leading role, a company’s core competence must be constantly increased. This requires recruiting specialists, carrying out research and development (R&D), and monitoring technical developments in related fields.

When the production of goods and services is not organized according to vertically integrated large firms (as it used to be until the late twentieth century), but is instead organized by a network of highly specialized producers, the whole economy is affected. For example, the need for a specialized workforce and stimulus for public research increases for each economic activity. Hence, the knowledge-based economy is an economy made of specialized firms with specialized personnel, and it calls for and draws on specializations regarding many economic activities that used to be covered by larger and unspecialized organizations.

From the point of view of the first and the second dimensions, the knowledge-based economy is necessarily related to hi-tech industries, innovation, and science-driven product development. The third dimension, however, is not necessarily linked to science and high-tech. There, the economy is based on knowledge, as it produces innovation through specialization in all parts of the economy, be they high- or low-tech. Companies can specialize in producing components that seem to be far removed from research and higher education, but the production processes or the logistics behind these components may still benefit from specialization and a core competence made of adequately skilled workers.

Hence, this understanding of knowledge-based development denotes strategic decisions at the firm level, most importantly the shift toward a
narrow focus on competencies and products, and, following on from this, certain structural changes in the organization of the economy, namely a higher degree of separation of production processes and of collaboration and networking. The growing attention to networks of all kinds, not only in geography but also in all social sciences, is inseparably connected to the emergence of the knowledge-base economy (OECD 1996).

From this brief discussion of the dimensions of the knowledge-based economy and the processes behind it, several important issues emerge that can only be touched on here. First, it is important to note that the knowledge-based economy is not only developing in the advanced economies. Although higher education, public science, and corporate R&D are concentrated in the advanced economies, many developing countries are catching up. The rise of China’s education and science sector is the most striking example of a change that fundamentally affects the composition of production factors in many developing countries, and provides the basis for knowledge-based developments. Moreover, companies in developing countries are part of global value chains and global production networks, and thus have the chance to specialize, to upgrade and learn, and to compete on the basis of knowledge. The latter point is illustrated by the rise of multinational firms from developing countries.

Hence, the knowledge-based economy has increasingly become a global description of the economy, and it is unlikely to be a short-term phenomenon. As long as companies are more profitable when they specialize and outsource, that is, as long as communication and transport are cheap, the knowledge-based economy will continue to be the key feature of today’s economic structures and dynamics.

This has profound implications for economic geography that are already visible in the major trends of the recent academic debate. Networks and networking, the nature of contacts and collaboration, the issue of university–industry linkages, the spatial consequences of public commitment to education and science, knowledge sharing and knowledge spillovers on various scales, as well as the notions of tacit knowledge and sticky knowledge, dominate a large part of the work of economic geographers.

Politics will have to respond to the need for education and science, and will have to ensure that conditions for corporate R&D are favorable. Moreover, communication and the openness of information flows, as well as trade flows, need to be on the agenda.

Knowledge-intensive business services and regional development: strategic importance of

Richard Shearmur
McGill University, Canada

Although it has become commonplace to refer to a certain category of services – high knowledge content intermediate services – as knowledge-intensive business services (KIBS), these services are also referred to as high-order business, or producer, services (Wood 2006). This semantic point is useful for understanding the connection between KIBS and regional development because much of the work by geographers on the topic, under the influence of Christaller (1966), uses the latter term (Coffey 2000).

This entry will briefly discuss the structural changes to the economy that explain the rise of KIBS, focusing more specifically on the way in which regional economists and economic geographers have perceived these services as actors in the revival of local economies. Whilst there is consensus on the role that these services play in assisting their clients in a wide variety of business functions, information gathering, and knowledge transmission, understanding of the geography of this assistance – that is, where KIBS firms locate relative to their clients – has evolved and continues to be the subject of debate (Wood 2006). The purpose of the paper is to flesh out these statements, explaining the way ideas have evolved.

The rise of KIBS

Since the 1950s, and especially since the rapid decline of manufacturing employment from the 1970s onwards, economies in the Western world have been shifting from secondary (manufacturing) to tertiary (service) employment. This has led to concerns about the decline in productive capacity, but also to detailed assessments of the causes of this shift and of the new role that service sectors – high knowledge content services in particular – play (Daniels 1985).

Broadly speaking, three processes are evoked to explain these structural changes (Bryson, Daniels, and Warf 2004). First, the “New International Division of Labor” has led manufacturing activities to seek cheap labor in developing countries, whilst Western countries specialize in high-knowledge content services. This has certainly occurred, though it probably is not the principal explanation of KIBS growth. Second, the vertical disintegration of firms, under the impetus of new technologies and new competitive pressures, led to the rise of an independent producer service sector as management, research, accounting, and other service functions were hived off. This same process – driven partly by the automation of production – also accounts for some of the decline in manufacturing employment. Third, there have been fundamental changes in the way value is created: in affluent societies in which all basic needs are met, consumption increasingly turns towards symbolic goods. (This does not mean that each person’s basic needs are met. It means that enough is produced to meet all basic needs: poverty and inequality cannot be attributed to lack of resources or productive capacity.) Firms
are required to innovate in order to distinguish themselves from competitors, and continuously renewed information and know-how are required in order to do so. In addition, as the economy globalizes, regulatory frameworks, logistics, management, and markets have become more complex. Specialized high-order business services are required to penetrate these information thickets, to identify and compile useful information and to pass it on to their clients, either by way of simple information, as subcontractors, or by way of collaboration (MacPherson 2008; Shearmur and Doloreux 2015).

There is still debate as to which of these processes carries most weight in explaining the rapid rise in the role of KIBS. Furthermore, some would argue today that creative industries are taking precedence, and that KIBS – almost systematically the fastest growing sector in Western economies from the 1970s to the early 2000s – may have run their course. The weakness of this argument lies in the difficulty in defining creative industries: there is no clearly defined “creative” function, creativity being a social process in which ideas are generated and confronted with an audience, which will ultimately decide what is creative or not. High-order business services, such as research and development (R&D), management consultancy, and design, are contributors to the creative process (which occurs across the whole economy) and in particular to cultural industries (which, like all other industries, require service inputs).

Thus KIBS continue to play a key role as knowledge intermediaries, information compilers, and transmitters of know-how across the economy (Strambach 2008). The tapering-off of their growth rates is partly attributable to the major structural changes having run their course, and partly to the simple arithmetic of growth rates (which necessarily slow down as the denominator gets larger, except in cases of exponential growth).

**KIBS and their strategic regional role**

Given the role played by KIBS in the economy, the connection between KIBS and regional economic development has been of concern to economic geographers. Three moments in the evolution of this concern will be described below.

**KIBS as footloose industries: an alternative to manufacturing**

In the 1980s, as widespread manufacturing decline was being experienced across most Western economies, certain regions were hit harder than others. In particular, resource-based regional economies (such as mining or smelting towns) and those relying on large factories (such as automobile or ship-building) lived through severe upheaval – some of these regions, such as the Nord-Pas-de-Calais in France, have never fully recovered. In this context, and bearing in mind the rapid growth in high-order services, this sector caught the attention of regional development specialists: the idea that producer services could stabilize, or indeed revive, lagging regional economies was explored (Marshall 1982; Bailly, Maillat, and Coffey 1987).

The argument is two-pronged. First, it rests upon the fact that KIBS were considered “footloose.” Unlike manufacturing, which requires machinery, large buildings, and other physical investment, KIBS were considered free to locate anywhere – their requirements being labor (available, almost by definition, in regions undergoing job losses), offices, and – at the time – a fax and phone line. Given the rapid KIBS growth, it was believed that they could be attracted
to lower-cost locations, or that, at the very least, local KIBS start-ups could be encouraged. However, as pointed out by analysts at the time, this idea is problematic since high-order services tend to locate in larger cities further up the urban hierarchy: this is partly as a consequence of Christallerian processes (high-order services require extensive markets, more readily accessible from central cities), and partly due to the specialized labor required (a preponderance of university educated personnel).

This approach, which may seem quaint in the light of work on innovation, cities, and knowledge exchange, is more relevant today than it was in the 1980s, since improvements in communication technologies are such that the advantages of city location may now be less decisive (Macpherson 2008). Already in 1996, Beyers and Lindhal (1996) documented “lone eagles and high-flyers” – that is, service professionals who, often in mid-career, decide to live, and run their consultancies, in remote communities (albeit communities located within an hour of a regional airport, allowing the consultants to travel easily). Currently, many regions in France are thriving because of consultants and other professionals who have chosen them as places of residence, working part of the time from the region, and traveling frequently towards the larger metropolitan areas where their jobs are officially located.

The second prong to the argument that KIBS can revive declining regional economies is that KIBS provide crucial inputs to manufacturers. Thus, notwithstanding the tendency of KIBS to locate towards the top of the urban hierarchy, Marshall (1982), for instance, argues that a concerted effort should be made to develop KIBS sectors in declining regions in order to enable local economies to revive. The idea is that start-ups and SMEs (small and medium-sized enterprises) – those best adapted to the new economic realities – can only emerge if they have access to KIBS, and that regional policymakers should ensure this access either by supporting the service sector directly or by providing the services through development agencies.

As we will see in the next section, this idea also retains some currency. The key difference between the ideas expressed in the 1980s about the strategic regional role of KIBS and those that are expressed today is their underlying vision of regional development and policy. In the 1980s regional development was understood to be, in large part, a consequence of the location decisions of manufacturers (and, marginally, of the service sectors): location theory, a series of ideas that explain the location of economic activity on the basis of cost minimization and access to markets, prevailed, and the role of KIBS was thought of within this framework. Furthermore, it was believed that central governments could and would implement regional development policies, such as incentives for particular sectors – KIBS, for example – to locate in particular regions.

KIBS as territorially embedded: milieu and innovation systems

The theorization of regional economies evolved in the 1980s and 1990s in tandem with the structural changes described above. At the same time there was a shift away from government intervention under the impetus of neoliberal ideas, epitomized by Mrs Thatcher (a UK prime minister) and Ronald Reagan (a US president). Two diametrically opposed, yet convergent (in terms of the way regional development is envisaged), lines of thought developed. On the one hand, a neoliberal reading of regional economies argued against policy intervention: regions and localities were understood to be in competition with one another, not part of an integrated system of interdependent territories but individuals in competitive struggle with
KIBS AND REGIONAL DEVELOPMENT

one another. On the other hand, regions and localities were seen by neo-Marxist geographers as the locus of resistance to globalizing mobile capital; and although the idea of resistance was watered down as the idea spread, the notion that regional economies are local systems which develop endogenously on the basis of local communities, institutions, and knowledge began to dominate the economic geography discourse. (From this perspective regions develop under the impetus of institutions, actors, networks, and resources (such as human capital) that exist within the region (i.e., that are endogenous to it). This contrasts with the view that prevailed in the 1960s and 1970s whereby regions developed under the impetus of economic actors choosing to locate in regions because of cost advantages and because of fluctuating world markets for their exported commodities (these factors are not within the region, they are exogenous to it).) Both the neoliberal and the critical perspectives emphasize that regional economies are identifiable entities which should (or need to) fend for themselves.

From these perspectives, KIBS are understood as strategic local assets, activities which enable innovation and economic growth (Cooke and Leydesdorff 2006). KIBS are seen as part of each region’s “technological infrastructure,” of its innovation system, and local economies are thought to be at a disadvantage if they do not house these services. Needless to say, not all KIBS are the same: of specific relevance to the local economy are technological KIBS, those concerned with engineering, design, and research.

KIBS’ role in local innovation systems is conceptualized in various ways. First, KIBS gather and enshrine specialized local knowledge, particularly tacit knowledge which is difficult to communicate in codified (i.e., written) form. Within a local innovation system KIBS firms act as knowledge and know-how relays between firms: as KIBS provide advice and interact with local companies they gain experience which makes them more valuable to the local system (provided, of course, that one accepts the idea that knowledge and know-how can be specific to a territorialized system). A second role played by KIBS is one of subcontracting: local firms may require specific service functions (such as accounting, R&D, product testing) for short time periods, and the local availability of these services facilitates their use. A final role is that of knowledge and information relay: Florida (1995) describes learning regions as those regions with the capacity to identify knowledge – whether local or nonlocal – that may be of relevance, and to translate it into terms useful for regional economic actors. KIBS, which constantly monitor new trends, new ways-of-doing, new regulations, and new markets – whether they emerge within the locality or beyond – are vectors of knowledge transfer within and towards the local economy.

If regional development is of concern, this view of KIBS in local economies can lead to two types of conclusion. The first is that only those regions with a well-developed KIBS sector are able to develop fully fledged endogenously driven local economies. Given that high-order services cluster in larger cities, this has led to the idea that large cities are the quintessence of well-functioning regional economies. Second is the idea that regions, whether urban or rural, should nurture local KIBS since they are key constituents of well-functioning local innovation systems.

KIBS, the Internet, and distance: back to basics

A recent approach to understanding the strategic role played by KIBS in regional economies
is, paradoxically, a return to some of the earliest work on the subject. Important work by Macpherson (2008) has empirically established that innovative firms do not rely on local service providers. He shows that firms in upstate New York identify potential KIBS providers by searching on the Internet for likely candidates (or by word of mouth), then travel in order to meet the providers, select them, and exchange hard-to-communicate information. They then rely on Internet and other modes of distant interaction for day-to-day communications. Shearmur and Doloreux (2015) show, furthermore, that the more strongly a KIBS subsector is connected with innovation the further the distance which separates the service provider from its client. Tether, Li, and Mina (2012), who examine two types of service provider (architects and engineering consultants), show that a Christallerian logic applies to architects whereas engineers seem to choose their location based on considerations largely unrelated to the urban hierarchy or to local markets (they are mainly global firms). In both cases local regional markets have little impact since these firms, especially the larger ones, tend to have a national or international client base. Finally, a pioneering study by Echeverri-Carroll and Brennan (1999) shows that innovative firms in southern US cities tend to search for strategic service providers up the urban hierarchy.

These studies have in common that the spatial economy is approached as a network of functionally interdependent regions. Endogenous regional development is not an applicable concept given these interdependencies; rather, it is understood that different functions will locate in different places according to costs, market extent, local availability of resources (including information and qualified workers; Polèse and Shearmur 2004), and communications technologies. It is not because particular functions are absent from a territory – KIBS, for instance – that the local economy will cease to perform. Quite the contrary: if a function is missing locally, economic actors will turn to the outside and identify providers elsewhere.

This does not preclude the fact that some KIBS will tend to function within and serve local markets: accounting and legal advice, for instance, will tend to be sourced locally – partly because they are required on a frequent basis. Other types of KIBS – particularly specialized innovation-related services required on an ad hoc or project-by-project basis – will tend to operate from accessible central places, with clients traveling occasionally to visit the consultant, or the consultant traveling occasionally to work with the client. The rapid rise and adoption of the Internet has made the identification of, and day-to-day communication with, KIBS far easier, thus undermining many ideas that focus too exclusively on local endogenous dynamics and territorialized knowledge systems.

Once it is recognized that KIBS need not be located within a region to play a strategic regional role, the way in which this role is conceptualized can evolve. Kautonen and Hyypiä (2010), for instance, view KIBS as knowledge mediators between different regional contexts. In their view, some KIBS can only play their role efficiently if they possess a geographically extensive client base. This enables them to transfer know-how between regions. KIBS too closely tied to a local system may in fact be detrimental to the local economy: KIBS which, from a metropolitan base, function both internationally (“up” the hierarchy or along “pipelines”) and regionally (“down” the urban hierarchy to a regional client base) transfer knowledge across borders and across scales.
Conclusion

The role of KIBS as a source of wealth creation, enabling firms to focus on their core activities whilst having access to specialized knowledge and know-how on demand, has grown rapidly since the economic upheavals of the 1970s. For a while it was felt that declining regions needed to attract KIBS either to replace lost manufacturing jobs, or to bolster failing local firms and fledgling start-ups. As the view of regional economies changed, as they were expected to become more entrepreneurial and competitive through endogenous processes, KIBS were increasingly seen as important elements of local knowledge and innovation systems: since knowledge and innovation are understood to be key drivers of economic development, the local presence of KIBS was seen as an enabling condition for regional growth.

Today, with almost ubiquitous availability of high-speed Internet and cellular coverage, there have been two important changes relative to the late 1990s. First, there is no reason to believe that geographically isolated firms cannot identify and interact with service providers from elsewhere. There remain geographical restrictions, since temporary face-to-face meetings are still important, but this places far looser constraints on the location of service users. Service providers, however, still tend to locate at the top of the urban hierarchy since accessibility – both to global markets and to national markets – is easier from these hubs. Furthermore, qualified labor is more plentiful in these places.

The second change relates, notwithstanding the previous sentences, to the fact that some service providers can also now locate away from major metropolitan areas. These relocations are unlikely to alter the basic hierarchical distribution of service providers, but can have sizeable impacts on receiving communities. Globalized service firms may not require location at the heart of a metropolitan area, and may consider location in places within easy reach – about an hour or so – of one: as Tether, Li, and Mina (2012) describe, these firms rely on internal economies of scale rather than on external ones. Accessibility remains important, but does not need to be maximized. Smaller consultants may likewise locate in amenity-rich areas, provided they are relatively accessible. Finally, KIBS workers increasingly perform part of their work from rural or isolated locations, traveling to their KIBS employer (or clients) on a regular but intermittent basis.

To conclude, it is important to emphasize that little space has been devoted to considering the way in which different types of KIBS subsector locate and/or interact with their clients (Tether, Li, and Mina 2012). Likewise, the increasing difficulty in distinguishing between KIBS and high-tech manufacturing has not been discussed (Daniels 2011); however, to the extent that these are beginning to resemble each other, the location and role of high-tech manufacturing (or of the knowledge-related functions within global value chains) may begin to resemble that described here for KIBS. Finally, given the focus upon regions, the entry does not deal with the distribution of KIBS globally.

Throughout much of the twentieth century, geographers drew upon neoclassical economic theory to understand firms’ locational dynamics. At least four dominant approaches can be identified. First, a generation (if not more) of geographers used the work of Alfred Weber (1929/1909), who developed a “least cost” model which explained the locational decisions of independent, single-plant firms in terms of the relative weight of their transportation and labor costs, and what he called “agglomeration forces.” Second, an approach drawing upon Hotelling (1929), and exemplified by the famous example of ice-cream sellers clustering on a beach, focused upon the geographical behavior of businesses whose location is dependent upon that of their competitors. Third, the work of August Lösch (1954) was seen as a way to make the leap from understanding why individual firms behave the way they do to understanding what this behavior means for the creation of entire economic landscapes. Finally, the growth of behavioral geography in the 1960s led some to seek to understand firm dynamics in terms of the idiosyncrasies of various corporate decision-makers.

With the influx of Marxism (see Marxist geography) into geography in the 1970s, however, these approaches began to be critiqued. For one, they were seen as largely disconnected from consideration of the broader political economy of capitalist accumulation and the drive to extract surplus value from labor. For another, many were paradoxically aspatial in their approaches – they largely assumed that the economic landscape is simply an inert stage upon which economic actors interact, implying that the economic geography of capitalism is simply a reflection of the economic relations between firms. They also were derided for their positivist philosophy. Finally, by principally telling the story of the making of the economic geography of capitalism from the perspective of managers, their explanations largely ignored the role of workers. As it developed, this Marxist critique provided a way to link the behavior of firms into broader questions of the nature of capitalist accumulation, the extraction of surplus labor, the periodic crises that the capitalist mode of production experiences, and the production of economic landscapes. However, Marxist geographers initially conceptualized workers largely in terms of their being “variable capital” or a “pseudo-commodity,” rather than as embodied sociospatial actors. This is perhaps not surprising, as Marx himself was largely interested in understanding the nature of capital accumulation and how competition affects capitalists’ behavior. Nevertheless, since the 1990s this lacuna has led a growing number of geographers to focus upon labor as a geographical actor. Adapting Marx’s famous aphorism that “people make their own history but not under the conditions of their own choosing,” these geographers have sought to show how workers make their own geographies but not under the conditions of their own choosing. Framed as a shift from studying the “geography of labor” to studying
“labor geography”, the focus of such geographers’ writings has been to look at how workers’ spatial embeddedness affects their economic and political behavior, and how that behavior in turn affects how the geography of capitalism is made. Below is detailed some of the research conducted by labor geographers in three areas: how workers have shaped individual firms’ structures and investment patterns through their activities; how workers have shaped networks of firms; and how workers have convinced various elements of the state to implement policies which have affected the geographical structure of firms and corporations.

Workers as shapers of corporate investment strategies

Geographical research has explored how workers’ activities shape the spatial investment strategies of individual corporations in three principal ways. The first approach has shown how workers have influenced corporations’ organizational and geographical structures reactively, as workers make themselves more or less attractive to capital, which then responds to their actions. In such studies the economic landscape’s making is viewed through the eyes of corporate decision-makers who decide to invest (or not) in particular places because of the actions or inactions of workers. It is these corporate decision-makers, then, who are seen to be thinking in a geographically deliberative manner as they use the uneven spatial distribution of labor’s characteristics (workers’ wage rates, levels of unionization, gender, and so forth) to their own advantage. The focus is upon capital as actor choosing between workers, rather than directly upon workers’ own agency, even though such agency – workers’ militancy and/or quiescence – shapes what corporations choose to do. For example, Peet (1983) has shown how many firms relocated in the post-World War II era from regions with high wages, high unionization rates, and high regulatory burdens to those with little or no unionization, low wages, and more “business friendly” state and local governments as part of the so-called Snowbelt to Sunbelt migration of US capital. In related fashion, other analyses have looked at how workers have modified their behavior so as to make themselves more attractive to corporate decision-makers. Hudson and Sadler (1986), for instance, explored how British steel-workers toned down their rhetoric when the government-owned British Steel Corporation was deciding which steel mills to shut down as it rationalized the industry in the 1980s. Successful labor organizing, then, is one way in which workers’ activities shape corporate investment strategies – their unionism is something which mobile capital seeks to avoid. Others, though, have suggested that corporations have a more nuanced relationship to labor organizing as it affects their locational decision-making. Hence, Page (1998) has shown how meatpacking firms relocating from Chicago after World War II did not seek to avoid unions per se. Rather, they avoided Midwestern communities with militant unions and chose to relocate to communities with more passive ones. In many ways, such studies are similar to the “geography of labor” approach articulated by neoclassical and some Marxist scholars, although they see workers as embodied economic actors rather than simply as “factors of production” or “variable capital.”

The second way in which workers have shaped corporations’ organizational and geographical structures is proactively, through consciously engaging in behaviors that force particular corporations to reorganize their own structures in response. The difference with the situations described above is that here the making
of the economic geography of capitalism is seen through the eyes of workers rather than corporate decision-makers. These are what have come to be called “labor geography” approaches. For instance, with the introduction of containerization into the maritime cargo-handling industry in the 1950s, US dockworkers began to feel the effects of job losses on the waterfront. Dockworkers in places like New York, Boston, and Philadelphia also feared that the growth of the interstate highway system and the ease of transporting cargo due to the new container technology would encourage shipping companies to unload cargoes in the less unionized southern ports, where labor costs were lower, and then use the rail or road system to transport their loads to the cities of the Northeast. Herod (1997a) showed how dockers, in light of such fears, began a spatially conscious campaign to transform the industry’s system of bargaining from one in which contracts were signed on a port-by-port basis to one in which a national system of collective bargaining – one that would lead to national wage rates – was used. Dockworkers’ actions, then, forced shipping companies to restructure their operations and to create new national employer associations. The dockers also negotiated a series of work rules dictating that certain types of cargo-handling work had to be done in ports rather than at warehouses located further inland, rules that shaped which warehouses the shipping companies could utilize and thus the geography of warehouse work in the industry. Looking more globally, Wills (2002) has shown how unions, through signing international framework agreements, have forced firms in some economic sectors – such as the hotel industry – to change how they conduct business. Sadler (2004), meanwhile, has examined how unions and environmental groups collaborated to introduce resolutions at shareholders’ meetings of the global mining giant Rio Tinto, pushing the corporation to change its business practices with respect to the rights of indigenous peoples, the environmental consequences of mining operations, and respect for workers’ rights.

The third way in which workers and their organizations have been seen to shape corporations’ organizational structures is through practices which, though not directly aimed at such corporations, have nevertheless proactively opened up paths for investment that they have then sought to exploit – unions, in other words, have served as shock troops allowing corporations to come in behind them to invest in certain regions. For example, as part of its own efforts (separate from the interests of US corporations) to undermine communism in Latin America and the Caribbean, during the twentieth century the American Federation of Labor–Congress of Industrial Organizations (AFL-CIO) encouraged US corporations to expand their operations into the region (Herod 1997b). Its goal was to facilitate the spread of US capital into Latin America and the Caribbean, thereby more tightly binding the region’s countries to the United States and inculcating “democratic” (i.e., noncommunist), pro-American political organizations and economic practices. The AFL-CIO hoped that this would not only help the United States win the Cold War but also provide material advantages to US workers – dominating the economies of the region would, it was believed, translate into domestic jobs for US workers. Through working with pro-US unions, subverting communist ones, and participating in several coups over the years (as in Guatemala in 1954 and Brazil in 1964), the AFL-CIO paved the way for US corporations to establish many subsidiaries in the Western Hemisphere where they could work with compliant unions who frequently restrained worker militancy in their branch plants. The AFL-CIO engaged in similar policies during the
LABOR GEOGRAPHIES AND THE CORPORATION

1960s and 1970s in Southeast Asia, for similar reasons. Thus, its Asian-American Free Labor Institute worked closely with leaders of the Trade Union Congress of the Philippines to create a more favorable investment climate for American business during dictator Ferdinand Marcos’s rule. Similarly, the AFL-CIO, together with a number of other international labor organizations, such as the International Metalworkers’ Federation, supported the spread of Western corporations into Eastern Europe after the collapse of communism there, seeking to jump-start these regional economies and help establish democratic institutions. At a more local level, unions also have often been part of local growth coalitions seeking to encourage capital investment into particular communities (Humphrey, Erickson, and Ottensmeyer 1989).

Labor and global production networks

Whereas this first generation of labor geography research tended to focus upon how workers shape the actions of individual corporations, the rise of “globalization talk” in recent years has led many geographers to research the structure of global commodity/value chains (GCCs/GVCs)/global production networks (GPNs). Essentially, GPNs are networks of geographically embedded firms through which various commodities and parts thereof pass, as they are manufactured and brought to market. These networks’ social and spatial organization generally is viewed as responding ultimately to the demands of the corporation sitting at the GPN’s apex. However, labor and its institutions have often been seen to be rather passive entities in GPN analysis. Capital is pictured as shaping a GPN’s sociospatial structure through determining whence raw materials will be sourced and how and where various components will be brought together as a commodity is assembled and moves through the network, as well as by playing off workers in different locations against one another, given their militancy, wage rates, productivity, and so forth. Workers, especially those toiling for third- and fourth-tier subcontractors at the supposed bottom of the network, though, have frequently been seen simply as social beings who are subject to the locational whims of corporate decision-makers and have little impact on shaping GPNs (for more on this, see Global production networks; see also Global commodity/value chains).

There has been growing criticism, however, that treating labor as simply one factor amongst many underplays workers’ impacts upon GPNs. As Coe, Dicken, and Hess (2008) argue, this failure to see workers as active geographical agents within GPN analysis has resulted from the tendency to view the firm as a black box. However, given that labor process dynamics strongly influence work organization and conditions within any one firm in a GPN, together with the relationships between firms, workers have the capacity to exert great influence upon the geography of activities within a network and thus the network’s overall form. As a result, labor geographers have argued for placing labor at the center of GPN analysis, focusing upon how workers’ spatial embeddedness shapes their economic and political behavior and thereby the relationships between the firms making up a GPN. For example, whereas corporations like Walmart are often imagined to be unchallengeable, their reliance upon tightly coordinated logistics within their distribution systems is actually a significant weakness that workers can exploit to force improvements in wages and working conditions. Even workers in small firms, often perceived in the GPN literature to be quite weak, can exert tremendous pressure upon the corporations atop the networks. This potential power was clearly illustrated in a dispute at two
small components plants in 1998, which brought virtually all of the North American operations of General Motors (GM) to a halt because of GM’s use of just-in-time production systems (see Just-in-time production system), allowing the dispute to ripple quickly through its production network. Likewise, although the result of a natural disaster rather than a strike, the March 2011 Japanese tsunami closed several component manufacturing plants operated by suppliers who are part of Toyota’s and Honda’s keiretsu, which led both auto assemblers to halt production at several of their US and European assembly plants. The point, then, is that the closure of even fairly small second- or even third- or fourth-tier suppliers – whether due to natural causes or strike action – can force firms like General Motors, Toyota, or Honda, which are assumed to be presiding over the GPN, to have to close their facilities.

Whilst there has been much interest in how commodities are put together within GPNs, until recently there was little interest in what happens after these commodities have been used and disposed of. In the past few years, however, a growing number of scholars have advocated for examining the “after life” of commodities, as part of what has come to be known as “ongoingness research.” In this context, Herod et al. (2014) developed the concept of global destruction networks (GDNs) as, in some ways, “Other” to GPNs. Whereas GPNs link different communities and independent firms or parts of corporations together in the process of assembling commodities, GDNs link together places and firms involved in the process of commodity disassembly and the reclamation of their constituent elements. As with GPNs, labor’s power to shape GDNs’ structure has been clearly demonstrated. For example, the processing of electronic waste (“e-waste”) in different parts of the globe is fundamentally shaped by the labor practices involved in its disassembly. In the Global North, e-waste dismantling is typically capital-intensive, using large machines to break up old electronics. In the Global South, on the other hand, it is generally much more labor-intensive. As a result, the kinds of elements reclaimed from disassembled commodities are quite different. In the Global North there is a higher overall recovery rate for waste elements than in the Global South but the higher labor costs mean that it is less likely that parts thus recovered (e.g., computer chips, circuit boards, hard drives) will be repaired and directly reused in new products. Instead, these are usually melted down for the metals and plastics they contain. By contrast, in the Global South it is more common that components recovered from, say, brand-name computers will be resold as parts, either to repair other brand-name computers or from which to construct non-brand-name, locally assembled computers that are essentially built from scratch for sale nearby in the backstreets of a place like Bangalore.

Labor’s influence on the structure of a GDN is also evident in the global shipbreaking industry. Although the cutting apart of ships at the ends of their working lives largely takes place in the Global South, much of the industry itself is coordinated from global shipping capitals like London, Rotterdam, Singapore, and Dubai. The process works as follows. When a shipping company seeks to scrap a ship, brokers in these cities inform breaking yards in countries like India, Bangladesh, and China, to which the ships are sailed, to begin the process of retrieving metals and other components. In China, ship-breaking generally is undertaken in docks using large-scale machinery and relatively few workers. In countries like India and Bangladesh, on the other hand, ships are usually beached in shallow waters and then broken up by gangs of workers who often use little more than sledgehammers and axes. This difference in how the ships are
broken up primarily reflects variations in wages, which are much lower in Bangladesh and India, and in Chinese workers’ greater unwillingness to tolerate the poor working conditions faced by Indian and Bangladeshi workers. In short, workers’ willingness to do certain types of work fundamentally shapes where and how shipbreaking is done.

Labor and the state

A further way in which labor can shape corporations’ geographical organization is through convincing various governments to enact regulations that limit corporations’ abilities to structure themselves in particular ways and/or to invest in certain places. For example, Rutherford (2013) has examined the Canadian Health Employees’ Union’s legal victory when the Canadian Supreme Court recognized collective bargaining as a fundamental right in the country’s national Charter of Rights and Freedoms. As a result, corporations operating in Canada must now respect certain labor rights, which undoubtedly will shape how they operate. Likewise, Clark (1989) has shown how US unions’ successful exhortations to the National Labor Relations Board (the federal entity charged with adjudicating disputes between employers and unionized workers) have limited corporations’ freedom to do as they please, with significant implications for how the economic geography of the United States is made. For their part, in studying day labor markets Peck and Theodore (2012) have detailed how various local governments have passed ordinances regularizing worker centers. Such centers have arisen because of the growing use of day laborers and other contingent workers not only by small, local firms but also by large, transnational corporations (Peck and Theodore 2006). These ordinances restrict the abilities of firms and individuals to force day laborers into a “race to the bottom” through underbidding each other for work. As Peck and Theodore put it, worker centers represent an effort to counter neoliberal labor-market deregulation from the bottom up.

Other scholars have shown how workers and their organizations have managed to get various arms of the state to pressure firms directly concerning their operations and where they locate. Herod (1991) detailed how the International Ladies Garment Workers’ Union in New York City successfully lobbied the city government to create an area within its Manhattan garment district in which conversions of manufacturing lofts would be severely restricted through new zoning regulations. The union’s goal was to protect space for garment manufacturers at a time when market pressures were encouraging many building owners to rent their structures to corporations as office space. There are myriad other examples of unions agitating for laws that limit corporations’ abilities to structure their operations in the name of profitability. For example, the United Food and Commercial Workers and the Service Employees’ International Union have worked with local community groups to persuade municipal governments across the United States to ban Walmart stores. Numerous unions also have pushed the federal government to enact various national rules and regulations overriding state laws, undermining advantages that companies might otherwise gain by relocating from highly regulated to less-regulated US states. In the 1930s this included national legislation limiting child labor and creating a national minimum wage and various union protections; the 1960s and 1970s saw legislation preventing employment discrimination on the grounds of race, sex, religion, and national origin; and in the 1980s and 1990s it included federal laws providing for family leave and requiring advanced notice of mass layoffs.
Such legislative agitation can have unintended impacts on corporations’ structures, however. For example, after the United Auto Workers (UAW) helped pass protectionist legislation in the 1970s to keep Japanese imports out of the United States as a way to save American autoworkers’ jobs, Japanese corporations simply established assembly plants in the United States. Whereas the first such plant (Honda’s St Marys facility) was built in the fairly union-dense state of Ohio, most of the subsequent “transplants” have been built in southern states, where union density is much lower. This has undermined the UAW, both because these plants are hard to organize (they are mostly in right-to-work states, where state laws do not require all workers in a unionized workplace to belong to the union) and because the growth of a nonunion labor force in southern states has allowed the companies to press for wage and other concessions in their unionized auto plants in the American manufacturing belt.

Conclusion: beyond unionized labor

This brief entry has detailed some of the research demonstrating how workers have shaped corporations’ structure, behavior, and spatial organization. To date, much of this work within labor geography has focused upon unions. There are some good reasons for this. For instance, unions often have good documentary archives available to researchers and readily identifiable leaders whom they can interview. Given that labor geographers’ initial goal was to make a theoretical claim that scholars seeking to understand the making of the economic geography of capitalism cannot just focus upon the spatial actions of capital but also must look at those of workers, and given that workers tend to be more powerful when they behave collectively, it seemed reasonable to examine unions as collectivities of workers. However, with labor geography now an established field of study, what might be called labor geography 2.0 has begun to emerge. The geographers associated with this development – many also central in developing labor geography 1.0 – have suggested that (at least) two major developments are necessary. First, geographers need to explore the lives of more than just unionized, Global North workers if they are to gain a more complete picture of how workers shape corporations’ and firms’ structures and how they play active roles in making the economic landscapes of capitalism. Consequently, some have begun to research the activities of nonunion and Global South workers, as well as of those trapped in precarious (temporary and part-time) rather than full-time work (see Precarious work). Second, they have suggested that labor geographers need to develop a much more nuanced and situated understanding of agency, one which recognizes how sociospatial context differentially shapes workers’ abilities to exercise power in making the economic landscape (Coe and Jordhus-Lier 2011; Rutherford 2010). Through such efforts they hope to more fully develop Marx’s insight that people make their own histories (and geographies!) but not under the conditions of their own choosing.

Labor geography

Steven Tufts
York University, Canada

Labor, human efforts to produce goods and services, is a key subject of geographic inquiry. The study of labor has, however, evolved theoretically from determinist treatments as a mere “factor of production” to a more contested agent in the formation of economic landscapes. Following a brief history of geography’s engagement with labor, we discuss four key themes in contemporary “labor geography”: agency, scale, class, and the state. We conclude with some recent theoretical developments and the future trajectory of labor geography as a field dedicated to analyzing the spatiality of work, workers, and workplaces.

Labor and geography

Modern geographic inquiry has studied what people do and how people organize themselves for social and economic reproduction over space. In the dark moments of environmental determinism, Ellsworth Huntingdon linked the industriousness of different groups to the specific climate conditions. The regional tradition within geographical research incorporated labor into descriptions of how patterns of production and reproduction develop across both time and space. Indeed, the different skills accumulated in local labor markets remain central to research on regional economic development and global economic competitiveness.

Labor, as a “factor of production” also played an important role in the quantitative revolution. Early location theory, inspired by Alfred Weber, conceptualized labor as a “factor of production” that, if its costs are lowered, “deviates” the location of a plant from its minimum transportation cost location. Industries that shift to lower labor cost locations are deemed to have a “labor orientation.” Economic geography’s quantitative revolution, similarly, was concerned with modeling the location of economic activity and included labor as a factor on par with transportation costs, resource availability, and market access.

It was the reduction of workers to just another factor of production, however, that was challenged by radical Marxist geographers. The emergence of Marxist geography in the 1970s and 1980s centered the conflict between labor and capital as key to the formation and transformation of economic landscapes. At the same time, feminist geographers also focused on questions of labor as fundamental to gender relations and economic relations. Here, not only were inequities within the gendered division of labor noted and investigated, but the importance of unpaid labor in the reproduction of capitalism was foregrounded (see McDowell 1993).

In the mid-1990s, critiques emerged against traditional Marxist geography’s theorization of economic landscapes that centered capital in analysis and overlooked the actions of workers within capitalist economies. Andrew Herod (1997) called for an economic geography that did not privilege capital and its agents over labor.
Labor Geography

in shaping economic landscapes. His call for geographers to assert labor as a more active agent in economic landscapes inspired a decade of research that shifted focus from the “geography of labor” toward a “labor geography” (see Lier 2007; Castree 2010).

Recently, Herod’s initial call has been critiqued for too easily dismissing economic geography as overly “capital-centric.” Storper and Walker (1989) in their now classic (yet difficult) schematic of employment and the construction of labor markets did center the employment relationship. Similarly, Peck (2013) has argued that the groundbreaking work of Doreen Massey (1995/1984) could easily be categorized as “labor geography”:

Intellectually and politically, Doreen Massey was a labour geographer long before the label existed. The path-altering analysis in Spatial Divisions of Labour not only marked but also helped realise a paradigm shift in economic geography – from positivism and location theory to critical realism and political economy – after which there have been many turns but very few returns. In a quite distinctive way, the not-so-little yellow book that all of us were carrying at the time put labour on the map, not just as an analytical category, but also as a social agent (Peck 2013, 113).

The counter criticisms against the “labor geography” project may overstate Herod’s original intentions in which he clearly indicates that his “capital is not all” premise should not be read as “labor is all” (Herod 1997, 3). In the 1980s, Marxist economic geographers in the United States and those directly involved in the locality debates in the United Kingdom, were undoubtedly challenged to celebrate the agency of labor in the midst of Thatcherist and Reaganist assaults on workers. In contrast, Herod’s minor corrective in the 1990s emerged at a moment where union decline had, momentarily at least, stabilized in the United States and the anti-globalization movement and other labor-friendly formations appeared to be gaining some momentum. Herod’s intervention also gave geographers a way to enter discussions of labor union renewal that emerged in Anglo-American countries in the 1990s.

At the same time, there were geographers in the 1990s that looked at issues of work and workplaces from feminist perspectives that were overlooked in the rush to establish a new “labor geography.” One example (among others) is Susan Hanson and Geraldine Pratt’s Gender, Work and Space (1995), which situated women’s power and place in the economy also without the “labor geography” label. Similarly, the work of Linda McDowell (1997) from the same period on the spatial dynamics of gender relations and work in capitalist landscapes must also be acknowledged as casting a feminist lens on the activities of labor and the geographies within which it is embedded.

Four themes

In the past decade there have been a number of rich assessments of labor geography as an emergent subdiscipline (Lier 2007; Castree 2010; Coe 2013). Four key central themes can be identified: agency, scale, class, and the role of the state. In some areas, advances building on Herod’s initial call have been significant, yet debate does persist in others.

Labor and agency

From its formal introduction in the 1990s, labor geography has argued that workers are active producers of the geographies of contemporary capitalism. Whether it is acknowledged or understood by workers or their organizations,
Labor geography is also a fundamental part of the structures workers confront as they change the terms and conditions of their employment and their lives more broadly. Social actors are geographically embedded, quite often in contradictory ways, and this embeddedness in turn shapes the possibilities for their social action. The focus on labor agency has led to a rich and wide-ranging register of case-study research that examines the question of what workers do besides work as they navigate the world. This scholarship has illustrated that neither workers nor employers are passive elements in the geographies of social relations, for both actively construct the world around them, although not always exactly in a way they would prefer. The control of space and place is thus crucial to the way that jobs are exported, created, lost, and fought over. This work demonstrates how thinking geographically enriches our understanding of labor’s agency and activism.

Unions and collective action have been the key mechanisms for workers to make changes in the economic landscape and both have been central objects of study in labor geography. Jane Wills and others have illuminated some of the ways in which various collective practices, cultures, and ideas are constructed in particular places and how these traditions are translated across space. Yet within early research on unions most labor geographers failed to differentiate between workers as individuals and workers as collective actors – working predominantly through trade unions. As such, while a major empirical focus in labor geography has been on the relevance of unions and how their changing strategies and tactics are being deployed in different places and across scales, the micropolitics of power and geographies of struggle within unions has not often been emphasized. While one of the identified limits of labor geography has been its institutional focus on trade unions, researchers have begun to expand the horizons of labor geography by conducting research into low-wage/no-wage geographies and alternative workers’ organizations as well as given greater focus to labor geographies outside of the advanced capitalist economies and the flows of migrant workers between and within the Global North and Global South.

The focus on labor’s agency has yielded important insights into how workers and their organizations are transforming political and economic geographies, so that we can see that how economic lives are shaped is not solely at the discretion of capital. While capital’s typically much greater geographic mobility can be a source of power, many political, social, and practical challenges often get in the way of allowing employers to move their operations anywhere they might choose. Yet as a number of studies in labor geography have demonstrated, the “rootedness” of labor may at times, and under particular circumstances, become a source of power when workers and their families, friends, and neighbors are able to create distinctive local communities, cultures, and organizations or use their location in global supply chains as a point of leverage against their employers. Capital and labor create different verities of place consciousness, both progressive and reactionary. For example, while capital often seeks temporary spaces for profitable production, for workers these spaces are also places in which to live, and thus places within which they have considerable individual and collective cultural investment. This has led some to conclude that whereas space is the domain of capital, places are the meaningful situations established by labor.

While this binary formulation lends perhaps too much power to capital as the dominant commander of space, it is a useful starting point for understanding that place is an important site and basis for workers to forge bonds of solidarity.
Indeed, workers will often utilize what David Featherstone calls “maps of grievances” to describe the place-based “dynamic practices through which political activity makes sense of and brings into contestation relations of power” (Featherstone 2012, 18). Yet, place-based identities or consciousness may also lead to an incredibly reactionary and dangerous politics, not simply through the forging of alliances with employers that obscure class conflict, but in producing, for example, violent xenophobic responses to outsiders. Workers are moving through systems of global migration in increasingly large numbers and their exit from and entry into different labor markets can be not only a form of resistance and adaptation, but also a significant source of conflict.

Critical commentary on the field has argued that the agency labor geographers lend to workers is often undertheorized and premature. Don Mitchell, for example, has compellingly argued that labor geography research needs to be more attuned to the materiality of the world in which labor exists, rather than overly focused on labor’s activities and power to change its geographies. That is, as we seek to see how workers create economic spaces and landscapes we must also closely examine those spaces and landscapes that they have not made, at least in any basic sense, but in which they find themselves and must live – those landscapes that are through struggles and the exercise of power, produced not for them but for others, those landscape that make “a new kind of community all but impossible” (Mitchell 2011, 567). Even harsher is Raju Das’s critique that “agency has often been used as a quasi-empirical category: a tool to describe how labor is making a difference to the spatial organization of capitalism, here and there. Agency in opposition to capital’s own existence, agency in collaboration with capital, and agency involved in gaining concessions, without challenging capitalist class relations, are all problematically put together” (Das 2012, 21). Put differently, simply focusing on the activities of workers within capitalism as a way to highlight the significance of labor’s agency does not get us very far, analytically or politically, if we operate with a conception of agency that captures any and all things that workers might do.

Coe and Lier (2011, 14) largely dismiss these concerns and continue to focus on “developing more precise concepts for describing the politics of work.” Their goal is to theorize agency more rigorously, and in so doing they turn to Cindi Katz’s typology of agency – resilience (adaptive, getting by), reworking (shifting distribution systems), and resistance (changing the forces of production, balance of power). They understand labor agency to be both embedded and constrained (Coe 2013) while others conceptualize any meaningful labor agency as a distinct force “autonomous” and independent from capital.

Despite these more nuanced conceptualizations of agency, a fundamental question remains of exactly “whose” agency is being spoken about? Recent scholarship conceives agency and consciousness (or subjectively more broadly) as being shaped by a whole range of contingent factors, structural locations, identities, and ideology. For instance, Bergene, Endresen, and Knutsen (2010) have suggested that all of these elements may come together and form a “chaotic consciousness” among workers, which can effectively be navigated and transcended by unions and other political organizations that workers construct to shape their economic landscape. Castree likewise notes that researchers need to pay extraordinarily close attention to the “geographies of employment and labor struggles not in and of themselves but as windows onto the wider question of how people live and seek to live” (Castree 2010, 468).
Production of scale

The second programmatic area within labor geography is the production of scale, the level at which resistance and negotiations with capital take place. For many traditional Marxist geographers action always begins locally, but it must quickly “scale up” to a level compatible with multinational capital in order to avoid the limitations of localized militant particularism. Geographers have focused on how workers organize at the microscale of the workplace, from local coalitions with community groups to tapping into national organizations and build transnational labor alliances (Waterman and Wills 2001). Some debate remains among scholars as to which scale (e.g., the workplace, local, national, global) is the most practical means of achieving greater power for workers and the ways in which different scales of organization both conflict with and complement others. Some emphasize that workers organize locally and globally by forming relationships with workers in different places and other classes (e.g., local developers) depending on their time and place specific needs. Others have emphasized the limits to organizing at international scales as local labor inevitably confronts a “geographical dilemma” as workers compete in a global economy for investment and jobs in their communities. Yet, there seems to be somewhat of a consensus emerging among labor geographers that organizing is often necessarily multiscalar as workers mobilize locally and globally simultaneously to influence their employers and public policy to improve their conditions.

Thus, one of labor geography’s main strengths is that it moved away from framing questions of scale within a rigid binary: either privileging organizing labor at a global scale to match the extent of capital or stressing the need for labor to dig into more local, community-based organizing. Labor geographers have contributed to a new labor internationalism/transnationalism with an understanding that organizing is inevitably multiscalar, both in the past and present. Further, labor geographers have recognized that targeting key nodes of the capitalist space-economy (e.g., global cities or logistics hubs in global production networks) is vital to labor power and that these key nodes shift with time and place. Even with more “local” organizing, geographers have called for an expansive research agenda that pushes our analytical focus beyond workplaces and trade unions arguing that unions need to build reciprocal alliances with communities as a key weapon in the struggle to reverse labor decline.

The centrality of class

The extent to which labor geography centers and advances class analysis is a question that continues to be raised. Coe and Lier (2011) contend that, aside from Wills (2008), labor geography has yet to contribute much to an analysis of class. As Wills (2008, 33) notes “when we try to map the working class, e.g. according to workers’ relation to the production of surplus value, we discern a landscape of highly uneven political possibilities.” Too narrow a focus on what constitutes “working-class” actors limits the possibilities and evidence of resistance. It is increasingly recognized that the working class is greatly fragmented and workers are unevenly embedded in economic systems, political regimes, and social networks. Numerous scholars have called for analysis of workers and their production of economic space and resistance in workplaces as constituted by gendered, racialized, and global imperialist power relations within and among classes. Labor obviously must be broadened as a category beyond unionized male industrial workers and unionized professional female public sector workers to include a diverse and expansive range of precarious workers.
LABOR GEOGRAPHY

It is not that the actions of declining male, blue-collar industrial workers are irrelevant, but rather that the labor geographies of fast food workers, unpaid interns, and the unemployed, for example, are just as worthy of attention by researchers. A labor geography that embraces the complex diversity of the working class while simultaneously respecting the unity among those who are required to sell their labor power to reproduce themselves has yet to be attained.

But there are more expansive understandings of work and workers inspired by feminist, antiracist, and anticolonial scholarship, such as Ruth Wilson Gilmore’s *The Golden Gulag* (2007), a rich antiracist feminist economic geography of the prison industrial complex and its relations to state restructuring and racialized labor in the United States. Here, we see how uneven labor geographies are produced by racialized bodies imprisoned in the prisons or trapped in marginalized urban labor markets. A narrow conception of labor geography that does not recognize these processes and fails to incorporate such theoretical and empirical insights in its research agenda will be limited.

There remain, however, concerns by those who fear that “de-centering” work and class in labor geography through a shift to intersectionality and extra-workplace activity may weaken analyses. Das (2012, 23), for example, argues that “reformist” labor geography conflates labor (i.e., paid workers and their institutions) with the working class (a much broader group) and an already anti-essentialist labor geography simply lacks a theory that encompasses the “unity that defines class.” Class is historically divided by sex, age, ethnicity, physical ability, and, of course, *geography*. Labor geographers will continue to study how workers can produce and remake economic geographies in ways that promote the necessary unity, or not, whether this is done with an increasing focus on class or other relations that constitute people’s identities will continue to be debated.

The role of the state

There is also the question of the role of the state within labor geography. Some scholars contend that labor geographers have demoted the state relative to other institutions and relationships. Again, this claim holds if a narrow definition of labor geography is used. Geographers have, however, paid significant attention to the role of the state and its links to work and economic development. Feminist studies of how access to affordable daycare and public transportation shape labor markets and urban economies had a huge influence on understanding the geographies of work.

Institutional relations have perhaps received less attention than the role of labor law in structuring worker action, but the two are interdependent. For example, Jordhus-Lier (2012) has argued that public sector workers have also been relatively neglected as an empirical focus, and one should add, theoretical subject of analysis. In many advanced capitalist economies experiencing significant declines in the private sector union density, a feminized public sector workforce has served as the reserve of union power and sometimes the only remaining institutional opposition to neoliberalism. And in the United States alone, there are over a million low-wage contractual workers employed by municipal and state governments, whose degraded and precarious employment conditions – and the struggles to transform the relations that underpin these relations and arise as a result of them beyond the workplace – are in desperate need of a critical geographical investigation that relates the experiences of these workers and their activities to the institutional transformation of both state and labor market institutions.
Although this lack of focused attention to the state may not be surprising given that the study of labor action within the context of neoliberal attacks has perhaps rendered the state as a given antagonist – and therefore no longer of any strategic value to workers, state power, and the changing contours of government employment relations in particular, will remain a pivotal research focus for labor geographers to explore as the field continues to evolve. At the same time, extra-state strategies of labor as its organizations, like unions, continue to attempt to out-maneuver neoliberal governments and private sector employers have and should continue to receive attention. And while labor geographers have begun to explore the variety of ways workers engage with local, regional, and national governments in order to shape economic development strategies, less has been done to develop a labor geography influenced theory of the state. In an era of intensified austerity, however, further attention to the state will become paramount.

**New worlds of possibility**

In many jurisdictions today, labor faces multiple challenges of declining institutional power, geographically fragmented workplaces, uneven capacities, and perhaps most significantly, the addition of millions of workers to the reserve army of labor each year. Presently, states continue to embark on austerity programs (although unevenly) across even the most regulated labor markets. How can a labor geography premised on the ability of workers to exercise agency survive eras of increasing austerity and deepening precariousness? What kinds of agency can labor exercise if researchers do not expand the scope of inquiry and analysis into questions of political strategy and new organizational forms for resistance? There is a continuing need to develop strategies and research that allow us to both understand and organize these new geographies of labor. A good deal of scholarship in labor geography has sought to explore the limits to traditional union organizing but the formal labor movement is not the only form of regulation and often fails workers in the informal economy where pay is low and conditions poor. If labor geography itself is to survive the current conjuncture of austerity, precarity, and environmental crisis, several theoretical and political issues will need to be addressed in the future, some of which have been discussed. Fortunately, there are already signs of labor geography rising to the challenge to confront these.

First, there is the lingering question on the centrality of class and the continued fragmentation of workers. For many, reading class as an essentialist concept – by which we mean a conceptualization that sees class as the principal sociospatial process shaping labor and its geographies – will remain central to advancing labor geography within an historical materialist framework. For others, the importance of addressing fragmentation of a working class that has failed to achieve any singularity in voice or action will involve exploration of how class is constituted by gender, race, sexuality, able bodies, and geography. Following the often neglected feminist and antiracist labor geography work, some of which has already been mentioned above, it is possible to address such “identities” as co-constitutive of class without de-centering a class analysis. Building class unity across space has been the objective of many social movements. Building such solidarity starts with a nuanced understanding of capitalism’s continued fragmentation of working people at multiple scales. These issues come together clearly in the experience of migrant workers in the global city, and fortunately recent work has focused on these workers (Wills et al. 2012).
LABOR GEOGRAPHY

Second, there is the question of shifting labor geography away from the study of sectors with strong institutional presence (e.g., unions in specific industries, the public sector). If labor geography is to understand how to overcome the fragmentation of workers, it must not “cherry-pick” sectors where unions have been established. Uncovering the “agency” of the marginal and unemployed must be part of the project. Peck and Theodore’s (2008) work on the role prison labor plays in shaping precarious day-labor markets and how churches have attempted to organize such workers is a relevant example. Labor unions are powerful, but are not the only example of workers exercising collective power. Mass social movements at urban, regional, and international scales in a variety of sectors must be studied in conjunction with capital’s attempts to restructure services and labor markets. Recent success in the US with implementing higher minimum wages at the municipal scale through community action is one example. Coalitions, alliances with migrant groups and the unemployed, are increasingly part of how labor builds power for political action. By rediscovering feminist scholarship on work that has been overlooked and integrating new antiracist and anticolonial approaches labor geography will be able to shift from a narrow investigation of workers in workplaces to workers in communities.

Moving beyond institutional actors, however, does not mean that labor geographers should completely abandon unions. There are those who undoubtedly see unions as creatures of capitalism and incapable of overthrowing its structures. Trade unions are uniquely situated in the economy and are vested with specific resources. It is premature to abandon, analytically or politically, institutions that continue to exercise significant power with employers and the state, despite the bureaucratic frustrations that plague such organizations. New social movements are often related to trade union successes and resources. Understanding how, when, where, and why trades union practices and structures can adapt to the challenges of precarious labor remains an open and timely empirical question.

Third, a labor geography that ignores the environmental crisis will be largely irrelevant in the midst of climate change and the very dependence of capitalism on the production of nature. Labor geographers have focused on the conflicts between workers and environmentalist and are now looking at how “blue” and “green” alliances are forming to deal with questions of more sustainable development within capitalist systems of exchange. Understanding that labor and capital produce nature in ways that benefit them materially will be increasingly important to labor geography. A labor geography that understands capitalism’s ability to produce nature for its own means will be able to counter neo-Malthusian interpretations that see the radical reduction of production (and perhaps the overall supply of labor) as the only immediate remedy rather than increased redistribution and economic security.

Lastly, there is the question of whether or not labor geography can ever truly break free of its theoretical roots in processes of capitalist reproduction. Das (2012) argues that it is necessary to discuss whether labor geography can encompass a more revolutionary project. For example, a “revolutionary” labor geography would map how workers build anti-capitalist economies. Das’s critique is aimed squarely at what he sees as a limited reformist, labor geography project. Ironically, however, he may have simply opened a new door of possibilities for labor geography as workers imagine new worlds of possibility.

Labor market segmentation

Christian Berndt
University of Zurich, Switzerland

It has long been argued in the scholarly literature that the assumption that labor power is allocated according to the same universal laws that match the supply and demand of ordinary goods such as apples is fundamentally wrong. Yet this critique notwithstanding, this is exactly how labor markets are imagined and represented in public discourse and in our daily life. This is a good example of how orthodox economics works: statements like these are not about how real labor markets operate, rather they are about how labor markets should work.

It is against this truncated notion of labor and labor markets that scholars of different theoretical stripes put forward more realistic and complex representations. A prominent example is the heterogeneous body of work that has been assembled under the label “labor market segmentation theory” which emerged as a leading alternative to standard economic thinking in the 1970s. The various segmentation approaches share an understanding of the labor market as a multiple entity, fragmented into separate submarkets that subject market participants to different rules and work according to different logics. These submarkets provide employment opportunities that differ markedly in quality, resulting in a corresponding compartmentalization of the labor force into workers of higher and lower value (Peck 1996).

Scholars across the disciplines have engaged with labor market segmentation theories providing an overview of the evolution of this perspective and pointing to its strengths and also its weaknesses. It has been criticized that segmentation theorists explained labor stratification almost exclusively as a capital-driven process, attributing it either to the changing technical imperatives of the production process or to the controlling and disciplinary strategies of employers. Power asymmetries loom large in the latter account, capital implementing strategies of “divide and conquer” (Reich, Gordon and Edwards 1973, 361), exploiting existing ethnic and gender differences in the workforce, and in so doing actively reproducing and deepening these cleavages (Peck 1996, 53–54).

In geography it has mainly been Jamie Peck who introduced labor market segmentation into the discipline and addressed the blind spots of its various strands. This refers above all to the insight that labor segmentation processes are contingent both in time and space. Historically, interest in segmented labor markets emerged roughly at a time when the transition from competitive to monopoly capitalism made itself felt in industrial societies and in labor markets. Geographically, these arrangements were embedded in decidedly national territorial frames. This was the time of economies that combined cross-border mobility of finished goods with limited mobility of labor and capital, a national compromise that was to be challenged in the wake of the cascading rounds of outsourcing and offshoring that gave rise to the contemporary global division of labor. The emergence of what has variably been termed “network capitalism” (Boltanski and Chiapello 2005) or “supply chain capitalism” (Tsing 2009)
LABOR MARKET SEGMENTATION

posed new challenges for the “problem of labor,” challenges that are being met with a peculiar mix of old and new divide and rule strategies.

As commodity production morphed into a dizzying array of intertwined supply chains, production networks, and markets for semi-finished goods, newer generations of segmentation theorists put forward more complex explanations. There has been an increasing awareness that the primacy given to capital hides from view that employers are often simply reacting to changes in product markets, production processes, labor market constraints, and the regulatory environment rather than proactively formatting their environment according to their needs. With regard to labor supply, capital may put to profitable uses social differences in the labor force, but does not create these cleavages in the first place. All this led to a more detailed engagement with the “supply side” of the labor market, with labor being given a somewhat more active role. This crucially included a more systematic account of social reproduction (e.g., occupational socialization in the family, household division of labor), the regulatory role of the state at various spatial scales, and the role of organized labor (Peck 1996, 57).

These developments notwithstanding, however, labor segmentation theory appears to have lost traction in the scholarly community. More recent reviews within human geography and other social science disciplines rarely go beyond the comprehensive account given in Peck’s seminal contribution. This may at least partly be a reflection of the shortcomings of a still predominantly demand-side focused and capital-driven approach at a time of increasing geographical and social complexity. The remainder of the discussion therefore adopts a more flexible approach, putting emphasis on the question of difference and diversity in labor markets more generally. In doing so, attention is directed to three key developments associated with the rise of neoliberal capitalism.

Entrepreneurial subjects and labor as a diverse human resource

The first of these developments concerns the evolution of labor management strategies. In particular, this refers to recent developments within economic practice disciplines such as strategic human resource management and the emergence of diversity management strategies.

With the rise to prominence of the resource-based theory of the firm after World War II, Human Resource Management (HRM) emerged as a booming social science discipline. In its dominant mainstream variant, HRM is mainly about techniques to raise the commitment and performance of workers. It is generally assumed in the HRM mainstream that the interests of workers and employers are congruent and that both sides profit from good HRM practices.

The rise of HRM has a lot to do with the changing economic environment and the uncertainties arising from this. Insofar as individual knowledge and creativity and the social networks of the workforce replaced hard assets as key factors deciding about economic success, traditional management tools declined in importance. Because of the noncalculability of these resources there was an urgent need to develop different means of evaluation. The solution was provided by HRM: it is the individual worker, his/her skills, and his/her social connectivity that is becoming ever more important. In so doing, HRM developed into a powerful calculative tool to evaluate employees according to their individual capabilities.

Underlying the transformation is a radical shift in the way that issues of workforce difference are handled. During the heyday of the
Fordist corporation, the key to efficient production was mainly to organize labor in a way that social differences did not matter. This was helped by relatively homogenous workforces. More recently, however, the role of social difference in the private firm has been re-evaluated. In many countries of the Global North there have been marked shifts in the composition of workforces manifested in the feminization of employment, the aging of populations, and the increasing presence of migrant labor.

It is in the wake of these changes that diversity management emerged as an increasingly popular branch of HRM. A socially and culturally diverse workforce is valued as a competitive asset in its own right and HR departments are expected to actively manage, promote, and harness workforce diversity. Rather than just being an add-on to the “labor problem,” social differences are actively performed and utilized by HRM practices, making labor possible in today’s global production systems. In the newly emerging configuration the discovery of diversity and identity as a corporate asset and resource is underpinned by a liberal notion of equality. Workers are treated as separate individuals, capable of different, unequal performances. Accordingly, valuable resources controlled by employees due to their perceived gender or ethnic position are individualized. It is only those identity prescriptions that fit into the representation of workers as entrepreneurs that are acknowledged. Critical observers argue that by individualizing “diversity,” representations like these successfully hide from view that power asymmetries persist. In particular they point out that diversity management practices ignore collective sources of disadvantage, privilege those in society who happen to display the right mix of individual character traits, and render attempts to make claims based on collective, social aspects of identity positions extremely difficult (Gedalof 2013).

A concrete manifestation of this is the presence in many workplaces of a mosaic of employment statutes with extreme diversity of wages and other entitlements. The initiative is with capital and management in these processes, allowing the continuation of divide and rule strategies in different forms. However, just as in the case of segmentation during Fordism, division is never enough for effective rule. There is a corresponding necessity for (re)integration into a larger common frame and entity. The previous stratification of the workforce in primary and secondary labor markets was embedded in national systems of labor regulation. Today, the common ground is being provided by the corporate community, the mythical “firm as a family” transported in the mission statements and slogans that aim to rally workers behind a greater good: the globally competitive firm.

The new corporate world continues to distinguish core from peripheral workers. The latter include “unskilled” labor that has been virtually abolished in the Global North and moved to locations in the Global South, the temporary labor working “onshore” often next to more privileged colleagues, the rising labor market precariat unable to find anything else than spurious employment, and the unemployed. It is in these disadvantaged segments of the workforce that conditions accumulate which are not valued highly in today’s resource-driven organizations: workers who arrive at the labor market with the wrong set of qualifications and skills, who find it difficult to comply with the flexibility, communicative skills, mobility, and total commitment demanded by management (Boltanski and Chiapello 2005, 231–232).

It is frequently argued that it is the readiness on the part of workers to perform the subjectivities inscribed by the omnipresent rhetoric of workers as resources that explain part of the success of the new world of work. In her
account of the type of labor that is mobilized in what she terms “supply chain capitalism,” anthropologist Anna Tsing (2009) is adamant that tiring, repetitive, and physical work has certainly not disappeared. However, the problem of labor (i.e., the need to secure the consent and collaboration of wage-earners in order to realize capitalist profits) is now addressed in a different way. It is no longer done through the collective, political integration of workers into a society that equated economic and technological progress with social justice, but rather by means of developing entrepreneurial projects of self-realization that emphasize individual performance, responsibility, and mobility. In this logic, the individual worker’s autonomy is fostered as a means to her control, turning labor into active agents of self-regulation (Fraser 2003, 165).

Work tasks and job profiles are framed in particular ways in the corporate family. They are gendered, ethnicized, and coded according to nationality and age. And workers establish themselves by performing those very attributes. An investment banker must perform competitiveness, unscrupulousness, and readily embrace risk, a care worker empathy, affect, and availability. It is this double process of self-exploitation and external inscription that makes supply chain capitalism possible (Tsing 2009, 158).

Supply chains and the de-centering of the business firm

A second challenge concerns the ongoing blurring and reconfiguration of the organizational boundaries of the firm. The familiar argument is that the rigid corporate hierarchy has gradually given way to more spurious organizational designs, variably discussed with reference to concepts such as heterarchy, project-based forms of organization, or the network firm. As a result of this, it is no longer individual firms that compete with each other, but rather networks of firms bound together in ever more complex supply and value chains.

There is broad agreement in the literature that oligopolistic chain- and network-like governance structures are the key organizational units in today’s global economy. The rise in importance of practice disciplines such as logistics and supply chain management that deliberately extend governance regimes beyond the boundaries of the individual firm is testimony to this development. This development notwithstanding, however, it is often the case that a particular successful firm assumes the position of a role model for a specific configuration of capital–labor relations (e.g., Fordism, Toyotism). In the case of the network perspective with its imaginations of supply chains, logistics, and track and trace technologies, this role has most frequently been assigned to Walmart (Tsing 2009; Boltanski and Chiapello 2005, 223).

The apparently clear-cut boundary around the business firm is additionally dissolved with a view to what has traditionally been regarded as lying outside the realm of the formal economy, that is, the realm of social reproduction. This concerns both the emerging boundary zone of precarious, “informal” and “illegal” work that feeds the apparently formal production chains and networks as well as work that has been shifted from waged employment into a wide array of nonwage forms, be it voluntary, domestic, hobby, and forced work (Abbott 2006, 307–308). Social differences play a crucial role in maintaining both the hidden extension of ostensibly formal processes of the production of goods and services into less tightly regulated realms as well as successful attempts by economic and political decision-makers to reproduce an apparent clear-cut boundary between the economy proper and that which lies beyond. To a
LABOR MARKET SEGMENTATION

large extent it is the migrant woman that provides the labor in the latter realm, for instance, as cleaner, care worker, au pair, or maid. What those employment relations have in common is an expectation of almost unlimited flexibility and availability, connected with what André Gorz (2004, 27; author’s translation) termed “total mobilization of capacities and skills, including sentiments and emotions.”

One result of this is a blurring of the boundary between work and leisure time, between emotional engagement and the role of a professional, detached service worker. The task to police those boundaries is largely delegated to the worker herself. It is the individual care worker, cleaner, or maid who is responsible for making sure that she does not involve herself too much emotionally, for regulating her working time, or for making sure that the challenge to navigate five or six different workplaces per day remains manageable. Empirical research illustrates that these practices easily turn into self-exploitation, in so doing making the low wage and apparently unskillable character of this work possible in the first place.

Governing at a distance: the offshore logic of supply chain capitalism

A key reason for the changing role of social difference in the labor market has arguably been the growing social and spatial complexity of production, distribution, and consumption outlined above. As those organizational constellations are far more difficult to control than individual firms, the traditional solution of relying solely on stabilization via standardization can no longer be a viable option. This is another reason for the more indirect and subtle way in which to organize labor in today’s supply chains and production networks, a way of disciplining that governs workers “at a distance” (Fraser 2003, 167).

There is both a social and a spatial dimension to this. Starting with the former, this concerns the move toward more autonomy and responsibility for the worker, and a corresponding possibility for corporate decision-makers to detach themselves from the consequences of their actions. However, this “social distancing” is only one side of the coin, for the apparent organizational detachment is going hand in hand with tighter monitoring of other features of the supply chain, for instance, those involving prices and marketing arrangements (Tsing 2009, 156). And both moments come together if one looks at the increasingly prominent role of technological and quality standards in supply chains. At the same time as firms transfer responsibility for product quality and consumer satisfaction to workers and subcontractors, they increase the pressure on those actors with the implementation of ever more sophisticated track and trace technologies. These devices do not allow the slightest deviation from the script and do not forgive the tiniest mistake or lapse of concentration, making it possible to confront workers with their performance long after the product in question has left the shop floor or workplace. Supply chain technologies create an environment in which periods of idleness are abolished, creating a potentially unlimited repository of deeds and gestures that make workers subject to remote control and that are constitutive of “governance-at-a-distance” (Boltanski and Chiapello 2005, 247).

The geographical materialization of this is “offshoring.” Understood in an abstract form as a defining feature of contemporary capitalism, offshoring involves a double framing process. First, the articulation of people, things, and regions with global supply chains and markets, by way of transforming heterogeneity and contingency
LABOR MARKET SEGMENTATION

into productive labor, advanced production sites, special economic zones, and by disarticulating those elements from their social and spatial contexts. And second, a new moment of dis/entanglement that allows powerful interests to decouple the profitable exchange of labor and goods in global supply chains from the responsibility and liability for the social and geographical implications of these operations (Appel 2012). The attention turns to mobile standards, templates, and infrastructures as boundary-making objects. And it is with the help of various registers of social difference that this redrawing of boundaries is accomplished. This occurs by ritualized evocations of age-old stereotypes, such as the one manifested in the representation of southern female workers as “disposable” and “unskillable” (Wright 2006). Another example is the racialized legitimization of “old” disciplinary labor regimes in ostensibly advanced production sites, with hints at cultural traits that are apparently unsuitable for modern production and the corresponding paternalist “obligation” to be a strict northern father to southern factory daughters.

This is made visible with the help of ostensibly objective technologies that calculate defects per million parts, scrap rates, or productivity numbers. It is because these dis/entanglements are extremely complex and are constantly prone to fail and overflow that they require continuous logistical effort and financial investment. Methodologically, it is multisited ethnographic research, following things, people, and ideas and the plurality of relations they assemble, that is able to shed empirical light onto the realization of new regimes of labor control and stratification. Such an approach is also capable of illustrating how new organizational models travel to less privileged workplaces, above all in the Global South and how a key observation of early labor market segmentation, namely the dual labor market, has assumed a new global form. The last point takes up the observation that less desirable and overflow work continues to be outsourced to the Global South, either by moving jobs to locations in countries such as China or Mexico, or by mobilizing largely female migrant labor for reproductive tasks in northern households.

A labor market is most commonly defined as a platform that facilitates the buying and selling of labor power. Labor power refers to the mental and/or physical capabilities that can be used to generate use-values (e.g., the physical strength of a porter generates a capacity to carry luggage and thus replaces the physical strain that would otherwise be placed on the luggage’s owner) and/or exchange value (the same physical ability to carry luggage is priced monetarily and sold to any luggage owner who wishes to purchase this ability). In neoclassical economic terms, forces of supply and demand underpin the utility of any labor market, namely the generation of a price for which a transaction between a buyer and a seller of labor power becomes possible. Economists assume transaction prices are able to automatically “correct” and reach equilibria; when this occurs, the quantity of labor power supplied will match the price that buyers are willing to pay for that quantity of labor power.

To Karl Marx and Karl Polanyi, two major critics of neoclassical economic presuppositions, labor markets are not objective expressions of abstract forces of demand and supply – they are the precondition of a historically specific mode of production known as capitalism. This is because labor power is a fictitious commodity: people pre-exist labor markets as workers, builders, designers, and so on, and their capabilities are not inherently meant for sale. It is only when labor markets became recognized as legal institutions that these capabilities could be transposed into saleable commodities. And it is this saleable entity that constitutes the basis of value generation and capture: the labor power that goes into the production of a commodity could, in contemporary corporate parlance, be costed in monetary terms. Through this process, the producer is able to calculate how much value can potentially be captured from each unit of commodity – provided, of course, someone is willing to purchase this unit – through adjusting the quantity and quality of other variables that contribute to the production of this commodity (raw materials, machinery, output, etc.).

To understand labor markets as fictitious entities within the contemporary global system of capitalism is to understand these entities as unnatural in the first instance. This calls attention, in turn, to how this fiction is constructed and how it has come to be accepted as socially “normal.” After all, wage labor is taken as a primary basis of survival in many countries today. What is invariably more complicated is the appearance of labor markets: some labor markets are clearly defined for specific kinds of labor power (e.g., legal requirements for electricians or plumbers to pass province- or national-level tests before they are allowed to sell their labor within specified territories), while others have unclear definitions of what constitutes a labor market and where it exists (e.g., electricians or plumbers in many developing economies often do not possess formal qualifications; are not required to pass tests in order to sell their skills; and could move from place to place to “practice” as informal economic agents). It is the lack of a universally acceptable notion of a
labor market that reinforces its fictive nature: how well defined a labor market is in one place is contingent on how well regulators are able to weave together a coherent system of control, monitoring, and, perhaps most important, social compliance.

Noncompliance would lead to new spatial divisions of labor (Massey 1984). This refers to a situation in which the needs of buyers and/or sellers of labor power can no longer be met within pre-existing markets. For capitalists, the inability of local labor markets to satisfy growth objectives – often, if not always, expressed through the quest for increasing rates of profit – would trigger a search for labor power in alternative locations and/or the adoption of labor-substituting technology (e.g., cash deposit machines in banks taking the place of tellers). For laborers, the inability of local labor markets to satisfy their personal needs – such as the lack of sufficient job openings to match their skills or unsatisfactory remuneration – would cause them to relocate elsewhere to take up the same jobs or move into other local labor markets (e.g., a change in jobs).

Cognizant of the threat of noncompliance, state regulators operating at different scales often try to determine both supply- and demand-side practices in labor markets. On the supply side, they generate direct entry barriers (e.g., mandating a minimum working age and rigorous health checks for particular occupations, which in turn affect supply), leading in turn to labor market segmentation. A labor market becomes segmented when different subgroups are created on the basis of citizenship, residency, qualifications, gender, and numerous other variables. On the demand side, state regulators determine what count as “legitimate” and “fair” transactions (e.g., the imposition of a minimum wage, the control of foreign worker employment in specific sectors or locations, and the right to call an end to strikes, which in turn affect demand). The primary goal is not only to ensure that employers provide adequate social welfare; it is just as, if not more, important to minimize the number of interruptions to the capital accumulation process. In this regard, supply- and demand-side regulation of labor markets is the hallmark of a capitalist state.

It could be added, then, that a labor market is an institution – a political-geographic institution. This is because (i) its functions are governed by regulations that are underwritten by the state apparatus; (ii) these regulations apply to predetermined territorial parameters; and (iii) its reproduction is contingent on the extent to which existing regulations could serve the needs of buyers and sellers of labor power within these territories. Unfortunately, though in some ways unsurprisingly, social-scientific research has taken as unproblematic the state-centric presuppositions and quantifications of labor markets. After all, labor markets have become expressions and extensions of territories defined by the capitalist state. State agencies are also often in charge of collecting and publishing “official” labor market statistics, namely those on employment, unemployment, wages, and economic inactivity. These figures are often then further differentiated by industrial sectors, administrative geography, age, race/ethnicity, and gender.

Even when the state is taken as the primary unit of analysis, labor markets are inherently varied because regulations exemplify the ideology of the governing political party. Conservative or liberal political parties are likely to advocate more flexible labor markets through cross-border immigration and less regulation over minimum wages, while nationalist or left-wing parties tend to emphasize resident-first hiring practices and more secure employment tenure. Differing ideologies also impact on how the state
views labor movements. While some territorial jurisdictions constitutionalize the right of workers within particular jurisdictions to organize and represent themselves (including the right not to supply labor power) so as to secure improved employment terms, there are states that are fully committed to the demands of capital and refuse to legitimize autonomous collective bargaining in fear of strikes and social instability. The ideological orientations and/or vested interests of political actors in power at national, subnational, and supranational levels thus engender direct effects on market entry and exit for both buyers and sellers of labor power.

Economic geographers are aware of and have worked assiduously at transcending the limitations of state-centrism in labor market research. As Jamie Peck (1996, 84–85) argues in Work-Place, a highly influential account of local labor markets, unevenness in labor market phenomena and regulatory forms could just be as pronounced within as they would be between nation-states. While not conceding the importance of the national scale as a unit of analysis, Peck (1996, 105) calls for more incisive research on how local and regional forms are at once distinct and embedded within their national and international contexts (see Christopherson 2002). This emphasis on the interscalar socioeconomic linkages of labor markets is reflected subsequently in research on transnational migrant workers (Pratt 2004; McDowell 2005); on the relationship between policy transfers, the emergence of “workfare states” and the naturalization of precarious flexi-jobs (Peck 2001); and on the fast-growing field of labor geography which emphasizes the quest by working communities to carve out their own “spatial fixes” while remaining relevant to the increasingly transnational process of capital accumulation (Herod 2001; Lier 2007; Wills 2009). Where labor markets are taken as fixed within state space across much of the social sciences, economic geographers have demonstrated how the buying and selling of labor power is a gendered, multidimensional, and often transnational process that is always in the making – it is never about the self-correction of prices by the abstract forces of demand and supply.

Labor migration

Dennis Arnold
University of Amsterdam, Netherlands

Migrations have shaped modern history at least since the Atlantic slave trade and the dislocation, enclosure, and dispossession of the rural poor to populate the cities and fuel the booming labor needs of industry in England and other European countries (Casas-Cortes et al. 2015). In the century following 1820 about 60 million Europeans left for what they called the New World. These movements across the Atlantic were a critical aspect of industrialization and expansion into American frontiers. Less recognized are migration flows in Asia between 1846 and 1940. During that period, 48–52 million migrated from India and Southern China to Southeast Asia, the Indian Ocean Rim, and the South Pacific, and 46–51 million migrated from Northeast Asia and Russia to Manchuria, Siberia, Central Asia, and Japan. Despite the global nature of migration patterns over the past 200 years Western models and theoretical paradigms have, until recent years, been dominant.

The early moments of mass migration are important for at least three reasons (Casas-Cortes et al. 2015). First, the scale of Euro-Atlantic migration and capitalist development continues to inform the concepts used to investigate migration across the world. Second, migration studies emerged in the heyday of the process of mass industrialization and proletarianization in the early twentieth century. “Modernization” became the benchmark and model upon which much economic development theory rests, and the role of migrants in development processes has long been debated. Third, a concern for the social and economic integration of the migrant in nation-states has long dominated migration studies, marked by the bounded discourse of citizenship.

Contemporary labor migration challenges all of these points, and this entry addresses the following three aspects in turn. First, labor migration is globalized, moving well beyond the Euro-Atlantic world region. And, even when connected to industrial labor, contemporary labor patterns are qualitatively different, and characterized by precarization. The second section looks at the transnationalism turn in migration research, to understand both migrant subjectivities and the emergence of the migration–development nexus, which centers its attention on migrant workers’ remittances. The third section focuses on borders and the bordering of labor migration, to understand state attempts to manage both mobile labor and capital.

Globalization, precarization, and labor migration

A migrant laborer is generally defined as a person who goes from one place to another especially to find work. Migrants work across the entire occupational spectrum, from highly paid and skilled occupations in the knowledge economy, finance, and other sectors, to some of the world’s most exploitative jobs in agriculture, manufacturing, care work, and services. According to World Bank estimates, in 2011 more than 215 million people lived outside their countries of
LABOR MIGRATION

birth, an increase from 84.5 million in 1975. Of this figure, an estimated 105 million are international migrant laborers. Furthermore, over 700 million migrate within their countries. In China alone, some 145 million internal (rural-urban) migrants are currently working in coastal special economic zones and other urban and peri-urban areas. Migration figures are likely to be considerable underestimates, as “illegal” or irregular migrants are extremely difficult to collect reliable data on.

As early as the late nineteenth century, E.G. Ravenstein had observed that most migrants left their homes in order to search for work of a more remunerative or attractive kind. Ravenstein developed his 11 major laws of migration, which summarized the regularities that could be identified from data gathered from the 1871 and 1881 censuses. Some of Ravenstein’s findings remain valid, for example, the majority of migrants continue to move over short distances and large towns still grow more from migration than from demographic increase (Boyle 2009). In the 1960s, neoclassical economists built on Ravenstein’s laws and formulated a series of hypotheses concerning the volume of migration and its streams and counterstreams, with a focus on the push factors at the origin that stimulated moves and the pull factors at the destination that attracted movers. This approach continues to influence thinking around issues of labor migration.

Neoclassical economic theory, which assumes individual free choice and free flows of factors of production, predicts that workers will migrate from low-wage to high-wage areas. This theory attempts to explain both flows from the poorer South to wealthier countries in the North, and migration patterns between neighboring countries and within countries. The approach has been criticized for positioning migrant workers as being determined and overwhelmed by economic structural forces (Mezzadra and Neilson 2013). It does not reflect the complex set of motivations that lead migrants to leave their families and communities, nor does it consider migrants’ agency in their new jobs and communities.

People who migrate specifically for work purposes may involve at least four channels (Samers 2010). First, people may migrate because they expect better employment conditions, such as higher wages. Second, people migrate because friends, relatives, and acquaintances inform them of work opportunities. Such networks may help the migrants establish themselves, with help in housing, information on work permits and other state regulations, and other daily necessities. Third, people may migrate because an employer recruits them. Recruitment may involve friends, private (for profit) labor agents, and/or governments. Fourth, and related to the previous three points, migrants may be recruited illegally, often trafficked. Such migrants are most likely to do low-paid and highly exploitative work.

If one agrees that migrant workers are not simply pushed and pulled around the globe in an individualized, rational manner, then the question arises of how migration patterns can be conceptualized. Recent scholarship under the broad banner of globalization studies offers insight on political economic structures that frame migratory experiences. The following section turns to this literature, before considering labor migration as a social process shaping these structures.

Global precariousness

A prominent approach to understanding migrant labor is the dual labor market theory. This view claims that there are two sectors in modern, industrial labor markets: a primary sector with decent pay, job stability, and generally good working conditions, and a secondary sector
composed of work with low pay, lack of stability, and poor working conditions. Migrants have long been seen as most likely to take jobs in the secondary sector. This perspective was overly simplistic even at the height of the Fordist labor accord in the industrialized countries, when significant proportions of the working and middle class could expect decent wage and state welfare provision. The reality is migrants are no longer at the fringes of labor markets or viewed as an anomaly. In fact, migrants are now considered the paradigmatic worker, part and parcel of broader labor trends in global capitalism.

On the one hand, migrant labor is a response to competitive pressures from capital. On the other, capital's increased global mobility and need for flexibility is a reaction to the wave of struggles and strength of labor in the industrialized countries in the 1960s and 1970s. The saturation of markets, along with the high levels of competition that introduced the process of global outsourcing, obliged firms to develop techniques and technologies to enhance or create mobility and flexibility, which also created new barriers to labor organizing. These processes have diminished workers' bargaining power and rights across different countries and contexts, and at the same time generated new forms of struggle.

Over the past several decades, the growing power and reach of global capital has exceeded the ability of nations and labor movements to regulate it, exacerbating inequality, precarious work, and broader social precarity. Numerous labor trends have been associated with neoliberal globalization, including a decline in attachment to employers, an increase in long-term unemployment, growth in perceived and real job insecurity, increasing nonstandard and contingent work, risk shifting from employers to employees, a lack of workplace safety, and an increase in work-based stress and harassment. The lack of public and private investment in skills and development is accompanied by a lack of access to schooling, where women and ethnic and racial minorities disproportionately bear the brunt of these disadvantages. Yet precariousness is about not only the disappearance of stable jobs and other workplace-specific issues, but also the questions of housing, debt, welfare provision, and the availability of time for building effective personal relations.

These trends are not entirely new, and follow previous patterns. Capital is continually in search of spatial, technological, and product fixes, but with each phase of innovation the intensity of capital investment and productivity requirements increases. Not only have global production networks stretched across national boundaries to cover greater geographic scope and new “frontiers,” but also lead times have become shorter to respond to oscillations in consumer demand. As the geographies of production continue to expand, the process is often reproduced with tighter margins for lower tier producers and employers, which tend to provide lower remuneration for workers. Greater flexibility is the mantra of the day, from labor-intensive garment factories, to retail and service sectors, to knowledge work in the academe. In short, precarious labor regimes, and the central role states have played in configuring and reproducing them, have reconfigured the geography of the reserve army of labor. Migrants are at the center of the contemporary labor process (Wills et al. 2010).

In addition to their appeal to capital, they also have major political advantages as a flexible labor supply. Even those who cross borders legally find themselves politically disenfranchised. Lacking citizenship, they are more likely to encounter restrictions on their access to employment,
LABOR MIGRATION

welfare, and the political process. In contemporary globalization, migrants are not only less likely to organize trade unions, they are the sine qua non of flexibility that many employers seek. Migrant workers are attractive to employers precisely because they are migrants (Wills et al. 2010).

Studying migrant labor reveals a general shift of responsibility that follows the capitalist dream of an available labor force disconnected from the need for its reproduction. Not only has capital increasingly outsourced beyond national borders in the contemporary wave of globalization, so too has the social reproduction of labor been outsourced across borders, generally to migrants’ home communities and countries. The neoliberalization of social reproduction entails a reduction in state-provided social assistance for its citizens. Migrants are typically not afforded any support for the social reproduction of their own families, whether in their home or host country. This is a clear example of re-regulation that places burdens on families and individuals, away from capital and states.

This line of analysis leads to a simple equation: the less social support and the fewer rights migrants have, the more vulnerable and docile they are likely to be (Samers 2010). While not a universal truth, this contention helps to understand the rights claims that migrant labor may or may not make of employers and states. This is most salient when workers fear being sacked and/or deported. Clearly, a precarious migrant labor force has been central to processes reworking the balance of power between capital and labor. With that in mind, consideration should be given to how it is that migrant labor has come to be viewed by many analysts as a key contributor to economic development, and how migrant subjectivities are understood in relation to global-scale transformations.

Transnationalism and the migration–development nexus

It is only recently that the labor migration debate has begun to take account of the complexity of the development–migration interaction (Munck, Schierup, and Delgado Wise 2012). Munck and colleagues contend that in the 1950s and 1960s the dominant modernization perspective saw a synergy between the two – migrants were deemed “modernizers” who could contribute to economic growth in the receiving country through their labor, and in the sending country through remittances and their return with “modern” skills and values. In the 1970s and 1980s a structuralist Marxian–influenced model prevailed, which focused on negative consequences, such as “brain drain” and new patterns of dependency oriented around remittances. This “development of underdevelopment” model was replaced in the 1990s by middle range theories, most prominent the focus on transnationalism and transnational household livelihood strategies. The transnational turn in migration research increases the awareness of diverse strategies of mobility, while raising questions about migration–development precepts (Bailey 2010). Informed by post-left scholarship around the same time, it follows that gender, class, age, ethnicity, and racializations came to be viewed as key to mediating the migration–development nexus. Both transnationalism and migrant–development nexus approaches have received much attention, and have informed multiple actors’ views of migrant workers as agents for social and economic transformation.

Transnationalism

Transnational theorizing began in the early 1990s, when scholars found that the migrants
with whom they worked had developed transnational practices that conventional migration theories did not adequately capture. The approach critiqued traditional migration theory and its binary treatment of migrants as individuals who either departed (emigrants) or arrived (immigrants). Traditional approaches contributed to “methodological nationalism,” as the nation-state was deemed the primary unit of analysis in migration scholarship.

To overcome this dichotomy, and to better understand migrants’ multiple attachments, researchers proposed that migrants be understood as forming part of two or more dynamically intertwined worlds and transnational migration be seen as the processes by which immigrants initiate and sustain social relations that link together their societies of origin and settlement. Thus, sending and receiving societies became understood as constituting one single field of analysis, in which migrants often maintain a variety of social, economic, cultural, and political ties with their home. In short, migrants are more likely to develop complex affiliations, meaningful attachments, and dual or multiple allegiances to people, places, and traditions that lie beyond the boundaries of nation-states (Cohen 2006).

The transnationalism approach has also contributed to understanding labor markets, work processes, and industrial relations within localities and the ways in which they are also shaped by various flows across space. In contrast to a proliferation of research on the flows of investment capital, traded commodities, or organizational processes in transnational firms and the differential embedding of capital flows in space, transnationalism has contributed to highlighting the transnational flows and connections established by workers themselves. In many respects, studies of migrant transnationalism are the complementary inverse of scholarship on large corporations and intergovernmental organizations, representing instead a view of globalization from below.

Transnational migrants at various levels in the labor market are frequently separated from their immediate families. Transnational household arrangements often imply a significant restructuring of the division of unwaged domestic labor, including the reproductive work of running a household, maintaining a home, and raising children (Kelly 2009). This is pronounced in wealthier countries where migrants do domestic work, while impacting migrants’ families in poorer countries. This phenomenon is known as “care-chains.” It is characterized by the increase in dual-earner couples and single parents in wealthier countries, in part a result of the dissolution of the gender contract in which (typically) male breadwinners were paid a family wage and women did unpaid domestic labor. While care has always been labor, the social relation has changed with the increasing number of migrants who are paid to do the task of social reproduction. For the migrant families back home, social reproduction is often undertaken by an array of social networks, as these families typically cannot avail of state-derived assistance.

For many migrant workers in low-paid and insecure employment, it is precisely their transnationalism that undermines their capacity to assert rights in the work place. As citizens of one territory but workers of another, they may only be protected in theory by labor laws. In practice, their migrant status and their transnational obligations to family members back home mean that there would be a heavy price to pay for pushing back against abusive employers or the authorities of host states. Yet transnational migrant experiences are diverse. Many increase not only their incomes, but also their social status. Going further, Hardt and
Negri (2000) have argued that migrants are a special category of the poor imbued with an irrepressible desire for free movement. Mobility and migration are viewed as a powerful form of class struggle. Migrants play a role in constructing an alternative hegemony, in which they normalize movement and treat the globe as a common space. These and related claims to migrant “cosmopolitanism from below” have generated critiques that the migrant experience is overly romanticized. Against this backdrop, the migration–development debate opens another line of inquiry that considers both migrant subjectivities and global transitions.

Migration–development nexus

Analysis on the link between international labor migration and development has been contentious. On the one hand, many view the outflow of people not only as a symptom of underdevelopment but also as a cause of its perpetuation, and on the other hand are researchers who regard migration both as a short-term safety valve and as a potential long-term instrument for sustained growth (Portes 2007). Since the 1940s in the case of Mexico, with the implementation of the Bracero program, and the 1960s and 1970s for countries including the Philippines, Morocco, and Turkey, governments have encouraged under- and unemployed workers to migrate to the United States or Western Europe. The expectation was that the workers would contribute to economic and political improvements and stabilization in their home countries. However, the long-term results of labor migration schemes often proved disappointing (Castles and Wise 2007). This resulted in a generally negative view of migration, that it undermines the prospects for local economic development and yields a state of stagnation and new patterns of dependency (Massey et al. 1998). Fueling the negative view, “brain drain” became the popular view, arguing that it was generally “the best and the brightest” that left.

Beyond these debates, theories of national development have seldom paid much attention to international migration (Portes 2007). At best, migrant labor flows were treated as a marginal phenomenon – a reflection of the problems of underdevelopment. In recent years this has changed. The size of migrant worker communities and the volume of the remittances they send home have prompted theoretical models that emphasize financial flows. Over the past two to three decades migrants have been redefined as “heroes of development.” The links between migration and development are increasingly seen in a positive light, and “brain gain” replaces “brain drain” as a key metaphor.

In many countries, remittances now represent a significant contribution not just to their families and communities, but also to the national economies in which they are spent. According to the World Bank, remittance flows to developing countries were estimated to have totaled US$401 billion in 2012, an increase of 5.3% over the previous year. Global remittance flows, including those to high-income countries, were an estimated $529 billion in 2012. The top recipients of officially recorded remittances in 2013 were India ($70 billion), China ($60 billion), the Philippines ($25 billion), and Mexico ($22 billion). Remittances sent home by migrants to developing countries are equivalent to more than three times the amount of official development assistance.

For some, remittances play a key role in resolving past financial bottlenecks and providing the necessary resources for social and economic development. Furthermore, remitting involves economic and noneconomic resources and flows, and includes the exchange of money, knowledge, and universal ideas (Bailey 2010). Recognizing
LABOR MIGRATION

the economic importance of migrant workers and remittances, organizations including the World Bank have become champions of migrants as key contributors to development. Indeed, the World Bank (2014) argues that “Remittances generally reduce the level and severity of poverty and lead to: higher human capital accumulation; greater health and education expenditures; better access to information and communication technologies; improved access to formal financial sector services; enhanced small business investment; more entrepreneurship; better preparedness for adverse shocks such as droughts, earthquakes, and cyclones; and reduced child labor.” The Bank’s activities are centered on mobilizing migrant remittances to develop financing instruments for leveraging migration and remittances for national development purposes.

Bailey (2010) identifies other trends in the migration–development nexus literature. Drawing on transnationalism studies, it is recognized that promotion of remittances and the realization of any benefits occur through increasingly diverse and flexible forms of migration, notably temporary, return, circular, and transnational migration. Furthermore, the potential benefits of diverse remittances and diverse migration are most efficiently realized through coordination of the activities of an increasing number of stakeholders, including individual migrants, social networks, households and transnational families, communities, hometown associations, epistemic communities, diasporic knowledge networks, regional and national governments, and international organizations.

Looking at the matter from a different perspective, Castles and Wise (2007) contend that the World Bank and other organizations associated with the Washington Consensus emphasize the positive potential of the migration–development nexus as a result of the crisis of legitimation of neoliberal globalization. As discussed above, globalization has failed to deliver economic inclusion and greater equality for the majority of the world’s population. Migrants have become part of a solution to these and other failures of widespread liberalization, structural adjustment, and commoditization. Remittances have become part of a new development mantra, with the belief that they can be channeled into investments that will lessen or even overcome underdevelopment, thus making up for the failures of mainstream approaches to development. This approach has proven particularly attractive to states that lack a coherent national development strategy.

At present, the evidence for the links between migration and development remains weak. Portes (2007) argues that the rosy predictions are exaggerated. He contends that there is no precedent that any country has taken the road toward sustained development on the basis of the remittances sent by its expatriates. Importantly, migration can lead to vastly different consequences – economic stagnation, the emptying out of sending places, and the massive loss of talent with wide-ranging impacts on the energizing of local economies, new productive activities, and significant contributions for scientific and technological development (Portes 2007). Thus, many scholars have returned to the long-held view that international migration does not stem from a lack of economic development, but from capitalist development itself (Massey et al. 1998, 277).

Borders, the state, and migrant labor regimes

Transnationalism research has clearly been instrumental in the shift away from methodological
LABOR MIGRATION

nationalism. Yet there exists a polarity in migration studies between an economic consideration of migration under the headline of exploitation, explored in the first section, and the more positive views among many transnationalism scholars that highlight migrants’ hybridity and “cosmopolitanism from below.” Labor migration has always been a contested field in state regulation of populations in capitalism. Capital’s solicitation of labor mobility has always gone hand in hand with manifold attempts, particularly on the part of states, to filter, to curb, and even to block it (Mezzadra and Neilson 2013). Geographical literature has been attuned to heterogeneous migrant, state, and capital practices through the continuous reworking and reshaping of both social and geographical borders and scales, the focus of this section.

Cohen (2006) provides a summary of the shift from open immigration policies in much of Western Europe and the United States during the postwar era, to the more restrictive policies from the 1970s when sharp restrictions were first imposed (While in the United States there has not been an absolute decline in legal immigration, there have been significant qualitative changes in the occupational and legal categories admitted – from immigrants to refugees and from agricultural and mass production workers to the professional, technical, and independent proprietor categories. Japan has not permitted significant numbers of labor migrants throughout the postwar era.). Cohen attributes the shift to several factors, including:

- the oil crisis, which contributed to a wave of redundancies in energy-intensive industries;
- the rise of xenophobia, particularly among the working class fearing competition in the labor market;
- the organization of migrant workers who increasingly pushed for family reunification policies, contributing to many politicians and interest groups pressing for more restrictions;
- the rise in the cost of reproduction in terms of child care, language training, and education;
- economic restructuring, or the general shift from Fordist mass production to flexible specialization and offshoring of production and services.

Speaking to contemporary state policy, Cohen contends that the modern state has sought to differentiate the various people under its sway by including some in the body politic and according them full civic and social rights while seeking to exclude others from entering this “charmed circle” (Cohen 2006). Currently, formal citizenship and visa regulations are the most prominent form of regulation at national governments’ disposal. Typically, they are used to control access to and the duration of different kinds of work. This is known as “differential exclusion,” describing the incorporation of migrants into some areas of national society, especially the labor market, and their exclusion from others, such as social welfare and citizenship. While a good starting point, this binary concept is easily complicated when considering the different experiences of skilled and unskilled migrants, those “legal” or not, and variation across national contexts. It is more useful to view migrant labor management as creating different degrees of precarity and vulnerability, as well as opportunities and empowerment.

To understand how migrants traverse and reshape the multiple spaces of globalization, the study of borders and labor migration provides much insight. Borders are complex social institutions that can both connect and divide not only migrant labor, but also the times and spaces of global capitalism. This includes both political borders, whose relevance has altered yet certainly not gone away, and the multiplication
of social borders that very often shape migrant workers’ experiences. In migration studies, the border has typically been comprehended as a wall, both literally and figuratively, that excludes migrants from a national territory. The US-Mexico border is the prototype of the border-as-wall, an “economic dam” that seeks to prevent migrant flows from “contaminating” the US body politic, an approach and discourse that has been replicated elsewhere, including the Thailand-Myanmar border (Arnold and Pickles 2011). Border securitization has not only failed, it has contributed to riskier efforts on the part of migrants to evade authorities, while also leading to a proliferation of human traffickers and others capitalizing on the criminalization of certain migrant labor populations – very often police and military officials mandated to “protect” the border.

Yet national borders are no longer the only or necessarily the most relevant borders dividing and restricting labor mobility (Mezzadra and Neilson 2013). Migrant labor encounters complex sets of social relations that seek to reinforce labor power as a commodity by turning migrant flows into mobile governable subjects. In addition to the renewed emphasis on political borders, social borders have multiplied. Social borders play a central role in shaping labor markets by filtering and differentiating labor and bodies according to skills, citizenship, race, ethnicity, and gender. Indeed, the production and reproduction of differences is key to capital accumulation strategies. Impacts include the differential allocation of rights across populations. Very often, this entails being “in one’s place out of place” and “out of place in one’s place” (Casas-Cortes et al. 2015). All labor is subject to bordering, yet migrant workers’ experiences are most pronounced. In particular, capital has proven particularly adept at exploiting the continuities and the gaps – the borders – between different migrant populations.

Social borders are very often regulated and reproduced by states. Indeed, states remain a pivotal institutional apparatus that regulates the lives and politics of workers (Coe and Jordhus-Lier 2010), and are key to understanding power configurations and their articulation with capital-labor relations (Mezzadra and Neilson 2013). However, governments are far from being in control of labor migration, much less capital flows. One approach to understand the asymmetries among nation-states, migrant labor, and global capital flows is the continuous reshaping and intertwining of different geographical scales. The local, national, regional, and global have never been given, and a nested hierarchy of these scales has long been a running debate among geographers. Migrant laborers are a particularly interesting group, because they regularly traverse and intersect different kinds of scales and spaces, making the very concept of scale increasingly complicated in its constitution.

The variegated politics of scale and the centrality of migrant labor have received much attention. In their work on the Indonesia–Malaysia–Singapore Growth Triangle, Sparke and colleagues (2004) view cross-border economic zones as crystalized spaces of multiple ambitions. In this context the strong state withdraws to allow forms of economic autonomy that enhance profitability, or “exceptions” to state regulation of territory and (migrant) population in other spaces. Studies have suggested that the Growth Triangle is not so much a question of market versus state, or a transition from state to market, but that the creation of markets is occurring in settings where the state is sometimes very strong while in other areas it is nearly absent, creating a spatial variability in managing
LABOR MIGRATION

migrant and other populations, particularly in cross-border economic zones.

In Greater Mekong Subregion economic zones, a different state–labor arrangement has been observed (Arnold and Pickles 2011). At one Thailand-Burma border textile and garment manufacturing zone, the convergence between cross-border regionalization and globalization is “articulated in localized spaces conducive to mobile capital that, on the one hand, straddle and blur national boundaries, and on the other, redefine and reify borders, particularly in terms of flows of migrant labor” (1599). It is a softening of the border as far as its geopolitical function and its role in the control of the flows of capital and commodities are concerned. To this there corresponds a new rigor in the control of labor mobility. A multiplicity of borders surround the life and labor of migrant workers from Myanmar, ranging from widespread racism to differentiated legal statuses. In this context, it is certainly a zone of exception but not because the state’s role is compromised or because the state has withdrawn from that space. Instead, it is precisely the way in which state agencies, particularly the police, national security agencies, and border guards, work together to regulate migrant workers’ lives to create and sustain the conditions for a regime of precarious migrant labor that enables the garment industry to survive in the region. Neither the state nor employers are responsible for the social reproduction of labor power, and both avoid engagement in tripartite functions associated with industrial relations prominent in the Fordist era.

In these and other contexts in which migrants face multiscalar challenges, the question of labor organizing becomes critical. In US workplaces trade union efforts to defend the rights of their (immigrant) members elicit an “enclave of rights” (Parks 2014). Parks’s study shows that immigrants occupy their workplaces as both subjects of immigration policy and protected workers. The workplace is identified as a highly localized sphere of engagement that both generates its own practices and realizes the local manifestation of multiple scalar phenomena including global capital and migration flows, national state policy regimes, corporate management structures, and trade unions. For undocumented immigrant workers, the workplace produces both illegality and legal protection – the former under immigration law, the latter under labor and employment law. Unions negotiate the uncertain and often conflictual intersection of these two legal domains by inhering in place workers, rights (conferred by federal law) and rights attained through social membership (union registration). Thus, workers are accorded an enclave of rights at the local (workplace) level, contributing to the highly uneven space of (in)security of migrant workers in the United States.

Conclusion

Labor migration has profoundly impacted hundreds of millions of people worldwide since the mid-nineteenth century. Past labor migration scholarship tended to treat migration patterns as discrete events, auxiliary to labor markets and national development trends and economic growth. Contemporary migrations are typically viewed as heterogeneous, as is scholarship on the patterns, trends, and implications. There is an increasing recognition that migration is a complex and multifaceted process, rather than a discrete event, and labor migration is more fluid than many commentators have assumed in the past.

Over the past 30 years, global outsourcing and precarization of work has become central to the reconfigured geography of the reserve army of
labor. Both trends have contributed to delimiting the collective power of labor. Indeed, economic growth has occurred alongside a reduction in workers’ share of overall wealth. In the process, migrant workers have become the paradigmatic figure in the contemporary labor process. On the one hand, global capital drives migration and reshapes its patterns, directions, and forms. On the other hand, labor migration is an important factor in bringing about fundamental social transformation of both home and host countries, and is, in turn, itself a major force reshaping communities and societies.

The “transnationalism turn” in labor migration studies argues against both “methodological nationalism,” and depictions of migrants as passive victims to global forces. Focusing on transnationalism implies that local and national scales are not sufficient to understand contemporary migration processes. It centers migrant subjectivities and seeks to understand migrants’ multiple attachments that stretch across national borders, communities, and other relations previously viewed as bounded containers. Transnationalism research has contributed to a growing body of literature on the migration–development nexus, which claims that remittances can promote local and national development in their countries of origin. Migrant workers’ remittances are seen as a way of alleviating the ravages caused by globalization, which include increasing inequality and marginalization of large population segments. Both transnationalism and migration–development literature have, however, been critiqued for celebrating migrants’ “cosmopolitanism from below.”

The study of borders and states’ efforts to manage mobile capital and labor may privilege scalar analysis, hybridity, and the implications of racialization, gender, and citizenship in shaping labor markets. It is an approach that recognizes global capital trends without viewing them as paralyzing blows that determine subjective experiences. Instead, the spaces that migrants traverse are mutable and multiple, offering opportunities and constraints. The spatial reorganization of labor has multiplied and fragmented its forms. In these and other debates, geographical literature has been attuned to the continuous reworking and reshaping of migrant experiences. The theoretical and empirical diversity of research has made significant contributions to understanding important political, economic, and social changes.

LABOR MIGRATION

Lake climates

David A.R. Kristovich
University of Illinois, USA

Thermal and surface roughness characteristics of lakes can lead to significantly altered nearby climate conditions, referred to as “lake climates.” For example, locations close to large lakes tend to have moderated annual temperature variations, with cooler summers and warmer winters than outside the region of lake influences. Depending on the lake size, shape, depth, location, and surrounding topography, lakes can influence a wide range of climatic conditions, including atmospheric humidity, cloudiness, precipitation, and winds. Large lakes, such as those in the Laurentian Great Lakes in North America, Lake Victoria in East Africa, and the Great Salt Lake in Utah, affect climate conditions over areas of $10^4$–$10^6$ km$^2$ or more. Smaller lakes also can have significant local effects, but on correspondingly smaller areas.

Fundamental causes of lake climates

The fundamental reasons that lakes exert large influences on nearby climate conditions are twofold: (i) lake surface temperature variations tend to be delayed behind those of the air surrounding the lake, and (ii) lakes tend to be less rough (more flat) than the surrounding land surfaces (discussed later). The former reason is illustrated in Figure 1, which shows 10-year average annual temperature variations for Lake Michigan water temperatures (measured at Muskegon, MI) and air temperatures (Milwaukee, WI). The causes and effects of these two influences are described below.

Lake surface temperatures vary largely in response to changes in the overlying atmospheric conditions and in heat loss/gain through radiation processes. However, lake surface temperatures vary much more slowly than regional air temperatures, resulting in important differences between the lake and the overlying air. For example, at night when air temperatures cool below the lake surface temperature, heat is transported from the lake surface to the air through conduction, longwave radiative loss, and convective processes, resulting in a cooling of the lake surface. If the air has a low water vapor content, relative to the content slightly above the lake surface, upward moisture transport leads to evaporation, further decreasing the temperature of the lake surface. The following day, incoming solar (shortwave) radiation would tend to warm a thin layer of the nearby land areas rapidly, while slower warming of a deeper layer of the lake surface takes place. Eventually, the air near the lake can exceed the lake temperatures, resulting in downward heat transport. Finally, this downward heat transport slowly reheats the lake surface, which starts the diurnal cycle over again. Therefore, diurnal or annual temperature variations for lake surfaces are delayed relative to those of the air in the same region.

Lake surface temperatures vary more slowly than nearby air temperatures because water has a specific heat content that is approximately four times as great as air ($1.1 \text{ITcal g}^{-1} \text{K}^{-1}$ and $0.24 \text{ITcal g}^{-1} \text{K}^{-1}$, respectively). Therefore, it takes more than four times as much heat to increase the temperature of water by 1 K as it
LAKE CLIMATES

Figure 1 Ten-year average (1970–1979) air temperatures for Milwaukee, WI, and lake temperatures for Muskegon, MI. Modified from Kristovich (1988). Reproduced by permission of David Kristovich.

It takes to warm the same mass of dry air by 1 K. So, because air temperatures respond quickly to changes in nearshore land surfaces, but lake surface temperatures can only respond slowly to air blowing from the land over the lake, time periods of average “climatic” lake temperatures lag behind those of the air. For the Great Lakes (cf. Figure 1), these processes result in annual average lake surface temperature variations being delayed by about 1 month, with a decreased magnitude of variation, relative to the nearby air temperature variations.

The temporal lag in the annual cycle of lake water temperatures provide for time periods when the lake surfaces tend to be warmer than the overlying air (fall and winter) and times when the overlying air tends to be warmer (spring and summer). For example, Figure 1 shows that averaged over long time periods, air temperature tends to be 2–5°C warmer than the lake during the spring to early summer months, from about April to July. During the autumn and early winter time periods, September through February, average lake temperatures can be more than 10°C warmer than the nearby air temperature, which results in rising air parcels. Therefore, autumn and winter months are considered unstable lake climate seasons and spring and summer months are considered stable lake climate seasons.

Atmospheric and lake dynamics, such as winds and currents, also play a large role in the development of lake climate regions. During the cool season, air temperatures exhibit occasional “cold-air outbreaks,” with warmer temperatures between outbreaks. Those outbreaks are when the air is much colder than the lake surface, often producing the most intense lake-effect storms. Therefore, while the long-term climatic average conditions look smooth (as in Figure 1), the strongest modification of the local climate occurs episodically.

Water movements in lakes also have important influences on lake climate regions. Long-distance horizontal movements of lake waters are hampered by the lake shores, but vertical movement within the water column can greatly influence lake surface temperatures. During the stable season, warming of the lake results in a shallow warm layer near the top of the column of water. Transport of heat downward into deep layers is inhibited because the warm layer is less dense than the colder waters below. During the unstable season, cooling of the lake surface causes the water to become more dense (down to temperatures of about 4°C). Such dense water tends to sink and mix through the water column, slowing the rate at which the surface temperatures cool. For this reason, the average spatial variation in lake surface temperatures is highly dependent on the lake water depth during the cool unstable season, but not as dependent in warm months.

The magnitude of the influence of lakes on their local environments is largely determined by the rates of exchanges of heat, moisture, and momentum between the lake surface and overlying air. These rates are not only driven
by differences between the water surface and air temperature and moisture content, but are also strongly influenced by such factors as wind speed, lake water salinity, ice cover (Assel 2005), oils on the water surface, and so on. Wind speeds over lakes tend to be greater than over nearby land areas because of a lack of surface obstacles (i.e., trees, buildings, etc.), and this tends to increase heat and moisture transfer rates between the lake surface and overlying air.

It should be noted that lake climates can be quite similar to climates close to oceanic shorelines, due to many of the same physical causes. However, there are a few distinct differences: large-scale oceanic currents transport thermal characteristics of water over large latitudinal distances, which is not possible in lakes. In addition, because lakes are more confined to smaller areas, lake climate regions often experience the influences not only of the lake waters, but also of the land areas upwind and to the side of the lake. Therefore, lakes tend to influence climate conditions less than oceans and over a smaller area.

Cool, unstable season lake climates (autumn and winter)

Some of the most severe winter weather conditions observed in mid-latitudes occur through modification of the atmosphere by lakes. Such “lake-effect” storms are responsible for the Great Lakes snowbelts, and have large positive (tourist industry, building repair contractors and suppliers, etc.) and negative impacts (snow removal costs, health impacts, etc.) for affected communities. For these reasons, considerable effort has been made on characterizing the cool-season lake climate within the Great Lakes region and elsewhere.

Snowfall may be the most discussed aspect of cold-season lake climates, particularly after events dropping excessive snowfall (e.g., 1.75 m in northern Ohio in November 9–14, 1996, near 3 m on the Tug Hill Plateau, NY, in February 2007, 1.65 m near Buffalo, NY, in November 2014). However, lakes also modify many other climate conditions. In a comprehensive investigation for the Great Lakes region, for example, Scott and Huff (1997) compared climate conditions close to the lake shores (within 80 km) to those further away from the lakes, using climate data collected over a 30-year period. They found that during the cool season, lake climate regions were warmer (daily minimum temperatures by up to 8°C, maximum temperatures up to 2°C), skies tended to be cloudier (average of 1/10 sky cover increase), and the humidity (measured by vapor pressure) was greater. Average snowfall in the lake climate regions was more than double that outside of those regions in some locations.

Isolated and groups of smaller lakes also have been shown to have marked local influences on cool-season local and regional climate. However, many small lakes tend to become covered with ice, which can greatly decrease these influences during later periods in the cool season. Small lakes that are sufficiently deep (such as the New York Finger Lakes) or have high salinity (such as the Great Salt Lake in Utah) can remain ice free and influence local climatological conditions throughout the cool season.

Some of the most cited impacts of cool-season lake climates occur through changes in the atmosphere at the surface (ground level), but changes in deeper layers of the atmosphere can also be quite important to regional climate conditions. For example, many studies have indicated that the Great Lakes tend to lead to intensification or development of synoptic-scale low-pressure storm systems and weakening of high-pressure systems. Ultimately, these influences can lead
LAKE CLIMATES

to changes in weather conditions much further from the lakes than those typically considered to have lake climates (e.g., Petterssen and Calabrese 1959). Other, less obvious influences of lakes include moistening of lower layers of the atmosphere, which can ultimately lead to development of convective snow showers over land due to daytime surface heating or formation of dense advective radiation fogs when nighttime radiational processes result in cooling of the moistened layer (e.g., Eichenlaub 1979). In some cases, clouds that develop over the lakes can be blown far downwind, affecting temperatures of wide regions.

Typical patterns of movement of large-scale atmospheric features (synoptic-scale cold air masses, high pressure, wind patterns, etc.) largely determine the long-term lake climate conditions. However, since lakes tend to have the most influence during short, intense episodes of favorable conditions (on the order of hours to days, as discussed above), we must consider factors determining which locations will receive the biggest lake modifications in those short episodes. For example, wind patterns that develop over lakes through a combination of large-scale atmospheric features and local lake-induced wind circulations, determine whether a lake-effect snow storm will occur over a wide area of the downwind shore or in a single community. Such wind circulation patterns are called “mesoscale lake-effect” wind fields (tens to hundreds of kilometers) that organize the lake-effect snow into “mesoscale bands” (Figure 2).

Many factors influence the mesoscale lake-effect wind fields and the resulting lake-effect snow bands: lake–air temperature differences, wind direction relative to the orientation of the long axis of the lake, magnitude of the upward motions (convection) over the lake, atmospheric stability, wind changes with height (wind shear), and so on. A considerable amount of research has been conducted, and continues to be devoted to understanding what combinations of lake, land, and atmospheric characteristics result in different types of mesoscale wind fields. Some of the most fundamental controlling mechanisms of mesoscale wind patterns fall into two major categories: (i) surface frictional and topographic forcing, and (ii) thermal and isallobaric forcing. The former mechanism is important because wind direction and speed near the surface are influenced by the magnitude of “surface friction” (the amount of roughness of the surface due to such features as hills, vegetation, structures, etc.). Over land areas, obstacles make the surface friction large, which causes the winds to slow and move toward areas of atmospheric low pressure. Over lake areas, the wind is smoother, resulting in higher wind speeds with directions oriented between high- and low-pressure areas. Locations where the air moves between high and low surface friction can exhibit complex wind patterns, greatly influencing the local weather.

The second mechanism, thermal and isallobaric forcing, describes the atmospheric response

![Figure 2](image1.png) Terra MODIS visible wavelength satellite image of the Great Lakes at 16:25 UTC on February 13, 2016. Reproduced from NASA.
to the development of regions of warm air (due to heat fluxes from the lake to the air) and nearby cold air (which has not been modified by the lake). The areas of warm air exhibit decreasing atmospheric pressure, while the areas of cold, unmodified air maintain higher air pressure. These pressure differences, in turn, further change the mesoscale wind patterns. The balance of the two mechanisms discussed above, modified by several other factors (such as lake shape, wind direction and shear, lake–air temperature differences, ambient atmospheric stability and humidity, determine the mesoscale lake-effect wind patterns and the types of lake-effect snow bands that develop.

Many types of mesoscale lake-effect snow bands have been identified. Short lake-axis parallel (SLAP) bands, also called broad area coverage or widespread cloud streets, tend to occur when the mesoscale winds flow across the short axis of a lake (e.g., Kristovich 1993). Lake-effect snow bands that are oriented along the long axis of a lake, recently called long lake-axis parallel (LLAP) bands, have previously been called shoreline parallel bands and mid-lake bands. Lake-effect bands can also exhibit curving patterns, sometimes resulting in “vortices” of different sizes (e.g., Hjelmfelt 1990). Finally, in areas with multiple lakes (such as the Great Lakes region), lake-effect bands extending from one lake to another (lake-to-lake, L2L, bands) are also recognized as an important type of lake-effect mesoscale system.

Mesoscale lake-effect convective structures on smaller lakes have received much less attention, but have been identified for mid-latitude lakes as small as 100 km² in surface area or even less. Studies of lake-effect convection over the Great Salt Lake in Utah, Lake Champlain on the border of Vermont and New Hampshire, Lake Tahoe on the border of Nevada and California, and the New York Finger Lakes, indicate that these lakes can produce snow multiple times each year (cf. Laird, Sobash, and Hodas 2009; Steenburgh, Halvorson, and Onton 2000). Compared to lake-effect storms over the Great Lakes, small lake storms tend to occur less frequently, over a lesser range of environmental conditions (especially lake-air temperature differences and low-level wind direction), and have fewer mesoscale band types.

The combined influence of all the mesoscale band types determines the overall influence of lakes on the local climate. While long-term trends in most aspects of lake climates have not been investigated, there is a general consensus that lake-effect snowfall increased during much of the twentieth century. Recent studies have identified a slowing of the lake-effect snowfall increases with time or even a reversal to snowfall decreases in some of the snowbelt regions (i.e., Bard and Kristovich 2012). There is disagreement in the literature on the causes of these snowfall changes, and more research is needed.

Warm, stable season lake climates (spring and summer)

During the warm season, the influences of lakes on the local climate tend to be weaker than those during the winter, largely because the relatively cool lake waters only influence a relatively shallow layer of the atmosphere. In addition, since the lower atmosphere is cooled, the air resists rising vertically (“stable” conditions), further limiting the depth of the lake influences. Scott and Huff (1997) found that precipitation near the Great Lakes was, on average, 25–50 mm less than in areas far from the lakes, even though there was only a slight decrease in cloud cover. They found a weak tendency for decreased vapor pressures over and near the lakes. This might have been
LAKE CLIMATES

anticipated, since during warm, humid times of the year, water vapor in the atmosphere would tend to condense onto the lake surface much of the time.

The impacts of lakes on local climate conditions in the warm season can be more complex than during typical cool seasons. For many mid-latitude lakes, water temperatures usually only vary by a few degrees over the course of a day, while air temperatures can be more than 20°C greater during the afternoon than in the morning. The result is that, frequently, lake temperatures are cooler than the air temperature during most of the daytime hours, but can be warmer than the air for portions of the night. Indeed, Scott and Huff (1997) found that minimum temperatures tended to be slightly warmer over and near each of the Great Lakes by up to 3°C. However, considerably cooler maximum temperatures (up to 4–6°C over and near Lakes Superior and Michigan) were observed.

The change in the lake-air temperature differences between night (positive differences) and day (negative differences) gives rise to a unique oscillating pattern in the mesoscale wind patterns (e.g., Eichenlaub 1979). During the day, the warmer land surfaces cause the air to rapidly heat, resulting in a deeper planetary boundary layer. Because this expansion does not occur over the lake, winds between about 200 and 2000 m above the surface flow from land toward the lake. To adjust for this higher-level wind flow, winds near the surface move from lake toward land — the well-known “lake breeze.” The overall circulation provides an area of sinking, cloudless air over the lake and rising air with clouds over the land. Figure 3 shows an example profile of temperature, humidity, and winds at the shore in afternoon lake breeze conditions. During the overnight hours, if the lake becomes warmer than the air over land, the opposite circulation can develop — the “land breeze” circulation.

Lake breezes can play instrumental roles in relieving summertime heat waves in coastal urban areas such as Cleveland, OH, and Chicago, IL, but can also contribute to regional transport of pollutants, influencing air quality. Even though the afternoon lake breeze tends to decrease precipitation near the shoreline, the front edge of lake breezes can often be a location of thunderstorm events (Figure 4). In areas where lake breezes from multiple lakes tend to collide, frequent severe summer storms have been observed. Considerable research activities have focused on understanding how lake breezes move through urban areas, are affected by local topographic features, and interact with other types of mesoscale circulation patterns. For example, the Lake Okeechobee lake breeze in southern Florida frequently interacts with sea breeze fronts from the Gulf of Mexico and the Atlantic Ocean, thunderstorm outflow boundaries, and occasional fronts.
Relative to winter lake-effect snows, little work has been carried out to understand long-term trends in lake breeze occurrence. One of the reasons for this is the difficulty in identifying lake breezes in climatological surface datasets. Multiple ways of identifying when lake breezes were likely or have occurred have been developed to examine their climatological characteristics (e.g., Laird et al. 2001). Methods such as these will be necessary to understand the influences of long-term climate changes on warm-season lake climates.

Comments and knowledge gaps

Much is known about large-lake modification of the climate conditions in their vicinity throughout the year, particularly in locations typically downwind. Over time, communities and ecological conditions adapt to the usual conditions (such as average conditions and “usual” extreme conditions). The largest impacts are often experienced when climate conditions are extreme and outside those previously experienced in socially or ecologically relevant time frames.

Many fewer research papers have been published on the varying nature of lake climates, particularly during the warm, stable season. Additional field studies and numerical modeling studies are needed to understand interactions between severe thunderstorms and over-lake stable boundary layers, for example. Even in better-understood cool, unstable seasons, predictability of interannual variations is limited due to the complex interrelationships between large-scale oceanic temperature anomaly patterns, synoptic airflow configurations, lake surface (such as ice cover) and vertical profile conditions, and periodic air-mass conditions. For example, the question arises as to whether reported long-term variations in winter lake-effect snowfall are experienced as more extreme storms or as more frequent weaker storms.

Research continues on the ecological responses to climate change in many lakes, but little work has been reported on how biological processes, in turn, influence local climate. A critical area of continued research is how climate changes are manifested in changing extreme events and how, in turn, these events impact the lakes themselves and their surroundings.

**Definition**

In lakes, an ice flood occurs when ice and flood water overflows lakeshores and comes in contact with the riparian environment (Figure 1a). Such events can leave traces in riparian ecosystems when water levels, covered by drifting ice rafts, reach the upper part of the shore. The phenomenon does not occur each year. Ice floods generally occur at spring breakup, when the ice cover is lifted by rapidly rising water levels, due to a massive water input during snowmelt in the lake’s drainage basin. Ice rafts are pushed against the shore by wind and pile up on the shore (ice piling) and can induce severe mechanical erosion. Sedimentary levees (ridges) of coarse, ice-pushed sediments may form in the most exposed lakeshores. Such ridges are usually maintained by frequent and powerful ice push action. Disturbed trees growing on the shores where frequent ice push occurs may bear scars that are indications of past ice push activities. Such scars can be dated through standard tree ring analysis methods, and used to reconstruct the magnitude and frequency of past ice push events.

Drift ice season

The drift ice season can be divided into three phases. The first phase corresponds to the ice cover formation (ice buildup). Ice covers usually start forming during frigid weather conditions, most frequently at night and over calm waters protected from winds and waves. The thin, newly formed ice is relatively fragile and may disappear rapidly if temperatures rise above the freezing point, rainfall occurs, or even if the water surface becomes more agitated. If the newly formed thin ice cover persists over a few days, it begins to grow vertically towards deeper water layers, and horizontally towards more agitated and exposed water layers. Black ice forms when crystallization occurs in calm waters, and by opposition, white ice forms in more agitated, aerated conditions (Ashton 1986). Thermal accretion of the ice cover towards its base continues until water heat losses to the atmosphere become negligible. The distribution of heat in the water column is also an important aspect. Water’s maximal density is reached at precisely 3.98°C. Thus, when water cools down from the surface to the bottom at the beginning of winter, surface water become denser, less buoyant, and precipitate. This process therefore forces deeper, yet warmer water to become buoyant and mechanically climb to the surface while mixing with less dense waters. This mixing process occurs until water’s density falls below 3.98°C. Water’s density decreases and cold surface waters rapidly reach the freezing point, which accelerate the freeze-up. The phenomenon ends when water stops transgressing the freezing point, most often when the ice cover (but also the snow mantle) becomes thick enough to prevent water heat losses to the atmosphere.

(b) Ice cover degrades in early spring and breaks into large rafts that can be carried against the shore by the wind. (c) An ice push ridge (see person standing for scale). (d) Ice rafts pushed against riparian trees. (e) Multiple ice scars found on a single individual tree exposed to ice push disturbance.
When the ice covers the full water surface, a second phase begins: the ice pack period. The ice stops growing vertically and horizontally, and is immobile. The ice cover protects the low shore from the erosive actions of waves. In rare cases, cracks can form in the ice cover which allow for the penetration of meltwater (or rain) into the ice, which will rapidly freeze up. In such conditions, lateral movements of the ice cover become possible and, although they are limited in amplitude, the slight, marginal movements can damage the shore. However, such fractionation events can only occur if water levels fluctuate during the ice cover season following, for example, winter showers or winter mild spells. For this reason, the phenomenon is quite rare in dry and frigid climates. Nevertheless, since ice contraction and extension are a temperature-sensitive phenomenon, it is sometimes possible to observe some advance and encroachment of the ice pack on the lakeshore.

During the ice pack season, the ice behaves as an emerged surface capturing the falling snow. The amount of snow that the ice cover can support varies according to the climate (mean temperature and variability, amount and type of precipitation) and exposure to winds. Temperature controls the crystalline state of the snow. In climates where the temperature is maintained at below approximately \(-12\, ^\circ\mathrm{C}\), snow crystals are unaltered and are found at the particulate state, while under warmer temperatures, snow crystals fuse with one another and snow pack becomes cohesive (Michel and Ramseier 1971). Individual snow crystals may be mobilized by wind, which allows the redistribution of the snow cover over the lake. The size and shape of the lake, with respect to wind orientation, have important implications for snow mobility at the surface of the ice cover. In fact, the longer the fetch (the length to which winds can blow without encountering obstacles), the greater is the eolian force on the snow pack. A small lake bordered by a dense forest cover often represents a snow pit; a large lake exposed to wind gusts will capture snow which will ultimately be transported against island margins or against the shores. Thermal insulation of the ice by snow is proportional to the thickness of the snow accumulation. This will influence the rate of accretion of the ice, especially at the beginning of the ice season. Hence, small lakes that are rapidly covered by a thick snow mantle often exhibit a thinner ice cover.

In frigid climates with cold and dry winters, the characteristics of the ice cover breakup have an important influence on hydrological and geomorphological processes. An extended cold season is crucial in order to maintain a thick, dense, and coherent ice cover that will ultimately induce some severe mechanical effects on riparian ecosystems when it is mobilized. The lateral movements of the ice cover usually start at the time when the snow pack begins to melt. The thicker the snow pack is, the faster the melt will be, inducing a rapid rise in water levels. The hydrographic position of the lake in the watershed, the watershed’s shape and slope, and the efficiency of the lake’s outlet(s) are all important factors that control the amplitude of spring flood fluctuations.

The mechanism by which ice transports sediments and disturbs riparian ecosystems is also linked to wind action. Essentially, spring flood augments the open-water area at the margin of the ice cover (Figure 1b). The ice pack also gets thinner and reduces in size, starting near the shoreline. The combined effect of these two processes leads to the creation of an open-water fringe bordering the ice cover. Under the persistent force of wind, ice drifts and impinges on the islands and the peripheral shorelines. This results in various erosional and depositional phenomena that shape ice-affected shorelines.
LAKE ICE

Among other things, ridges (Figure 1c) represent alluvial levees recognizable from their linear, yet semichaotic, microtopography. The ice push therefore occurs during a very short period of time, at the moment of breakup. When ice breakup is advanced (mature), the ice becomes rotten, too friable to pile up, and thermally degraded, and the ice flood season comes to an end. It is inevitable that an ice flood can only occur when winds can mobilize the ice cover.

Latitudinal variations in ice flood properties

Winter and spring climatic conditions have a determining effect on ice flood magnitude and frequency. This activity will culminate at mid-latitudes, between temperate–cold climates and arctic climates. Under temperate–cold climates characteristic of the boreal zone, snow is abundant but stays for a very short period at the particulate state. It is generally sticky when it falls (temperatures often over 1–2°C), or becomes sticky in the following days when temperatures become milder. In spring, the snow pack melts in place, forming a thick water layer over the ice cover (Michel and Ramseier 1971). This ponding process is often mistaken for the “sinking” of the ice below the lake’s water surface. But this phenomenon would contradict the fundamental laws of physics, because ice has a lower density and cannot sink in fresh water. In arctic and subarctic environments, this phenomenon is rare, if not nonexistent, simply because less snow accumulates due to powerful winds and cold winter temperatures that maintain the snow at the particulate state. In such conditions, snow is blown away by wind and does not accumulate on the ice cover. Ice will therefore degrade either by thermal processes (under the control of rising temperatures, solar radiation, or heat transfers from the water to the ice) or by mechanical processes, after the agitation of water on the lake.

Lake ice floods’ magnitude and frequency vary with latitude, along with the corresponding impact on riparian ecology and geomorphology. Conditions that favor the most frequent and intense ice flooding activity are squeezed between the cold arctic climate and the more temperate boreal climate. Ice floods are therefore a typical subarctic phenomenon. A similar ice flooding activity could potentially be found in high-altitude environments; however, large water bodies are rarely found in mountainous relief.

By comparison to the geographical extent of river ice floods, lake ice floods are much more restricted spatially. River ice floods (see River ice and ice jams) result from a combination of factors that are found in a much broader range of conditions. Such events are caused by the blocking of the channel by the ice (ice jam), a situation that can be caused by an abnormally thick and resistant ice cover and/or by an early spring flood that occurs before the ice cover has thermally degraded. These conditions are commonly found in areas where air temperatures drop below 0°C for at least one month and can be aggravated by various channel properties that restrict the mobility of drifting ice rafts, for example, a sinuous or constricted channel. By contrast, lake ice floods are much more zonal (i.e., predominantly subarctic, but occasionally high-boreal) and require a precise combination of factors including (i) an important spring flood to lift and detach the ice cover from the lake’s bottom and shore, (ii) little snow accumulation to reduce the thermal insulation and spring ponding effects, (iii) a long fetch that will generate sufficient drag force to push the ice against the lakeshore, and (iv) an ice cover that is thick and mechanically strong enough to persist during the spring flood.
Lake ice flood reconstruction

Since most important lake ice floods occur during high water levels, it becomes possible to link spring flood magnitude to the abundance of ice-related damage left on the lakeshore (Bégin 2001). Most of the literature that aimed at reconstructing past lacustrine ice floods also aimed at investigating past water levels in lakes where local hydrological fluctuations have some regional significance (e.g., Bégin and Payette 1988). Reconstructing spring water levels allows the records to be extended beyond the observed (instrumental) variability in order to better appreciate interannual variability and long-term trends in regional hydrology. To do so, dendrochronology is often used to construct chronologies of past ice flood events and make attempts at dating damages left by ice during ice floods on riparian trees.

Most common ice flood dendrochronological markers are scars developed by trees on damaged portions of the trunk (Figure 1d–e). Such scars form when ice impacts against rigid and inflexible riparian stems and results in the partial destruction of the cambium (a thin envelope of dividing cells), a situation that hampers lateral growth. At the periphery of the injury, cambium cells are found to be intact, and lateral growth is uninterrupted. Wood cells form each year and are typically organized as tree rings that can be counted to date the injury. Using this technique, ice flood history can be reconstructed and the magnitude and frequency of past events are to be interpreted as a function of the abundance and height of the damages left on trees, according to statistically verified procedures.

In order to represent a useful marker of past ice floods, four groups of criteria need to be considered: the lake’s configuration, the shore’s exposure to winds, the forest structure (age, density, species), and the position of the trees on the shore. Headwater lakes are not related to large rivers and their water level fluctuations are closely related to precipitations, while lakes located downstream in a watershed collect water from higher-order basins and integrate the complex combination of variables that control the shape of the hydrograph. Circular lakes are also ideal for ice scouring phenomena to take place, because the fetch is long in all wind directions, therefore resulting in an equivalent probability of scouring (comparable exposure) for all shores. Steep slope shores are affected by the most intense ice push events. On such shores, it is not uncommon to observe ice pile-ups and ice push ridges. This situation is also true for highly exposed islands and capes jutting into the water. On these exposed shore segments, trees are not frequent. By contrast, lakeshores presenting a gentle subaquatic slope are less exposed, and ice impinges against the pre-littoral zone and rarely reaches forested ecosystems found on the upper shore. Only in rare extreme events will these ecosystems be disturbed by lake ice. In order to reconstruct the history of past lake ice floods, it is recommended to focus on the tree ring analysis of moderate severity, where the forest line comes into contact with water. Forest structure also influences the recording. The absence of trees does not imply the absence of a spring flood, but the probability of recording an event increases with the number of trees available for recording. It is therefore necessary to weight the number of ice scars from a given year against the number of trees available for recording that same year. It must finally be underlined that riparian tree populations growing along subarctic lakes can be disturbed by other factors, including forest fires and insect outbreaks. Finally, the position of trees on the lake shore is an important parameter to consider in the analysis, as trees growing close to the mean high water level are the most exposed to ice conditions.
scouring. The analysis of past ice scouring events and relationships with past lake water levels need to be analyzed while taking into account all these parameters.

Lakes and limnology

Sally P. Horn
University of Tennessee, USA

Lakes are inland bodies of relatively still water that occupy depressions formed by a variety of natural geomorphic and biological processes, or by human activity. They are the focus of the fields of limnology, which is the study of the physical, chemical, and biological characteristics of all inland waters, including fresh and saline lakes, streams, and wetlands, and of paleolimnology, which investigates lake sediments as archives of information on past climates and environments. Although lakes contain less than 0.5% of all fresh water on Earth, they are significant for human wellbeing as sources of water, food, and economic and recreational activities, and as avenues for water transportation (Wetzel 1975). Lakes in various parts of the world are considered sacred by modern human societies, and archaeological evidence indicates that they also held special significance for prehistoric peoples. They contribute to biological diversity, and may serve as sentinels of future climate and ecosystem change, just as they also provide valuable evidence, in their accumulated bottom sediment, of past changes in climates and environments resulting from natural processes and anthropogenic activities. Geographers have contributed to the study of modern lakes, lake sediments, and human interactions with lakes using both traditional, “muddy boots” fieldwork and new geospatial techniques.

Lakes and their study

Freshwater lakes range in surface area from less than a hectare to tens of thousands of square kilometers, in the case of the North American Great Lakes and the large lakes of East Africa, western Asia, and Canada. Lake Superior has the greatest area (83,300 km²) of any freshwater lake in the world, while Lake Baikal has the greatest depth and volume (1741 m and 23,000 km³) (Horne and Goldman 1994). The Caspian Sea, more than four times the size of Lake Superior, is the world’s largest inland water body, but this remnant of the ancient Paratethys Sea is saline (Cohen 2003). Small, shallow lakes are often termed ponds, but scientific definitions vary, and the use of “lake” or “pond” in naming water bodies is inconsistent.

Natural lakes and ponds of all sizes owe their origin primarily to geomorphological processes. Glaciation, volcanism, tectonics, fluvial dynamics, landslides, wind, changes in sea level and coastal shorelines, and the weathering of carbonate rocks create depressions by scouring, explosion, crustal extension, deflation, or collapse; by damming stream valleys with sediment or lava; and through faulting (Figures 1 and 2). Plant growth may be sufficient to dam some depressions (Wetzel 1975), and beavers create ponds by damming streams. Adding to the Earth’s natural lakes, humans have created large numbers of lakes by damming streams for hydropower and water management, and by creating farm ponds and other impoundments. Lake origin determines morphology, which
along with climate influences lake stratification and ecology. In his useful review of mechanisms of lake formation, Cohen (2003) made the important point that lake basins have histories that are partly independent of the lakes that fill them, and that basin evolution also affects both limnology and the nature of sediments available for paleolimnological study.

Using new statistical approaches, Downing et al. (2006) recently estimated that there are 304 million natural ponds and lakes over 0.1 ha (0.001 km²) in the world, covering an estimated 4,200,000 km². Small lakes dominate, with nearly 91% of these predicted lakes less than 1 ha in size, and a further 8% between 1 and 10 ha. Reservoirs and other artificial impoundments cover 260,000 km² of Earth’s surface, and farm ponds cover 77,000 km². Adding these water bodies to natural lakes leads to the estimate that 3% of the Earth’s surface is covered by lakes, ponds, and impoundments – an estimate more than twice as high as previous inventories, which underestimated small lakes.

In an earlier paper on lake distributions, Meybeck (1995) noted that the global distribution of lakes was addressed by geographers beginning in the eighteenth and nineteenth centuries, but that this information was not of interest beyond geography until much later. Only after the earth and biological sciences had evolved to a global perspective, a transformation Meybeck linked with the establishment of the International Geosphere-Biosphere Programme (IGBP) in 1987, did lakes and wetlands get due credit in consideration of regional and global water balances and biogeochemical cycles. Lakes are now seen as major regulators of carbon, nitrogen, and phosphorous cycles through the production of organic matter, sedimentation of organic detritus, and precipitation of carbonates and evaporites (Meybeck 1995) – and so their geography (distribution, sizes, volumes) now matters.

The latest estimates of global lake distribution by Downing et al. (2006) suggest that rates of material processing by aquatic ecosystems may be twice previous estimates, and that processes most active in small lakes and ponds may be of previously unrecognized global importance.

Lakes are significant sources of biological diversity, supporting terrestrial as well as aquatic biota, including endemic species of fish, sponges, bacteria, zooplankton, phytoplankton, and other algae that have evolved in particular lakes or lake systems. Differences in lake depth, water temperature, chemistry, and light create different environments within and between lakes, and over the seasons, affecting the geographic distribution of aquatic biota. Advances in remote sensing now enable remote monitoring of some physical, chemical, and biological parameters, at least for larger lakes. But other measurements, and sample collection, must be done on-site. Limnological field sampling typically involves the use of small boats or inflatable rafts to reach sampling sites, together with various devices to
measure lake transparency, water color, depths, temperature, oxygen, conductivity, and pH; samplers to recover water at different depths for chemical analysis and for quantification of phytoplankton in the water column; nets for zooplankton; and dredges for surface sediment (Figures 3 and 4). Advances since the early 2000s include data loggers that can be left in lakes to monitor temperature or dissolved oxygen until a return to collect them, or set up to transmit data to users. Self-propelled floating devices combining Global Positioning System (GPS) receivers with sonar and other sensors and probes are coming online that can speed limnological study; current versions are operated by radio control from shoreline to map lake bathymetry, measure temperature and selected chemical properties, and collect water samples. Limnological researchers of the future might also plan to use automated underwater vehicles to collect data and samples, or drones that collect data from above the lake surface.

The value of lakes in providing habitat and resources for aquatic and terrestrial wildlife, and various other benefits to the natural world and human society, are increasingly discussed in terms of *ecosystem services*, a concept that gained wide exposure in the United Nations
Figure 3 A Secchi disk used to measure lake transparency. The depth at which the disk disappears from sight when lowered below the water surface is the Secchi depth. Algal blooms and suspended sediment can change Secchi depths seasonally or over longer time periods, making this inexpensive device an important monitoring tool.

Millennium Assessment (Millennium Ecosystem Assessment 2005). Lakes and lake processes contribute ecosystem services across all four categories defined in this assessment, namely: provisioning services (water and food); regulating services (biogeochemical cycles, as described earlier, and in other ways); supporting services (nutrient cycling and aquatic photosynthesis); and cultural services (recreation, aesthetic, and spiritual benefits). The long-term viability of ecosystem services provided by lakes is a cause for concern, however, given the rate at which natural lakes are being altered or destroyed by human activities.

The increased recognition of the regional and global importance of lakes has spurred limnological research, which now exists for all continents and most countries of the world. Most of the Earth’s large lakes have been studied, but gaps

Figure 4 Temperature measurements made by lowering a probe through the water column reveal whether lakes are stratified, with a warmer, upper body of water separated from a cooler, lower body of water. This temperature profile from Lago Cote, Costa Rica, made on March 9, 1998, shows the lake to be stratified at 5 m. Repeat measurements reveal whether lakes maintain temperature stratification for long periods, or frequently overturn, mixing the water body. Lakes that mix frequently are known as polymictic lakes.
exist in knowledge of other lakes and in particular regions. The latest estimates of global lake distribution suggest that small lakes, in general, need additional attention, to quantify processes whose significance at regional and global scales has likely been overlooked. Limnologists have also called for additional monitoring of lakes as sentinels that can help to reveal effects of current climate change at the ecosystem scale in understudied areas, and to disentangle the effects of climate change and other influences on the environment (Williamson et al. 2009).

Growing interest in the reconstruction of past climates and environments has also driven research on modern lakes and on the records of past conditions preserved in lake sediments. Geographers have contributed to paleolimnological research at lakes throughout the world, recovering sediment cores (Figure 5) and studying plant and animal remains, stable isotope signatures, and other environmental indicators, or proxies, preserved within them. Studies of aquatic microfossils in sediment cores, such as diatoms and nonbiting midges or chironomids, have motivated regional limnological surveys to determine the relationships between lake parameters measured today and microfossils in modern sediments, information needed for interpreting past conditions. Much of what we know about the history of climate, vegetation, fire history, and human land use over the Late Glacial period and Holocene has come from the study of lake sediments. The pollen, diatom, chironomid, charcoal, stable isotope, and other proxy records that paleolimnologists have developed provide key information for understanding the development of aquatic and terrestrial ecosystems; interactions between climate, vegetation, and fire; and patterns of prehistoric land use. These records provide data for paleoclimate models and perspectives for modern ecosystem management, and can help society understand, anticipate, and perhaps mitigate the consequences of future global change.

History of research in limnology and paleolimnology

The field of limnology was established by the Swiss physician and scientist François Alphonse Forel (1841–1912) with the publication of his three-part monograph on Lake Geneva (in French Lac Lemán). The contents of his Le Lemán: Monographie Limnologique (Lake Geneva: Limnological Monograph) illustrate the interdisciplinary nature of the new science and the overlap with the subject matter of physical and human geography. Volume 1 (published in 1892) covered geography, hydrography, geology, climatology, and hydrology; volume 2 (1894) focused on hydraulic, chemical, thermic, optical, and acoustical processes and patterns; and volume 3 (1904) focused on biology, history, navigation, and fisheries. Forel coined the term
“limnology,” which at the time referred only to the study of lakes, and published the first textbook in 1901, *Handbuch der Seenkunde: Allgemeine Limnologie* (Handbook of Lake Study: General Limnology).

Though considered the father of limnology, Forel was not the first to systematically sample and describe lake characteristics or biota (Horne and Goldman 1994). Two centuries earlier, Antonie van Leeuwenhoek initiated studies in biological limnology with descriptions of the green algae *Spirogyra* from a shallow lake in the Netherlands. Important contributions to physical limnology were made in the 1700s with observations of periodic surface waves, measurements and interpretations of temperature stratification in lakes, and exploration of how light, heat, water temperature, and wind interact to structure water bodies. The discovery of zooplankton, and initial work on estuarine salt wedges and river pollution (all in western Europe) also predated Forel’s work, as did the earliest research on lakes in the United States. In 1850 Louis Agassiz, then three years into a professorship at Harvard, published *Lake Superior: Its Physical Character, Vegetation, and Animals*, which combined a travel narrative with observations on the lake (especially its fish) and its regional geography (Agassiz 1850). In 1887 Stephen Forbes presented a landmark paper before the Peoria, Illinois, Scientific Association. Entitled “The Lake as a Microcosm,” Forbes’s paper was the first to describe lakes as ecosystems, a key concept of modern limnology.

Early limnology shared techniques with oceanography, which was also developing in Europe during the latter half of the nineteenth century. In the 1860s the Italian astronomer and priest Pietro Angelo Secchi experimented with disks of various size, color, and material to measure the transparency of coastal waters of the Mediterranean. The metal or plastic disk that now bears his name also became a key tool for measuring the transparency of lake waters, used to this day by limnologists and in a global citizen science monitoring program developed by biologists and a geographer at Kent State University (www.secchidipin.org). Other traditional tools for lake study, including encased thermometers for measuring water temperatures at depth, silk nets for sampling plankton, and the Forel–Ule scale for gauging water transparency and color came into use in the latter half of the nineteenth century.

This period also saw exploration of the great lakes of Africa, supported in part by the Royal Geographic Society: Lake Malawi by David Livingstone in 1850; and Lakes Tanganyika, Victoria, Albert, Edward, and Turkana by others between 1858 and 1888. European and American explorers had reached the large lakes of North America earlier: Great Slave Lake in Canada in the late 1700s, and Great Salt Lake in 1824. The large lakes of Asia were known early by Chinese and Russian scientists, and the Caspian Sea was described by Greek historians (Meybeck 1995).

The first scientific society in limnology was the International Society of Limnology, established in Europe in 1922 as the Societas Internationalis Limnologiae (providing the enduring acronym SIL). The Limnological Society of America was founded in the United States in 1936, and reorganized to include oceanography and marine biology in 1948, when it was renamed the American Society of Limnology and Oceanography, or ASLO. In 2011 the society changed its name to the Association for the Science of Limnology and Oceanography to reflect its increasingly international membership (the acronym was conserved). SIL and ASLO each have several thousand members. SIL holds international congresses every three years and publishes two journals, *Fundamental and Applied*
Researchers who study paleolimnology attend limnology meetings but also have their own societies – the International Limnogeology Association (established 1993) and the International Paleolimnology Association (established 2003) – and journal, the highly ranked Journal of Paleolimnology, which launched in 1988 (2014 impact factor 2.1). Paleolimnologists are also active in organizations focused on the Quaternary period, such as the International Union for Quaternary Research, and national groups such as the American and Canadian Quaternary Associations; and on particular proxies, such as the International Society for Diatom Research, and AASP – The Palynological Society. Paleolimnologists in the United States also belong to the Association of American Geographers, which has a specialty group devoted to paleoenvironmental change; the Geological Society of America (Limnogeology Division); and the Ecological Society of America (Paleoecology Section), among other disciplinary societies.

A concise definition of paleolimnology, used by the Journal of Paleolimnology, is the reconstruction of lake histories. This definition suggests a focus on conditions and processes only within lakes, such as changes in algal productivity and community composition as indicated by diatoms in sediment cores. Early uses of the term were in this more restricted sense, for example by the ecologist E.S. Deevey in his 1953 book chapter on “Paleolimnology and Climate.” However, with the explosion of interest in using lake sediments to reconstruct past climates and environments, paleolimnology has come to include all studies that make use of these lacustrine archives – even those focused on proxies that derive from, and inform us about, processes outside of the lake itself, such as the pollen of terrestrial plants and charcoal fragments from watershed or regional fires.

Thus, although related to limnology, paleolimnology has a broader parentage, with stronger contributions from geology, physical geography, and terrestrial ecology and botany. As with limnology, the field of inquiry predates its name (which Deevey in 1953 may have been the first to use). Geologists were identifying and interpreting old lake deposits in the early to mid-nineteenth century, although relationships between Pleistocene lake sediments and climate did not become clear until the end of the century (Cohen 2003), and as late as 1953 Deevey called for better integration of geological and ecological approaches. Investigations of diatoms and pollen grains in sediments began in the early twentieth century, coincident with improvements in microscopes. Studies of pollen in Pleistocene and Holocene lake and bog sediments spread rapidly in northern Europe and the United States in the 1920s, 1930s, and 1940s. Most early pollen studies focused on the effects of climate change on vegetation, and early work on diatom communities focused on understanding the changing trophic states of lakes. In the second half of the twentieth century, paleolimnological studies began to address human impacts on lakes and
LAKES AND LIMNOLOGY

their watersheds more often, including prehistoric impacts. Diatom analysis expanded greatly in the 1980s as the technique came into use as a means to identify the impacts of acid deposition on lakes. The establishment of the Journal of Paleolimnology and professional societies and conferences in paleolimnology since the 1980s reflects the further growth and vibrancy of the field.

Land change science

B.L. Turner II
Arizona State University, USA

Land change science, also known as land system science, is an interdisciplinary subfield of study addressing the causes and consequences of changes in land use and land cover, especially as related to the themes and topics and explanatory lenses consistent with the global environmental change and sustainability sciences (Turner, Lambin and Reenberg 2007). Its historical and intellectual antecedents can be found in geography, perhaps more so than any other field of study, and professional geographers make up a substantial proportion of the practitioners in the subfield. The development of land change science as an international research endeavor, however, resides in the contemporary and interdisciplinary research programs addressing changes in the Earth system, landscapes, and ecosystems, and in sustainability and sustainable development. Land change science now spans a full array of environmental, social, spatial, and remote-sensing sciences, complete with new journals and journal sections devoted to various aspects of land change.

Formal programs

Land change science formed as an international and interdisciplinary subfield of study with the development in the early 1990s of the Land Use/Cover Change (LUCC) program of the International Geosphere–Biosphere Programme (IGBP of the International Council of Science) and the International Human Dimensions Programme (IHDP of the International Social Science Council), constituting the first joint research program of these two organizations. The IGBP, foremost its ecological dimensions, realized that understanding and forecasting the biophysical changes in the terrestrial surface of the Earth was inadequate, lacking a human or social dimension addressing land-use dynamics, and that the observed changes required long-term monitoring at a global scale. The IHDP was seeking ways to develop integrated human–environment research within the larger global environmental change agenda and welcomed a linkage to the IGBP. LUCC was envisioned as a truly integrated research effort joining the various disciplines interested in the observation, monitoring, understanding, modeling, and projecting of land change from the local to the global spatial scales. With a few important exceptions, however, the effort captured “tweeners” – those whose research is situated at the intersection of social and environmental sciences – interested in land systems, more so than disciplinary specialists interested in some facet of land change related to both its social and its environmental subsystems. Subsequently, a more expansive Global Land Project (GLP) emerged from the IGBP–IHDP, one that sought to be integrative in terms of the human and environmental dimensions and interactions of land systems, drawing on researchers from the social, environmental, spatial, and remote-sensing sciences. The level of intended integration was abbreviated, however, by the development of another international science program, DIVERSITES, focused on biodiversity and ecosystem
LAND CHANGE SCIENCE

change and the consequences for ecosystem services and human wellbeing. As result, the land systems and ecological landscape communities, represented by the GLP and DIVERSITAS, respectively, tended to work in a complementary, albeit informal, way. The newly minted Future Earth program of the International Council of Science blends both programs through a set of sustainability themes that require not only the kinds of knowledge gleaned from the two programs but also a union of them framed into “actionable” or “use-inspired” basic science.

Geographic legacy

The antecedents to the contemporary discipline of geography had a rich tradition of interests in human–environment relationships. Influenced by the works of Alexander von Humboldt, the modern geographic foci addressing land systems may be situated with the concept of *Landschaft* (landscape) in nineteenth-century German geography (Turner 2002). The various definitions of the concept notwithstanding, influential proponents championed a geography based in the systematic sciences in which the phenomenon of study was the landscape, a human–environmental or social-environmental system in contemporary parlance. This orientation, not necessarily linked to land systems, rose to prominence in the late nineteenth and early twentieth centuries under the label of “the geographic factor” – the environmental determinants of humankind. Championed by a number of prominent scholars, especially in elite, private institutions in the United States, this orientation morphed into environmental determinism, the negative repercussions of which scarred human–environment research in the discipline. As a result, a more reasoned human–environment approach – human responses to environmental conditions – championed by Harlan H. Barrows in the 1920s – was derailed until the latter half of the twentieth century, when it re-emerged as natural hazards or risk hazards research. Advocated by Gilbert F. White and his students, this human–environment subfield focused on socially defined problems with an “actionable science” orientation. An explicit landscape approach, however, commonly referred to as landscape morphology, had been established in the late 1920s by Carl O. Sauer. Directly tied to the *Landschaft* theme, it sought to give geography a phenomenon of study – the landscape or land system as an integrative, human–environment product – consistent with the foundational needs of the systematic sciences. Practitioners diverged in intellectual orientations, however, embracing natural history (as opposed to systematic science), cultural-historical, and humanistic approaches to landscape questions, themes, and understanding.

In the mid- to latter half of the twentieth century a science-based approach to land systems emerged under the rubric of cultural ecology (Turner and Robbins 2008), sharing many attributes with research under that label in anthropology and, within geography, sharing research space with risk hazard studies. This specialty began to splinter as critical and social theory entered the human–environment subfield, generating political ecology. Given the subsequent critiques of risk hazards and cultural ecology and the social-cultural theory turn of much of geography by the 1990s, practitioners favoring a systematic science orientation to human-environment issues opted to join – indeed, in many cases helped to create – new, integrated sciences and science-based subfields. Sustainability science is one example (Kates et al. 2001), a newly minted field of study that has embraced risk-hazard research, relabeled as “vulnerability” and linked to resilience, and land change/system science. Currently, many
of the topics of study undertaken in political ecology and land change science are similar, if not the same. What differentiates the two subfields is their framing: land change as post-positivist science and political ecology as a primarily structuralist and constructivist project.

Land change/system science

Land change science seeks to understand and explain land dynamics. These dynamics are viewed as a product of the interactions of the two subsystems comprising land use and cover, thus marking land systems as a type of social-environmental (or coupled human-environmental) system. Land change science seeks to identify and understand the causes and consequences of changes in land systems, which in turn require attention in the way of observation and monitoring, especially through the use of remote-sensing methods, as well as reconstructing land change throughout human history. Various modeling methods are used to test theories and themes of land change as well as to project these changes into the near-term (decadal) future. Significant portions of land change science overlap with the research interests of landscape sustainability, including attention to products that can be used to inform decision-making.

Causes and consequences

As a type of social-environmental system, land systems conform to the attributes of complex adaptive systems. They are associated with general drivers, causes, and processes, but the complexity of interactions between the components comprising the two subsystems and the variations in the base conditions in which they operate lead to place-specific outcomes (Kates et al. 2001). Land change science seeks to identify the general factors and principles underpinning land change and their mediation by a myriad of case-specific factors. For example, considerable research has demonstrated that over the long term and at the global scale the factors comprising the IPAT identity (environmental impact \( I = \text{population} \times \text{affluence} \times \text{technology} \) ) track with land change, pointing to these sources of demand and efficiency in production and consumption, or the causes of their change, in the reshaping of land uses and cover. At finer spatiotemporal resolutions, however, other factors, some more distal (e.g., markets, migration, environmental teleconnections) and others more proximate (e.g., local institutions, ecosystem services) reconfigure the outcomes of these demand factors or overpower them in regard to the explained variance of specific cases (types and locations) of land change (e.g., Lambin et al. 2001). For these reasons, the causes of land change are treated both quantitatively and qualitatively, although qualitative research tends to inform, not supplant, statistical approaches.

A large range of social, environmental, and interactive consequences of land changes has been addressed. Examples include such theories and themes as forest transition or the loss and gain for forest cover with changing economic conditions and household life cycles, the “hollow frontier” hypothesis addressing abandoned landscapes, “virtual” land change or the “out of place” consequences of “in place” land changes, and the agricultural intensification–land-sparing hypothesis. In these and other examples, such socioeconomic consequences as migration, remittances, and household income, and such environmental consequences as human-appropriated net primary productivity or biodiversity lost are addressed. Increasing attention is given to urban land change,
and urban–hinterland and urban–distant land interactions.

Observation and monitoring

Major progress has been made in land observation and monitoring, advancing the acquisition, processing, and analysis of data at multiple scales (e.g., NRC 2013). Workhorse imagery data, such as that from the Landsat or SPOT system of satellites, now provide a four-decade record of land change. As this archive of data grows, as well as the temporally dense MODIS dataset, land change studies have increasingly shifted toward more complex time-series assessment techniques. Previously constrained by data and computational power, current research is able to make use of growing cyberinfrastructure and supercomputers to analyze long time series of data, providing insights into changing phenology and system response times. The resolution and frequency of MODIS data have also created rich datasets that support and improve global land-cover models. Meanwhile, the availability of very fine resolution datasets, including multiband aerial photography, and new methods for image analysis (i.e., object-based image analysis) enhance opportunities to map microscale heterogeneous landscapes, facilitating land change observation and analysis in highly complex urban areas, treating such topics as land system composition and configuration on urban heat islands. Coupled with LiDAR data to detect elevation, fine resolution data increasingly offers opportunities to model three-dimensional changes in landscapes, and the implications for such fine-grain issues as the role of trees on air surface temperature and thus household energy expenditures and water use.

Past change

The historic human imprint on ambient environmental conditions and the function of land systems regionally and globally have been advanced with much improved mapping accuracy (e.g., Ellis and Ramankutty 2008). Paleo-environmental, archaeological, and historical evidence has been used to reconstruct past land system dynamics, providing strong clues about the use of prehistorical and historical land systems as analogs for current and future land systems. Past outcomes of social-environmental system dynamics are less useful than is information about the kinds, trends, trajectories, and rates of change of past interactions. Coupled with an understanding of complex land change dynamics, these improvements have led to new assessments of the role of land changes in proposed social-environmental collapses.

Modeling and projecting

The array of land change issues that can be addressed with multiple modeling approaches is staggering (NRC 2013). Land change models have been widely applied for descriptive assessment that simulate spatial changes in land use, as well as for prescriptive applications to optimize land use configurations for a given objective. These include, but are not limited to, land change models of agent (human actors) land use choices, including in urban areas, predictions of deforestation and agricultural change patterns, and time-series and economics models of land use change. In an effort to increase the relevance of land change models for social and ecological outcomes, recent research emphasizes models of land use and land functions, rather than simply land cover change. Perhaps of special interest to geography, various efforts are underway to specify not only what kind and degree of land changes will take place, but their location and
Land change science is a field that examines the spatial arrangement of land use and land cover changes over time. It is an interdisciplinary science that combines insights from the spatial sciences and land change science to inform one another. This synergy has begun but has much room for growth.

**Landscape and application**

Finally, advances in almost all facets of land change science have developed in tandem with land-based research in landscape ecology. The major distinctions between the two are landscape ecology’s emphasis on the ecological consequences of land change, especially on ecosystem function and ecosystem services, relative to that of land change science. Both subfields, however, share an interest in how changes in ecosystem services affect human wellbeing and sustainability in general (Wu 2013). In this regard, these two research communities have begun to address changes in land systems and landscapes as a means to mitigate and adapt to environmental change, global to local in kind, consistent with the international and integrated research efforts of the Future Earth program. Special attention is given to the environmental and socioeconomic consequences of policy interventions on land systems, such as REDD+ on the retention of tropical forest through direct payments, and to the design or reconfiguration of land systems, including those in urban-suburban areas, accounting for environmental tradeoffs to inform sustainability decisions.

Land degradation

Lindsay C. Stringer
University of Leeds, UK

The United Nations Convention to Combat Desertification (UNCCD) defines land as “the terrestrial bio-productive system that comprises soil, vegetation, other biota and the ecological and hydrological processes that operate within the system” (UNCCD 1994). Land degradation describes a broad range of processes, operating across scales, from the local to the global, that cause a reduction in the quality, complexity, and functions of land and its cultural, recreational, and heritage values. Some land degradation processes are relatively fast-acting and move quickly, for example, soil erosion following an extreme weather event. Other land degradation processes move slowly, operating over longer time frames, for instance, nutrient and organic matter losses. While some people view land degradation as an end point, it is more commonly seen as a process, with degradation occurring once a particular tipping point or threshold has been exceeded.

Broadly, land degradation takes three main forms which may occur separately or in combination. The first form is biological degradation, in which soil biota and biodiversity (including bacteria, fungi, algae, protozoa, nematodes, and insects) are lost due to changes in vegetation, temperature, and moisture that alter the amount of organic matter in the soil. The second form is the physical degradation of land. In this case, the land surface is removed by water or wind erosion, or is altered or damaged in situ by processes such as compaction (e.g., due to plowing) or sealing (covering of the soil with impervious materials). The third form is chemical degradation, linked to nutrient losses, salinization, or contamination. Each form of degradation can reduce the ecosystem services and economic benefits that society can gain from the land, both during the present time under the current land-use system and into the future. Many published definitions distinguish land degradation from environmental change by emphasizing that degradation is part of a long-term negative trend in the particular context of an area’s land-use system. Some forms of land degradation are effectively permanent. For example, degradation in the form of bush encroachment is permanent unless actions are taken to clear the bushes.

Land degradation is considered to be an important threat to sustainable development. It is of particular concern in light of an increasing global population and climate change which lead to growing competition for land and water, particularly for use in food and fuel production. The maintenance of land quality and its functions underpins food production and climate regulation as well as providing the basis of livelihoods for billions of people across the world. It is therefore seen as imperative that actions are taken to prevent and reverse land degradation, and rehabilitate degraded areas where it is economically viable.

Land degradation is caused by different interacting drivers in different places. It is widely accepted to result from a combination of human and environmental (including climatic) factors. Large- and meso-scale climate and hydrological processes and patterns are superimposed with sociopolitical and economic structures and processes such as markets, property rights,
LAND DEGRADATION

Technological changes, population and demographic changes, and human migration. These interact with current and historical land-use and land management practices at smaller spatial scales (e.g., watershed or farm scales). The effects of land degradation can be experienced directly at the landscape site at which the degradation occurs, as well as indirectly in other places, for example, through increased food prices, food insecurity, and water quality decline, as well as reduced ecosystem service provision at larger scales.

Policymakers often need to know what land degradation costs in order to determine how much to invest in addressing and preventing the problem. The diffuse nature of degradation impacts means that assessment methodologies are required that measure the costs of land degradation both on- and off-site. Some methodologies, such as total economic value (TEV) approaches (e.g., Turner et al. 2003), consider the costs and benefits of actions to mitigate degradation, to rehabilitate and restore degraded areas, as well as to instigate a shift toward more sustainable land management practices. TEV approaches can also encompass the costs and benefits of inaction against land degradation.

People who heavily depend on the natural resource base to support their subsistence are considered most vulnerable to the impacts of land degradation. While it is often presented as a developing world problem, affecting primarily agricultural economies, land degradation is an issue for several different sectors and occurs throughout the world. For example, transport and industry (including mining and ore smelting) can cause chemical land degradation through the emission and deposition of sulfur oxides and nitrous oxides. These chemicals acidify soils, damage vegetation, and negatively affect water quality in places far away from the original site of emission. Similarly, physical degradation in the form of soil sealing can occur as a result of infrastructure development and urbanization, as the land surface is covered with impervious materials, reducing, among others, its climate regulation and water purification functions. In Europe, nearly 10% of the total land area is estimated to be covered with impermeable material. Projected trends in population growth and migration suggest that soil sealing due to urbanization will continue into the future, in both developed and developing countries.

Whether land degradation is seen as a problem in need of remediation or not depends largely on the context and scale of analysis (Warren 2002). Land degradation for one group may be seen merely as an environmental change for another (Blakie and Brookfield 1987). This gives the management of land degradation a clear political dimension in many settings in which it occurs. Degradation takes place when the economic and ecosystem service benefits that people obtain from the land are negatively affected in the context of the local land-use system. For example, the encroachment of woody species in rangeland areas (unrelated to rainfall patterns and dynamics) may be seen as an environmental change by scientists. Yet, pastoralists who require a variety of grass species to feed their livestock may see that change as land degradation, in the context of their local land-use system. For them, bush encroachment represents a change in vegetation cover and community species composition and complexity, and has a negative economic and livelihood impact.

Various attempts have been made to estimate the extent of land degradation in recent decades. However, each assessment has used different methods, measured different variables over a range of temporal and spatial scales (using different indicators), and has focused on different systems. This makes comparison between the various assessments highly challenging. For
example, the Millennium Ecosystem Assessment (2005) estimated that 10–20% of the world’s drylands are degraded (with medium certainty; 65–85% probability), while Oldeman, Hakkeling, and Sombroek (1991) looked across all climatic zones in their global assessment of soil degradation (GLASOD) and suggested that 3.5 billion ha of land is suffering from soil degradation. The wide variation in these figures that focus on different systems and different components of land means it is difficult to identify the precise magnitude and speed of land degradation, as well as to ascertain the urgency with which it needs to be addressed.

In recent decades, emphasis has been placed on multispectral remote sensing analyses that allow calculation of the greenness of live canopy vegetation, using the normalized difference vegetation index (NDVI). Live, healthy, green plants reflect in the infrared part of the electromagnetic spectrum. The NDVI ratio is ascertained by dividing the difference in near-infrared and red color bands by the sum of the near-infrared and red colors bands for each pixel in an image. Although NDVI analyses provide useful insights that other methods cannot attain, the limitations of the approach are now widely accepted. These include, for example, acknowledgment that NDVI cannot determine vegetation height, making it difficult to tell the difference between grass-dominated rangelands, bush-encroached areas, and expanses of natural tree cover. Ground truthing is required within the local land-use system, alongside evaluation of meteorological data, particularly in dryland systems given their high levels of rainfall variability. Such additional layers of information are vital, particularly for time-series analyses, because without them, it becomes impossible to determine whether any change in green vegetation cover over time is due to land degradation, or whether it is due to changing rainfall patterns, changing land use, or changing land management practices.

Due to the challenges associated with measuring land degradation directly, using any single method, reliance tends to be placed on indicators, which assess a range of slow and fast variables. Indicators allow focus on a particular state or trend, and can be used to explain how land degradation is changing both temporally and spatially. Indicators also permit measurement of the antithesis of land degradation: sustainable land management (SLM). Many groups consider that focusing on SLM is more useful than measuring land degradation. This is because donors and investors, interested in improving the land quality, often want to know the extent to which their efforts are improving the land in relation to the baseline situation.

The international political community has agreed to strive toward land degradation neutrality by 2030 as part of commitments to the Sustainable Development Goals (2015, Goal 15.3). In order to be able to monitor progress toward this, agreement will be needed as to which variables and processes should be measured and at what scale(s) assessments should be carried out for the various types of land degradation. This, however, remains challenging. Land degradation is difficult to assess and compare across contexts, not only because of differing interpretations of what constitutes degradation, but also because the type of degradation experienced in one location may differ from that occurring elsewhere. For example, some parts of the world suffer from salinization due largely to inappropriate irrigation, while others may be experiencing soil erosion in the form of gullying due to a combination of overgrazing, fire, and extreme weather. Such diversity implies that different indicators will be appropriate to different contexts.
LAND DEGRADATION

Historically, indicators have been developed by scientists to allow assessment of the various land degradation forms. However, the UNCCD – the main international treaty that deals with land degradation – notes that the locally held knowledge of dryland communities can assist in recognizing, coping with, and adapting to degradation by anchoring indicators more securely in the context of local socioeconomic and land-use systems. Consequently, researchers have recently sought to combine scientific rigor and accuracy with greater relevance and sensitivity to local perspectives and context, in their use and development of indicators (Stringer and Reed 2007). Delving into locally held knowledge can also provide valuable insights into traditional SLM measures. These can include agronomic, vegetative, structural, and/or land management measures that help to maintain productivity and sustain the land’s physical, biological, and chemical properties. They include, for example, green manure and cover crops, intercropping, the use of stone bunds, and low or no tillage treatments. Such SLM measures are often locally appropriate, inexpensive, and can be tested by researchers with regard to their upscaling and applicability to larger areas. Computer models that consider the biophysical and economic characteristics of a particular area can be used to ascertain the feasibility of upscaling particular SLM measures. The findings of modeling exercises may then be usefully evaluated with stakeholders, allowing appraisal of their applicability within different local social and cultural contexts.

The international community has acknowledged that land uses and land management practices are shaped by interacting processes and decisions made at scales from the local to the international. This led to the negotiation of the UNCCD as a framework for international, regional, sub-regional, and national action to address land degradation, desertification, and drought. The UNCCD was one of the three Rio Conventions, agreed upon at the UN Conference on Environment and Development (UNCED) in 1992 (alongside the UN Convention on Biological Diversity (CBD) and the UN Framework Convention on Climate Change (UNFCCC)). Although the UNCCD is international in its scope, it places particular focus on desertification, land degradation, and drought in Africa and the arid, semiarid, and dry subhumid parts of the world, reflecting the understanding that the world’s drylands (i.e., arid, semiarid, and dry subhumid areas) are considered particularly vulnerable to land degradation. Countries that are party to the UNCCD and which consider their territories to be affected by land degradation are obliged to develop a national action program (NAP). NAPs identify the types and locations of land degradation in each country, alongside the actions necessary to prevent and reduce degradation, and to rehabilitate already degraded areas. The UNCCD further notes the need to draw on a range of different scientific and locally held knowledges about land degradation given its contextual nature. As such, it advocates an approach to NAP development that involves the active participation of affected land users.

Although the UNCCD entered into force following its fiftieth ratification in 1996, it has been widely criticized for its limited on-the-ground impact in terms of reversing, preventing, and reducing land degradation. Because it is grounded in soft law, there are no sanctions should parties to the agreement fail to meet their obligations. Consequently, the UNCCD has suffered from limited donor resources and, in many countries, a lack of institutional, financial, and human capacity for NAP development and implementation (Bauer and Stringer 2009). The challenge is further complicated because land degradation touches on so many sectors, ranging
from forestry, agriculture, water, energy, and mining to health, education, and development. This means that cross-sectoral capacity building is required. However, many capacity building investments by donors to date have been sector or issue specific (Akhtar-Schuster et al. 2011). In some countries, national focal points (those individuals responsible for interfacing with the UNCCD on behalf of their countries) are based in weak ministries. This provides a further limitation. In countries where tackling land degradation has limited political resourcing and capacity, the role of nongovernmental organizations (NGOs) becomes more important in raising funds for and implementing projects that tackle land degradation issues. Indeed, NGOs play a vital role in UNCCD implementation activities across the world.

At the international level, donor resources are perceived to be more easily available and accessible for initiatives under the CBD and UNFCCC. However, the problems dealt with by these conventions set at Rio are thought to be more clear-cut than that of land degradation. For example, the UNFCCC tackles climate change, a problem that can be clearly defined (i.e., rising average temperatures related to an increase in atmospheric CO₂ levels). It is relatively straightforward to set a target to reduce greenhouse gas emissions by a certain amount by a particular date and to monitor progress made toward that goal. Furthermore, the atmosphere is more obviously an open-access common property resource, changes to which by one group of actors will affect others. Land degradation is complicated because land is often seen as a national concern, which is subject to national laws and regulations (and their enforcement). Despite various different property rights that enable the sale or rent of land, many countries are reluctant to sign up to any agreements that could ultimately interfere with the ways in which their territory is governed. Indeed, even within the European Union, agreement recently failed to be reached on the development of a soil framework directive (which focused on only soils – just one element of land). Some member states felt that land matters should be managed at the lowest possible governance level in line with the subsidiarity principle. Consequently, discussions on a soil framework directive have currently been halted.

A further challenge to taking a common approach to tackling land degradation links to the ways in which the problem is measured, monitored, and communicated. The multisectoral nature of land degradation demands scientists take interdisciplinary and multidisciplinary approaches in defining both the extent of the problem and the urgency with which action needs to be taken (Stringer and Dougill 2013). Unlike the UNFCCC, which receives regular scientific updates from the Intergovernmental Panel on Climate Change (IPCC), and the CBD, which is supported by the Intergovernmental Panel on Biodiversity and Ecosystem Services (IPBES), the UNCCD’s institutional structure has historically hampered the ability of the scientific community to draw together a fragmented, multidisciplinary science base and channel research on land degradation into policy solutions. A decision by the UNCCD’s eleventh Conference of the Parties (COP-11), held in Windhoek, Namibia, in 2013 nevertheless marks an important step forward, with parties’ recognition of the need to develop an improved science-policy interface to bring together the current state of knowledge on land degradation and sustainable land management. It is hoped that this initiative will underpin efforts to deliver a reduction in land degradation and a widespread shift toward SLM.

Recent land systems science (LSS) literature refers to interdisciplinary and multidisciplinary research that improves our understanding of land-cover and land-use dynamics as part of coupled human-environment systems. It includes theoretical and conceptual advances, improvements in data sources and innovations in numerical modeling, and applications relevant to environmental and societal problems at local to global scales. Rounsevell et al. (2012) identify four multidisciplinary aspects of LSS: behavior of people and society, the multilevel character of decision-makers and of land units, the connections between people and land globally, and past and future change.

The origins of contemporary LSS lie in research conducted in international science and social science programs that were organized by International Geosphere Biosphere Program (IGBP) and the International Dimensions of Global Change Program (IHDP), in particular the Land Use and Land Cover (LUCC) and the Global Change and Terrestrial Ecosystems (GCTE) programs. LSS emerged as the preferred term under the Global Land Project (GLP) and through the Danish Network for Land Systems Research (Reenberg 2009). While these programs comprise the terminological family tree, other key influences on contemporary LSS include the Millennium Ecosystem Assessment and the National Science Foundation’s Coupled Natural Human Systems (CNH) program. The GLP, which is now part of Future Earth, set itself two major challenges. First, to improve our understanding of the complex feedbacks between societal and environmental components of integrated land systems; and second, upscaling local and regional process understanding to enable global process understanding.

The critical role of land surface changes in the Earth system is underpinned by a substantial volume of research conducted in the last three decades (Turner, Lambin, and Reenberg 2007, and references therein) and has enabled land-use and land-cover change to evolve into land systems science. LSS is important because the Earth system supports over 7 billion people with higher per capita standards of living than at any time in history. This is increasingly understood in terms of provisioning, supporting, regulating, and cultural (ecosystem) services, which though only termed ecosystem services recently, have been changing the Earth system through land system transformations locally across the world for over 60 millennia, but in terms of major global impacts since the seventeenth century.

LSS has four objectives (Turner, Lambin, and Reenberg 2007): first, to increase our ability to observe and monitor contemporary land changes. Improvements in and better access to satellite image data, image archives, and innovations in information extraction have brought about improved surveillance. Though satellite image data is not the only data source for land systems science, it has a primacy that has survived the transition from land-use and land-cover change to LSS; second, to enable land system changes to be understood in an
integrated and holistic framework that couples human and natural systems; third, to provide spatially explicit modeling of land change, which has become a necessity because of the complexity of the parameters required to monitor and understand change, and the feedbacks between parameters. The requirement for spatially explicit modeling, as against nonspatial modeling, arises because of the availability of spatial datasets and the continued developments in GIS. Turner, Lambin, and Reenberg (2007) state that land change science is played out at the interfaces of social science, natural science, and geographic information-remote sensing science; and finally, to assess and evaluate land system outcomes in arenas that matter to society globally; arenas such as vulnerability, resilience, and sustainability.

The complexities in researching any of these objectives, but particularly the latter three, lie in the fact that land change trajectories, and therefore Earth system change pathways, are governed by local- and regional-scale human actions which involve interactions between decision-making, institutions and mechanisms of governance, patterns and trends in production and consumption of ecosystem services, technological development and diffusion, and the local and regional impacts of global environmental change. Moreover, once mapped and understood, these local- and regional-scale decisions have to be scaled up to understand their influences on LSS globally.

Rounsevell et al. (2012) identify three emerging questions to be addressed in the next phase of LSS. First, how can the analysis of empirical and historical land system datasets provide insight into human–environment interaction? Second, how can integrated modeling and the ecosystem services concept contribute to the testing of hypotheses about land system functioning and decision-making? Third, how can our current understanding of land systems inform the choices that society has about future landscapes? The first question is interesting as it creates a space for historical geographers within LSS and the ability to understand past land-use decisions which will help explain the current state of the land units, as well as providing better datasets for model testing and validation. The second question acknowledges the increasing integration of land system science with ecosystem services. The final question underlines the importance of this academic project to the future of Earth and its people, a point acknowledged by its inclusion in Future Earth.

LSS is situated in a strategic area of geographical enquiry – the nature–society divide. Its interdisciplinary and multidisciplinary nature suggests many disciplines have large stakes in LSS: yet geographers have been influential in the development of LSS globally, and continue to be at the forefront of the development of theory and practice in LSS.

Landforms and physiography

David R. Butler
Texas State University, USA

Richard A. Marston
Kansas State University, USA

Landforms are recognizable topographic features on the surface of the Earth with a distinct shape and position in the landscape, as well as a characteristic local relief, composition of geologic materials, age, and processes of formation, maintenance, and change. Landforms are commonly found in assemblages that geomorphologists term a landscape. Landforms result from the interplay of the resisting framework, driving forces, and time. By resisting framework is meant the geological and biological features on which processes act, including lithology (rock type), stratigraphy (the layered sequence of rock types), and geologic structure (the geometry of rocks). Vegetation exerts resistance to landform change through effects such as the root-binding effects on soils, and the roughness against wind and flowing water. Driving forces refer to the endogenic processes of vulcanism and diastrophism (uplift, folding, faulting); the exogenic processes (weathering, erosion, transport, deposition) controlled by the agents of water, wind, ice, gravity, and biota; and the extraterrestrial processes (meteorites, asteroids, comets). Time refers to development of landforms over time. Because the resisting framework and driving forces both change over time, landforms can be active or relict, having formed under a former set of conditions. More often than not, landscapes are assemblages of landforms that are polygenetic in origin, that is, relict landforms are inherited from prior situations and are being modified by current processes. Almost all landforms observed on Earth today have been created during the Cenozoic Era, or last 65 million years. A relationship exists between the size of a landform and the length of time over which it typically develops. The difficulty in predicting (or reconstructing) landform change over time is nicely explained by Phillips (2007). On the one hand, all landscapes develop under the laws of chemistry and physics. On the other hand, each landscape develops with its own history of environmental perturbations that render each landscape as perfectly unique. The search for the “Theory of Everything” in geomorphology remains elusive as a result.

The earliest book on physiography can be attributed to the Scottish science writer Mary Somerville, who authored a book in 1848 titled Physical Geography, which featured detailed reporting on the topography of each continent. Thomas Henry Huxley published a book titled Physiography in 1877 in Britain, after which physiography became one of the most popular subjects in geography (Holt-Jensen 1999). In the United States, the earliest effort to describe regional geomorphology was authored by John Wesley Powell (1896) and included a map that was adopted by other geomorphologists in subsequent efforts. The term “physiography” was coined as a contraction of the words “physical geography” and was a steadfast part of academia in the early twentieth century.
Figure 1  The physiographic provinces of the contiguous United States, following the boundaries of Fenneman, with subdivisions. US Geological Survey (USGS) map colored by paleogeological areas and demarcating the sections of the US physiographic regions: Laurentian Upland (area 1), Atlantic Plain (2–3), Appalachian Highlands (4–10), Interior Plains (11–13), Interior Highlands (14–15), Rocky Mountain System (16–19), Intermontane Plateaus (20–22), and Pacific Mountain System (23–25). Reproduced from USGS.

The term physiography was clearly intended to serve as an overarching term for the universe of concepts typically taught in physical geography classes, including geodesy, meteorology, climatology, soils, plant distributions, and geomorphology. Widely used textbooks from the early twentieth century (Tarr and Martin 1917; Salisbury 1929) used the term physiography in their title and were topical compendiums of the entirety of the field of physical geography. However, after the publication of Isaiah Bowman’s *Forest Physiography* (1911), the field of physiography began to change and to mean regional physical geography. More specifically, the term began to mean regional geomorphology as associated with the boundaries of physiographic provinces as a result of the works of Nevin Fenneman, who was appointed by the Association of American Geographers in 1914 to chair a committee tasked with preparing a map of the physiographic divisions of the United States. The boundaries of the US physiographic provinces, which encompass regions with similar geomorphological histories and landforms, became standardized (Figure 1) and were subsequently the topics in Fenneman’s landmark volumes on the
physiography of the western (Fenneman 1931) and eastern (Fenneman 1938) United States. Beginning in the 1930s, Hungarian born Erwin Raisz produced thousands of maps and two atlases featuring landforms drawn with pen and ink for all regions of the world. Books by Atwood (1940), Thornbury (1965), and others continued the regional geomorphology (physiography) tradition in the United States well into the period when process geomorphology was becoming a dominant paradigm in the discipline. As part of the celebration of the centennial of the Geological Society of America, Graf (1987) edited a volume titled *Geomorphic Systems of North America* with 13 chapters that describe regional geomorphology and also synthesize process-based research for each region.

Vitek, Giardino, and Fitzgerald (1996) traced the changes in mapping landforms from paper mapping, through computer mapping, to virtual reality. The availability of digital elevation models (DEMs) has led to an area of research known as geomorphometry, where derivative properties of landforms can be measured. These properties, such as slope angle, slope aspect, slope curvature, and channel networks, can then be delineated for watersheds. Global DEMs are available from the shuttle radar topographic mission (SRTM), with 1 arc-second (approximately 30 m) horizontal resolution and vertical resolution in meters. Laser ranging surveys (LiDAR) are acquired with aircraft that can produce submeter spatial resolution. Accurate, high resolution (±1 m vertical) even exist for Mars. Starting with sampling land surface data from a DEM, a land surface model (landscape) can be generated and soil, hydrology, and land use/land cover can be added to the model. Remotely sensed data can be draped over the land surface model (Figure 2).

Bailey (1983) and Omernik (1987) introduced the concept of ecoregions, which are mappable units derived by integrating maps of physiography, soils, geology, potential natural vegetation (or land use/land cover), hydrology, climate, and wildlife. The schemes of both Bailey and Omernik are hierarchical in scale. Bailey tended to rely on one or two subject maps at each of the different levels in his hierarchy, whereas Omernik attempted to integrate most of the elements of the landscape. Ecoregions provide a template for designing field sampling schemes or formulating regional, continental, or global-scale geomorphic comparisons (Simon, Dickerson, and Heins 2004). Ecoregions more clearly represent regional physical geography to a greater extent than did the early classic books on the subject cited earlier, because ecoregions recognize that the landscape consists of landforms interacting with other elements of the landscape. Hence, ecoregions represent another step in the regional study of landforms and offer linkages between the study of geomorphology and the fields of biogeography and ecology (Figure 3).

Landforms of other planets

René De Hon
Texas State University, USA

While resolutions and coverage of the surfaces vary considerably, the terrestrial planets and most large satellites of the outer planets have been imaged in sufficient detail to recognize their major landforms. Satellite-borne radar altimetry and imaging radar provide elevation data and images of surfaces hidden by an atmosphere. Physiographic maps at varying scales have been prepared for all of the planetary bodies that have been imaged by spacecraft. The first venture into describing and interpreting a landscape other than the Earth’s was by telescopic examination of our nearest neighbor, the Moon. Modern telescopic viewing limits resolution of lunar landforms to about 500 m. Landforms of other planets and satellites are identified by spacecraft imaging, which began in the 1960s and continues with increasing detail at this time. Table 1 provides a list of terms applied to various landforms in naming features on the planets.

Four chief groups of processes shape planetary surfaces: tectonism, volcanism, gradation, and meteor impact. Volcanism and tectonism are products of a planet’s internal temperature distribution and density variations which drive mantle convection. As the planetary body cools, that engine shuts down and internal movements cease. The lifetime of that engine is a function of planet size, as small bodies lose heat much more rapidly than large bodies. External processes are tied to surface gravity, atmospheric interaction with rocks, and infall of meteoric debris from space. Planetary bodies without significant atmospheres tend to preserve primitive landscapes only slightly modified by erosion. Table 2 summarizes the land-shaping processes observed on the various planetary bodies.

Outer surfaces of terrestrial planets are composed of rocky (silicate-rich) materials. Their early history records volcanically generated surfaces which were highly cratered by meteor impacts. Planets evolved along divergent paths dictated by differences in size, internal thermal cooling, atmospheres, and distance from the Sun. Large bodies such as Earth and Venus retain sufficient internal energy to reshape the surface within fairly recent geologic timescales. Smaller bodies such as Mercury and the Moon, having lost most of their internal energy, retain landforms generated during their earliest history. Mars, intermediate in size, retains some of its early cratered crust, but it exhibits an extended period of volcanism and hydrologic modification of the surface. The gas giants of the outer solar system retain primordial gases and have no clearly defined surface.

Satellites of the outer planets include a few extremely unique bodies such as Io’s active sulfur volcanism and Titan’s hydrocarbon lakes. Most large satellites have surfaces of ice or ice-rock mixtures. Landforms are impact craters and fractured ice terrains. Some icy surfaces are resurfaced by more recent eruptions of liquid water to form smooth, icy plains that have lost all evidence of early impact-dominated terrains.

Major physiographic provinces

Many planetary bodies can be divided into major physiographic provinces based on average elevations, origin of landforms, extent of cratering, or relative age of surface materials. Planetary bodies that retain surfaces from their earliest history usually have heavily cratered surfaces and later, volcanic plains materials. Planets with active tectonics and atmospheric-driven erosional processes may have lost evidence of extensive cratering.

Major provinces are seen as variations in the style of volcanism or tectonic deformation (Figure 1). Mercury is divisible into intercratered plains, heavily cratered terrain, and lightly cratered plains. Venus consists of mostly lowland, basalt plains with a small percentage of continental-like crustal plateaus surrounded in part by intermediate elevation shelf. Earth has distinct continents and oceans. The Moon consists of bright, cratered highland terrae and dark, low-lying maria. Mars is divided into a cratered upland and sparsely cratered lowland separated by a planet-encircling escarpment. Straddling the dichotomy boundary in Mars’s western hemisphere is a massive volcano-tectonic province known as the Tharsis bulge.

Landscape-forming processes

Meteoric and asteroidal impact

The early solar system was awash in asteroidal debris in planet-crossing orbits. Early planetary surfaces were subjected to intense bombardment that saturated surfaces with overlapping craters of

Figure 1  The topographic maps of Venus (NASA/JPL Magellan Laser Altimeter), Earth (NASA, USGS), and Mars (NASA/JPL Mars Orbiter Laser Altimeter). Venus and Earth have relatively high-standing continents surrounded by low-elevation plains. Neither planet preserves ancient terrains from the early period of meteorite and asteroid bombardment. Mars exhibits a sparsely cratered, low-elevation, northern plains and a higher-standing, highly cratered southern highlands. Reproduced from NASA and USGS.
LANDFORMS OF OTHER PLANETS

Figure 2  The far side of the Moon displays the heavily cratered surface associated with high impact rates from the early period of high-impact flux (NASA Apollo 16 photograph). Reproduced from NASA.

varying sizes (Figure 2). As planets cleared their immediate vicinities and orbits of debris, impact rates declined to the present very low frequency of impacts.

The relative velocities of meteors in planet-intersecting orbits are very high in respect to planetary surfaces. Impact at hypervelocity (velocity greater than the of speed of sound in the target) results in a near instantaneous conversion of kinetic energy of the meteorite’s mass and velocity to shock and heat energy in the target. The result is total destruction of the meteorite and excavation of an explosion crater surrounded by a rim of material ejected from the crater. Young craters typically have high albedos and sharp topographic features. They are also associated with crater chains of secondary impacts and bright ray patterns radiating away from the crater for great distances.

Crater morphology is a balance between impact energy, target material strength, atmospheric interaction, and planetary gravity (Melosh 1989). Small objects do not survive passage through an atmosphere. Large bodies that pass through the atmosphere retaining most of their kinetic energy leave indelible scars on the surface. Small craters, less than 5–20 km, are simple, bowl-shaped depressions with a well-developed raised rim. As impact energy increases, crater diameter increases and the crater develops terraced interior walls, a flat floor, and a central peak. At greater impact energies, the central peak breaks into multiple peaks and transitions into an inner ring of peaks. At still larger impacts, multi-ring basins greater than 100 km in diameter are created. Weird terrain is the vernacular term given to hilly and furrowed terrain antipodal to the Caloris Basin of Mercury. It is thought to have been formed by the convergence of shock waves from the Caloris impact.

Crater topography degrades over time. Crater rims are lowered, rays fade, secondary craters are lost, interiors fill with material eroded from the rims, and the number of superposed craters increases. Extremely old craters and basins may be reduced to faint circular features of little relief. On rocky planetary bodies degradation is accomplished by various erosion processes, including repeated impact of more recent craters. On icy bodies, basins are degraded by topographic relaxation in weak substrate materials (Schenk 1991).

Earth and Venus preserve a small number of craters because they have young, tectonically active surfaces. Portions of Mercury, the Moon, Mars, and many satellites of the giant planets retain heavily cratered surfaces from the early period of high impact flux. Heavily cratered moons of outer planets display surfaces of dark, ice-rock mixtures which are highly cratered. Small satellites and asteroids are little more than
irregular chunks of rock pitted by repeated impacts. Many are remnants of larger bodies that were broken apart by highly energetic impact with other large bodies.

**Volcanic landforms**

**Silicate volcanism**

Volcanism includes all processes by which material – gas, liquid, or solid – is expelled from the planet’s interior. Most planets were at least partially melted in their earliest history, allowing for differentiation and separation of materials into core, mantle, and crust components. Early volcanism spreads fluid lava across the planet’s surface to form vast, nearly featureless, volcanic plains. The timing and duration of plains formation is largely controlled by the size of the body, which determines how rapidly it cools. On small bodies, this episode ceases early, while on relatively large bodies, basaltic plains formation and volcanic structures persist to late stages of the planet’s history.

Vast low-relief, lightly cratered surfaces of planum and planitia on Venus and Mars and maria of the Moon (Figure 3) are formed of highly fluid flood basalts emplaced after the period of high impact rates. Slightly more viscous lavas build low, broad shields as seen on Venus, Earth, and Mars. Less fluid lava and lava extruded at low expulsion rates tend to build surface constructs as domes, cones, and caldera. The morphology of these features is a function of rates of extrusion, gas content, and silica content. Thus a range of features varying from very low, broad, basalt shield cones to steep-sided, andesite stratovolcanoes and rhyolitic explosion craters is possible. Most planetary volcanoes are simple shield cones similar to Hawaiian volcanoes. At small scales, individual lava flows and flow fronts are distinguishable, and lava channels incised into the surface of some planets can be observed.

Venus displays a wide range of volcanoes (Head et al. 1992), including eruptive shield volcanos (Figure 4), complexly fractured volcano-tectonic structures (coronae), and low, flat pancake domes. Radar-bright, rugged flows are found associated with volcanic constructs and rift zones, and as impact melt from large craters. Because the surface of Venus is so hot, lavas are able to cut very long lava channels across its surface.

Volcanism on Mars is represented by large shield volcanoes, wide, relatively low patera, and volcanic plains (Figure 5). Olympus Mons, 20 km high and 600 km in diameter, is the largest volcano in the solar system. Individual flows and flow fronts are identifiable in several regions.
LANDFORMS OF OTHER PLANETS

Figure 4 Radar image of the Sapa Mons on Venus. Radar-bright surfaces are rugged materials and radar-darker surfaces are smooth materials. Lava flows extend from the shield volcanoes on to the surrounding plains material. The scarcity of impact craters indicates that the surface is relatively young (NASA/JPL Venus Orbiting Imaging Radar). Reproduced from NASA.

Nonsilicate volcanism

Volcanism in the outer solar system is quite diverse. Io, the innermost satellite of Jupiter, has a diameter of 3660 km. Tidal flexing provides a continued input of energy that melts a large portion of Io. The surface is covered with very young flows and more than 400 active volcanoes (Figure 6). The surface consists mostly of plains of overlapping sulfur flows which color the surface in varying shades of yellow, red, white, black, and green due to the many polymorphs of sulfur and its compounds.

Cryovolcanism is common on the icy satellites of outer planets (Kargel 1995). Jupiter’s moon Europa, 3120 km in diameter, has the smoothest surface in the solar system. Its surface is a bright blue-white of water-ice crisscrossed by large fractures. Only a few impact craters survive. The youthful surface is maintained by tidal flexing, which allows a sub-ice water ocean to exist. Fractures in the icy surface allow for frequent resurfacing events. A few large areas of chaos occur in which the surface has been disrupted and large blocks of grooved ice float in a hummocky frozen ocean (Figure 7). Ganymede, at 5260 km in diameter, is the largest of the Galilean moons. The surface appears to be composed of an ice-rock mixture that is dominated by heavily cratered terrain and large patches of young, bright, grooved terrain (Figure 8). The grooved material is formed by floundering of old crust and flooding with liquid water from the interior. The bright satellites of Uranus, Titania, and Ariel are surfaced with fractured ice also.

Triton, the largest moon of Neptune, is 2706 km in diameter and has a very thin
atmosphere of nitrogen and methane. Its surface is poorly resolved by spacecraft imaging. An ice cap of frozen nitrogen covers much of the southern hemisphere. No heavily cratered terrain is preserved on Triton. Highly grooved surfaces were probably formed by repeated fracturing and subsequent filling with viscous volcanic ice or flooding by mixtures of molten ices of water, methane, or nitrogen. The Voyager 2 spacecraft imaged erupting plumes of dust entrained in nitrogen.

**Figure 6** The multicolored surface of Io shaped by sulfur volcanism. Active eruptions are marked by eruptive centers surrounded by dark haloes and by the plume of eruptive materials seen on the limb (NASA/JPL Cassini spacecraft). Reproduced from NASA.

Tectonic landforms

Tectonics includes all processes causing deformation of a planet's crust. On Earth, the movement of convective cells in the mantle leads to shifting of ridged plates on the surface. This system of *plate tectonics* began about 2.5 billion years ago when the crust obtained sufficient rigidity. Interaction along the plate edges is responsible for most of Earth’s large structural features. Plate interiors are only lightly deformed. The smaller terrestrial planets (Moon, Mercury, and Mars) have thick lithospheres that show little tectonic deformation over much of their history. Although plate tectonism is not observed on the other planets, convective movement in the interior and intrusions of igneous material into the crust are responsible for stresses in the crusts. Grooved and furrowed (Figure 8) terrains are formed on the surface of icy bodies by convection cells in underlying oceans (Hammond and Barr 2014).

The most common structural elements observed on the planets and their satellites are *scarps* produced by normal faults attributed to extension in the crust. A few tens of meters to several kilometers in relief, they occur singularly or paired as opposing scarps to form fault troughs (graben). Long, narrow fault troughs, called *rilles*, are common features on many planetary bodies (Figure 4).

Parallel low scarps, narrow graben, and large rift zones are indicators of tension in the Venusian crust. *Rift zones* consisting of complex graben formed of multiple inward-facing scarps are probably formed by extension above upwelling convection cells. Also on Venus, distinctive volcano-tectonic rings called *coronae* are formed above upwelling plumes in the mantle. Large coronae are circular features 200–600 km across consisting of gentle domes with superposed concentric fractures outlining a central depression.
Compressional stress is manifested by folded strata and thrust faults. On Earth, structural disturbance is revealed by deformed strata modified by erosion of materials of different resistance. Compressive stress, primarily at the edge of convergent plate margins, is recorded by crumpling of the crust into a series of tightly folded anti-clines and synclines. The largest mountain chains on Earth, such as the Alps, Appalachians, and Himalayas, are linear fold belts several tens of kilometers to 100 km wide and several hundred kilometers to 1000 km in length. Local folding and doming also is associated with vertical movements of igneous magmas or salt doming in the crust.

Low ridges (mare ridges or wrinkle ridges) a few hundred meters high, a few kilometers across, and 10–100 km long occur on volcanic plains material on the Moon, Mars, and Mercury (Figure 1). Wrinkle ridges typically occur in
LANDFORMS OF OTHER PLANETS

Figure 8  Ganymede is the largest satellite of Jupiter and the largest satellite in the solar system. The surface consists of an older, dark, heavily cratered rock-ice mixture and bright, lightly cratered, grooved terrain (NASA/JPL Cassini spacecraft).

parallel to the edges of circular maria at the junction of the shallow outer shelf and deeper inner basin. They also form rings that mark the position of buried craters. They are interpreted as anticlinal, fault-propagation folds accompanying local thrust faulting created as basalt flows cool and contract. Sinuous lobate scarps on Mercury, Venus, Mars, and the Moon are the surface expression of thrust faults generated by global contraction (Watters et al. 2004).

Wrinkle ridges and folded ridge belts are evidence of compression stresses on Venus (Solomon et al. 1992). Major fold and thrust belts are often located at the margins of kilometer-high plateaus. Intensely disturbed highland plateaus are thought to have been subjected to compression above downwelling plumes in the mantle. Tesserae are complexly folded regions cut by later tensional fractures.
LANDFORMS OF OTHER PLANETS

Gradation

Weathering

Weathering is the process of breaking down surface rocks to smaller sizes. Weathering prepares surface materials for erosion and redistribution by gravity, wind, water, or ice. Weathering may be chiefly physical or may involve chemical changes in minerals by reaction with an atmosphere. Chemical weathering produces new stable minerals in equilibrium with the atmosphere. On Earth and Mars, weathering has produced clay minerals. Weathering on Venus is very different from that on Earth or Mars. The style of weathering varies with altitude on Venus. At high altitudes and low temperatures, sulfur in the atmosphere reacts with lava flows to form the mineral pyrite ($\text{FeS}_2$). Pyrite is highly reflective of radar waves and may explain why mountain peaks and high plateaus of Venus are radar bright. At lower altitudes and higher temperatures, magnetite ($\text{Fe}_3\text{O}_4$) and anhydrite ($\text{CaSO}_4$) may be the stable minerals produced by weathering. In the absence of an atmosphere, physical weathering is primarily in response to changes in temperature and fragmentation by impacts. On airless bodies, space weathering occurs by the bombardment of surficial materials by fast-moving atomic particles and shortwave radiation from the Sun and deep space.

Mass wasting

Mass wasting is the downslope movement of rock and surface debris under the influence of gravity. This process is universal; it operates on all planetary bodies. Movement may be aided by the presence of ice or water, but it is not required. At largest scales mass wasting is observed as landslides and slump scars on crater walls and other steep slopes. Iapetus exhibits long runout landslides, or *sturzstroms*, possibly supported by ice sliding. Massive landslide scars in the canyon system of Mars are characterized by huge concave scarpss on the canyon walls and long runout deposits on the canyon floors. The basal scarp and the *hummocky aureole materials* that surround Olympus Mons are likely lahars or submarine landslides. On Earth and Mars, rock glaciers consisting of angular rock fragments and interstitial ice form lobate masses that creep slowly downslope. Rock glaciers often form in valleys previously occupied by true glaciers. The result of creep is observed on most planets as the accumulation of an *apron of loose materials* at the base of slopes. Individual tracks of boulders rolling downslope are observed in high-resolution images of the Moon and Mars.

Fluvial landforms

Surface fluids

Flowing water or other fluids are an active agent in erosion and deposition. Detrital materials are removed from their site of weathering and moved to regions where the flow ceases. On Earth, liquid water is found in oceans, lakes, and rivers. Driven by solar energy and gravity, flowing water shapes distinctive landscapes. The surface is dissected by a multitude of gullies, streams, and rivers. Intervening drainage divides and basins become the dominant elements of the landscape. The premier landform associated with streams and rivers is the channel eroded by water over time. Channel morphology and drainage patterns on Earth provide insights into both surface configuration of the land and underlying controlling factors of geologic structure. Sediments carried by channel flow are eventually deposited as channel fill, deltas,
LANDFORMS OF OTHER PLANETS

or basin filling materials. Young drainage systems generally exhibit inefficient, nonintegrated drainage; whereas, long-term drainage tends to develop well-integrated systems of channels which are effective in draining large regions.

Early Mars had a thicker, warmer atmosphere than at present. Rain and snowfall delivered water to the surface as did possible outbreaks from the subsurface. Large catastrophic flood channels (Figure 5), sinuous sapping channels, and smaller dendritic systems are found primarily in the highland regions (Mars Channel Working Group 1983). Deltas and alluvial fans are found at the terminus of some channels. Later, a significant portion of water escaped to space and, as temperatures fell, the remaining liquid water became locked up in the pore spaces of rock and soil as groundwater or ice. Since that time it has been released by magmatic heating or meteor impact.

Titan maintains a thick, nitrogen-rich atmosphere. At 5150 km in diameter it is larger than the planet Mercury. Surface relief is low. Presence of liquid lakes, rivers, and oceans is confirmed by images from the spacecraft Cassini. The surface of Titan, described as “complex, fluid-processed, and geologically young,” is marked by broad regions of bright and dark terrain. These include Xanadu, a large, reflective equatorial area about the size of Australia. The convoluted region is filled with hills and cut by valleys and chasms.

Groundwater

Surface water seeps into the ground and moves beneath the surface in pores and fractures. It may re-emerge at the surface in springs and seeps. Water reacts with and dissolves some materials which are moved as ions in solution. Dissolved ions recombine to form new minerals as water evaporates or local chemistry changes to favor precipitation. Newly deposited minerals may form new bodies of rock, such as limestone formed in the Earth’s oceans, or they may form the cementing material that helps consolidate loose sediment.

Solutions of limestone or other soluble rocks by groundwater produces karst topography characterized by caves, sinkholes, and solution valleys. On Mars, chaotic terrain and large outflow channels, such as Maja Vallis (Figure 5), are thought to be formed by the sudden release of large volumes of water from the subsurface to the surface causing collapse of surface materials. Theater-headed, sinuous channels with short, stubby tributaries are cut by groundwater sapping.

Eolian landforms

Wind-related landforms are restricted to bodies that have an atmosphere and loose aggregates at the surface – Earth, Mars, Venus, Titan, and Triton. At low resolutions, eolian processes are seen as albedo streaks aligned with planetary atmospheric circulation patterns. At higher resolution, albedo streaks become windswept, bare rock areas or depositional mounds. Dune fields and individual dunes can be seen. Dune shapes and distribution provide information regarding prevailing wind direction and sand supply sources. Wind erosional features include shallow pits and hollows – blowouts – and elongate, wind-sculpted hills – yardangs. Imaging of active dust storms and dust devils yields information about local, near-surface wind patterns.

In the dense atmosphere of Venus, wind speeds at the surface are very low, but high atmospheric pressure allows for effective transport of surficial materials. Dune fields are identified on a very small percentage of the planet – only 0.004%. Wind streaks and possible yardangs are also identified.
LANDFORMS OF OTHER PLANETS

Even at telescopic resolutions, planet-wide dust storms are visible on Mars. In spacecraft images, wind action is evidenced by wind streaks, sand dunes, sand ergs, and large areas of erosional yardangs. The north circumpolar sand sea (greater than 700,000 km²) is larger than the largest sand sea on Earth (Breed, Grolier, and McCauley 1979). Dune fields are found elsewhere on the planet, including in many craters. Dune types vary from barchanoid sand sheets, barchans, and linear dunes, to small dome dunes. Erosion by wind includes dark wind streaks presumably formed by scouring the surface of loose sediments and regions of exposed rock shaped into yardangs. Dust devils are observed to leave scoured paths on the surface over which they have traveled.

Lacustrine and marine landscapes

Lacustrine and marine-related landforms require standing bodies of water or other liquids. The most common landform, and the one that is most easily resolved, is the lake bed itself. Lake beds are perhaps the smoothest level surfaces to be found on Earth. Lakes may also be inferred by the presence of inlet or outlet channels associated with craters and other closed basins as well as by the presence of deltas. Ocean or large lakes with sufficient fetch have distinctive shoreline features such as bars, spits, and wave-cut cliffs or terraces.

Although channels on Mars exhibit many points of intermittent ponding, overall drainage eventually empties onto the northern plains. An ocean has presumably existed for a time in the northern plains (Baker et al. 1991). The basal scarp of Olympus Mons may be a wave-cut cliff and the aureole deposits around the volcano may be evidence of submarine landslides (Figure 5). Currently, Titan is the only body other than the Earth to have stable bodies of liquid (probably methane and ethane) at the surface.

Ice-dominated landscapes

Glacial and periglacial landforms are seen on planets with atmospheres that contain water and on which temperatures fall below freezing for significant periods of time. A glacier is a large body of ice deformed by the pull of gravity. Continental or polar glaciers cover very large tracks of land; alpine or mountain glaciers are confined to valleys. Glaciers erode the surface over which they move and deposit materials at their terminus as ice melts. Periglacial activity is produced by freezing and thawing of water-saturated loose surface materials. Currently, glacial landforms and polar caps are only seen on Earth and Mars. Morainal deposits, ice wedge polygons, and pingos indicate a period of glaciation in the equatorial belt of Mars.

In contrast to terrestrial planets, many satellites of the outer planets are surfaced with ice or ice-rock mixtures. Some of these satellites (such as Europa and Dione) consist of an ice cover several kilometers thick over a liquid ocean. Many satellites exhibit low-relief, grooved and furrowed terrain suggesting large-scale fracturing and rehealing of an ice mantle (Figure 8). Water escaping to the surface along fractures freezes to form large featureless plains. Those satellites with ice-rock mixtures (such as Ganymede and Callisto) retain craters, although their relief is severely reduced by ice’s tendency to flow (McKinnon 1985). Those satellites with mostly water-ice at the surface have very few craters.

Landlocked states

Alexander C. Diener
University of Kansas, USA

Though a geopolitical condition known to all political geographers, landlocked states draw direct attention today largely in textbooks and from regional experts making specific case references. Rarely is a systematic analysis undertaken by border studies experts despite the fact that, at present, there are 48 landlocked states in the world including four partially recognized countries. Only Bolivia and Paraguay are outside of Afro-Eurasia. Europe contains 14 landlocked states including several that are rather prosperous by world standards. In contrast, the vast majority of landlocked states are considered “developing.” Thirteen African and four Asian landlocked countries rank among the United Nations’ 48 “least developed states” (UN-OHRLLS 2016). By this count, a third of the world’s poorest states have no coastline. Within the increasingly integrated system of global economics premised on minimal transport costs, lack of access to the sea is a major detriment (Collier 2008). This has not always been the case.

There have been times in history when isolation from the sea was valued as providing a measure of security from a wide range of dangers including hurricanes, tsunamis, pirates, and invaders. Changing transport technologies, however, catalyzed a reimagining of the value of sea access. For example, the relevance of overland routes between Europe and Asia known as the “Silk Road” was dramatically lessened by the advent of large seafaring vessels and the opening of ocean routes to the “Far East.”

Other advances in transport technologies were coupled with modifications to absolute sovereignty in favor of more liberal trade regimes in Europe. By the eleventh and twelfth centuries many European powers were giving access rights to landlocked countries and internationalizing rivers. By the nineteenth century, the heavy tolls and transit restrictions common to previous eras began to give way to recognition that development of industry and commerce required ease of movement. Railroads and other new forms of transport technology reduced the significance of waterways and offered new transit economies and bargaining power to landlocked states (Glassner and Fahrer 2004).

International conventions on transit in the early twentieth century sought to ensure access to the sea for Europe’s landlocked states. One of the more conspicuous efforts involved the creation of corridors through which landlocked countries would access short coastal frontages or navigable rivers. The most famous of these was the Polish Corridor, which proved more a geopolitical irritant than an economic salve. This period also saw important agreements forged concerning the transnationality of railways, pipelines, ports, power lines, and other transport facilities. What failed to manifest, however, was an international provision for freedom of transit to the sea and access to sea resources for noncoastal states.

Building upon the 1921 Barcelona Convention, Article 5 of GATT (General Agreement on Tariffs and Trade) and Article 33 of the Havana Charter incorporated transit provisions into an elaborate system of expanding world economies and bargaining power to landlocked states (Glassner and Fahrer 2004).
trade. The process of decolonization left many new states in Asia and Africa with limited or no coastal frontage. This condition inspired the 1964 Convention on Transit Trade of Landlocked States, which was the first international lawmaking conference to deal exclusively with the question of access to the sea. This convention heightened awareness of the plight of landlocked states and prompted its treatment within the United Nations Convention on the Law of the Sea (UNCLOS III 1973–1982). Though the focus of specific international law, the problems of landlocked states remain unsolved. Transit states retain the capacity to exploitatively or punitively enact sovereignty and thereby restrict resource, corporeal, and commercial movement across their respective territories.

Renewed efforts to improve the lot of the world’s landlocked developing states took form in the 2001 Millennium Development Goals and the 2003 Almaty Programme of Action (APoA). Integrating a wide range of actors (landlocked developing states, transit states, donors, private sector, international and regional organizations), the APoA places emphasis on five priority areas: (i) fundamental transit policy issues; (ii) infrastructure development and maintenance; (iii) international trade and trade facilitation; (iv) provision of development assistance and technical support from the international community; and (v) implementation and review. In the period since the APoA’s launch, development levels of landlocked states have improved (UN-OHRLLS 2013). Better roads, enhanced railways, larger ports, containerization, and cheaper fuel have opened vectors of transit previously unavailable, but establishing neoliberal regional institutions that would unencumber transit for landlocked states is far from a fait accompli. Moreover, to what degree such institutions can be achieved equitably and in an environmentally responsible manner remains a significant question.

While Switzerland stands as the foremost example of a successful landlocked state, the reality of most is more akin to the Kyrgyz Republic. Limited resources, politically assertive neighbors, black and gray market detractors from the national economy, and an unrelenting dependence on other states to facilitate exports and imports render the Kyrgyz Republic vulnerable. Like many other landlocked states, it possesses limited options in terms of geoeconomic policymaking and restricted prospects for development. At present no “right of innocent passage” exists on land as it does on the sea. Until it does, landlocked states will continue to be challenged by the territorial sovereignty of their neighbors.

Further reading

The term landscape ecology (in the original German *Landschaftsökologie*) was first used in 1939 by the German geographer Carl Troll as the name for a particular way of looking upon the landscape (*Anschauungsweise*) based on a holistic perspective integrating geographical and ecological insights into the nature of terrestrial environments (Troll 1939). Troll's previous research into the coupled relationship between vegetation, environment, and land use had brought him to conduct extensive fieldwork registrations of vegetation patterns in landscapes in Northern Europe. These experiences, in turn, had inspired him to take up aerial photography as an instrument to identify and describe spatial units of vegetation cover, the heterogeneous pattern of which he was then able to relate analytically to both social and environmental processes of change. On these foundations, Troll proposed a science of landscape processes that would be based on the new technology of aerial photograph interpretation, to classify the Earth's surface into discrete land units. On the basis of such inventory classifications, it was possible for Troll and his contemporaries to integrate analytical perspectives from a range of otherwise discrete sciences in their analysis of landscape processes. In this way, the development of landscape ecology, characterized by its specific focus on the ecological significance of spatial form and pattern, was closely associated both with the novel perspective provided by aerial photography and also with older geographical perspectives of analysis inherited from classical cultural and physical geography.

Troll had been trained in the traditions of geography defined by Alexander von Humboldt and Carl Ritter, the two great initiators of the field as a modern science in the first half of the nineteenth century. From them and their immediate successors he had picked up a certain breadth of scope and an interest in the interconnected nature of geographic phenomena, which he emphasized in his writings. He had studied the work of Humboldt and Ritter extensively and had been impressed especially by their ability to correlate natural and cultural phenomena. From Humboldt’s scholarship he had understood the need to abstain from disentangling research objects from their environment, but rather to delve into the multifaceted empirical relationships linking otherwise seemingly disparate elements with larger patterns of distribution and causality. For Troll and his contemporaries, it was never enough to understand the nature of a species or habitat type in its own right – the aim was to explain how species and habitats interact with each other and other facets of their environment, with reference to actual, empirical histories of change.

On this basis Troll was increasingly critical of the growing specialization of academic
geography in his day. Since the late nineteenth century the universalist approaches advocated by Ritter and Humboldt had been superseded in mainstream scholarship by an outspoken (and in Troll’s view unwarranted) reductionist stance towards the organization of scientific knowledge. Researchers within geography had sought to establish biological, physical, and demographic modes of analysis as distinct fields of research, and within these fields it had become the norm to seek for the smallest possible and most basic units of analysis in order to be able to study each environmental subprocess individually, as if in a laboratory. Troll saw this development as an understandable but tragic detour from the unified perspectives of earlier geography, and one that made it increasingly difficult to correctly observe and describe the cohesive, interdependent nature of geographic phenomena. Therefore, Troll sought to conserve and reformulate a unified perspective on terrestrial surface processes. Hence, landscape ecology from the outset was conceived as an approach to environmental research that was to be unrestrained by disciplinary and methodological dogma.

When, in 1959, Troll was asked to address the geographers of the British Association for the Advancement of Science on the centenary of the death of Humboldt and Ritter, he made his views on contemporary geography remarkably clear. In his speech he located the inspiration for a range of seminal landscape ecological concepts and instruments within the work of his two academic idols. These included: forms of spatial pattern analysis, which Troll became inspired to apply and further develop upon reading Humboldt’s pioneering work on ecological zones and associated patterns of plant distribution; the method of regionalization developed by Ritter, which Troll employed to classify heterogeneous areas (i.e., landscapes) into analytical units based on similar form, genesis or character; and types of early socioecological analysis developed by Ritter through his work on the relationship between land use, culture, and civilization (Troll 1960).

These concepts and instruments came to inspire the development of landscape ecology, as a counterbalance to the fragmentation or disintegration of geographic–ecological thought in the twentieth century that motivated landscape ecologists to establish their field as an explicitly integrative science. In the 1950s and 1960s, landscape ecology consisted of a synthesis of geography with soil science and ecology. From the late 1960s especially, island biogeography increased in importance (MacArthur and Wilson 1967). Parallel to this, a corresponding, spatially-oriented vegetation science developed, and among conservation-oriented zoologists a strong school of dispersal ecology and metapopulation theory developed (Gilpin and Hanski 1991). The methods and perspectives of these fields were combined by applying them to the same spatially defined land units at various scales – from single landscape elements or land units to larger complexes of functionally and historically associated sets of elements, up to whole landscapes defined by heterogeneous patterns of landscape elements.

Figure 1 illustrates the type of method for spatial analysis that is typically used. It allows researchers to organize the many multidisciplinary insights flowing into landscape ecology into a common empirical understanding of landscape dynamics, by referencing all relevant explanatory understandings to a common set of land units and the landscapes they constitute. In this way it becomes possible to examine the spatial distribution and overlap of explanatory understandings spatially based on map analysis. As the field developed, this
Figure 1  Landscape patterns analysis typically starts with a mosaic of vertical aerial imagery such as the sample shown here (left). Through imagery analysis supported by fieldwork observations, the remote sensed data are transformed into a classified map of internally homogeneous land cover units (center). Considered as a whole, the land cover units form a set of heterogeneous landscape patterns (right), each indicating a particular processual relationship between life forms on the Earth surface (including humans) and their geoeccological basis. The sample shown here illustrates how rural land use is adapted to the geoeccological conditions in an agricultural landscape near Skive in Northern Jutland, Denmark. In the north there is an intensively used and closely settled agricultural landscape dominated by arable fields situated on well-drained loamy soils (A). A narrow erosion valley covered by grassland habitats intersects the arable land from the north, draining into a broad glacial valley of low-lying waterlogged soils covered by paddocks and remnants of moorland at the center of the area (B). South of the central valley there is a relatively complex pattern of agricultural land use, which is adapted spatially and functionally to the heterogeneous soils of the area, characterized by a variety of gravel, sand, and clay deposits (C & D). Analytical approaches of this kind, which link spatial pattern with landscape functionality and landscape history, are used within landscape ecology to integrate perspectives from ecology, soil science, cultural geography, sociology, and the humanities into a common, spatially explicit framework of analysis. On this basis, otherwise potentially incongruent theories explaining landscape dynamics can be tested and compared. Source: Imagery recorded by the Royal Airforce in 1980, held by the Royal library of Denmark.
and postcolonial landscapes. These changes were pioneered in Eastern Europe, where they were associated with centrally-planned collectivization of agricultural properties into specialized, large-scale agroindustrial units. In Western Europe and North America, agricultural industrialization developed later, in most cases driven by a combination of government subsidies and competition among producers, so landscape ecology as an applied scientific practice developed more slowly and later here than in Eastern Europe (Ruzicka and Miklos 1990).

Cultural landscapes and holism

The growing influence of applied perspectives meant that landscape ecologists came into sustained conflict with traditional ideals of scientific practice, leading some researchers to define their field as an explicitly action-oriented, solution-driven practice integrating scientific discovery with direct intervention in landscape management practices. This has remained a widespread perspective within landscape ecology, which now includes a comprehensive array of planning and policy-related fields of research. In addition to these developments, landscape ecological research has also extended in the direction of historical and social disciplines. This has taken place gradually as researchers within the field have cultivated an increasingly integrated relationship with scholarship from the human and social sciences, which was considered a critical component to include within landscape ecology to fully appreciate the complex trajectories of change in human-dominated cultural landscapes.

Cultural landscapes have remained a dominant research object throughout the history of landscape ecology, which has progressed from descriptive accounts of human–landscape interaction to more intricate attempts at understanding, conceptualizing, and quantifying the nature of socioecological relationships in a landscape context. Such research demands a highly developed model for integrative research, because human landscape management is a process that mediates both between the ecological and social sides of human existence and between natural and anthropogenic facets of ecosystem functioning. As the German geographer Ernst Neef, one of the founders of socioecological research within the field, expressed it: “The transfer from societal changes to the natural systems is based on the spontaneous effect of the laws of nature, whereas the transfer from the natural area to the regulation of natural processes is achieved by cultural forces, human perception and decision making” (Neef 1984, 6). As such, cultural landscapes are a human construct and a biophysical system at the same instance, and any attempt to analyze, theorize or interfere with landscape dynamics must be able to account for both of these dimensions. Within landscape ecology the challenge of accounting for these two sides of landscapes in an integrated way has motivated the formulation of a landscape concept where the landscape is seen as a holon: an assemblage of interrelated phenomena that together forms a complex whole, which is “more than the sum of its elements” because “all parts are internally related to each other by the general state of the whole” (Naveh 2000, 11).

This perspective has become a characteristic feature of landscape ecological research. It explicitly challenges both the basic division between anthropogenic and natural phenomena, as well as the mono-disciplinary reductionism prevalent in mainstream science, by claiming that the socioecological processes constituting landscape holons and their constituent parts cannot be understood without accounting for
LANDSCAPE ECOLOGY

the multifaceted relationships that unite individual elements into a spatially and functionally integrated whole.

In terms of empirical work, such relationships have been investigated by focusing on the processes or “functions” linking ecosystems with each other and with human agency. In this way, empirical evidence of the organization of landscape holons is collected by characterizing and mapping the extent, magnitude and coupled interplay of ecosystems processes (ecosystem functionality), social processes (societal functionality), and intentional practice (transcending functionality) within landscapes (Brandt and Vejre 2004). By integrating intentional human practices related to human culture, cognition, belief, planning, and decision-making with respect to landscapes into the field on equal terms with other more tangible types of functionality, landscape ecologists were able to outline a broad-ranging holistic science devoted to examining the full interplay between socioecological processes and biophysical patterns in landscapes (Nassauer 1997).

Aerial vision: a new perspective in the study of landscapes

From the outset, landscape ecology was characterized by a visual approach to analyzing landscapes from a bird’s-eye perspective, making it possible to detect minute nuances in land cover patterns, while at the same time retaining a distanced landscape-scale overview. This perspective was made possible mainly due to the new technology of vertical mono- and stereographic aerial photography, which became gradually more widespread in the period after World War I. The technology of aerial photography had been pioneered with recordings from balloons over Paris in the 1850s and in Boston some years later, but due to navigational challenges the method proved unsuited for systematic recordings of large areas.

It was the advent of airplanes in the early twentieth century that kicked off what was to become an explosion of vertical aerial photography. At first, images were recorded in limited numbers and with rudimentary instruments, but technological development and funding for recording campaigns soon became fueled by public investment as the potentials for military use of the imagery became evident. During World War I recording efforts grew rapidly. Mobile laboratories for photographic processing became available in 1915, making it possible to analyze images swiftly at locations along the front lines. This meant that aerial photography became a critical technology to the war effort, and the increasing entrenchment of the western front raised a demand for intensive small-scale scrutiny of long stretches of frontline, to a point where at the height of the war the French side alone was processing more than 10,000 images each night. In the period after World War I, images and recording technology became available for other uses, forming a growing resource for landscape research, and a broad spectrum of researchers, planning, and policy professionals picked up the new technology.

The idea of an all-encompassing bird’s-eye view of the Earth’s surface goes back to antiquity and cartographic representations of the Earth as seen from above formed part of established practices within the scientific community long before airplanes made it possible to actually see the Earth’s surface from above. In spite of this, however, it had an unanticipated effect on landscape research when actual remote sensed imagery became available. Earlier map-makers based their delineations of areas, lines, and point features on fieldwork observations collected on the Earth’s surface, which were then transposed
onto a spherical or flat medium in order for patterns of landscape elements to be made available for visual inspection “as if” seen from above. In this sense, all earlier maps reflect a form of inquiry where research design, sampling, and data collection precedes the rendition of raw data spatially. In such mapping processes, the data becomes spatial in coverage only by way of analysis, not beforehand.

When remote sensed imagery eventually became available, it represented an altogether different type of resource for map-makers than previous types of spatial data. Mosaics of aerial imagery offered researchers a continuous field of spatial data to begin with, making the Earth’s surface an observable research object in its own right, rather than a canvas on which to drape existing observations. And when series of images of the same areas at different points in time were recorded, it also became possible to classify processes of landscape change by way of direct overlay analysis. This was the key condition for the development of early landscape ecological analysis methods, and for the particular concept of landscape processes that still characterizes the field.

In the period since World War II, the range, coverage, and resolution of remote sensed imagery available for scientific analysis has grown rapidly. The Cold War, which succeeded World War II and culminated with the formal dissolution of the USSR in December 1991, meant that American and Soviet intelligence gathering efforts were in constant preparation for armed conflict. New, more precise recording devices and new platforms for carrying them, such as the U2 high altitude jets and the Corona and Landsat satellite programs, are examples of the tremendous development of remote sensing technology that took place. When imagery from these programs was gradually declassified and older platforms began to be replaced by new in a succession of technological improvements, a broad range of new materials were added to the repertoire of data available for landscape ecological analysis. This spurred a rapid development of spatial analysis tools within the field, supported by the new technology of user-centered computing, which became available from the 1970s onwards.

As such, landscape ecology became one of several arenas where geographical information systems (GIS) and associated geostatistical tools were pioneered and developed. In conjunction with these efforts, an array of computational approaches and indexing-methods for measuring and comparing the configuration, complexity, and diversity of land cover patches was developed, including the important Fragstats software package that empowered individual researchers to conduct quantitative spatial analysis (McGarigal and Marks 1995). This initiated a shift in landscape ecology away from analogue pattern recognition towards the use of computational tools able to quantitatively assess landscape patterns and associated processes across vast expanses of land.

**Current methods**

Current landscape ecological methods involve a combination of fieldwork and analysis of imagery to identify the relationship between patterns and processes. Pattern in this sense refers to heterogeneity in the horizontal dimension of the landscape, i.e. differences between land units, while ecological processes typically transpire within a single land unit and refer to the vertical relationships between organisms and their abiotic environment. The various approaches within the field relate to either of these two parallel analytical perspectives: (i) the chorologic, dealing with the horizontal patterns and processes of
land units on the Earth surface, and (ii) the topologic, dealing with the vertical processes of energetic, informational, and material exchange between organisms within their habitats (Neef 1963; Zonneveld 1989).

In a chorologic perspective the primary dimensions of the landscape are its geometrical and temporal characteristics. Here landscape dynamics are approached analytically by measuring alterations in the shape, extent, and distribution or pattern of land units in the landscape, and by analyzing exchanges occurring between individual units. Trajectories of landscape change through time can be appraised by determining the rate of change, its frequency, and magnitude (Antrop 2000).

In a toplologic perspective the character of a land unit is investigated by examining its internal functioning as defined by the societies of species within it and its geoecological potentials in the form of substrates, climate, and hydrology, including the flows of information, matter, and energy taking place through vertical vectors within it.

Today, the patch-corridor-matrix model introduced by Richard T.T. Forman and Michael Godron has become the most widespread conceptual model with which to approach pattern-process relationships (Forman and Godron 1986). It consists of a spatial language designed to describe landscape patterns and related processes. The basic idea of the model is that landscapes are made up of a mosaic of patches (areas differing from their surroundings), connected by corridors (strips of land that infiltrate the landscape and support flows of information, matter, and energy) in a matrix (defined as the dominant, most extensive, and coherent landscape element type) (Forman 1995). In this perspective a landscape is defined by the pattern formed by patch, corridor, and matrix elements repeated throughout its extent. By measuring the size, shape, and distribution of these three types of elements, landscapes can be compared quantitatively in a number of ways. Key parameters include the connectivity, diversity, and composition of landscapes, which have been shown to be systematically associated both with types of human land-use practices affecting landscapes, with biodiversity, and with ecosystem functioning within patches.

Landscape ecology today and its challenges

Landscape ecology has grown to become a widely recognized approach to environmental research, distinguishable from other scientific traditions by the type of spatially explicit, interdisciplinary, and empirically-focused analytical perspectives detailed above. By 1980 researchers from across the world had become involved in the development of the field, with a world conference convened in the Netherlands in 1981. The following year the International Association for Landscape Ecology (IALE) was established as a focal point for dialog and mutual exchange of ideas by organizing regular conferences and through publication of newsletters and journals. These organizational activities take place at international, regional, and national levels through local chapters of the association. They have proven to be instrumental for the further development of landscape ecology, because the local working environment of many landscape ecologists is delimited by traditional mono-disciplinary or sectoral organizational structures and associated domains of expertise within the academic community. Therefore, most landscape ecological research relies on the application of a combination of skills and insights from researchers and practitioners who retain their commitment to one or more disciplines.
while contributing to landscape ecology through cross-, inter- and transdisciplinary cooperation. On this basis, a substantial literature on how to facilitate interdisciplinary exchange and organize action research has developed within landscape ecology, which has come to form a significant scientific contribution in its own right (Tress, Tress, and Fry 2005).

But, at the same time, landscape ecology is also haunted by its fragmented character, and one of the most persistent threats to its continued success is the challenge of translating concepts and methods that have been harvested eclectically from other disciplines into a common analytical framework. These efforts are made increasingly difficult by the fact that the field itself has become subdivided to some degree, because researchers from different parts of the world are basing their analytical efforts on differing theories of science and validity, and thus also on different criteria for scientific achievement within the field. Today, mainstream American and European approaches differ in research priorities and theoretical perspectives for example, which is reflected in books designed to provide an overview of the field from either of the two perspectives. The introductory text by Bastian and Steinhardt is a European example, while the reader compiled and commented by Wiens et al. is an American parallel (Bastian and Steinhardt 2002; Wiens et al. 2007).

In a global perspective, the main differences between perspectives within landscape ecology, including those between American and European scholars, have tended to reflect underlying disparities concerning: (i) the way in which human interference or engagement with landscape processes is handled analytically and theoretically; (ii) the degree to which researchers lean towards epistemologies derived from the human sciences and/or the natural sciences; and (iii) the degree of practical engagement with landscape management and policymaking.

When landscape ecological research is reviewed along these lines it is clear that a particular disparity within the field tends to inform and support the others, namely that between approaches advocating theoretical pluralism on the one hand, and approaches characterized by exclusive theories of truth and validity on the other. This appears to be a dividing line that cuts across other variations within the field, and it has become particularly clear with respect to research identified either with a strict positivist stance or with a constructivist conception of truth.

This may illustrate that while landscape ecologists have succeeded in reconciling their multifaceted perspectives on the landscape when dealing with tangible empirical problems, policy advice, and action research, it has proven more difficult to resolve differences pertaining to the variety of underlying, a priori theoretical foundations within the field. Landscape ecology was united not by a common theoretical debate but rather by a set of methods and research interests, and a fascination with a common empirical domain. At times this has been a great advantage to landscape ecology, which has been able to include and cultivate a host of different perspectives, but it also makes it a challenge to uphold a unified perspective able to make good on Carl Troll’s original ambition to understand landscapes holistically.

This would entail the further parallel development and amalgamation of three existing subject areas within landscape ecology.

1 Research focusing on the basic, persistent structural and processual character of landscape types and processes of landscape change, which provides insights into the long-term natural history of landscapes, enabling society to better understand and
adapt to general conditions for land-use management.

2. Studies of historic and actual, anthropogenic and natural landscape structures and their development through time, which illustrate past and present relationships and barriers within landscapes, supporting improved understandings of how to conserve and/or improve valuable landscape resources.

3. Studies of the cultural and ideological dimensions of human engagement with landscapes and associated types of management practices, making it possible to understand the sociocultural and political background for sustainable landscape management.

The main challenge for landscape ecology, therefore, is not to focus or broaden its scope, but rather to improve the way in which insights gained in one area of the field are communicated, compared, and combined with insights from other areas.

Landscape iconography and perception

Yves Luginbühl
National Scientific Center of Research, France

For a long time it has been recognized that the evaluation of landscapes is based on the weight exerted by pictorial representations on the social imagination. It is undeniable indeed that the painting of landscapes, the pictorial genre of Europe that became established as an autonomous artistic movement with regard to religious painting, had a considerable role in our way of thinking about landscape. The painters, first of all, especially Italian, Flemish, French, English, and Spanish ones, built landscape models that were imperative in their representations of the European as a way of qualifying the landscapes, of appreciating them with regard to the reality of the landscaped forms offered to the eyes of European societies (Cosgrove 1998).

But the emergence of questions asked by the evolution of landscapes, in Europe as well as in the rest of the world, turned upside down the conceptions that dominated the thinking about landscapes: the transformation of landscapes was the object of conflict between diverse social groups and, little by little, from the 1970s, a new conception appeared that separated the seen landscape from the real-life landscape and gradually imposed the notion of the everyday landscape. This entered the legislative texts and, in particular, the European Landscape Convention adopted in October 2000 in Florence and, as of June 2013, ratified by 38 member countries of the Council of Europe (www.coe.int).

The everyday landscape means that the fundamental objective of landscape policies is one shared by the great majority of the population of the planet, whereas for several decades these policies had been centered on remarkable landscapes, in accordance with national measures peculiar to particular countries or in accordance with the 1972 World Heritage Convention of the United Nations Educational, Scientific and Cultural Organization (UNESCO). Nevertheless, these remarkable landscapes still take up an important place in public policies, because they catch the eye of the elected officials who try to highlight, with a kind of territorial marketing, their region or singular sites, sometimes considered exceptional, as well as landscapes experienced daily by the populations who live there.

These social representations of landscapes diversified, the American continent building its own model, after the first European models were strengthened; for a long time even Asia pursued its way of fengshui, today gone out of use and subjected to the new rules of the political systems of the emerging countries of the Far East. Social evolution, the new relationships of societies with nature, the development of mobility, and environmental problems have considerably modified social relationships with landscapes. New models appear, without the old completely disappearing, making the understanding of contemporary thought on the landscape complex. It is, however, necessary to understand what perceptions and social representations of landscapes mean before proceeding to an historic reading that will allow us to approach the overlapping and interweaving of the models.
LANDSCAPE ICONOGRAPHY AND PERCEPTION

Landscape perceptions and/or social representations

While they have different meanings in different geographical and scientific contexts, terms of landscape perception or social representation are used in common or administrative language without distinction. Perception is centered on the individual and his or her apprehension of the landscape through feelings and the senses, that is, through sight, hearing, touch, taste, and smell. For example, the ringing of cowbells evokes a landscape of the Alps, and the call of birds evokes a littoral landscape. An example of feelings might be the enjoyment of contemplating a beautiful landscape, or a landscape that one’s own work contributed to creating, or anger at seeing a degraded landscape, or sadness inspired by a landscape because it reminds the observer of a painful event in their life. In British and American scientific circles perception was used to explore the sensations that evoke landscapes of green countryside or dry country or an urban street. These methods gave interesting results, ranking the analyzed landscapes in order of satisfaction in a register of felt sensations: this landscape is “hotter” than that one, one evokes coldness, another agitation and noise, and so on (Luginbühl 2008).

Social representations of landscapes, used more by authors of southern Europe and Romance-speaking countries, express what landscapes represent for a specific social group: in other words, collective representations. A landscape can represent a place to which we are attached, or, on the contrary, an unknown, distant place, or a place where we had a difficult experience, such as that recalled by an inhabitant of a municipality in Central France, evoking a landscape of a forest of fir trees that reminded him of his captivity in a German camp during World War II. Social representations of landscapes are structured according to “scales of representation”: three scales relate to different images or meanings.

The first scale, which can be considered “global,” refers to “landscape models,” symbolic outlines that were developed in the course of history by the evolution of social relationships with nature. Ancient literature proposes at least one, well known to the readers of Virgil: the bucolic or pastoral model evokes a more or less wooded landscape where the shepherd guides his herd; it can be found in Psalm 23 of David’s hymn: “The Lord is my shepherd; I shall not want. He makes me lie down in green pastures. He leads me besides still waters. He restores my soul. He leads me in the paths of righteousness, for His name’s sake.” This landscape is also the one where man experiences a feeling of peace and justice, a sensation of freshness. Among the bucolic or pastoral landscapes, we can cite for example the landscapes of the English countryside with its enclosures, the western landscapes of Europe where the meadow dominates, or the landscapes of “dehesa,” the agro-forestry system made up of open forests of holm oaks or of cork oaks, as can be found in Andalusia or Estremadura.

The second scale of social representations refers to the landscapes lived locally by the population of a place, such as a city or a small area, and refers to the culture of the place (some specialists evoke the “spirit of the place”), that is, the empirical knowledge of the inhabitants of the place, which is not unanimous and which also relates to local and sometimes conflicting social relationships. It is also about the culture of the natural environment, that is, the knowledge, sometimes passed on orally by the inhabitants, of how nature has evolved locally. Planning professionals can resort to it by questioning elders to find out dangerous places, such as an avalanche corridor in a mountain, the hillside of a valley that is subject to landslides, or an easily
flooded river bed. It is social memory that is thus questioned, as empirical knowledge that can complement scientific knowledge.

The third scale is that of the individual: each individual builds his or her own experience of landscape from his or her culture of landscape, and it is different from one individual to another and not reproducible. It asserts at the same time the uniqueness of the human being and his or her own social identity. A father and a mother do not have the same landscaped culture as their children; however, this scale, although it has an undeniable interest in the theoretical field of knowledge of social representations of landscapes, is not useful for this inquiry, precisely because of the diversity of individuals and the uniqueness of the human being. Only the global and local scales can be interpreted by the inquiry, because they refer to symbols and collective meanings.

These three scales allow us to understand the complexity of social representations of landscapes and especially their sometimes fuzzy, ambiguous, or contradictory nature; the same individual can indeed build different representations of the same landscape, because of the interweaving of scales. A landscape can be considered beautiful because it is part of one of the landscape models previously mentioned, but it can also evoke a situation of injustice for an individual or for a certain social group: for example, some inhabitants of the Beauce, a French region of the Paris Basin, a vast cereal plateau, rather flat and not very wooded – only a few groves break the dullness of the landscape – consider that this landscape is too uniform, not very pleasing, but at the same time, they mention the effect produced by sunbeams at the end of the afternoon, giving a golden color to the wheat; either they compare this landscape to an ocean (as Emile Zola in La Terre 1980/1887) where the big isolated farms are similar to ships and the villages to archipelagoes, the landscape then becoming sublime, or the landscape is seen negatively because of the still recent memory of the times when farm workers were exploited by the local country squires of the region.

This aspect of social representations emphasizes the values attributed to landscapes: these indeed relate to positive or negative values (Figures 1 and 2). They appear in the language used by individuals to qualify landscapes: harmony or beauty and freedom, or conversely, ugliness or disharmony and constraint. But each of these values has diverse dimensions: esthetic, social, ecological. Harmony can mean esthetic harmony (that is, of form) but also social harmony (that is, harmony between the people and readable in a landscape). Both ecological harmony and harmony between people and nature can be read in the landscape of a clear, nonpolluted lake. Conversely, esthetic disharmony is an ugliness of form, but it can also involve social disharmony, such as that evoked by certain individuals in urban “cities” where crime or violence reigns; ecological disharmony is that which man can observe in polluted landscapes, filled with the smoke of exhaust fumes from cars or factories.

Furthermore, these social representations of landscapes are not unchanging: they evolve with change in society and with the change of relationship between societies and nature. For several centuries, in Europe landscape was indeed linked to the countryside produced by peasant farming – a normal situation for a continent in which the economy was essentially, until the eighteenth century, based on agricultural production. Since the 1990s, this conception has changed, agriculture becoming industrial and productivist. Since then the landscape has been more associated with nature, but not just any nature: it is about distant nature, that of Amazonia, the African savannas, or the taiga, landscapes where the individual supposes that
nature has not been degraded by the mindless practices of people. The American situation is doubtless different, for this continent does not have the same history: the American landscape is more evocative of the “wilderness.” However, in Latin America, the import of European models qualifies this situation, because certain regions were transformed by colonists from Europe,
such as the south of Chile, where Germans reproduced landscaped forms close to those of Bavaria, or Uruguay, where a Swiss colony created the “Nueva Helvecia.”

The situation is different still in Asia, in particular in China where landscape was for a long time created according to the theory of *fengshui*, which expressed the telluric strengths stemming from mountains and the ordering of valleys by the currents of waters arising from them: a house is positioned on a mountain hillside to overlook the valley where agricultural activity is concentrated. This situation was disrupted by the implementation of strong town and country planning policies, corresponding to the strengths of an economy that was both collectivist and capitalist.

The role of art in the construction of social representations of landscape

As previously described, the global scale of social representations of landscapes was powerfully influenced by pictorial and literary production, but also, and more recently, by photography and cinema. Some authors believe the term “landscape” to come from the artistic field, although it most probably originates in town and country planning in the fifteenth century. However, art played a considerable role in the elaboration of the landscape models that structure the global scale of social representations of landscapes. It is also true that terms equivalent to “landscape” appeared at the end of the fifteenth century when the painting of landscape released itself from religion and when it became an autonomous pictorial “genre.” It can be asserted that landscape began to dominate religious scenes and that it displaced representations of the deity, saints, and so on at the time of the Renaissance (Sereni 1955; Figure 3). The first pictorial representations of landscapes always involve religious scenes with inspirational landscapes, whether they are the supposed Paradise or symbolic places where religious events took place. If, for a long time, painters did not dare to represent landscapes of big nature in a fantastical way, it was the rural, bucolic, or pastoral landscapes that dominated, as in the painting of Le Lorrain, or landscapes where the abundance of fruits and produce reigned – a kind of land of plenty, as we find in Breughel’s painting for example.

The domination of these landscape models – bucolic, pastoral, or of plenty – can be understood in the economic environment of feudalism when the fundamental activity was the production of goods essential to the survival of the essentially peasant societies. But the medieval agricultural system gave priority to the production of cereal for bread-making while animal
breeding was a by-product of the cultivation of wheat, rye, or barley. The herds were for the most part left to themselves or led by a shepherd—frequently children—and rambled in search of grass, which was rare because people did not yet know how to cultivate it; pastoral spaces were mostly collective lands. The agronomists of the Renaissance strongly insisted on the need to reform this kind of development of the landscape by giving priority to breeding, animal protein being infrequent in the food of medieval populations and for a long time afterwards. We can then understand the domination, in the painting of this period, of bucolic or pastoral landscapes (Figure 4), which represented a kind of hope for improvement in human food.

It is in the eighteenth century with the reform of systems of agricultural production that pictorial representations of landscapes decline. England was a pioneer: English agronomists invented the cultivation of forage crops (ryegrass, fescue, lucerne, clover, etc.) which allowed the establishment of modern breeding with fenced artificial meadows where animals, oxen and sheep, were enclosed without the need for a shepherd (Hoskins 1955). It is the moment when England becomes the first economic power of the world, this revolution in fodder coming at the same time as the industrial revolution and the exploitation of mines, the production of steel, and the invention of the steam engine. It symbolizes the victory of humans over nature; it makes it possible to surpass nature’s strength and speed thanks to the laws of thermodynamics discovered by science. This is when the feeling of superiority of man over nature inspires the landscape model of the sublime, a new model that also evokes the practice of mountain climbing, as represented in Gustave Doré’s paintings or in the countless others paintings of mountain landscapes that appeared everywhere in Europe at that time. The nineteenth century is the time when pictorial representations of mountain landscapes, and then of swamps or coasts, dominated. They had rarely been painted before then because they symbolized the horror of nature, the danger and the risks incurred by travelers venturing into these places. At the same time, they represented the fulfillment of the Promethean dream of men: to be the master of nature.

The picturesque (i.e., that deserving to be painted) is elevated to the sublime, but it becomes attached to the most charming sites, prompting the first tourists to travel across Europe, in particular on the “Grand Tour.”
new picturesque landscape model is the tasteless counterpart to the sublime; it has considerable success with the bourgeoisie in Europe, who take advantage of the enrichment of their social category thanks to the development of the industrial and commercial economy. But if the economic dimension is present in the painting of landscape, another aspect asserts itself: its political dimension. It was already present, particularly in the Renaissance, when, in Italy, the big patrician families from Tuscany, Lombardy, and Venetia inspired essential changes in territorial governance in accordance with their economic interests. Ambrogio Lorenzetti’s famous fresco The Allegory of Good and Bad Government in the ducal Palace of Siena reveals perfectly this political dimension by actually evoking the territorial governance of the province over which political power reigned. The political meaning of landscape also appears in some English paintings representing the landscape of enclosures, such as an anonymous painting on four boards showing the individual appropriation of ground, the foundation of liberalism; or Gainsborough’s painting “Mr and Mrs Andrews,” showing a husband and wife from the landed gentry posing in front of a landscape of enclosures. In reality, this political dimension is often present, but it was rarely noticed by specialists except by some British or American authors (Mitchell 2002).

Social and pictorial representations of landscapes thus maintain powerful associations. The first cover the entire register of social sensibilities in landscapes, while the second constitute symbols that give a political, economic, ecological, and esthetic meaning to landscapes (Luginbühl 2012). Today, the political, social, and ecological dimensions acquire a new meaning, inspired by the desires of society to contribute to political decision-making; the United States ushered in these approaches with John Dewey. From hereon in, for societies it is a question of taking control of the fate of their living environment, the landscape of everyday life.

Landscape

Mitch Rose
Aberystwyth University, UK

It has often been said that the field of landscape studies (LS) has an overinterest in, some would say an obsession with, its own history. It is a charge that is difficult to contest, given the number of monographs, edited volumes, and articles that have been dedicated to the term’s historical evolution and development. And, yet, it is ironic that, despite the amount of interest there is in landscape as a concept, there is relatively little work on landscape as an empirical phenomenon. Indeed, while geographers have written extensively on the history, development, and influence of LS, as a body of work, actual studies of landscape are relatively few relative to other geographic objects such as the city or the region. In this sense, it seems that LS punches above its weight; its “old man” position in the discipline allows it to operate as a touchstone or barometer for cultural geography, even as its actual subject matter remains underexplored. There are a number of positive and negative consequences for LS in this regard. No doubt it is positive for LS to be seen as one of the many crucibles of innovation in the discipline. But the lack of empirical work has engendered a somewhat conservative subfield. It is precisely the empirical exercise that creates innovation, albeit in a minor key. Thus LS’s tendency for major revolutions in theory, rather than minor transformations through empirical work, has kept the concept somewhat definable within particular schools – spheres of research that signal both a specific historical period and a distinctive modality of doing landscape research. While other geographic topics such as place and region have been associated with various schools, the surfeit of empirical work on these topics has forced many more theoretical iterations and thus suggest spheres of research that are far more varied and unruly.

It is for this reason that the following review of LS is organized around the three dominant modes of landscape research currently in operation. While not all landscape research comfortably fits within these schools, (i) they constitute three distinctive modalities for approaching what the landscape is and how it can be studied; and (ii) much contemporary work on landscape seems to work from, if not within, one of these traditions, although overlap and development are no doubt also present.

The Berkeley tradition

It was Carl Sauer who sought to convince American geographers that the landscape constitutes not simply a legitimate object of analysis but the discipline’s most significant and potent proxy for understanding the social forces that shape our world. Landscape interpretation, for Sauer, operated as an ideal type of geographic work, and his passionate pursuit of the topic effectively launched it as an independent field of geographic research for over half a century. Sauer’s main proposition for studying the landscape is the idea that the Earth’s surface is patterned and shaped by the material practices of past and present cultural groups. In this sense, the landscape is akin to a cultural artifact. Like shards of pottery...
or paintings on a cave wall, the landscape – in its organization and use – evidences traces of the cultural groups that settled it, its shape, formation, and adornment reflecting a community’s unique modalities of transforming the Earth. The purpose of geography, therefore, is to seek clues of inhabitation and reconfiguration. Sauer’s famous formulation that “culture is the agent, the natural area is the medium, the cultural landscape is the result” (1963, 343) presents the landscape as a canvas that cultural groups inscribe through the construction of material structures (e.g., barns, homes, and fences) and/or their distinctive patterns of tilling and organizing the land. The point, for Sauer, is that the landscape operated as a cultural hearth in which a community’s unique expression of land and life would be written and, crucially, read.

While there are a number of key texts that elaborate his thought and method in great detail, two broad points characterize Sauer’s conception of landscape and the distinctive approach to geography it establishes. First, Sauer resolutely understood landscape interpretation as a field-based practice. In order to study landscape, one must go outside and seek its material traces. The comparison to archaeology is apt, with the emphasis on exhuming signs of the past. But, rather than digging, geographers rely on their eye, relating clues in the landscape (an overgrown stone wall, a buried foundation, a system of field organization) to the imprint and layering of past cultural groups.

A second point concerns Sauer’s empiricism. Given that landscape is a record of culture, it is up to geographers’ visual acumen to interpret the signs they see. Landscape interpretation in the Sauerian tradition is an observational practice, steeped in inductive reasoning and an empiricist (but not positivist) epistemology. As Wagner (2009, 383) puts it, the geography that Mr. Sauer advocated was built on a foundation of direct immersion in field observations, interpreted in a broad, rather speculative fashion, informed by solid science, and directed above all toward environmental change over time in a close reciprocal relation with cultural development. Preformed deductive schemes could not compete with alert and insightful first-hand observation in concrete earthly context.

Where this tradition hit a conceptual wall, however, was in its theorization of culture. Because Sauer was primarily an empiricist, the trajectory, as well as legacy, of his work focuses on developing a coherent concept of what landscape is (a unique material expression of land and life imprinted on the material world) and how it could be studied (through visual observation). How and why culture imprinted the landscape in such a way was, for Sauer, a less interesting question. As Wylie (2007, 27) suggests, Sauer was “primarily interested in visible, material ‘evidence’ of culture in the landscape … and not with the ‘inner workings’ of culture in terms of shared cultural beliefs, rituals, ideologies, values, attitudes and so on.” This is not to say that Sauer ignored the question, but he dealt with it by borrowing from anthropology, and specifically Alfred Kroeber’s theory of superorganicism: the idea that culture’s rules, manners, and modes of living transcended individual experience and decision. Superorganicism was, in many ways, the “black box” that allowed Sauer’s concept of landscape to thrive, since it was culture itself (i.e., culture as an autonomous, causative force) that shaped the landscape. While there were many aspects of Sauer’s approach to landscape that were critiqued in the 1980s, the sharpest and most potent lines of attack pivoted on its weak conceptualization of culture. While many geographers who worked in the Sauerian tradition denied any abiding fidelity to superorganicism, this position was less about
rejecting a particular theoretical position and more about a commitment to an inductive project: that is, a belief that observation and description were the proper approach for a geographer and that any ambition to make broader claims must be born from evidence.

While this commitment to empirical description frustrated politically minded geographers emerging in the 1970s and 1980s, it is important to recognize that the empirical bias of Sauer and his students did not prevent their own theoretical revolutions. William Denevan’s work overturned long-held assumptions about the impact of native peoples on the precolonial landscape of the Americas. Drawing on his empirical work in Latin America, Denevan (1992) argued that the “pristine myth” – that is, the idea that native peoples’ impact on landscape change was minimal or benign – was not only racist but deeply Eurocentric, steeped in notions of the noble savage and ignorant of the industry and innovation of Indigenous peoples. Through a detailed discussion of native population figures, indigenous land forming, building technologies, and the extensive evidence of environment recomposition, Denevan precipitated something of a gestalt shift both in academia and in popular culture in terms of how presettlement America was imagined.

Today, work by Mathewson, Zimmer, and Sluyter continues to draw on fieldwork to analyze landscape change. While there is less emphasis on looking, regional expertise remains its defining attribute and maintains its distinctive relation to other forms of environmental history. Indeed, if there is one thing LS would clearly come to lose in its various revolutions, it is the emphasis on fieldwork and local knowledge. Few studies of LS in either the “new cultural school” or the “phenomenological school” from the Anglo-American world show any sustained interest in non-European case studies or in work in a language other than English. Today, work in the Berkeley School tradition overlaps with and intersects with cultural and political ecology. While such terms are no doubt broader and more encompassing than LS, the trajectory of LS interested in the cultural and political implications of landscape change certainly finds a comfortable home here.

In addition to mapping the way Sauer’s work has evolved, the innovative ways in which it has been retrieved are also worth noting. Ken Olwig, while not particularly interested in Sauer’s method (or in landscape morphology per se), follows Sauer into the Germanic pre-Renaissance tradition to recover what he terms the substantive nature of landscape: that is, the manner in which landscape operates as an expression of landed life – a life that is defined by, and expressed through, a relationship with the land. Explaining precisely what this relationship involves, and how it has changed, is a central feature of Olwig’s work, but principally it is founded on a conception of landscape as a unique legal administrative construct that binds a community to its geography and the forms of economy, community, and custom that geography bequeaths. In this sense, landscape is a comprehensive relationship between land and community – a legalistic administrative structure, to be sure, but one that positions land not simply as resource but as a means of defining communities. While much of Olwig’s work focuses on examining how this conception of land and life has been eroded since the Renaissance, there is a broad emphasis on recognizing the centrality of the land and life nexus that Sauer identifies as the engine of landscape development.

Ninety years after its initial publication, Sauer’s major work, “The Morphology of Landscape,” is cited by an increasingly smaller group of geographers. And yet there is little doubt that its legacy lives on. While landscape never took on the centrality and import in the discipline
that Sauer had hoped, this was perhaps more because of the venal critiques of Hartshorne and the scientism of the quantitative revolution than any shortcomings in the Sauerian method itself. Indeed, Wylie (2007) argues that there is an increasing appreciation of Sauer in the new biogeographical work of people like Sarah Whatmore, Steve Hinchliffe, Beth Greenhough, and Emma Roe, many of whom subscribe to Sauer’s insistence on the inseparability of nature and culture. Similarly, there is a more implicit recognition of Sauer’s influence in the phenomenological school of landscape studies, where landscape as an expression of land and life is being reconsidered. Most significantly, however, Sauer’s influence continues in the way North American cultural geography conceptualizes landscape as something material. While the British tradition has a tendency to approach landscape in visual and perspectival terms, American LS thinks about the landscape as a place—a hearth, or repository, for culture and cultural practices, however those may be conceived.

New cultural geography

If there was a moment when the critiques and new theoretical approaches that came to be called new cultural geography began, it was probably in 1980 when James Duncan published his critique of the superorganic theory of culture. Duncan’s central line of attack was that the theory was holistic, deterministic, and, crucially, long abandoned by anthropology and archaeology. The critique, and the response to it, are interesting events in the history (and sociology) of the discipline, but the event tells us less about the work of the Berkeley School and more about the issues and concerns of a new generation. As previously suggested, it is unclear to what extent traditional cultural geographers cared about culture. While their field ostensibly concerned the geography of cultural groups, their method focused almost exclusively on landscape change. Superorganicism, in this sense, was simply an easy way to sidestep the sticky question of culture. And, while some geographers (such as Wilbur Zelinsky) championed superorganicism as a ready-made solution, most of them ignored the question and hoped it would go away. Duncan, however, did care about culture. Steeped in the anthropology of Clifford Geertz and the symbolic interactionism of Irving Goffman, Duncan’s target was not the work itself but the atheoretical manner in which it proceeded, working with a deterministic theory of culture that was blind to question of power and meaning or indeed any issues that could be considered sociological.

It would be almost 10 years before these initial stirrings took shape in what would become known as the new cultural geography (NCG). In a flurry of publications that appeared in the late 1980s and early 1990s Denis Cosgrove, Stephen Daniels, Mona Domosh, James Duncan, Peter Jackson, Nuala Johnson, David Ley, and others would reorient and revive the study of culture in geography in both the United States and United Kingdom. For simplicity’s sake, their arguments can be broken down into ideas about what culture isn’t (the critique) and what culture is (the theory).

In terms of the critique, new cultural geographers responded to traditional cultural geography by arguing that culture is not deterministic, holistic, or innocent. It is not deterministic because it does not transcend individuals and individual choice; it is not holistic because it is made up of numerous subgroups and competing identity systems; and it is not innocent because the social frameworks it provides are imbued with relations of power. One of the keywords that came to
define NCG is *contested*. Culture is contested in the sense that it constitutes a realm of struggle where individuals strive to express the forms and signs that are meaningful to them onto the material world.

For new cultural geographers, landscape is not an artifact of identifiable cultural groups, but reflects social struggles to produce the material world in a manner that reflects one's ideas, values, and norms. Landscapes, in this framing, are *made to be read*. They are produced by powerful social groups to express a certain idea of how society is and/or should be organized. In addition, because landscapes are part of our everyday environment, they are a particularly insidious way of getting such ideas across, as Duncan and Duncan (1988, 123) point out:

> If landscapes are … read “inattentively” at a practical or nondiscursive level, then they may be inculcating their readers with a set of notions about how the society is organized: and their readers may be largely unaware of this. If, by being so tangible, so natural, so familiar, the landscape is unquestioned, then such concrete evidence about how society is organized can easily become seen as evidence of how it should or must be organized.

It is this combination of attending to the symbolic and meaningful dimensions of landscape, while being aware of the political implications of its meaningfulness, that is the hallmark of NCG. Stephen Daniels calls this the *duplicity* of landscape: that is, landscape’s capacity to be pleasurable and powerful at the same time. While the landscape provides a culturally specific manner of visual pleasure, it is also an expression of authority and ownership whose effects may be designed to exploit or control.

There are three further points to be made about NCG that explain both its impact and its enduring popularity. The first is that the rise of NCG coincided with a broader cultural turn in the discipline. While a systematic review of this work is beyond the scope of this entry, suffice it to say that questions of landscape became a minor player in a wider set of questions about the way power operates in and through space and place. Throughout the 1990s and early 2000s, a whole new set of geographies emerged, focusing on how space was produced by particular registers of power. Hence the emergence of an array of sub-subfields examining how taken-for-granted ideas about gender, race, sexuality, class, and youth insidiously insert themselves into our most everyday neighborhoods, parks, and playgrounds.

Second, it is often argued that the emergence of NCG was primarily a British phenomenon. This is true in the sense that many of its chief proponents were working in British geography departments, but also in the sense that it drew on the Birmingham School of Cultural Studies and British writers such as Raymond Williams, John Berger, and Stuart Hall. That said, the British character of NCG has been overstated. Certainly Meinig’s work on the symbolic aspects of “ordinary” landscapes is a significant contribution, as were Marxist geography (with its emphasis on the determinism of capitalist structures) and humanistic geography (with its emphasis on individual experience and sense of place), both of which were championed by geographers in North America. Indeed, Cosgrove (1978) argues that NCG was an attempt to bridge Marxist and humanistic geography, acknowledging the power-laden nature of landscape on the one hand and its role in generating meaningful subjective experience on the other.

This leads to the final point about NCG. If Cosgrove is correct that NCG represents a rapprochement between Marxist and humanist geography, it was by no means a comfortable one. For Don Mitchell, the representational emphasis of NCG fetishizes the look of landscape and
ignores how such imagery hides the exploitative labor relations that produce its aesthetic qualities. Similarly, Olwig illustrates how the development of landscape visualization (and the pastoral ideal) historically disrupted long-standing community relations with the land. For both Mitchell and Olwig, landscape aesthetics is a powerful social tool that is used to veil the implications of capital exploitation and/or land alienation. For others, however, the landscape is primarily a site of meaning and experience. Thus, in the work of David Matless and Karen Till, social and cultural identities that are vague or uncertain in the abstract become meaningful and concrete as they are expressed in and through the landscape. In Matless’s work on the Norfolk Broads, appropriate forms of leisure and conduct in the landscape are mechanisms by which Englishness is understood and enacted. Similarly, Till illustrates how German anxiety about its history is worked out in the landscape through the transformation of Berlin. In each case, the landscape is used to communicate abstract sensibilities rather than clear ideologies, and it is precisely the artful utilization of form and conduct that make ambiguous ideas meaningful and seemingly shared.

In terms of current work, a number of contemporary texts reflect the NCG tradition of providing regional and historical studies of landscape and landscape struggle. Dwyer and Alderman’s (2008) study of the memorialization of the Civil Rights Movement is an excellent example of how contests over material space bring to a head the subtle emotions that sustain segregation. In their study of the conflict to rename 9th Street after Martin Luther King in Chattanooga, Tennessee, Alderman and Dwyer make clear how latent and discordant feelings can be suddenly and eruptively made present by an act of geography. Similarly, Schein’s (1997) work on a suburban neighborhood in Lexington, Kentucky, draws attention to the diverse voices contributing to the development of a particular site over time. Schein’s argument is that landscape is discourse materialized, meaning that the landscape represents not only the voice of dominant authors but also the inconsistency and internal contentiousness present in all social discourse and ideology.

One of the distinctive features of NCG is its interest in theory. While NCG may be recognizable for its consistent attention to questions of representation and power, it draws eclectically from theory to make this point. Thus, Kirsch (2007) draws on sociology of science (e.g., Latour) to illustrate how landscapes operate not just as representations but also as scientific entities that carry within them their own forms of truth and necessity. Similarly, Della Dora (2013) draws together Cosgrove’s idea that “landscape is a way of seeing” and the concept of topia to examine how other cultures at other times have their own ways of seeing: that is, ways of making sense of the world through visual means other than perspective. Finally, there has been an array of sub-subfields that have emerged from the NCG tradition which highlight the various kinds of landscape struggle that can be potentially studied: for example, military landscapes, tourist landscapes, indigenous landscapes, imperial landscapes, and religious landscapes. In this sense, while NCG, as an approach to landscape, is over a quarter-century old, it continues to be practiced and developed in the discipline and has by no means been supplanted by emerging traditions.

Phenomenological school

The phenomenological school is often associated with the work of Paul Cloke, Owain Jones, Hayden Lorimer, Mitch Rose, David Seamon, John Wylie, and others. Its rise in the discipline is similar to that of NCG in three ways. First, its ideas were intimately connected
to developments in anthropology and archaeology, particularly the work of Tim Ingold. Second, the phenomenological school emerged from a broader critique of the way cultural questions are approached and pursued. And, third, the phenomenological school is primarily (and in many ways continues to be) a British phenomenon. Indeed, the ideas and concepts associated with the phenomenological school are closely aligned with nonrepresentational theory (NRT), a trajectory of thought developed by Nigel Thrift, Sarah Whatmore, Paul Cloke, and their graduate students at the University of Bristol in the late 1990s. While the connection between the phenomenological school of landscape and NRT are significant, that significance should not be understood as a seamless (or even comfortable) theoretical overlap. Indeed, as with many fields that were inspired by NRT, the points of connection flow from a broad approach to (and inspiration from) poststructural theory, rather than any consistency in theory or method. In this sense, it is useful to summarize some of the key ideas in NRT first, in order to properly understand its relation to the phenomenological school of landscape. While it is often suggested that NRT denotes an outlook and approach rather than a specific theory, NRT can nonetheless be characterized by three priorities: of ontology, events, and practice.

The prioritization of ontology can best be understood as a deprioritization of epistemology, the latter being the guiding conceptual frame for cultural geography since the mid-1990s. Prioritizing epistemology means understanding meaning, symbolism, and other forms of representation as coloring an otherwise objective world. Inherent in this epistemological framing is not simply a Cartesian dualism but, more significantly, a vision of the universe framed by the problem of knowing: that is, it is a framework born out of the question “How do we know the world?” Following Heidegger, NRT starts with a question not of knowing but of existence. Thus, it draws on ontologies oriented toward understanding how things exist rather than what they are. This leads to the second priority, which is NRT’s focus on events. The emphasis of the ontologies commonly used by NRT is that subjects are not self-standing beings but episodes, outcomes, or events that emerge from an ontological situation. While this situation is conceptualized differently depending on the theorist, there is a broad inclination in NRT to look beyond the nouns with which people engage on a daily basis (other people, pavements, pets, weather, etc.), in order to grasp the context from which these nouns emerge. In this framing, the world is not simply the Earth and its furniture but assemblages whose appearance is dependent on the relations that give them life. The final priority of NRT is practice. If NRT approaches the world not in terms of things but in terms of the background relations that allow things to appear, then concepts such as practice and performance take priority over questions of agency and will. In an NRT framing, space, place, and landscape are not produced because they cannot be wholly attributable to self-conscious agencies or a will. Rather, such events express the situation from which they emerge: that is, a context where certain things are (and are not) possible. To approach geography in such terms is to recognize how desires, affects, memories, energies, and other potentialities resident within a particular moment are concocted into forms and solidarities whose effects may be ephemeral or sustained, singular or repeating, limited or far-reaching, animate or barely audible. The point is that geography is not a noun but a practice; it is the cumulative effect of everyday enactments and events.
While this gloss of NRT leaves a number of significant topics undiscussed (e.g., affect), it is nonetheless indicative of ideas that have had an enduring impact on LS. Indeed, three characteristics of the phenomenological school of landscape broadly align with these themes: there is an interest in (i) the situation of landscape (ontology); (ii) dwelling (events); and (iii) practice.

Perhaps the most distinctive feature of the phenomenological school is its focus on the situation of landscape. Both traditional cultural geography and NCG focus on the landscape as an object, and (more specifically) an object that is produced. The phenomenological school, however, does not see the landscape first and foremost as something produced, but rather as a situation. When John Wylie ascends Glastonbury Tor, he attends to how the practice of climbing provides him and his companions with a means to see. Thus, the tor is not approached as an object to be viewed but as the means by which viewing takes place. It is itself a constitutive element in the emergence of a viewing subject: “the Tor is never an object for a gaze, nor a viewpoint on its own. It is a modulation of the visible world which lets there be a gaze to behold things open and hidden. Its elevation reveals and conducts the surrounding landscape” (Wylie 2007, 454; emphasis added). Thus there is an inclination to draw attention away from subjects and objects in order to focus attention on the conditions that allow a subject–object relationship to arise. Subjects come to be subjects through the practice of viewing: that is, through the process of being in an ontological situation that affords seer and seen to emerge through a set of practices and perceptions (e.g., walking and seeing). The emphasis, once again, is not on what the landscape is, but how it exists.

The second theme that characterizes the phenomenological school is an interest in dwelling. The dwelling perspective, as it is presented by Tim Ingold, presents landscape as a form of involvement rather than of representation. As he states, “the forms people build, whether in the imagination or on the ground, arise within the current of their involved activity” (Ingold 2000, 186). In his discussion of Koyukon hunters, he illuminates their capacity to use those aspects of their world that they have learned to see. Thus, it is only by being in the world in a particular manner that the world offers the subject particular possibilities. Similarly Cloke and Jones (2004) examine how trees in a cemetery in Bristol shape social memory in a manner that impinges on the expectations, planning, and management of the site. In this reading, the landscape does not exist as a representation of pre-established ideologies or ideas, but as expressions borne by inhabitants engaging with the world they are in. As Ingold (2000, 179) suggests, the world is not made before it is lived in: “the acts of dwelling are preceded by acts of worldmaking.”

The final and related characteristic of the phenomenological school is its emphasis on practice. If the landscape is an expression of involved activity, then it can be thought of as emerging from practices. This is why Ingold uses the term “taskscape”: that is, landscape as an expression of our everyday activities and tasks. In geography, Hayden Lorimer draws on journals and letters to explore how extraordinary landscapes can emerge from the most intimate tasks. In one example, Lorimer (2006) illustrates how the Scottish landscape emerges as a reindeer landscape through the activities of two people: Mikel Utsi (a nomadic Lapland reindeer herder) and Ethel Johns (a British anthropologist). What might be a story about the landscape being produced in a particular manner by two subjects becomes, instead, an exhumation of the relations and intimacies that bring this project to fruition: for example, Utsi’s familiarity with
reindeer, Johns’s attachment to Lapland, the ecological relations that make reindeer life possible, their love for each other, and their mutual sense of peace within the herd. The reindeer project is not the result of a particular vision but an expression of pre-established intimacies which are themselves informed by histories, attachments, desires, and relations.

While the phenomenological approach to landscape is fairly recent, it has been widely influential and has inspired an array of innovative work. This work can be broadly characterized by an attention to the manner in which insubstantial or affective modalities of sensation are critical components in the constitution of our engagement with, and experience of, landscape. This process can be seen in the work on absence and ghostly landscapes where the voices of the past, the remembered and the dead, generate (or undermine) gardens, housing developments, and heritage sites (see work by Franklin Ginn and Karen Till). It can also be seen in the increased interest in landscape experience and the various factors affecting our comportment to and involvement with a site (e.g., see Nina Morris’s and Tim Edensor’s work on luminosity, Chris Tilley’s experiential archaeologies, and Peter Merriman’s work on driving and mobility).

More broadly, the phenomenological school has had an impact on how landscape sensibilities are integrated into our expectations and even into policies relating to what people, communities, and governments desire from our environments and how those expectations are grounded in often precognitive expectations (e.g., see Catherine Brace’s work on climate change). In this sense, while the phenomenological school is relatively young, it is already influencing the trajectory of LS in geography, anthropology, and beyond, and it remains to be seen how this work will evolve and intersect with other long-standing traditions in the field.

Conclusions

This entry began with a justification for dividing the discussion into three sections, each representing a particular school of LS. Such a division leaves out and/or marginalizes a range of interesting landscape research. Indeed, inherent in such a division are the familiar dangers of categorization: overemphasizing difference, eliding similarity, ignoring the stuff in between. It is not that these schools supplant one another or even represent coherent spheres of research. They are traditions: modes of landscape practice that carry with them a particular perspective on, approach to, and interest in the landscape. In this sense, it is important to keep two things in mind: (i) scholars have always drawn on these traditions eclectically; and (ii) these traditions are very much alive and evolving. In the United States in the late 1990s, there were two schools of landscape research, traditional cultural geography and new cultural geography, each battling to define and defend their distinctive method and approach. Existential anxiety inhered in these debates: new cultural geographers fighting for acceptance and traditional cultural geographers fighting for their existence. Current debates do not show such anxiety. There is little sense of teleology in phenomenological critiques of new cultural geography, and there is no suggestion that issues of power and representation are no longer valid. This lack of tribalism and existential angst about the field has given LS greater range, and a number of distinctive approaches to landscape can be identified in current work as well as far greater eclecticism. In this sense, while the history of LS may have been written many times in the past, it has also been a fairly easy one to write. Future histories, if they are to be written at all, will be far more difficult.

Further reading

Over the last several thousand years humans have increasingly modified existing land use and land cover to meet various socioeconomic needs. It is noted that by 1990, 45.7–51.3 million km² of the global land surface (35–39%) was being cultivated, with forest cover decreased by approximately 11 million km² since 1750 (Pielke et al. 2011). By 2000, only a few desert regions, the central Amazon and Congo Basins, and the Arctic and Antarctic had not been affected by land-use/cover changes (LULCC). Over the last several decades LULCC has been increasingly recognized as a major forcing of local, regional, and global climate on multidecadal timescales (e.g., Mahmood et al. 2014; Pielke et al. 2011). Observations and modeling studies demonstrate that LULCC impacts meso-, regional-, and potentially global-scale atmospheric circulations, temperature, precipitation, and fluxes. These effects can be observed over multidecadal to longer timescales. Moreover, global climate modeling research demonstrates that the impacts of LULCC on extreme temperatures, for example at continental or smaller scales, can be equal to or greater than the radiative effect of a doubling of atmospheric CO₂.

In this context, the primary aim of this entry is to highlight the role of LULCC in the climate system. The impacts of LULCC can be both biogeophysical and biogeochemical in nature. Both biogeophysical and biogeochemical type responses of the climate, therefore, are discussed in the following sections. Biogeophysical changes can result in the modification of leaf area index (LAI), surface roughness, and albedo, while biogeochemical changes are changes that occur in the carbon and nitrogen budget, and the budget of other trace atmospheric constituents. The following discussion addresses the impacts of long-term systematic LULCC (e.g., agricultural land-use change, deforestation) and short-term abrupt changes (e.g., rapid urbanization).

**Climate System and LULCC**

LULCC has both biogeophysical and biogeochemical impacts on climate. Biogeophysical changes modify the radiation balance, energy partitioning, and exchanges of energy, mass, and momentum between the land surface and the atmosphere as well as the terrestrial water budget (Figure 1). Biogeochemical changes impact, for example, the nitrogen and carbon fluxes.

The surface energy and moisture budgets for bare and vegetated soils can be of help in understanding the impacts of LULCC and can be written as:

\[
R_N = Q_G + Q_H + Q_E \quad (1)
\]

\[
P = E + T + RO + I \quad (2)
\]

where \(R_N\) represents the net radiative fluxes, \(P\) is precipitation, \(E\) is evaporation, \(T\) is transpiration, \(Q_G\) is the ground heat flux, \(Q_H\) is sensible heat flux, \(Q_E\) is latent heat flux, \(RO\) is runoff,
and $I$ is infiltration. Physical evaporation plus transpiration is also known as evapotranspiration ($ET$) and can be expressed in energy terms (latent energy flux). Transpiration is a plant physiological process which is linked to photosynthesis and a variety of other plant functions. These equations (1 and 2) also show that the energy and water budgets are linked and that LULCC affects these budgets. Surface budgets could also be completed for carbon, nitrogen, and other chemical species. Each of these budgets will be changed if any characteristic of the land surface is altered. This includes changes caused by land management (e.g., deforestation) and also ones that arise from phenology, drought, and so forth.

Similar budget equations can be written for carbon and nitrogen fluxes. The carbon budget, for example, involves the assimilation of carbon dioxide into carbohydrates within vegetation, respiration of CO$_2$ from plants and animals, decay of animals and plants, industrial and vehicular combustion processes, outgassing from oceans and other water bodies, and volcanic emissions. The nitrogen budget has also been segmented into its different components. Among these components, for example, nitrogen deposition clearly has major LULCC interactions as the amount of material deposited on land is very large. However, more studies are needed because vegetation will be affected differentially by this inadvertent fertilization of plants, with resultant impacts on albedo, as well as transpiring leaf area.

Changes in the heat and water budget necessarily alter the carbon and nitrogen budget (and that of other trace constituents), and alterations in carbon and nitrogen budgets (and in the other trace gases and aerosols) change the surface heat and water budgets. A major reason for all of these fluxes are closely coupled is that the transpiration of water vapor through the stoma of plants is not only associated with changes in the heat budget,
as shown earlier in this section, but also intimately involved with the assimilation of carbon into plant leaf, roots, and stems through their stoma.

If the amount of plant material changes, this alters the transpiration of water vapor into the air and thus the amount of carbon that is assimilated. The amount of nitrogen compounds and other trace nutrients affects plant growth and vitality. The intimate coupling of all of the surface budgets is a fundamental aspect of the climate system. In short, land management practices and LULCC that alter any one of these budgets necessarily alter all of them.

The following sections highlight the climatic impacts associated with some of the most notable types of LULCC. They include impacts of agriculture, deforestation and afforestation, and urbanization. Due to their relevancy and importance, also included are the impacts of CO₂ and aerosols.

**Agriculture**

The concept of human-induced vegetation cover changes having an effect on climate is not new. Pioneers of the Great Plains of North America believed that “rain follows the plow.” While there is evidence that human agricultural practices may have begun transforming the Earth’s atmosphere thousands of years ago, direct large-scale anthropogenic impacts on the Earth’s land cover are difficult to document before historical times. The possible first impacts of human activities were on vegetation through hunting and fires that may have led to extinction of many native species. Subsequently, agriculture and the domestication of grazing animals began to alter land cover. The following discussion includes examples illustrating impacts of LULCC due to agricultural activities.

It is found that the shift to agriculture often results in a cooling in daytime temperatures and presents the largest magnitudes of cooling. For instance, up to a 1.41 °C cooling of maximum temperatures was found at irrigated locations in the Ogallala aquifer region (Figure 2). In a subsequent assessment, a 1.56 °C increase was reported in average growing season dew point temperature over irrigated areas, and also up to a 2.17 °C increase was documented in dew point temperature for peak growing season months. These changes were primarily linked to modification of energy partitioning led by enhanced latent energy flux due to the availability of additional water through irrigation.

One study noted significant reductions in mid-June to mid-July maximum air temperatures, diurnal temperature range, and solar radiation of 1.7 °C decade⁻¹, 1.1 °C decade⁻¹, and 1.2 megajoules per meter squared per decade (MJ m⁻² decade⁻¹), respectively, over Canadian Prairies associated with agricultural activities. This research also found a precipitation increase of 10.3 mm decade⁻¹. Again, the increased latent heat fluxes from increased agricultural vegetation could lead to increases in dew point temperature without necessarily resulting in increased precipitation.

In northwestern India, up to a 0.34 °C cooling of growing season maximum temperatures was determined to be due to the introduction of irrigation. For individual growing season months, up to a 0.53 °C decrease of maximum temperature was reported and long-term temperature trends were largely negative and also statistically significant. These changes in temperature were associated with increased latent energy flux (Figure 3). Subsequent studies also suggest modification of dry season precipitation associated with irrigation and increased soil moisture and latent energy flux. Other modeling studies suggest changes in circulation over the
Asian continent due to the widespread adoption of irrigation.

In a modeling study for modern-day land cover, there was a statistically significant warming for the austral summer (December–February) for mean surface temperature of 0.1–0.6°C in eastern Australia and a warming of 0.1–0.4°C for the coastal southwest corner of Western Australia, which is still largely covered by tall native forests. However, there was a significant cooling of 0.2–0.4°C over the inland wheat belt for summer and austral winter (June–August). Further analysis of daily rainfall events indicates an increase in the number of dry and hot days, an increase in drought duration, and a decrease in daily rainfall intensity and wet day rainfall in southeast Australia.

From an observational study, (the 2005–2007 Bunny Fence Experiment (BuFex)) in southwest Australia, a favored area of cloud formation was found that was linked to land-use change (Nair et al. 2011). The cooling effect was most prominent during the summer when the land use in the agricultural area deviates most from the native land in terms of albedo, leaf area, vegetation cover, and surface roughness. Analysis of radiosonde observations showed, on average, the noontime planetary boundary layer (PBL) height was found to be higher by approximately 260 m over the native vegetation during summertime,
Figure 3 Latent energy flux differences (W m$^{-2}$) for March 23, 2000: (a–c) CTRL-DRY05, 10, and 15 and (d–f) CTRL-WET05, 10, and 15. Soil moisture was systematically decreased (DRY) and increased (WET) up to 15% with 5% interval (Sen Roy et al. 2007).
while over winter time the difference was approximately 189 m. Observations of energy fluxes from aircraft show that the enhanced boundary layer development was driven by sensible heat fluxes that were consistently higher over the native vegetation areas, with peak differences of approximately 200 W m$^{-2}$ and approximately 100 W m$^{-2}$ observed during the summer and winter seasons, respectively.

To address the effects of increasing cropped areas and afforestation on atmospheric processes in South America, Beltrán-Przekurat et al. (2012) performed sensitivity experiments using a fully coupled atmosphere-biospheric regional climate model. The general effect of agriculture was cooling when the shift was from grasses (with C3 metabolism) to crops, and warming when the shift was from grasses (with C4 metabolism), wooded grasslands, or trees. Near-surface temperatures decreased when crops (such as wheat and soybean) replaced C3 grasslands. Increases in temperature were found when crops replaced evergreen trees and wooded grasslands (e.g., in Brazil) and C4 grasslands (e.g., in the central region of the Pampas). Near-surface temperatures decreased when crops (such as wheat and soybean) replaced C3 grasslands. Increases in temperature were found when crops replaced evergreen trees and wooded grasslands (e.g., in Brazil) and C4 grasslands (e.g., in the central region of the Pampas). The coolest (up to $-0.8^\circ$C) and warmest (higher than 0.6 $^\circ$C) 2 m temperature differences (the difference at 2 m above the ground) appeared in the spring (October–November) averages. Maximum temperatures showed a larger decrease than minimum temperatures. Minimum temperatures slightly increased in summer in the southern Pampas. This also means a decrease in the diurnal amplitude of temperature. The results are consistent with the observed trends in temperature over Argentina.

Based on the observed responses of the climate system to agriculture-related LULCC, these regions where cooling occurs can be considered as “Agricultural Cool Islands” (ACI). This terminology could be applied to the landscapes dominated by both rain-fed and irrigated agriculture.

Deforestation, afforestation, and desertification

In many parts of the world, vast regions of original forest have been cut to permit agriculture, urbanization, and other human activities. Large areas of the Amazon are currently being clear-cut for agriculture or burnt by fire. This land-use change is referred to as deforestation. To reverse this deforestation, in some regions trees have been planted either to recreate an originally forested area or even to introduce forests where none exists. An example of the latter is Nebraska National Forest in the United States. Moreover, in response to various policy responses related to conservation efforts and to increases in carbon sink, some regions in the world have made efforts to plant vegetation and create new forests. This type of land-use change is called afforestation.

Observational studies have shown that deforestation results in changes in regional temperature, cloud cover, convection, and precipitation and is linked to changes in albedo, surface roughness, and land surface hydrology. Deforestation has been shown in a modeling study to cause changes in regional and mesoscale wind circulations and cloud formation in the Amazon. The dynamics involved in LULCC-driven climate change in the subtropics are slightly different from those in the tropics. Land surface and atmospheric radiation balance plays an important role in the establishment and maintenance of semi-arid regions. Positive feedbacks from a reduction in vegetation cover and its concomitant albedo increase can further exacerbate desertification. It is suggested by the scientific community that the interplay between vegetation, moisture, and
weather in the subtropics may create preferred modes of variability and preferred states of stability of climate in these areas.

Desertification occurs when a region that was covered in grassland or even forests is replaced by sparse desert plants or even bare soil. Studies have shown that changes in albedo are key to the climate response. Moisture is an important limiting factor in the subtropics, and modeling studies show that reductions in surface moisture tend to disrupt further precipitation by inhibiting moisture recycling. Modeling research shows that vegetation degradation in the Sahel produced rainfall anomalies consistent with the observed multidecadal drought in that area.

Model simulations were completed to assess modern era vegetation and that of earlier times. Restoring vegetation for the times of the Roman Empire, for example, caused summer rainfall in the model to increase in southern Europe and the Atlas Mountains, the lower Nile Valley, and the Levant (e.g., Reale and Dirmeyer 2000). Model responses to LULCC in the mid-latitudes tend to be more subtle and complex, because agriculture displaces both forest and prairie/steppes, with opposite effects on albedo and roughness, making the response highly sensitive to the details of the experiment’s implementation.

As expected, afforestation also inadvertently modifies biogeophysical and biogeochemical characteristics of a region and thus regional climate. Afforestation in temperate and tropical South America has led to cooler and wetter near-surface atmospheric conditions over most of the afforested areas, associated with higher and lower latent and sensible heat, respectively, than in current land cover conditions (Beltrán-Przekurat et al. 2012). Modeling research found temperature differences between current and afforested conditions were 0.6 °C and 0.8 °C in spring and summer, respectively. Higher evaporation and transpiration rates and lower temperatures in forest compared to grasslands were also found in an observational study of the area.

Precipitation is also affected by the vegetation changes in temperate and tropical South America. Domain-averaged precipitation showed an increase in natural versus afforested simulations: absolute mean values were higher, up to 30 mm month⁻¹ in summer, compared to current conditions. Relative changes were up to 30% in the afforested condition. Spatially, areas of increased rainfall were associated with changes in latent heat, roughness length, and areas of moisture convergence. Some dependency of afforestation pattern and moisture flux convergence was also observed, indicating that interannual variability in the fluxes may also affect the simulated patterns and magnitudes (Beltrán-Przekurat et al. 2012).

Urbanization

Humans tend to concentrate in cities. Although covering less than 0.5% of the Earth’s land surface, cities still exert a significant effect, out of proportion to their fractional coverage, on regional and global climate both from their LULCC, through their effects on the surface energy budgets, the water cycle, and surface biogeochemical cycles (e.g., carbon, nitrogen), and from their aerosol and gas emissions. This type of LULCC is referred to as urbanization.

The urban heat island (UHI) (Figure 4) is probably the most well-studied process with respect to weather and climate processes. A net surplus of surface energy over urban regions can be explained by enhanced surface sensible heat flux, ground heat storage, and anthropogenic heating as well as changes in physical evaporative and transpiration cooling. Because urban
regions typically have lower albedo values than rural areas (except, for instance, for urban areas embedded in coniferous forests), they absorb more shortwave radiation energy at the surface. Smaller values of the sky view factor (SVF) below roof level result in decreased radiative loss and turbulent heat transfer and add to the UHI anomaly.

UHI’s impacts can vary depending on existing climate regime and the vegetation type both within and surrounding the urban area, latitude, seasons, and even time of day. For example, over temperate regions, UHI can produce urban–rural sensible heat flux differences leading to a city center as a significant heat source. This is linked to the removal of forests, vegetation, and wetlands and the replacement by the built environment. On the other hand, over arid and semiarid regions urbanization may result in the introduction of irrigation and the resultant increase of latent heat fluxes. Moreover, it is found that over high latitudes, the urban–rural temperature differences are the highest during winter.

Urban land use can also modify, amplify, reduce, or initiate precipitation cloud systems since the surface heat, moisture, and momentum fluxes are altered from the surrounding non-urban landscape. Rainfall is often, therefore, different over the urban regions and downwind compared to nonurban areas, as verified by both in situ and satellite datasets. Thunderstorm rainfall can be increased over urban areas, for example, when the added heat from urban areas invigorates these storms. In semiarid irrigated urban areas, the cities also add water vapor to fuel the thunderstorms. UHI is a well-studied process; however, uncertainties still exist and a better understanding of the built-up environment and its effects on various aspects of the Earth’s weather and climate system is still emerging (e.g., Shepherd et al. 2013).

Carbon dioxide (CO$_2$) and LULCC

The association of LULCC and the carbon cycle is well known. Eastman, Coughenour, and Pielke (2001) investigated regional weather conditions in the central grasslands of the United States for three experimental scenarios using a model: (i) land cover was changed from current to potential vegetation; (ii) radiative forcing was changed from 1$\times$CO$_2$ to 2$\times$CO$_2$; and (iii) biological CO$_2$ partial pressures were doubled. Results indicate that the biological effect of enriched CO$_2$ and of land-use change exhibit dominant effects on regional meteorological and biological variables, which were observed for daily to seasonal timescales and grid to regional spatial scales. Simulated radiation impacts of 2$\times$CO$_2$ were minimal on these space- and timescales, with interactive effects between the three experimental scenarios as large as the radiational impact alone. Model results highlight the importance of including 2$\times$CO$_2$ biological effects when simulating possible future changes in regional weather.
Other modeling studies have shown that the inclusion of biospheric feedbacks due to increased CO$_2$ impacts the LULCC simulations. These studies have noted that these impacts are non-negligible and could be compared to changes associated with radiative forcing. Separate modeling research suggests that the impacts of LULCC initially remain over the areas of change and subsequently could be found over remote areas as well. In addition, it has also been noted that increased CO$_2$ does not negate the impact of LULCC but rather produces statistically significant regional effects. Regional modeling studies show that LULCC and increased CO$_2$ impact temperature and precipitation in China. It was found that increases in CO$_2$ resulted in increases in both maximum and minimum temperatures. Precipitation intensity has also changed due to LULCC and accompanying increases in CO$_2$. Moreover, modeling research demonstrated that LULCC and increased CO$_2$ modify return values of extreme maximum temperature and convective precipitation over Europe and China.

**Aerosols and LULCC**

It is well known that the impacts of aerosols on atmospheric processes, especially PBL layer evolution, are strongly coupled to surface processes and thus underlying land use. Depending on the albedo of a surface, aerosols can result in either warming or cooling of the PBL. Typically, aerosols over a high albedo surface result in warming, while those over a low albedo surface lead to cooling of the boundary layer.

Different atmospheric responses to aerosol radiative forcing over different land-cover types imply that aerosols modify horizontal temperature gradients and mesoscale circulations induced by land surface heterogeneity. Numerical simulations found that radiative forcing resulting from Saharan dust is rapidly reflected in the surface energy budget for land, causing a daytime reduction in downwelling radiation at the surface, and a corresponding reduction in sensible heat flux and boundary layer air temperature. However, over the ocean, since the radiation is absorbed over a deep layer compared to land, radiative forcing has little impact on the surface energy budget at short timescales. As a result, over the ocean, direct heating of air by the dust aerosols dominates and leads to an increase in air temperature. The net effect of aerosols, therefore, is to reduce the land–ocean thermal gradient in the PBL.

The coupled aerosol and land-cover change impacts on the modulation of mesoscale circulations may thus be especially significant in maritime environments. Sea breeze circulations, for example, are an important driver of convective activity tied to small islands. As a result, concurrent land-cover change and biomass burning in maritime settings and the combined impact of these two forcing mechanisms will influence deep convection, but this is not well understood.

A recent work by Junkermann et al. (2009) shows that land-cover change can affect the atmospheric distribution of aerosols and cloud condensation nuclei (CCN) which thus impact cloud microphysics. Aircraft observations over southwest Australia show that the differing biogeochemistry of salt lakes in the cleared areas and emission of aerosol precursors lead to approximately doubled CCN concentrations over this region compared to adjacent native vegetated regions. Corresponding differences in cloud particle size distribution are also observed in the clouds over the native vegetation region. Higher concentration of cloud droplets with diameters greater than 10μm were found over native
vegetation, while the cleared agricultural regions showed higher cloud droplet concentrations for particle diameters less than 10 μm.

Final remarks

This entry clearly demonstrates many impacts of LULCC on the climate system at all spatiotemporal scales through a variety of pathways and mechanisms. Moreover, after decades of scientific work around the globe, LULCC is now considered as a first-order climate forcing. However, additional research needs to be conducted to permit a further understanding of the pathways through which LULCC affects the climate system. This requires the establishment of in situ observational platforms in areas of rapid LULCC and also in and around where LULCC has already occurred, for example, in and around irrigated areas. It is also important that sustained funding be available for already established high quality in situ networks. Examples of such networks are the US Climate Reference Network (USCRN), and the Oklahoma, Kentucky, Nebraska, and Delaware mesonets. Similar funding stability should be provided to maintain the continuity of various satellite missions (e.g., Landsat). These observational capabilities should be complemented by simultaneous efforts for the improvement in modeling of the weather and climatic impacts of LULCC. We conclude that observational capabilities are essential for improvement and validation of modeling of LULCC effects.

Acknowledgements: The authors of this entry gratefully acknowledge the authors of Pielke et al. (2011) and Mahmood et al. (2010, 2014) which initiated many interesting and thoughtful discussions on climatic impacts of LULCC. For Roger Pielke Sr., the preparation of this entry was supported by NSF Grant AGS-1219833.

of Agriculture in the Climate System and in Climate Change.” *Agricultural and Forest Meteorology*, 142(2–4): 234–254.

Language and geography are intimately and intricately interconnected. The relationship between words and the world is pervasive, consequential, and often politically significant and divisive. This is because language, a distinctive marker of human cultural capacity and identity, can be used to name, categorize, and contest our world, and because language always bears the stamp of someone’s cultural and political authority. We use words to name things in the world (and beyond it), and to describe or explain feelings about our world or about other human or nonhuman agents. Variations within or between languages in how humans describe or explain their world, or understand local places, may be revealing of profound differences in meaning about place and space.

The beginnings of formal interest in the relationship between geography and language date to seventeenth-century Biblical scholarship and, from the eighteenth century in Europe and America, to discussions over the origins of language and the connections between language, national identity, and to the issue of social difference as expressed in terms of rank, status, or, to use the terminology of the nineteenth century, social class. In the nineteenth century especially, and in continental European scholarship in particular, the study of geography and language centered upon the mapping of language areas, by nation or by ethnic group.

In contemporary scholarship, the study of language and geography falls broadly within cultural geography. Three main themes may be identified. The first has to do with toponomy and taxonomy, with the words and categories which we use to describe and order the world, including the terminology used in geography (but it does not include the study of proper names, which is the preserve of onomastics). This first theme is most evident in the associations between place names, geographical features, cartography, and identity. The second theme incorporates the connections between language and geographical area. At different times and in different intellectual contexts, this is variously termed “language geography,” “linguistic geography,” “geolinguistics,” or “dialect geography.” For each of these descriptions, the focus is upon language’s areal differentiation over time and space. In the last two named, attention is paid to the geographical differentiation of language’s internal structures, the spoken differences in language, often in relation to social class, or to the rural–urban distinctions in a particular language’s dialects or lexicon. The third theme embraces the study of language within geography as an academic discourse, and of language’s social usage – “words-in-the-world” (McGeachan and Philo 2014) – as a means to intellectual authority and cultural and political power.

It is not appropriate to see these themes as either typologically or chronologically discrete, as methodologically distinct, or, even, as the concern of geography alone. Work on the politics of place names, for example, may have close affiliations with studies directed at the political authority behind the use of one language and not another, and explanation of the changing
Language geographies

National or regional geography of language or dialect areas similarly involves questions of power and cultural difference. Study of these issues is shared with linguistics, sociology, comparative philology, and ethnology, and, just as these themes are related, so, too, they have further subthemes.

Language, naming, and identity

The study of toponomy, the names of places and of geographical features, may reveal the linguistic history of a place or region since such names may contain elements of a previous language or variant meanings from that which is currently understood or dominant. There is, in Britain and in continental Europe in particular, an established intellectual tradition of place name studies as a distinct subset of enquiry in historical geography, history, ethnography, and in the study of folk practices, given that some such practices may survive, for example, only in a relict vocabulary. Capturing the nominative role of language and of given words either in their current form or in their former ethnological context may disguise, however, the processes and the authoritative acts behind naming. Understanding the names of places and the words used to label the world – on the ground, in writing, in speech, and on maps – requires that attention be paid to the relationship between the fact of description, the act of inscription, and the consequences of any linguistic proscription since given words, speech forms, or, even, entire languages, were often forbidden or deprived of their cultural currency.

Within modern historical geography and cultural geography, numerous studies have examined the ways in which identity, meaning, and notions of political and cultural order have been inscribed upon human landscapes through authoritative acts of naming, or, by contrast, have shown how meaning in place and in landscapes may be lost through linguistic change or, ultimately, language death. In eighteenth- and nineteenth-century North America, the contact between European trader-settlers with indigenes often resulted in the “writing out” of native names by their “writing over” in the mapped landscape and by parallel processes of “speaking over” as native languages were replaced, by English, or French, or Spanish, in the different spoken domains of daily life. In such encounters, the written word commonly dominated over the spoken word, and print culture over oral culture. The archival traces of such unequal linguistic encounters exist, where they exist at all, in the language of the colonizer, hardly at all in those of the colonized. In Australia, New Zealand, Hawaii, and throughout the South Pacific islands, the sustaining myth of *Terra Nullius* held by Europe’s settlers, geographers, and, importantly, map-makers – that these lands were unnamed and “empty” – led to them being inscribed with the names and languages of the colonial conquerors. The politics behind the descriptive, inscriptive, and proscriptive historical geographies of language and naming in colonialism and imperialism have modern parallels. In Israel’s administered territories, for example, Zionist ideologies are manifest in the names chosen for settlements in the West Bank and other disputed territories. In the Caribbean, tensions between users of the local creole patois or “speak” and speakers of the official language reveal linguistic differences to be matters of longstanding cultural and social stratification (for these and other examples, see Withers 2000).

Several points may be noted of this work and of its implications. Studies in geography on the authority and politics of naming in an historical context, and upon language acts in the contemporary world, share a concern with how the legacies of colonial pasts inform the
Language geography/linguistic geographies: areal differentiation and variations in language and speech

The mapping of languages by area, commonly in association with national identity or ethnicity, is an established feature of language geographies. From the early nineteenth century, such work was a distinctive element of German geographical scholarship. The earliest known thematic maps of language by area are the language maps of four continents, the *mappae geographicopolylgottae*, produced by the Silesian philosopher and theologian Gottfried Hensel as illustration to his *Synopsis Universae Philologiae* (1741). Hensel sought to explain all the world’s languages as having a common origin in Hebrew. In Germany, Julius Klaproth produced language maps of Asia in his *Sprachatlas* of 1823 in order to distinguish the different language families in that continent. Although dialect mapping exists for earlier periods, of variations in spoken German in an 1821 work by Johann Smeller, for example, most language mapping in the nineteenth century was concerned with language groups rather than with internal variations in language form. It was associated with the

colonialisms of the present. Both are motivated by the importance of that continued questioning of received historical and geographical “truths” which is a feature of postcolonial enquiry, in geography and in other disciplines. Although it is not always explicitly acknowledged, geographical work on language, naming, and identity has its parallels in studies concerned with writing in geography, with the act of writing as a matter of style (Billinge 1983), and, more than that, with different forms of writing (and of speaking) within geography as embodying unequal relations of power within the discipline. This issue is discussed in greater depth in the third section below.

Exploring questions of language, naming, and identity as questions of power requires that we pay attention to the nature of political authority and to those institutions and individuals in whom an inscriptive power to name is vested. This is particularly true of language’s central place in mapping and is a common feature of interpretation in the more recent history of cartography. Following the work of Brian Harley and his use of the work of Jacques Derrida and Michel Foucault, maps are seen as intrinsically powerful and power-full documents, capable both of inscribing space and of silencing claims to it by virtue of the omission of, or selection from, one language or word or worldview over those of other user groups. The map is an enduring form of geographical language. Maps may thus, as Mark Monmonier phrases it, “name, claim, and inflame” in relation to place names, topographical features, and the politics of identity (Monmonier 2006). In nineteenth-century Great Britain and in Ireland, Ordnance Survey was the state institution most involved with the naming of places, its acts of mapping often involving the transliteration of names from Irish, Welsh, or Scottish Gaelic into English substitutes, sometimes at the loss of earlier name forms or of an originating meaning (Withers 2000). In Britain, a Permanent Committee on Geographical Names for British Official Use was established in 1919. In the United States today, names are decided upon by the US Board on Geographic Names which reviews proposals for names and renaming and which adjudicates upon federal policy for dealing with toponyms within and beyond that nation’s borders. At the world scale, names are the concern of the United Nations’ Conference on the Standardization of Geographical Names and the UN Group of Experts on Geographical Names (Monmonier 2006, 98).
development of ethnological and anthropogeographical perspectives in geography, in Britain and, in particular, in continental Europe, and with developments in comparative philology. Language mapping in the modern world echoes this earlier tradition and, additionally, is used as a means to chart language shift within and between nations, the rise to global hegemony of English (Crystal 2003), and to plot the world’s linguistic diversity (Asher and Moseley 2007).

Drawing upon such earlier scholarship on language and geography, the distinction may properly be made between the *Sprachenkarte*, where the mapped subject is a language or language group, and the *Sprachkarte*, which is, by convention, a map of linguistic forms (phonetic, morphological, orthographical, synthetic, or lexical) with regard to a specified geographical area. This difference in focus, and in the representation of languages and linguistic variation over space and over time, speaks to the difference between, on the one hand, language geography or, sometimes, the geography of language, and, on the other hand, linguistic geography or geolinguistics. Language geography deals with the distribution over time and space of language as a cultural artifact and with the explanation of such changes in terms of social, cultural, and political processes. Linguistic geography is more the preserve of linguists than of geographers. Linguistic geography is geographical only in the sense that the linguistic phenomena in question are spatially located, although the term has been used to assess the political authority and cultural identity that is rooted in certain forms of, or variations in, a language in modern multicultural contexts such as the speaking of French and the position of so-called minority languages in Canada (Breton 1993). In linguistic geography, conceptualizations of geographic space have tended to focus upon the region as a static “container” of variations in linguistic form, rather than to consider the region or other forms of areal differentiation as contested arenas of social or political meaning as might more widely be understood in contemporary human geography (Britain 2010).

The term “dialect geography” is used within linguistic geography – and is, perhaps, even seen as a subdivision of it – to describe the study of local differentiation in words or expressions within speech (usually within a predefined administrative region rather than a cultural area), and the variable distribution there of given speech forms. In dialect geography as in traditional dialectology, the region is taken as the primary, and, often, the only independent geographical variable. In England, there is a tradition of enquiry in linguistic geography/dialect geography directed at rural, rather than urban, variations in words, expressions, and linguistic elements, and in recording such variations almost as a linguistic form of “rescue archaeology” before the folk practices and tacit knowledge they embody are lost. Notable publications in English linguistic geography include the work of the Oxford philologist Joseph Wright in overseeing the *English Dialect Dictionary*, published in six volumes between 1898 and 1905, and the *Linguistic Atlas of England* (1978), which was the outcome of a survey of English dialects undertaken between 1950 and 1961 by scholars based at the University of Leeds, as also was the *Atlas of English Dialects* (1996). In the United States, the *Dictionary of American Regional English* (DARE), published in six volumes between 1985 and 2013 and based on nearly 1800 recorded interviews undertaken between 1965 and 1970, mirrors the English dialect survey but extends from it in incorporating elements of historical usage as well as contemporary geographical variations in speech forms and lexicon. In Germany, geographers in the University of Marburg have continued and
developed that country’s traditions of linguistic mapping and language geography.

The study of dialectal and linguistic variations within urban settings is concerned more with questions of social class and of internal differences within language as presumed markers of educational status and social hierarchy. In that sense, urban geolinguistics is a form of sociolinguistics, and is a subject of enquiry for sociologists and social psychologists as well as for geographers. The emphasis is upon describing and explaining differences in speech forms in relation to social and cultural circumstances. In such work, the geographical scale of the linguistic enquiry is less commonly an administrative region and is more often a neighborhood, a locale, or, even, a particular community of language users with its own distinctive idiolect (Trudgill 1983). Explanation of specific linguistic registers or idiolects, particularly in an urban context, is widely seen as a matter of social and political conditions. In contrast, some recent work by sociolinguists has argued that varieties in certain speech sounds may be a direct consequence of the natural environment occupied by the speakers (height above mean sea level, and levels of relative humidity), not of cultural circumstance (Everett 2013). Such environmentally deterministic explanations of linguistic variation do not have currency in contemporary geography.

**Language, geography, writing, speaking**

Human geographers have long been attentive to the nuances of language and to the problems of geographical description (Darby 1962). Of course, good writing in geography means more than choosing the right words and knowing how to balance description with interpretation so as to offer clear explanation and promote others’ comprehension. Audiences matter – or, at least, they should – to how geography’s authors write authoritatively. Different styles in geography have been shown to transmit different meanings and, in some cases, to obscure any clear meaning at all (Billinge 1983). In general, such issues are not the concern of physical geographers. For them and other natural scientists, geography’s terminology is largely unchanged over time, is assumed to be unproblematic and to have universal currency, and can be easily manipulated within the overall language of science: *this* is the way the world is because the method, expressed not in words but in the language of numbers, makes it so.

The recognition, most evident within certain quarters of human geography, that there are pervasive and consequential connections between language, social power, and the practice of geography is part of a wider “linguistic turn” within twentieth-century philosophy and social theory. Language, it is claimed, is a medium through which intersubjective meaning is established and negotiated. As with other cultural practices, language does not exist outside social relations of power. There is always a politics of language. These issues are apparent in several ways.

The work of Gunnar Olsson has been influential in demonstrating in geography how the limits to our understanding of the world may, indeed, be the limits of our language. With others, he has argued for the importance of questioning the social and cultural relations we are talking in and through, rather than considering the object of what, as geographers, we are talking about (Olsson 1992). Similarly, issues to do with the politics of language and with the authority vested in language are central to certain strands of ethnomet hodological and qualitative procedures in geography as part of attempts to capture variant or subaltern meanings in the world and so to do
interpretative justice to others’ words and worldviews. The use of particular linguistic registers within geography is thus closely associated with the possibility of the more ethical distribution of resources within society, and, for some, of a more moral geography altogether.

The dominance of the English language as academic geography’s *lingua franca* (see Crystal 2003), and of the hegemony of Anglo-American geographical discourse, has been a subject of concern (for a recent review, see Desbiens and Ruddick 2006). English in its spoken and written forms dominates the subject’s major conferences and the majority of its specialist publications, although several journals incorporate abstracts in French, Spanish, and Mandarin Chinese. Paradoxically, some of the anxieties expressed over the issue of English’s global dominance in geography – the subordination in the discipline of other world languages (French, Spanish, Mandarin Chinese), the authority within the academy of certain styles of writing, even of speaking, and of gender biases in language which permeate geography’s dominant epistemologies – are not always equally a matter of concern for the speakers of other languages, for whom proficiency in English and publication in that language are markers of professional attainment. Even so, and recognizing that much ethnological fieldwork and qualitative methodology in geography requires competence in languages and idioms other than “standard” English, and that “foreign language” training is available to UK postgraduates, for example, most accounts of the subject’s practices and intellectual traditions too commonly assume Anglo-American narratives to be geography’s only voice.

Language is important to the making and remaking of local geographical meaning. This is, of course, particularly the case in contemporary human geography as the examples above indicate, and because nearly all studies in the field are, in one way or another, dependent upon both the spoken and the written word. Historical scholarship in geography has long been attentive to the power of written discourse and so has privileged archival analysis based on printed and manuscript materials. Nevertheless, it is possible to work with the spoken and the heard, as well as with the written and the recorded, in historical geography. Allan Pred’s examination of the conflicts of meaning articulated in different language usage in nineteenth-century Stockholm emphasized the potential in studying the locally spoken word as an element of geographical significance (Pred 1990). Words used in the workplace, or at home, words used to report upon others or to describe one’s self can be used to supplement the written record. Ogborn has shown how speech acts were, often, quite strongly regulated – in courts of law, for example – and how attention to different forms of speech, and to the speech acts themselves, can disclose the practices by which people made sense of their world: “Also, since speaking is simultaneously, and indivisibly, linguistic and embodied, a matter of ‘performance’ and ‘representation,’ understanding speech practices in the past or the present demands a continued rethinking of those distinctions so as to acknowledge representations as ‘actions themselves’ in the on-going making up of the world” (Ogborn 2011, 110).

In such claims, it is possible to see a shift in emphasis in the study of language in geography away from the mapped presence of different languages or of variations in the form and content of a language – whose language, dialect, or idiolect was where, and why, in given national or regional spaces? – toward an understanding of the power of words, within geography as a discourse, and in the world more widely. Rather than map *where* words were, geographers might more commonly now ask what work do words *do?* As McGeachan and Philo (2014) argue, it is
vital to recognize that different types or orders of words embody different ontological status relative to one another, and that different words embody and represent different ways of being in the world. As illustration, they explore the words “chatter,” “testimony,” “lore,” “report,” “opinion,” and “discourse,” and the different levels of authority and power that are inscribed within them and the work to which these words speak.

Language in its different forms and words, spoken and written, has an everyday and enduringly powerful presence. Mapping and naming the world, giving meaning to the world, and being in the world, are all embodied in the words and in the languages which geographers and others use in thinking about, writing about, and talking about the world.

Late Cenozoic polar glaciations

Rob McKay
Victoria University of Wellington, New Zealand

The commonly held view of the evolution and development of major glaciation in the Earth’s polar regions is that the East Antarctic Ice Sheet (EAIS) first formed near the Eocene/Oligocene boundary 34 million years ago (Ma) and was highly oscillatory until the middle Miocene (≈14 Ma). This was followed by development of the marine-based West Antarctic Ice Sheet (WAIS) in the Late Miocene/Early Pliocene (≈7–5 Ma) and major ice sheets covering large areas of North America and northern Eurasia by the middle Pliocene (≈2.7 Ma; Figure 1). Because of the difficulties in obtaining direct geological records from the polar regions, either due to extensive ice coverage or due to widespread glacial erosion, this view of Cenozoic glaciation has largely been derived from proxy records far removed from the polar regions (Figure 2). Many of these proxies, such as marine oxygen isotope records and sequence stratigraphy–based sea level reconstructions, provide excellent, indirect records of changes in the globally integrated volume of past ice sheets. However, these cannot provide information regarding the geographical location and extent of past ice sheets at either pole. More detailed information regarding the onset and subsequent variability of major glaciation in each hemisphere is critical in order to understand the cause of polar glaciations through the Cenozoic, as well as the potential sensitivity of ice sheets to environmental change not only in the geological past, but also in the future.

Early Cenozoic initiation of Antarctic glaciation

The Paleocene and Eocene epochs of the early Cenozoic (65 to 34 Ma) are commonly referred to as the “greenhouse” world, on account of highly elevated concentrations of CO2 (>750 ppm; Figure 2). Antarctica has been centered over the South Pole for the past approximately 80 million years, yet during the peak of the early Eocene warm period (≈55 Ma), pollen-based and lipid biomarker proxy reconstructions indicate a subtropical to temperate climate, with winters that were essentially frost free. Following this peak warmth of the Cenozoic, marine oxygen isotope records indicate a global cooling trend that appears to have culminated in a rapid climatic and ocean cooling at the Eocene/Oligocene boundary 34 Ma (Figure 2). However, the exact age of the onset of Cenozoic glaciation on Antarctica currently remains unconstrained. Numerical ice sheet models point to nucleation of highly dynamic ice caps centered on East Antarctic highlands, which could have been present throughout cooler orbital configurations during the relatively cooler time intervals of the Paleocene and Late Eocene. This is because geological records are inherently biased towards marine records, and therefore if these early ice sheets were entirely land-based, there would be no iceberg-rafted debris or glacial signal deposited in these marine...
sediments. However, far-field sea level records suggest that sea level variations on the order of tens of meters may have occurred during the Paleocene and Eocene on timescales <1 million years, which can best be attributed to glaciation. Despite a lack of age control, evidence for the earliest phase of Cenozoic glaciation is still preserved beneath the modern-day EAIS. Geophysical surveys of the Gamburtsev Mountains, which are currently covered by the EAIS, indicate the presence of a pre-glacial fluvial landscape as well as alpine-style glacial valleys formed during the earliest phases of Cenozoic glaciation in Antarctica. The clearest indication for widespread intensification of Antarctic glaciation is a two-stepped approximately 1.5‰ increase in marine oxygen isotope values over a time period of approximately 400 kyr at the Eocene/Oligocene boundary (33.4 Ma; Figure 2). This isotopic shift is interpreted as a 4°C cooling in deep ocean temperature occurring alongside an increase of 80 m of sea level equivalent in ice volume being emplaced on the Antarctic continent. This is a larger volume of ice than is currently on Antarctica, which is difficult to reconcile without invoking the presence of Northern Hemisphere Ice Sheets at this time. However, prior to extensive glacial erosion and subsidence due to tectonic rifting much of West Antarctica, which is now largely below sea level, was subaerial at this time. This allows for the development of high-elevation terrestrial ice sheets covering the entire Antarctic continent in the Oligocene, and ice sheet models...
run on this reconstructed topography can now reconcile this apparent offset without invoking major Northern Hemisphere Ice Sheets.

Glacimarine and subglacial diamictons recovered from the East Antarctic continental shelf, and from iceberg-rafted debris in the Southern Indian Ocean, confirm that a continental–scale EAIS had reached the continental shelf edge and was calving icebergs into the Southern Ocean by the earliest Oligocene (≈34 Ma). However, glacimarine sediments from drill cores in the western Ross Sea may be as old as the Late Eocene, indicating that localized glaciation may have been occurring in the Transantarctic Mountains prior to the Eocene/Oligocene transition.

Figure 2  Late Cenozoic climate history from: (top) direct geologic records of East Antarctic Ice Sheet (EAIS), West Antarctic Ice Sheet (WAIS), and Northern Hemisphere Ice Sheets (NHIS); (center) δ¹⁸O values of benthic foraminifera – lower values represent comparatively warmer oceanic temperature and reduced ice volume (modified from Zachos, Dickens, and Zeebe 2008); (bottom) reconstructed atmospheric CO₂ concentration derived from the geochemistry of marine plankton (modified from Zhang et al. 2013). Modeled CO₂ thresholds for ice sheet initiation are from DeConto et al. 2008.
The tectonic opening of the Southern Ocean, in particular the “gateway” between Australia and the Antarctic, has long been considered to have thermally isolated the Antarctic continent, preconditioning it for glaciation. However, general circulation and ice sheet models suggest tectonic changes may have played a less direct role than altering oceanic heat transport, and point to a potentially related change in the carbon cycle being more important. These models favor a mechanism whereby declining atmospheric CO₂ decreased to a certain threshold value, lowering the radiative forcing of incoming solar insolation and thereby setting the scene for glaciation (Figure 2). Once this threshold was met, it enabled the rapid development of large ice caps on Antarctica’s highland regions, which eventually coalesced to form a single continental-scale ice sheet. Once formed, such an ice sheet is difficult to melt, due to height-mass balance and albedo-related feedbacks. However, marine isotope records indicate that, following the initial inception of the EAIS, large, orbitally paced variations in ice volume did occur throughout the Oligocene and Miocene.

Neogene cooling and development of a “stable” EAIS

Sometime around the Oligocene/Miocene boundary, the vegetation in the Transantarctic Mountains shifted towards an increasingly tundra-style landscape (between 25 and 17 Ma), and stratigraphic drill core evidence indicates this cooling was associated with a large erosional event offshore of the Transantarctic Mountains. This coincides with a 200-kyr-long positive marine oxygen isotope excursion, and appears to represent a glacial expansion of the EAIS close to or exceeding its present-day volume. Terrestrial outcrops and geomorphology in the Transantarctic Mountains provide evidence of highly voluminous subglacial meltwater outburst floods from the EAIS margin prior to 14 Ma, consistent with a warmer, more variable ice sheet at this time.

The approximately 1‰ enrichment of marine oxygen isotope value at approximately 14 Ma is generally regarded as representing the transition from an oscillatory to relatively permanent EAIS. Geological outcrops in the Transantarctic Mountains indicate a permanent transition from wet-based to dry-based glacial deposition, the extinction of the Antarctic tundra and Nothofagus vegetation in the Transantarctic Mountains, and the development of a hyperarid polar environment at this time. However, while there is no evidence of large subglacial meltwater outburst floods at high elevation in the Transantarctic Mountains after 14 Ma, late Miocene sedimentary sequences in Ross Sea drill cores and outcrops in Prydz Bay contain glacimarine facies that indicate that significant discharge of sediment-laden subglacial meltwater from the low-elevation, marine termini of EAIS outlet glaciers persisted well into the Late Miocene (11.6–5.3 Ma). Tundra vegetation persisted in the Antarctic Peninsula region until at least 12.8 Ma.

The relative stability of the EAIS since the cooling event at 14 Ma has been disputed for the past three decades, with some studies suggesting widespread loss of the EAIS as recently as 3 million years ago. However, this is at odds with hyperarid polar climates in the Transantarctic Mountains through this time, and far-field marine isotopic variations. Far-field sea level estimates suggest sea levels were approximately 20 ± 10 m higher than present during the mid-Pliocene (≈3 Ma), inferring loss of both the WAIS and the Greenland Ice Sheet, and up to approximately 10 m sea level equivalent (s.l.e.) from the EAIS (currently 53 ms.l.e.). This sea level budget from EAIS can be reconciled by the
presence of uplifted marine deposits from the East Antarctic margin indicating there was some limited retreat of the EAIS marine margin during the Pliocene, and by geochemical fingerprinting of muds deposited offshore of Wilkes Land in East Antarctica that indicate erosion by an EAIS that had retreated inland during the Early Pliocene, potentially by hundreds of kilometers.

**West Antarctic Ice Sheet evolution**

An increase in the delivery of terrigenous turbidites in the late Miocene/early Pliocene to the Weddell Sea Abyssal Plain is commonly interpreted as representing the first major expansion of the marine-based WAIS. However, seismic studies and drill core studies in the Ross Sea indicate the presence of large ice caps covering Marie Byrd Land in West Antarctica, as well as localized highs in the Ross Sea since Oligocene times (34–23 Ma). As mentioned earlier, it is likely that much of West Antarctic was above sea level at this time and this is a critical boundary condition to identify as it allows for growth of terrestrial ice sheets in a much warmer climate than would be required to initiate marine-based ice sheet growth (i.e., a higher CO₂ threshold in Figure 2). Seismic reflection data to reconstruct the paleogeography exist around the entire West Antarctic margin, but their ages are only (partially) constrained by drilling in the Ross Sea and Antarctic Peninsula. Deep Sea Drilling Project site 270 in the central Ross Sea indicates a terrestrial to marine transgression in the central Ross Sea occurred approximately 27 Ma. Seismic profiles in the central Ross Sea further indicate that middle Miocene glaciation was characterized by local ice caps on basement highs, and that the continental shelf was shallow and seaward dipping. A major shelf-wide unconformity in the Ross Sea provides the first evidence for a greatly expanded marine-based WAIS, although the age of this event(s) is poorly constrained and could have occurred anytime between 14 and 4 Ma, with a potentially similarly timed event also occurring in the Antarctic Peninsula. Such an over-deepening of the continental shelf in the Late Miocene/Early Pliocene allows for greatly increased warm-water intrusion across the continental shelves of Antarctica which is the key process that acts to melt marine-based ice sheet. Thus, there is potential that the WAIS may have been greatly reduced in size during late Miocene to Early Pliocene times compared to early times, as the climate and oceans were too warm to support regular advances of marine-based ice sheets (Figure 2). Drilling beneath the modern-day Ross Ice Shelf as part of the ANDRILL program provided the first direct evidence that the marine-based WAIS advanced and retreated during the Pliocene, but was probably reduced to its terrestrial remnants during the warmest periods of the Pliocene. However, the WAIS was a more persistent feature, albeit with orbitally paced retreat events, after a Pliocene cooling event between 3.3 and 2.5 Ma.

**Paleogene glaciation in Greenland and the Arctic margin**

The evidence for the earliest onset of Cenozoic glaciation in the Northern Hemisphere is even more sparse than for the Antarctic, but it is widely believed that major ice sheets covering large areas of North America and northern Eurasia did not appear until the middle Pliocene at approximately 2.7 Ma. Diatoms and ice-rafted debris infer the presence of sea ice in the Arctic Ocean Basin during the middle Eocene (47.5 Ma). Dropstones with surface textures indicative of glacial erosion are present in late Eocene (38–30 Ma) marine sediments from drill
cores in the North Greenland Sea and Arctic Ocean, arguing for the presence of marine terminating East Greenland or Svalbard ice caps and mountain glaciers. Evidence for glaciation since this time is sparse until the mid-Miocene when ice-rafted debris increases at 16 and 14 Ma in Arctic Ocean cores. A core collected offshore of Southeast Greenland records sporadic pulses of ice-rafted debris from 7.3 Ma until the Late Pliocene (≈3.6 Ma) when ice-rafted debris becomes ubiquitous. Although potentially biased by poor drilling recovery, these data indicate that Greenland and the High Arctic have supported ephemeral glaciations since Late Eocene times.

The establishment of larger and more persistent glaciation did not likely occur in the Northern Hemisphere until the Late Pliocene. In the context of the general cooling and lowering atmospheric CO₂ trend of the Cenozoic, modeling studies support the notion that the atmospheric CO₂ threshold (i.e., radiative forcing) of Northern Hemisphere glaciation is significantly lower (≈280 ppm) than that for the Antarctic (≈750 ppm), and helps to explain a delayed onset of Northern Hemisphere glaciation relative to Antarctica (Figure 2).

Late Pliocene development of a bipolar glacial world

The Late Pliocene and Pleistocene is characterized by higher amplitude glacial–interglacial cycles and gradually increasing values in the marine oxygen isotopes, interpreted to be related to the onset and intensification of Northern Hemisphere glaciation. This increase is associated with a major increase in ice-rafted debris in deep-sea cores offshore of Greenland and North Atlantic. The increase in iceberg-rafted debris offshore of Northwest America at 2.7 Ma, and glacial outwash gravels dated at 2.64 Ma, suggests the Cordellian Ice Sheet may have been a nucleation center of the early North American ice sheets. The exact timing of the development of the Laurentide Ice Sheet over much of North America is more difficult to constrain due to the difficulty of distinguishing the source of ice-rafted debris in the North Atlantic. However, a recent provenance study has suggested that ice rafting in the North Atlantic was dominated by Greenland and Nordic Sea sources, with little input from North America until after 2.64 Ma. However, this indicates that the major centers of major North Hemisphere glaciation (Greenland, Fennoscandian, and Cordellian Ice Sheets) were all covered by large ice sheets at 2.64 Ma. An important caveat in the iceberg-rafted debris evidence is that it does not preclude the gradual onset of terrestrial ice sheets prior to this time. However, evidence for a lack of major glaciation prior to 2.7 Ma in the Northern Hemisphere is further supported by a recent drill core record from Lake El’gygytgyn in Northeast Arctic Russia that indicates that Arctic cooling was insufficient to support large-scale ice sheets until the latest Pliocene (2.64 Ma).

Early Pleistocene advances of the Laurentide Ice Sheet appear to have extended further south than Late Pleistocene advances, with expansions to approximately 39°N around 2.4 Ma. Because Early Pleistocene advances were volumetrically smaller than later ones, the elevations of these ice sheets must have been lower, implying that the glacial dynamics (i.e., flow) of these early ice sheets were different. This shift in glacial dynamics has primarily been attributed to the unconsolidated and deformable nature of the subglacial sediments that were eventually eroded back to bedrock by glacial erosion during subsequent glacial advances.

Hypotheses for the cause of Northern Hemisphere glaciation are numerous, but as yet this remains unresolved. Proposed mechanisms range
from shifts in oceanic and atmospheric circulation patterns arising from tectonic changes, such as the closure of the Isthmus of Panama or the Indonesian oceanic throughflow, through to declining atmospheric greenhouse gases that allowed the build-up of glacial ice in both hemispheres (Figure 2). However, these changes in Earth’s boundary conditions only pre-conditioned the Earth towards bipolar glaciation. Another key variable is the changes in the orbital configuration of the Earth, which regulate how the distribution of incoming solar insolation is distributed on the Earth’s surface over the course of a year. These orbital cycles operate at various timescales – from the well-known 20, 40, and 100 ka cycles to longer term cycles exceeding 1 Ma.

Building on the earlier ideas of Joseph Adhémar and James Croll, Milutin Milankovitch first developed his orbital theory of the ice ages in the 1910s, when he suggested that build-up of continental Northern Hemisphere ice sheets was the consequence of changes in the seasonality related to periodic shifts in the Earth’s orbit. His theory reasoned that reduced seasonality – that is, a warm winter but cool summer – would result in glaciation because the winter snowfall would be able to survive through the course of summer, and this would eventually build up to form an ice sheet. However, it was not until the 1970s that a relationship between the ice age cycles and changes in Earth’s orbital configuration was clearly recognized. From this, it became apparent that orbital changes initiated a series of oceanic, atmospheric, and ice sheet feedbacks that greatly amplified the influences of changing solar insolation over time. Despite the clear orbital pacing of the ice age cycles, fundamental questions remain regarding the response of the Antarctic and Northern Hemisphere Ice Sheets to orbital variations. Firstly, why did 40 kyr frequencies (relating to changes in the axial tilt of the Earth) dominate glacial cycles between 0.8 and 3 Ma, with precession (≈20 kyr) signal only playing a minor role despite its stronger influence on summer insolation. Perhaps more puzzling is that after 800 ka, the pacing of ice ages shifted to 100 kyr cycles, paced by eccentricity (i.e., changes in the circularity of Earth’s orbit) despite this being the weakest influence on solar insolation. This later shift indicates that there is a strong nonlinearity in how changes in incoming solar insolation at the top of Earth’s atmosphere are transferred to ice sheet growth and decay on the surface of the Earth. Numerous theories exist to explain the orbital pacing of the ice ages, but efforts to comprehensively resolve these puzzles are hampered by a lack of direct long-term continuous records of ice sheet variability in either hemisphere (see the review by Raymo and Huybers (2008) for more detail on these issues).

The Mid-Pleistocene transition and further glacial expansion

The transition from 40 kyr to 100 kyr glacial cycles was also associated with the final phase of glacial intensification, when an increase in the amplitude of the marine oxygen isotope cycles implies that sea level variations through a glacial-interglacial cycle increased from <80 m to >120 m. While most of the expansion is related to expansion North Hemisphere Ice Sheets, notable cooling is also apparent in the Southern Hemisphere, with an intensification of the sub-polar westerlies and expansion of the Southern Ocean sea ice belt. With the possible exception of the Greenland Ice Sheet, the Northern Hemisphere Ice Sheets likely experienced full glacial retreat during most of the Late Pleistocene interglacial periods. However, the response of WAIS during the Late Pleistocene is entirely unconstrained. The presence of Pleistocene
LATE CENOZOIC POLAR GLACIATIONS

diatoms recovered from beneath areas of WAIS now grounded indicates open marine conditions occurred in the interior of West Antarctica some time(s) after 1.3 Ma, but the exact timing of this event(s) is equivocal. A likely candidate is the last interglacial period, with far-field sea level reconstructions suggesting Marine Isotope Stage 5e (≈120 ka) likely had global sea levels >6 m above present. Recent ice core evidence suggests that only a modest reduction (≈2 ms.l.e.) in the size of the Greenland Ice Sheet occurred at that time, and thus sea levels require a loss of the marine-based sector of the WAIS. Sediments in the Ross Ice Shelf indicate the WAIS has oscillated between a grounded ice sheet and floating ice shelf since 800 ka, but there is no evidence of open marine conditions during the past approximately 1 Ma. To date, Marine Isotope Stage 31 (≈1 Ma) provides the only conclusive evidence of the last major WAIS “collapse” event.

The Last Glacial Maximum saw ice sheets in both hemispheres reaching their maximum positions between 26.5 and 19 ka (Figure 1). Following this glacial maxima, ice sheet retreat began for most of the Northern Hemisphere ice sheets at 19 ka, but was delayed in Antarctica until after 15 ka. However, the exact chronology of retreat of ice sheets in each hemisphere is poorly constrained and remains hotly debated. Accurately reconstructing these chronologies is essential to identify the mechanisms that initiate glacial retreat, in particular rapid “collapses” of the marine-based ice sheets. Rapid collapses of these ice sheets are evident in coral reef records of post-Last Glacial Maximum eustatic sea level rise – with one event in particular the focus of much attention. This event, termed Meltwater Pulse 1A, saw a sea level rise of up to 4 m/century for a period of 300 years, yet there is little consensus over the source region of this rapid input of glacial melt in the global ocean. However, identifying the source of this meltwater pulse is relevant for potential scenarios of future sea level rise. If the source was in the Northern Hemisphere, then much of the ice capable of rapid retreat (i.e., marine-based ice) no longer exists. However, if it came from Antarctica, there remains 22 m of sea level equivalent in ice sheets grounded below sea level in both West and East Antarctica. Some of this Antarctic ice is thought to be capable of more rapid retreat than the rates that we are currently experiencing (0.3 m/century), in particular that of the marine-based sectors of the WAIS (3.4 ms.l.e) which sits on an over-deepened, reverse-slope continental shelf – a configuration that is particularly vulnerable to rapid retreat via marine instability mechanisms.

Description and purpose

The Geographic Society of Latvia is a non-governmental organization whose mission is to advance geography in Latvia. This mission is accomplished through a broad array of activities. The society coordinates scientific research in the field of geography carried out in different institutions, facilitates the advancement of methods of teaching geography in schools, coordinates the development of geographical terminology and toponymy research, encourages geographical local lore studies, national tourism, and travelling in Latvia, contributes to understanding geography and geology in Latvia and beyond, as well as popularizing geo-ecological and environmental knowledge and encouraging environmental awareness.

Journals or major publication series

Ģeogrāfiski Raksti, Folia Geographica. www.geo.lu.lv/petnieciba/geografiskieraksti

Current activities or projects

The principal activities of the society are the organizing of geographical workshops, conferences, regional symposiums and Latvian geographical congresses (the Latvian geography congress held in 2012 had 10 thematic sessions and symposia with 105 presentations); facilitating teaching and learning of geography, cooperating with the geography teachers association, and school geography olympiads; membership in the International Geographical Union (IGU) and the Association of European Geographical Societies (EUGEO) and participating in IGU congresses and conferences (the 32nd International Geographical Congress program had 12 presentations from Latvia); and publishing of Ģeogrāfiski Raksti, Folia Geographica.

Brief history

The Geographical Society of Latvia was founded in 1923. Its main purposes were to enhance geographic awareness and disseminate geographical knowledge across Latvia and beyond, to explore Latvia’s geography by organizing and carrying out research work, and to coordinate Latvian geography teachers for advancing the evolution of scientific and school geography. The society held regular meetings, geographical exhibitions, trips, as well as visiting scientific conferences. The activities of the LGB were suspended in 1940.

In 1952, a branch of the Geographical Society of USSR was established in Latvia. Its objectives were to develop and popularize geographic knowledge, to coordinate scientific research in the field of geography, and to promote the development of national economy. The society’s members explored Latvia’s natural resources.
and took part in physiographic and economic regionalization of Latvia’s territory.

In 1990, the general meeting of the Geographical Society of Latvian SSR made a decision to restore the Geographical Society of Latvia as an independent, voluntary, and creative organization. The society submitted the membership application to IGU in 1995. The Geographical Society of Latvia was officially accepted as a full-fledged member of IGU in 1996 at the 28th International Geographical Congress held in The Hague.

Legal geography

Benjamin Forest
McGill University, Canada

Legal geography is a heterogeneous subfield that is defined partially by its topic (law) and partially by its approaches to the study of that topic. Some scholarship defines itself explicitly as “legal geography,” while other work addresses legal issues but may be typically categorized as political, social, or critical geography. Moreover, applied geographic work dealing with environmental regulation, natural hazards, or resource management typically address bylaws, codes, regulations, and/or laws but is not generally classified as “legal.” None of the major English-speaking professional associations (American Association of Geographers, Royal Geographical Society, International Geographical Union) have specialty groups or commissions devoted specifically to legal geography, although there are periodic attempts to form them. (The Institute of Australian Geographers does have a Legal Geography Study Group, however, and there are periodic attempts to form a specialty group in the AAG.) Moreover, law itself is a complex object of study that includes legislation (law-making), jurisprudence (court decisions and legal doctrine), police and policing, and legal actors (attorneys, magistrates, and judges). There are also various types of law, such as civil law (including property law and environmental regulation), constitutional law, criminal law, and international law. Customary law, which may be more or less formal, is also an important subject of study, particularly in developing areas and states. Legal geography is further fragmented because formal legal systems and practices are typically defined by sovereign state boundaries, making comparative or systematic work relatively rare. Finally, legal scholars may address “geographic” topics or use “geographic” concepts, with or without reference to work in the discipline of geography. For the most part, however, this entry focuses on work that is self-defined as legal geography, published by geographers or in geographic journals.

Defining legal geography

The subfield remains highly fragmented despite several attempts to institutionalize legal geography as an area of study. Gordon Clark initiated a special issue of Urban Geography in 1990 on legal geography, coedited with Nick Blomley, an effort that continued with the “Legal Geographies” series in Urban Geography, starting in 1993 under Blomley’s editorship. Their original impetus was to draw attention to the consequences of Brown v. Board of Education, the 1954 US Supreme Court decision that ended de jure segregation in American public schools. (Urban Geography subsequently published a special issue to mark the decision’s fortieth anniversary in 1994.) The Legal Geographies Series is marked by particular attention to major court decisions in Western liberal democracies, and hence tends to emphasize geographic analyses of formal jurisprudence. Authors in the series are primarily geographers or scholars well connected to the discipline, rather than legal scholars publishing on geographic issues. Nonetheless, the original and subsequent editors adopted an open perspective, so publications in the series have tended to reflect...
Legal geography has also been used as a starting point in efforts to critique and reshape the social sciences more generally. In the mid-1980s Gordon Clark (1985) drew on the practice of judicial reasoning in local autonomy cases to advocate an interpretive approach to social theory. More recently, David Delaney (2010) has developed the concept of the “nomosphere,” a way to characterize the interpenetration and mutual constitution of law and space, and to provide a unifying framework for legal geography. His ambitious, programmatic book emphasizes the way in which law and space are both performed together, and thus “worlded,” creating legal spaces (“situations,” “settings,” and “nomoscapes”) such as “home” and “public/private space.” In addition, he draws attention to the role of “nomospheric technicians” (especially lawyers and judges) who have privileged positions to manipulate, shape, and change the nomosphere. This framework has received attention in conferences and favorable reviews, but has not (as yet) achieved a significant presence in scholarly publications.

Several edited books have also sought to define – or at least describe – the contours of legal geography. Blomley, Delaney, and Ford’s *Legal Geographies Reader* (2001), edited by two geographers and a legal scholar, is probably the first comprehensive attempt, and is divided into sections on public space, racism, property, state formation, and environmental regulation. A second collection, edited by legal scholars and published as the fifth volume in the series *Current Legal Issues*, adopts a similar categorical approach, with sections on boundaries, land, property, nature, identity, culture and time, and knowledge (Holder and Harrison 2003). Scholarship in both works reaches well beyond disciplinary geography and includes numerous contributions from legal scholars and legal anthropologists; indeed, in the latter work, there are only three geographers contributing to its 27 chapters.

The inclusion of legal anthropology in such collections broadens the treatment of law beyond formal jurisprudence and beyond liberal states, by including studies of customary law in developing societies. For example, the phenomenon of legal pluralism (where formal legal systems coexist, and often conflict, with customary ones) is a common topic in legal anthropology. While legal pluralism occasionally appears in work by geographers or in geography journals, generally the scholars and scholarship on such topics are not well connected to disciplinary geography.

Similarly, it is rare for a legal or sociolegal scholar to publish in geography journals. Law review articles address a vast array of topics, including many “geographic” ones, but the practices of publication and scholarship in the two disciplines means that there is little incentive for law faculty to publish in social science journals, and it is very rare for social scientists to publish in law reviews. Likewise, although sociolegal scholarship often touches on geographic subjects, and even employs geographical terms such as “place,” it remains generally disconnected from disciplinary geography. While geographers do publish in sociolegal journals on occasion (and vice versa), this remains exceptional. As with the relationship between geography and many other disciplines, when legal scholars appeal to “geography” they tend to hold a highly conventional view of the term to mean basic spatial relationships, cartography, or even simply physical geography.

In short, while the term “legal geography” can potentially cover a broad range of formal and informal legal and regulatory systems, a large set of disciplines and disciplinary approaches,
and a variety of legal-political regimes, in practice the term refers to a more narrow set of scholarship by practicing geographers primarily (but not only) concerned with common law jurisprudence in developed Western democracies. Within that set, however, there are several areas of significant focus, including race, property, and policing.

Race

Arguably, the subdiscipline crystallized around questions of race and law in the United States (and, to a lesser degree, in Canada), and the close association between racial power and spatial segregation makes the topic a natural one for geographers. For early work in legal geography, racial segregation was a vehicle to explore the nature of local autonomy in the United States, and was arguably an extension of political geography’s conventional interest in the definition of territory and jurisdiction (Johnston 1984). While much of the scholarship in legal geography focuses on the latter half of the twentieth century, David Delaney’s work is notable because he analyzes legal struggles over racial segregation in both the pre- and post- Brown eras. Some work focuses specifically on residential segregation itself, while other research considers its consequences, particularly for education and political representation.

The American case presents several important legal conflicts and dilemmas. First, the federal structure of the United States means that there are often conflicts between federal and state law, and racial issues have arguably shaped these conflicts from the first drafts of the Constitution. As the ultimate arbiter of constitutional meanings, the US Supreme Court’s decisions often have significant geographic consequences, and rely on (assumed) geographic relationships.

Second, amendments to the Constitution in the post-Civil War era (especially the 14th Amendment, adopted in 1868) provided a formal guarantee of racial equality. Nearly all local and state jurisdictions, and (within a short time) federal institutions, were deeply hostile to this principle. Consequently, courts were receptive to various legal strategies to defend white supremacy. In the landmark Plessy v. Ferguson (1896) decision, for example, the court ruled that racial segregation was permissible if facilities were allegedly equal for whites and African Americans. Similarly, while the court ruled that cities could not establish apartheid-like racial exclusionary zones (Buchanan v. Warley 1917), it permitted systematic private discrimination in homeownership and sales until the mid-twentieth century.

Geographers have focused on two aspects of legal reasoning in such conflicts. First, the law’s use of abstract language and categories, such as formal equality, to mask the lived experience of racial discrimination. Here “the law” as a force of abstraction is opposed to “geography” as a carrier of specific experience. A second and often related principle is the separation of public and private actions. Particularly in the American tradition, constitutional measures can only affect governmental activities, so anything that is deemed “private” is beyond the reach of (constitutional) law. What matters, for example, are the formal rules used by a public body rather than the practical outcomes. Under this view, as long as a city, for example, does not regulate the ownership of property on the basis of race, there is no constitutional violation, even if it remains impossible for an African American to buy from a willing seller. Of course, the outcome of such cases often, crucially, turns on what courts define as public or private.

This highly formalized approach was challenged fundamentally in the Brown v. Board of Education (1954) decision, which essentially
overturned *Plessy*. The concurrent Civil Rights Movement also led to a raft of federal legislation over the next 15 years that expanded restrictions on “private” discrimination (in housing sales and rentals, public accommodations and services, mortgage provision, employment, and the like). Nonetheless, states and local jurisdictions used a variety of legal and quasi-legal strategies to maintain the de facto racial separation of whites and African Americans. Courts could order the desegregation of schools within a particular jurisdiction, for example, but refused to do so across municipal boundaries. By moving out of racially mixed cities to mostly white suburban jurisdictions, whites could isolate themselves from African Americans and other minorities. School segregation became driven by racialized housing patterns, whose causes were judged too complex to address through legal regulation (Johnston 1984). Whites (of sufficient economic means) also had the option of withdrawing from the public school system entirely by sending their children to private schools, which could maintain racial exclusivity through high fees, entrance requirements, and/or informal barriers.

Constitutional issues are also often at the center of disputes over racial identity and political representation, and in some ways they mirror the pattern of residential and school segregation. In the United States, the definition of electoral constituencies (districts) is ostensibly a political decision, typically under the control of state legislatures or local jurisdictions. In the mid-1960s federal courts became receptive to legal challenges based on unequal populations (malapportionment) and on racial discrimination (racial gerrymandering). Over the next 20 years or so, courts defined and refined constitutionally mandated standards for election districts. The jurisprudence of equal apportionment and racial gerrymandering both have complex histories, but the current requirement for (approximately) equal populations between districts is clear and settled law, while the use of race in redistricting remains complex.

Starting in the 1950s, but especially after the Voting Rights Act of 1964, federal courts began to rule against electoral redistricting plans that clearly weakened the voting strength of African Americans. Classically, such gerrymandering was a strategy of “cracking,” which divided minorities between two or more districts so that they did not form a majority or effective plurality in any constituency. These cases primarily concerned minority populations that were reasonably large and compact, so the principal empirical questions involved measures of voter polarization by race. In short, the “geography” of such districts was assumed, and the major legal question was whether a jurisdiction had discriminated against minorities by reducing their voting strength. By the early 1990s, however, various political and technical developments meant that the principal legal question involving racial gerrymandering shifted squarely to “geography.” In essence, it became possible (and often politically expedient) to create very irregular and/or elongated districts with African American or Latino majorities. Whether such districts were efforts to fairly represent minority interests, or unconstitutional classifications of voters by race, turned on legal judgments about the geographic nature of political communities. Generally, the Supreme Court hewed to a fairly conventional conception of geographical community, requiring some degree of propinquity but without articulating a formal standard.

The scholarship on race and law in geography strongly reflects an emphasis on jurisprudence, and on US constitutional jurisprudence in particular. This work typically analyzes the geographic concepts used in legal reasoning, including ideas that are literally geographic (compactness, scale,
boundaries, etc.) and figuratively so (public and private).

**Property**

Research on property draws on the analysis of a similar set of geographic concepts. Arguably, the protection of private property lies at the heart of the liberal legal tradition, so the distinction between public and private is central to scholarship on property. Critical legal geographers – Nicholas Blomley and Don Mitchell in particular – have pursued two major themes in the study of property. First, over the course of several works, Blomley has laid out a perspective on property that emphasizes its link to violence. Rather than being antithetical to violence, law and property are fundamentally rooted in violent (dis)possession. Legal protection of private property serves to freeze the original acts of violence in place. As with racial geographies, he argues that the abstraction of property as a category serves to obscure both its origins and its unequal effects on material relations. Coming from a similar critical perspective, Mitchell has focused on the use of property and property rights to limit the rights and activities of already marginalized groups and classes: the homeless, the poor, and labor.

At the same time, such analyses leave room for the complexities of the law. The 2005 *Kelo v. City of New London* decision over eminent domain provides a good example. Eminent domain is a well-established principle that governments can take private property for public use in return for fair compensation. In the *Kelo* case, the US Supreme Court ruled that the city of New London, Connecticut could use eminent domain to obtain property even if the direct recipient was a private party. The court accepted the city’s argument that the (promised) redevelopment would benefit the city through increased tax revenues, and was therefore a “public use.” The decision attracted intense criticism from both libertarians and civil rights advocates, and would seem to show the power of local government over private property rights. Yet careful analysis of the decision reveals that its logic privileges certain classes of property owners, and serves to reinforce a conventional private property regime.

**Police, policing, and social regulation**

In several ways, geographic scholarship on policing is distinct from studies of either race or property because it includes significant attention to the activity and strategies of policing, rather than to just criminal law or jurisprudence. The ethnographic work of Steve Herbert is especially notable in this regard. His earliest work focused on the territorial strategies used by police, in particular how the demarcation and enforcement of boundaries are a routine, essential, if often unnoticed, technique of contemporary urban policing. Such methods, however, can exacerbate divisions and conflicts between police and residents by creating informal “safe and controlled” and “unsafe and chaotic” zones of the city. Subsequent work examines the practice of “community policing” from the perspective of both police and residents, and suggests why this popular idea faces significant limitations in practice. More recently, Herbert and his collaborators have used ethnographic techniques to study the use of exclusionary zones as forms of social control, discipline, and (allegedly) therapy for drug offenders and sex workers. Such ethnographic work remains relatively rare in legal geography, as does research on legal actors such as attorneys and judges (but see Martin, Scherr, and City 2010).
Research on policing and social control also includes a substantial literature in the jurisprudential tradition, with much of the attention focused on immigration control, homelessness, and speech. At the same time, this work often embraces nonformal and nonconstitutional notions of “rights,” particularly Henri Lefebvre’s concept of a “right to the city.” In doing so, it goes beyond narrow concerns with legal reasoning.

The regulation of immigrants and the control of immigration gained renewed attention after 2001 as the United States sought to “fortify” its borders, but much of the work in legal geography has focused on legal conflicts within the country rather than at the boundaries. As with race, this scholarship concerns conflicts between federal and state (or local) jurisdictions. Although immigration is formally under federal jurisdiction, some jurisdictions have sought alternative means to regulate or exclude immigrants, or have embraced federal efforts to use local police for immigration control. In other cases, however, cities and states have actively resisted federal efforts to identify and deport immigrants.

The regulation of the homeless, especially efforts to exclude them from public space and public services, is another significant focus of legal geography, particularly by Don Mitchell. Work in this area typically examines ways that local jurisdictions make it difficult or impossible for people to live without access to (their own) private property. Restrictions on begging and access to basic hygiene facilities mean that the homeless find it difficult to earn a livelihood or simply care for themselves in public space, even though liberal norms hold that such space is defined by its openness and availability to all. Echoing the scholarship on race, formal rights to speech (in the form of panhandling), legal representation, or simple presence are shown to be ineffective protection for the homeless, in contrast to a more robust concept of a “right to the city.”

While much of the literature on homelessness concerns speech, other research focuses specifically on the right and regulation of speech in public space. Despite formal commitments to free speech, jurisdictions and courts have arguably become increasingly hostile to unpopular speech in public by increasingly recognizing a “right to be left alone” (i.e., to be free from hearing unwanted speech). The legal treatment of restrictions, however, often seems politically driven, with greater restrictions tolerated for anticorporate or antiglobalization protests, and relatively greater protection for religious or corporate speech.

Leisure has and continues to be a term that is difficult to define, but it is most often associated with people’s free time behavior (Rojek 2010). Leisure and geography have long collided and Mercer’s (1970, 261) statement that “leisure remains a sadly neglected area of study in geography” remains relevant. Leisure geographies, opportunities presented by free time or what people believe and plan to do in time away from other obligations (most often assumed to be in juxtaposition with work), are produced, consumed, performed, practiced, embodied, and enacted across time and space. Leisure, as a concept, has become more permeable and now crosses subject and disciplinary boundaries. Geographers, and social scientists more generally, now prefer to define leisure by the activity itself. Leisure may involve cycling, running, traveling, skiing, gardening, shopping, watching movies, engaging with social media, online gaming, reading books/magazines/graphic novels, urban exploring, scrapbooking, sex, drugs, and many other hobbies, activities, and endeavors that are seen to be outside of those things that have to be done.

Yet participation in leisure remains contested. Cultural identities, issues of power, and access, gender, race, sexuality, meaning, and knowledge processes influence people’s understanding of what leisure is and the role it might play in their everyday lives. At the same time, concepts of lifestyle, wellbeing, mindfulness, and happiness are being increasingly extolled as the virtues of the freedom of leisure time. Nonetheless, researchers continue to explore the negotiations, constraints, and obstacles faced by individuals and communities whose ability to access leisure may be partial or nonexistent. As neoliberal societies and policies continue to dominate in many places, the commodification of leisure time increasingly calls into question whether this free time is actually “free.”

Leisure geographies can be seen to have outgrown the crises of leisure studies. They engage an interdisciplinary audience and recognize the plurality of what leisure is and what it means to individuals and society. They increasingly engage with poststructuralism, look beyond the mobile to consider (im)mobility, hybridity, stillness, and stickiness, and consider the more-than-representation. They deal with bodies, senses, performances, and emotions. Methodologically, leisure geographies are innovative in thinking through how to be a part of, or go with, when participating in leisure activities. Helmet cameras, video diaries, photography, and walk-along interviews complement more traditional methods. Yet despite theoretical and methodological growth, there remains a lack of focus on leisure geographies outside of the Western, predominantly Northern Hemisphere, world. Leisure, in all its forms and in its many spaces, needs to be more widely understood and leisure geographies are well-positioned to embrace the challenges to come.

American physicist Theodore Harold “Ted” Maiman invented the world’s first laser in 1960. In the following year, scientists put forward the idea of LiDAR (Light Detection And Ranging). Modern laser-based remote sensing technology began to be used in the 1970s by the US National Aeronautics and Space Administration (NASA), largely aimed at meteorology (John A. Dutton E-Education Institute 2014). Initial LiDAR systems were single-beam profiling devices and lacked accurate georeferencing on terrain mapping (Portland State University 2016). Between 1988 and 1993, the University of Stuttgart, Germany, invented the airborne laser scanner by combining laser scanning technology with a real-time positioning system. With the development of the Global Positioning System (GPS) and the Inertial Navigation System (INS), accurate real-time positioning and attitude determination could be achieved, which made it possible to deploy LiDAR on moving platforms, such as airborne LiDAR. Bathymetric LiDAR was actually one of the first uses of airborne LiDAR (NOAA 2012).

The LiDAR system

A LiDAR system includes a transmitter system and a receiver system. An airborne or satellite-based LiDAR also includes a position and navigation system. Figure 1 shows a basic LiDAR system (Chunlin 2008).

The transmitter system

The transmitter system is composed of beam expanders and one type of laser radiator, such as a carbon dioxide laser, diode-pumped Nd:YAG (neodymium-doped yttrium aluminum garnet), semiconductor laser, and so on. The laser can emit a laser beam with a fixed wavelength at a fixed pulse repetition, and the pulse duration is typically 10 ns. Different wavelengths have different resolutions, and a better target resolution is gained with a shorter wavelength. Each laser generates pulse energy at its wavelength. In general, an energy monitor is located within each laser canister to monitor if the level of the pulse energy is in the normal state. The role of beam expanders is to reduce the angular divergence between the transmitter system and the receiver system.

The receiver system

The receiver system is composed of a telescope, relay optics, electronics detectors, and signal processing devices. A signal returned from a target is received within a field of view (FOV) of 0.2–5 m and the stray light is blocked (Nayegandhi 2007).
LIDAR

The telescope has several mirrors and baffles to control light and to reduce the effect of a thermal gradient. There is also a visor mounted to reject solar illumination. The signal received by the telescope is collected by a hole mirror or a beam splitter (some polarization LiDAR are equipped with a polarization beam splitter) and sent to photodetectors (such as photomultipliers and silicon avalanche photodiodes), which convert the optical signal into an electrical signal. The electrical signal is amplified and digitized for computer processing.

The sensitivity of the receiver system is largely affected by the photodetector. A photomultiplier can provide low dark noise but has ordinary dynamic range, while an avalanche photodiode has good dynamic range but greater dark noise. The photodetector exhibits various quantum efficiencies at different wavelengths; for example, a photomultiplier has much better quantum efficiency at 532 nm than an avalanche photodiode. Figure 2 shows the basic LiDAR receiving system (Hongbo 2008.).

The position and navigation system

LiDAR sensors mounted on movable platforms (airborne, satellite) require the position and navigation system, as they must accurately confirm their absolute position and orientation. GPS and IMU provide good measurements in this situation.

Operation principles

The laser beam transmitted by LiDAR goes through the transmission media where it can be attenuated and scattered. The incident light is immediately reflected and scattered when it reaches the surface of the target. The LiDAR receiver telescope receives the reflected or backscattered signal falling into the FOV and transmitted to the photodetector. Through photoelectric conversion the optical signal is transformed to an electric signal (typically a current signal), which is computed and amplified and then finally displayed and recorded. Figure 3 shows the working principle of LiDAR.

For signals returned at different altitude, based on the increment of time between the laser emitting and receiving, the range from LiDAR to the target can be calculated by equation 1

\[ s = \frac{c \Delta t}{2} \]  

(1)

where \( c \) is the speed of light with a value approximately equal to 0.3 million km/s. Utilizing a combination of the laser height, scan angle, position of the laser determined by GPS, and emission direction determined by INS, the coordinates \( x, y \), and \( z \) of each spot on the ground can be accurately calculated. In general, the ground spacing of LiDAR spot elevations ranges from 2 to 4 m.

The general form of the signal to be calibrated can be written as equation 2, where \( P_R \) is the received laser power (unit: W), \( P_T \) is laser transmission power, \( G_T \) is the transmitting antenna gain, \( \sigma \) is the target scattering cross-section, \( D \) is the receiving aperture (unit:...

---

Figure 1  A basic LiDAR system.
Figure 2  Configuration of a receiving LiDAR system.

Figure 3  The working principle of LiDAR.

\[ m, R \text{ is the distance between LiDAR and the target (unit: m), } \eta_{Atm} \text{ is the one-way atmospheric transmission coefficient, and } \eta_{Sys} \text{ is the system parameter.} \]

\[ P_R = \frac{P_T G_T}{4\pi R^2} \times \frac{\sigma}{4\pi R^2} \times \frac{\pi D^2}{4} \times \eta_{Atm} \eta_{Sys} \quad (2) \]

\[ G_T = \frac{4\pi}{\theta_T^2} \]

where

\[ \theta_T = \frac{K \lambda}{D} \]

\( \theta_T \) is the laser beam width, \( \lambda \) is the laser emission.
LiDAR

wavelength, and $K_a$ is the aperture transmission constant (Dai 2002).

The LiDAR cross-section (LRCS) is the cross-section of a total reflection sphere on which the light intensity generated equals that received by the LiDAR receiver, and it is expressed as

$$\sigma_d = \rho_d \pi r^2$$

(3)

where $\rho_d$ is the spherical reflectivity, and $r$ is the radius of the sphere. Generally, the more closely an object resembles a sphere, the closer the relationship between the LRCS and the size of the object. The LRCS describes the target's ability to scatter the laser beam.

LiDAR characteristics

Small volume and light weight

Compared with the microwave radar, LiDAR’s volume and weight are much smaller. Radar’s volume is huge, with the size of antenna aperture a few meters or even dozens of meters and a weight of several tons. LiDAR’s structure is much more portable; its telescope’s diameter can be a few centimeters and it weighs only tens of kilograms. Assembling and disassembling are relatively simple, and it is easy to operate and maintain.

Good concealment and active interference resistance ability

Laser beams propagate in a straight line in the air and the beam width is very narrow. The information cannot be retrieved unless the receiver is on the propagation path. That is why LiDAR has good concealment. Microwave signals experience interference from electromagnetic waves widespread in nature, but a laser signal can resist electromagnetic interference. In a complex information environment, laser signals are not easily intercepted by enemies.

High resolution

LiDAR has a high angle, distance, and speed resolution. The range resolution can reach 0.1 m, and the velocity resolution can reach 10 m/s or less. Typically, the angle resolution is larger than 0.1 mrad (it is impossible for radar to achieve this), which enables two goals to be distinguished to within 0.3 m at a range of 3 km. In addition, LiDAR can simultaneously detect multiple targets. A high distance and range resolution means that the distance-Doppler imaging technology can be utilized to obtain the target image clearly. High resolution is the most significant advantage of LiDAR, and most applications are based on this characteristic.

Good performance at low-altitude detection

For LiDAR, reflection only occurs in the irradiation propagated area. So, no matter whether it is at high or low altitude, it is not influenced by ground object echo effects. Conversely, due to the influence of ground object echo effects, radar always has a certain blind area that it is unable to detect. LiDAR works far better than radar at low-altitude detection.

LiDAR classification based on LiDAR position height

Ground-based LiDAR

Ground-based LiDAR observation is fixed on the ground, with a high accuracy and signal-to-noise ratio (SNR) and convenient operation and maintenance, but its detection range is very limited.
and its detection height is restricted to no higher than the troposphere layer.

**Airborne LiDAR**

The airborne LiDAR measurement system is a kind of active remote sensing device. It is the leading international technology for acquiring high-precision three-dimensional (3-D) coordinates on the ground and image data quickly and synchronously and realizing the reproduction of the real-time, changing features of objects quickly and intelligently. Figure 4 shows airborne LiDAR in operation.

**Spaceborne LiDAR**

Spaceborne LiDAR can acquire global data and images with a wide range, overcoming the disadvantages of ground-based LiDAR regardless of weather conditions, but its low SNR ratio means that it is difficult to operate and requires a complicated algorithm. At present the most popular spaceborne LiDAR is the Cloud-Aerosol LiDAR and Infrared Pathfinder Observation (CALIPSO) which was launched in April 2006 to provide global vertically resolved measurements of clouds and aerosols. Figure 5 shows the CALIPSO satellite on-orbit and Figure 6 shows the receiver subsystem of the CALIPSO (Hunt et al. 2009).

**Applications**

**Military applications**

Lasers can collect 3-D data (including azimuth, dive angle, distance, speed, and strength information) and can display them in an image. Radiation intensity geometry images, range images, and velocity images can be generated at very high resolution. High-resolution LiDAR can produce real-time images of moving armored cars and the resolution is high enough to identify the vehicle model.

Since the late 1970s, LiDAR has been used in fire-control systems for tanks, artillery, ships, and aircrafts. Many specialists favor automatic tracking LiDAR on account of its precision range, accurate speed measurement, and perfect tracking advantages. Some developed countries have drawn up a plan to precisely track in-orbit satellites’ position and velocity, which provides support for research into gaining information on vehicle size, shape, and orientation from space.

LiDAR can also work for underwater detection. The blue-green laser with a wavelength of 0.46–0.53 μm can penetrate water from several hundred to several thousand meters. Using the high-power narrow blue-green pulse emitted by the laser and the reflected light, the military can obtain the parameters of a target’s velocity and position under the sea in high resolution. During the 1991 Gulf War, the American LiDAR “magic lamp” successfully detected torpedoes and mine chains.
Figure 5  CALIPSO working on-orbit.

Figure 6  CALIPSO receiver subsystem.
Agriculture

Lasers can help farmers make topographic maps which can be used to locate a region of high crop yield. With the maps fed into the computerized, variable-rate fertilizer applicators, farmers can divert more of their costly fertilizers to the highest-yielding zones and the least to the lowest-yielding zones (Comis 2010). This technology is important to farmers and has been tested in many areas.

Engineering survey

Much precision engineering requires a mathematical model for 3-D coordinates, for example, electrical power line selection, mining and tunnel surveys, hydrographic surveys, settlements, construction measurement, deformation measurement, and protection of cultural relics. LiDAR performs well in the detection of 3-D structures of buildings. A synthesis of high-accuracy laser point cloud data, textural information from wide-field cameras, and architectural models enables engineers to develop a building construction plan.

Atmospheric sounding

LiDAR has been widely applied in atmospheric sounding. The principle of atmospheric sounding is to use the backscatter signal of the emitted laser at different altitudes to analyze the vertical distribution of aerosol and cloud particles in the atmosphere. The latest achievement is to detect CO₂. The wavebands currently used include 532 nm visible green light and 1064 nm near-infrared light for aerosols and clouds, and 1.57 μm for CO₂.

There are several kinds of atmosphere detection LiDAR that are classified by measurement method. Mie scattering LiDAR is based on the Mie scattering of atmospheric molecules to detect cloud and aerosol particles in the lower atmosphere. As one characteristic of Mie scattering, the size of the scattering particles is similar to the wavelength of an incident laser and the scattering wavelength is equal to the incident wavelength. There is no energy exchange during this process.

Rayleigh scattering LiDAR can be used to detect atmospheric density, atmospheric fluctuations, and atmospheric temperature, based on a Rayleigh scattering mechanism in the intermediate layer at a height greater than 30 km. Rayleigh scattering happens when the scattering wavelength is much larger than the radius of the scattering particles.

Polarization LiDAR is used to detect and analyze the cloud moisture and the cloud micro-physical structure by measuring the nonspherical particles’ depolarization ratio. Figure 7 shows a polarization Mie LiDAR.

Resonance fluorescence LiDAR has been applied to study sodium and its related properties systematically. It can also be used to
LIDAR detect and study other similar kinds of atoms and ions. Because the resonance fluorescence cross-section is much larger than the Rayleigh scattering cross-section, atomic or molecular resonance fluorescence will be enhanced at some specific laser wavelength, so the atmospheric composition can be detected.

Doppler LiDAR, based on the Doppler effect, is used to measure atmospheric wind velocity. The temporal and spatial variation of the wind field can be obtained by measuring the scattering frequency relative to the Doppler frequency shift of the laser beam.

Raman scattering LiDAR can detect the vertical distribution of water vapor according to the Raman echo signal backscattered from water vapor and nitrogen molecules simultaneously. Raman scattering is a non-elastic interaction process between a laser beam and various molecules in the atmosphere. The major characteristic of Raman scattering is that the wavelength between the scattered light and the incident light is different. This LiDAR can be used to detect atmospheric humidity and temperature profiles at low altitude with high spatial and temporal resolution, and can also be used to measure the concentration of certain polluting gases in the surrounding environment.

Differential absorption LiDAR is used to detect atmospheric humidity and atmospheric pollution. It is widely used in environmental monitoring, such as detecting O₃, SO₂, and NO₂ in the atmosphere.

In recent years, the most popular atmospheric remote sensing LiDAR has been ground-based LiDAR and airborne LiDAR, as they have good SNR. In April 2006, CALIPSO, the world's most powerful spaceborne LiDAR, was launched together with the CloudSat satellite to observe the global distribution and properties of aerosols and clouds (Winker et al. 2009). The biggest advantages of satellite LiDAR are its wide measurement range and that it can provide observation on a global scale. However, it has relatively low SNR compared to ground-based and airborne LiDAR, on account of its very high altitude to geoid.

**Working for the power grid**

In the area of electrical communications network construction and maintenance, one advantage of LiDAR is that it can help find the terrain of the whole circuit design area and the situation of on-ground objects, with which information electrical engineers can design feasible schemes and estimate construction costs. When a disruption occurs in the circuit, LiDAR data can be used to quickly find the problem.

Life course approach

Irene Hardill
Northumbria University, UK

Janice Monk
University of Arizona, USA

Life course research is concerned not simply with exploring chronological age but also with addressing nondeterministic conceptualizations of age, and with individual and collective trajectories of experience in diverse spaces and places and through time as these are shaped by events, roles, memory, and retrospection. Transitions are seen as dynamic rather than determined. The studies attend to continuities, ruptures, and multiple pathways, and are taken up by researchers who focus on the Global South as well as the Global North. Currently the approach is more commonly used by geographers interested in the lives of children and youth, and of older people, than by those interested in midlife. Additionally, greater attention has been paid to examining women’s lives than men’s, though life course approaches have also been used to understand “coupledom” (primarily of heterosexual couples). Attention is paid to particular generations and also to intergenerational relations, to issues such as parenting, transitions from youth to adulthood, individual and household residential movements, grandparenthood, and retirement in older age. Given this breadth of interests, and the recognition that lives are linked, the range of research methods applied is diverse. They include quantitative analyses that often use census materials and other large databases, in-depth qualitative approaches, and, more recently, visual methods such as participatory video and experiments with the interpretation of sketches and diagrams created by research subjects (Fenster 2013). Less common, but emerging, is research that engages with geospatial technologies. The choice of methods is also acknowledged as having political and ethical implications and may adopt a single approach or increasingly be characterized by mixing methods.

Quantitative analysis

The application of quantitative methods in life course research is common in analysis of national or regional patterns of processes such as migration between communities and within countries, and intra-urban residential movements, as these vary across life stages, place, and time. These have considered both individual and household scales and draw on sources such as the long form collected by the US Census that includes data from two time periods, on specialized publicly available datasets such as the American Community Survey (ACS) and the Panel Study of Income Dynamics (PSID) in the United States which, since 1968, has measured the economic, social, and health aspects of a large representative sample of families and their descendants. Outside the United States, similar sources include the British Household Panel Survey, the German Socio–Economic Panel, and the Household Income and Labour Dynamics in Australia Survey. These include data that lend themselves to cartographic and graphic analysis and portrayal, and to statistical analysis with such
LIFE COURSE APPROACH

techniques as logistic regression modeling and multiple regression analysis. By disaggregating groups on multiple variables, they examine interactions, for example by gender, age, marital status, income level, education, and place of origin. In so doing, they demonstrate complexities of choices and behaviors in multiple stages of life beyond traditional notions of youth, midlife, and old age, and also reveal issues of intergenerational relations and changing patterns of marriage. In recent years authors have been able to link individuals within their household context, for example in the United Kingdom this has been possible since the 1991 Census of Population with the publication of household data in the Sample of Anonymised Records (SARs). The insights from these studies can inform and reflect policy changes, identify needs for social programs, and open questions for new research at other spatial scales. Among American geographers who have sustained applications of these methods are William A.V. Clark and David Plane (Plane and Jurevich 2009).

Qualitative approaches

An array of qualitative methods characterizes much life course research. Many studies employ in-depth qualitative interviews to investigate subjective interpretations and understandings of the life histories. The interview may take a number of forms, such as structured, semistructured, or open-ended, with structured and some semistructured interviews gathering interviewees' knowledge and experience of the outside world. In contrast, in more flexible interview formats all participants in interviews are seen as agents who construct meanings subjectively, not as objectively found, a view that is associated with feminist, life history and psycho-social studies. The in-depth interview is a collaborative process, constructed through the unique interaction between the interviewer and the interviewee, and as a technique it has been subject to evaluation and critique. Qualitative interviews, including field notes and digital recordings, need to be transcribed and analyzed. Researchers increasingly use qualitative software packages in combination with reading and rereading transcripts to facilitate data analysis. While such interviews yield rich data, the analysis is not always straightforward and geographers have identified situations in which interviewees express competing personal discourses on an issue.

Qualitative interviews are commonly undertaken with a purposive sample (or a judgmental sample), one that is selected based on the knowledge of a population and the purpose of the study. It can be very useful for situations in which a targeted sample exhibiting certain characteristics needs to be reached quickly and where sampling for proportionality is not the main concern. Purposive sampling is not confined to life course research but is used to select participants to explore issues such as personal and household biographies. It often forms part of a mixed methods approach. An example of this methodology is a study of the location and mobility decisions of heterosexual couples by Stockdale, McLeod, and Philip (2013) on midlife migration to a rural area in Ireland. They employed multiple stages and methods, beginning with a postal survey of a targeted set of households of recent arrivals including an item on willingness to participate in a follow-up interview. From 230 responses, they created a purposive sample of 13 households composed of couples in the 50–65-year age group who represented a range of mobility histories and backgrounds. In-depth interviews with these couples, in which they participated together, yielded diverse narratives of decision-making and assessments of experiences reflecting each
partner’s personal history in relation to the decision to move, their choice of location, and subsequent impressions of this community. Such research is not designed to seek a factual record of moves but to explore the interviewees’ interests, commitments, and “constructed subjectivity.” Interviews may be implemented in two stages in which both partners are first interviewed together and then separately, in the process revealing contrasting versions of their story.

As geographers have engaged with aspects of the subjectivity of individuals across the life stages, and in more depth than using the methods that include larger samples, some have engaged with phenomenology to explore deeper personal meanings. Though not widely practiced in geographic research, this approach is important to acknowledge for its capacities to reveal insights, to interpret and challenge preconceived notions of human experience over the life course. A key example bringing to light structures of consciousness and the meanings of places is the pioneering study of Graham Rowles (1978), who worked for a sustained period of time with five older men and women in a single neighborhood. The method seeks to reveal the first-person point of view, the significance of objects and events, of the self and others, and of the flow of time in and over life. As an approach this project required suspending the researcher’s potential judgments and stereotypes, following the subjects’ conversational leads, demonstrating sensitivity to their capabilities and preferences, considering daily and longer time frames, and engaging with their varied and multiple spaces.

Related, though not identified as phenomenological, are methods in which geographers reflect on their personal experiences of the life course and those in their own families or of people with whom they have close associations. An excellent example is Ann Varley’s (2008) blending of her developing responses and those of her father as he experienced dementia, in which she focused on meanings of home and of institutional spaces. Within that context she introduced ethical issues in research and writing about the personal. Other geographers, particularly those engaging with feminist work, have also used personal reflections to explore generational changes in mobility, work, and familial lives both within their own settings and cross-culturally.

**Participatory (action) research**

A growing number of studies engage with participatory (action) research, which refers to a variety of research practices that involve collaborative research, education, and action that is oriented toward social change. This method takes lived experience as a starting point, with approaches that aim to reduce the hierarchies between researchers, facilitators, and participants, and to generate accurate and reliable data using ethical and inclusive approaches. It has been used in both the Global North and South, and with diverse age groups, especially children and young people. It often employs contemporary technologies, such as community radio and TV, popular theater, public or community art, small format video, disposable cameras, Internet, information and communication technologies (ICTs), and auto-photography. Video is increasingly used to raise awareness of social difference or inequality for public education and advocacy. Although children may participate in collaborative and creative ways, they are not always involved in designing the research, choosing what methods to use, or in the analysis or dissemination that might result from it, such that there is participation in research rather than participatory research per se. While this work is valuable, it may not result...
LIFE COURSE APPROACH

in longer-term or deeper changes that may be needed if children’s power and influence are to be increased in decisions that ultimately affect their lives.

Mixed methods

For a number of years life course researchers have combined the collection and analysis of quantitative and qualitative data, bringing together census data or large-scale surveys with qualitative data derived from surveys conducted by the research team and sometimes by multidisciplinary teams. The central premise of combining methods in a single study or series of studies is that together they provide a better understanding of research problems than either approach alone. One such example is a study of the location and mobility decisions of heterosexual dual-career households in the United Kingdom which used a methodology with three main elements. Hardill, Green, and Dudleston (1997) first assembled and analyzed individual and household data and information from secondary sources, including the 1991 UK Census of Population and Labour Force Survey to provide a quantitative background for more detailed work in the Greater Nottingham area. They worked through contacts with five employers representing different economic sectors who helped the team identify approximately 140 dual-career households, who then responded to a semistructured self-completion questionnaire survey. The three-part questionnaire survey included sections on each partner’s career, including jobs held and places of residence over a specific time period, educational attainment, and “relationship career” (general household information). In most cases the female partner completed the section on “relationship career.” A subset (purposive sample) of 30 households was selected for in-depth interviews; both partners were interviewed together and then separately to gain insights into household decision-making relating to career prioritization. Another example using mixed methods is a Dutch study of the changing relationship between civic engagement and paid work undertaken by women in rural parts of the Netherlands between 1993 and 2007. Led by Joos Droogleever Fortuijn and Frans Thissen (2013), it combined survey data with semistructured interviews with women aged 18–50 years collected in two time periods, 1993 and 2007. The survey was conducted with a random sample of residents, while follow-up in-depth qualitative interviews were carried out with a representative sample of women, chosen in terms of life course stage and residential context. By comparing two time periods and two sources of data, they were able to discover how the labor market participation of women increased substantially while civic engagement decreased.

The burgeoning research with children and youth has perhaps been the most experimental in mixing methods. Groups of young people are engaged, for example, with visual methods such as creating videos, photographing their environments and/or making drawings, and in activities such as local walks or games. These may then be combined with participant observation by the researcher and semistructured interviews as illustrated by Nancy Worth’s (2011) study of transitions to adulthood that combined narrative interviews and audio diaries with life mapping as a participatory tool to capture “fateful moments” of transition to adulthood. Many examples of the use of these creative and experiential methods are reported in the journal Children’s Geographies.

In identifying this range of mixed methods, it is clear that geospatial technologies have not been
widely used in life course studies, though one such example by Oliver et al. (2014) compared the data from daily self-reported trip diaries kept by young people in an urban setting with data generated from GPS monitors that they wore for a week. This method revealed that only slightly over half the records were fully or partially matched, though the diaries tended to provide contextual information but not completely accurate sequencing.

**Ethics and politics of methodological approaches and the challenges they present**

Recurring themes in methodological discussion in the life course literature, especially that on children and those working with vulnerable older adults, are ethical and political aspects of research that have been elaborated in numerous articles in *Children's Geographies*. The complexities of these concerns center (though not exclusively) on ethical guidelines and clearance issues, including the ability to give informed consent; personal relations between researchers and those being studied; aspects of power relations when the research involves engagement with couples or groups, not only between a researcher and an individual subject. Protocols in the researcher's home institution, for example, may not mesh with those in a host community, especially where research occurs in a foreign cultural setting, and may involve multiple layers of review. Beyond such official requirements, however, are ethical and political concerns that arise when members of a group have differential power. These may involve what are parental rights in relation between adult researchers and young subjects, how an adult researcher establishes rapport in engaging with youth or children, or how gender and personal relations impact in group interviews or collaborative creative projects. The issues are further complicated if the research is being conducted in different cultural settings, for example in the Global South, by Northern researchers, where language differences and cultural expectations (for example, in relation to local hierarchies or questions of payment for participation) may arise.

Other examples that have been raised are whether and how “insiders” or “outsiders” should be engaged in interpretation or presentations. This is especially the case when the methods include participatory action in projects that aim not only to generate academic research but to bring about social change that crosses boundaries between subjects and practitioners in social or political community agencies. Joint interviews can reveal shared realities, and household dynamics, while separate interviews offer participants greater freedom to express individual views by allowing them privacy, but they can disrupt collective memory or understanding of events.

Finally there is a common assumption in the literature that “families” are composed of heterosexual couples, of a married couple, a husband and wife (possibly with children). But family arrangements today are also changing – they are diverse, fluid and unresolved, with a broad range of gender and kinship relations in the “postmodern family.” There is now a greater choice of lifestyle: to live alone, with a partner (of the same or other sex) or with other individuals; to stay single or marry; to remain in or terminate relationships and subsequently divorce/marry/cohabit; to forgo/postpone childbearing or to have children within/outside marriage or other consensual unions. In settings where diseases such as HIV/AIDS have disrupted families, researchers are finding particular challenges, while those working with older adults find that adults often live alone following bereavement.
LIFE COURSE APPROACH

Though greater choice may exist, living together remains a conjugal norm, and the heterosexual household, the most common form in many life courses.

References

The concept of the life course was developed by researchers in the 1970s to counter the dominant tradition of social sciences in the 1950s and 1960s that had promoted the use of social surveys to generate grand theories. Against this abstraction of the social, the development of life course approaches sought to collate individual life histories to account for continuity and change in human lives and how these trajectories were shaped by interpersonal, structural, and historical forces. For example, Glen Elder’s (1974) major study, *Children of the Great Depression*, developed a historical, social, and psychological account of the relationship between childhood experiences and adult outcomes and behaviors. The development of life course theory has been characterized by interdisciplinary approaches, and the mainstreaming of life course in the social sciences has been codependent on the development of longitudinal data collection and analysis. A paradigmatic principle of the life course is that it is not prescriptive; it does not provide a blueprint against which individual lives are expected to develop, as in the case of other temporal configurations such as the life cycle. Instead, life course assumes a biographical approach to study connections between individual transitions and trajectories, to examine the sequencing and synchronicity of key events. Metaphorically, the life course can be compared to the unpredictable flow of a river rather than the more mechanical and predictable turning of a wheel. Yet this unpredictability cannot be reduced to individual circumstances and experiences. The foundation of life course analysis is not to study individual life events in isolation but to account for how individual lives are intertwined with social institutions through coordinated sequences of events, such as leaving home, completing education, and starting work. Life course analysis considers the collective significance of individual biographies and how these progress through institutional and social contexts.

**Geographical approaches to life course**

The founding principles of life course analysis were essentially geographical, through considering the significance of place in shaping formative experiences and transitions. Yet this does not imply that life course has been seamlessly adopted into geographical analysis. While more mainstream life course research has focused on analysis of individual data and appropriate quantitative methodologies, geographical analysis has foregrounded relationality and the contingency of individual biographies to more directly consider the spatial context of life course events. For example, the development of life course approaches in migration research has foregrounded the significance of the relationality of mobility, against more individualistic human capital frameworks. An important development in studies of “family migration” considers the tensions between individual trajectories within families and the potential for conflict between individual and collective mobilities, through exploring phenomena such as the tied mover/stayer (e.g., “trailing” spouses or “left-
behind” children) and how individual mobilities are moderated through relationships with others. Tom Cooke’s (2008) claim that all migration is family migration alerts us to the possibility that individual mobility is framed with reference to others, either through moving away, with or from or to be with others, or by corresponding immobility. Mobility practices can also anticipate life course events: for example, moving house prior to having children, or moving to be closer to relatives in older age in anticipation of frailty. Yet the significance of relationality cannot be reduced to interpersonal forces; mobility decisions are not just influenced by immediate family members and significant others, but are also given meaning in particular social-cultural contexts. For example, Ní Laoire’s (2000) biographical study of rural Irish youth migration considers the cultural construction of mobility biographies to reveal the contradictions of individual mobilities that are negotiated with reference to others and differential situated meanings.

Age

One genre of geographical research that has developed through life course analysis is the study of age and generation. While age is clearly a key dimension of life course, from a life course perspective it is not theorized as a linear development demarcated by concrete “stages.” Life course approaches resist the deterministic undertone of the life cycle; individuals do not simply move from one “age stage” to another. This resistance of a monolithic repetition of stage and time has been particularly apposite in geographical studies of childhood. The development of children’s geographies has been influenced by the social studies of childhood approach, which considers the social and cultural construction of childhood. In this approach children are not passive objects to whom things are done, but agents constructing their own identities and capable of resisting adultist interpretations. The revelation that the study of children should be carried out with, rather than on, children has stimulated a rich and varied empirical legacy, with appropriate participatory methodologies and analyses. This approach has also raised pertinent questions about the relevance of childhood itself and the extent to which it is necessary to dismantle rigid age demarcations. If life course is taken as an emphasis on flow, through which all experiences are relevant and the threads of different encounters can stretch over different spatial and temporal settings, then does it make sense to demarcate specific ages? In other words, do we need subdisciplines that are concerned with particular ages? Yet the demarcation of life course by age has a historical and cultural legacy: childhood is more than a category – it is also a social and political entity. A reasonable response to this tension between stage and flow is to consider the construction of childhood at particular times and places. Other researchers have argued for the importance of intergenerational relationships, and suggest that geographers are particularly well suited to analyze the complexity of intergenerationality, both familial and extra-familial, and how this complexity creates spatial networks of connectivity.

Transition

Life course is not a linear construct. While the notion of the trajectory is a key constituent, and this might suggest that the life course develops in a unified way over time, trajectories do not need to be straight lines. The development of the life course is not simply a matter of progression, but rather of interplay between continuity and discontinuity, pauses, fresh starts, and reversal
LIFE COURSE

as well as advancement. Thus, while life course does not assume linearity, it is demarcated by significant events that are associated with an acceleration of change. Much life course research is therefore concerned with demarcating the significance of these transition events. One main area of interest is the transition to adulthood. While denoted as a unified event, the use of the definitive article is misleading, as the study of the transition to adulthood is concerned with varied practices and developmental changes. This transition is more properly understood as a series of interconnected events, as young people move between different situations relating to education, employment, housing, and relationships. Thus the focus on transitions alerts us to changes in everyday practices and their deeper personal and social significance. Some of these changes are contemporaneous: for example, leaving home to go to university, take up a job, or move in with a partner. Yet many of these transitions are characterized by less celebrated events that are stretched out over time, and moreover key events, such as leaving home, may be reversed. For geographers, transitions also imply spatial practices; movement is not just in time but also spatial. However, space is not just the backdrop for these events, but is created and transformed through these transitions. For example, researchers have considered the meanings of home in leaving-home transitions. Fortier (2003) describes how, during this transition, the family home is always in construction, through the active emotional labor of all those involved and in individuals’ imaginations and memories.

Summary

There is considerable scope for life course approaches in geographical research, as its original conception incorporated the significance of events in time and place. Yet it could be argued that the potential of life course has not been realized, and, while many geographers might claim a life course approach, there have been fewer attempts to engage with what this signifies for geography. In particular, the spatial significance of life course can consider how spatial practices anticipate key transitions and the continuous development of spatial relations through life course events.

Line simplification

Bin Jiang
University of Gävle, Sweden

Geographic features such as mountains, rivers, and city boundaries are fractal, and so are the cartographic curves that represent the geographic features. However, the fact that geographic features are fractal has not been well received in the geography literature, due to the limitation of fractal dimension. The definition of fractal dimension requires that change in scale ($r$) and change in details ($N$) meet a power relationship (Mandelbrot 1967, 1982). This definition is so strict that it would exclude many geographic features from being fractal. Recently, Jiang and Yin (2014) proposed a relaxed definition of fractal: a geographic feature is fractal if, and only if, the scaling pattern of far more small things than large ones occurs multiple times. The present entry attempts to clarify the recurring scaling pattern, or fractal geometry in general, and how it can be used to guide line simplification.

Line simplification removes trivial points or, equivalently, keeps vital points, without destroying the line’s essential shape or overall characteristic structure. Conventionally, the task of line simplification is conducted manually by trained cartographers while producing small-scale (or fine-scale) maps from large-scale (or coarse-scale) ones. Computer algorithms have been developed to automate the simplification process, but the most difficult and challenging issue is how to effectively measure the essential shape or the characteristic structure. In this regard, efforts in the past have been very much guided by Euclidean geometry, using measures such as angularity, distance, and ratio to characterize cartographic curves. However, these efforts have proved to be less effective. This is because geographic features are irregular and rough, while Euclidean geometry is used to describe regular and smooth shapes.

Euclidean versus fractal geometry

Euclidean geometry is widely known; it appears in high school mathematics and has a history of more than 2000 years. It can be used to measure many things, including cartographic curves in terms of angles, lengths, and areas, or sizes in general. Fractal geometry arrived much later with a history of three decades (Mandelbrot 1982). Despite its relatively short history, fractal geometry has found many applications in disciplines such as physics, biology, economics, and geography. Fractal geometry concerns or examines how things of different sizes form a scaling hierarchy; that is, whether there are far more small things than large ones. To put the two geometries in perspective, if one measures the height of a tree, he or she is using Euclidean geometry; if one measures not only the height of a tree, but also the length of all its branches, and recognizes far more short branches than long ones, this is fractal geometry.

Euclidean geometry is used for regular and smooth shapes, while fractal geometry is used for irregularity and roughness. The difference between Euclidean and fractal geometry can be further seen from Koch curves (Figure 1),
one of the first fractals, invented by the Swedish mathematician Helge von Koch (1870–1924). In the literature, Koch curve refers to the single curve when iteration goes to infinity, and therefore it has an infinite length. This infinite length is closely related to the so-called conundrum of length, that is, the length of a cartographic curve increases as the measuring scale decreases (Richardson 1961). Importantly, the relationship between the measuring scale \( r \) and the length \( L \) can be expressed by a power function, for example, \( L = r^{1.26} \) for the Koch curves — where the exponent 1.26 is termed the fractal dimension \( D \). This power function implies the recurring scaling pattern of far more small things than large ones or, more specifically, far more small triangles than large ones. The notion of “far more small things than large ones,” implying a nonlinear relationship, differs fundamentally from that of “more small things than large ones,” indicating a linear relationship. This nonlinear relationship does not exist in Euclidean geometry.

The plural “Koch curves” refers to curves with finite lengths at some limited iterations. Unlike the baseline of one unit, the structure of the Koch curves cannot be described simply using Euclidean geometry. A common feature of all the Koch curves is that there are far more small things than large ones. This is particularly true as iteration becomes high. For example, the Koch curve of the third iteration contains a total of 1, 4, and 16 triangles with respect to scales of 1/3, 1/9, and 1/27. The recurring scaling pattern of far more small things than large ones is captured by the ht-index (Jiang and Yin 2013) as an alternative index of fractal dimension for quantifying the complexity of geographic features. The baseline has a dimension of one, while the Koch curves all have a fractional dimension of 1.26. The Koch curves can hardly be characterized by their lengths. For example, the Koch curves have lengths of 4/3, 16/9, and 64/27, respectively, for the scales of 1/3, 1/9, and 1/27. The length information does not add anything new to the understanding of the Koch curves, and neither do the angles, for they appear to have the same 60°. Therefore, the Koch curves were referred to as pathological before fractal geometry was established.

![Figure 1](image.png)

**Figure 1** Koch curves and their basic statistic. (Note: The baseline of iteration 0 is also called the initiator, while the shape of iteration 1 is referred to as the generator.)
Figure 2  (a) Scaling hierarchy of the Koch curve; (b) the 21 triangles plotted in a rank-size distribution.

Ever since geography was established as a discipline in Ancient Greece, Euclidean geometry has been an important tool for measuring and describing the Earth and its surface. Although the Earth is not a perfect sphere, it can be approximated as a globe for the purpose of map projection. Euclidean geometry plays an important role in the transformation of the globe into two-dimensional maps. Beyond this, however, Euclidean geometry adds few insights into the understanding of geographic forms and processes. This is because Euclidean geometry can only be used to measure regular and smooth shapes, whereas geographic features appear irregular, wiggly, and rough. Unfortunately, Euclidean geometry has dominated geography for a long time and it is time to change our mindsets. The following section illustrates how line simplification, using the third iteration Koch curve as a working example, can be achieved with the guidance of fractal geometry.

Line simplification based on head/tail breaks

The third iteration Koch curve contains a total of 21 triangles of different sizes – specifically, 16, 4, and 1 with respect to sizes of $1/27$, $1/9$, and $1/3$. The 21 triangles, defined in a recursive manner, constitute a scaling hierarchy and are plotted in a rank-size distribution (Figure 2). The scaling hierarchy implies that there are far more small triangles than large ones, that is, 16 small and five large. The scaling recurs again for the five large triangles, that is, four small and one large. Therefore, the Koch curve has an $ht$-index of 3. Given the scaling hierarchy, line simplification can be conducted by removing small triangles or keeping large ones; in other words, removing the 16 smallest ones (blue) first, and then the four mid-sized ones (green). The line simplification sounds very simple and straightforward for the Koch curve. How can the idea be applied to a cartographic curve?

A cartographic curve is usually far more complex than the Koch curve, but both show the same scaling pattern of far more small things than large ones. What are the “things”? And how can

Figure 3  Illustration of geometric measures for a cartographic curve (note primary measures such as angle $\alpha$, distances $d$ and $x$, and secondary measures such as ratio $x/d$, and triangle area $d \times x/2$).
they be defined for a cartographic curve? The “things” refers to certain geometric measures, including both primary and secondary. The primary measures refer to angles and distances of various kinds, while the secondary measures are derived from the primary ones (Figure 3). One example of the measures is the distance \((x)\) of the furthest point from the line, with distance \(d\), linking two ends of a curve. Jiang et al. (2013) showed that both the primary measure \((x)\) and the secondary measure \((x/d)\) exhibit a heavy-tailed distribution, implying far more small values than large ones. This is the same for the measure area \((d \times x/2)\), that is, far more small triangles than large ones. Note that the values of the measures should be understood in a recursive manner and the recursive process ends up with a series of values for each measure. Once the things (or measures) have been determined, the next question is how to differentiate small and large things.

The small and large things are differentiated simply by the arithmetic mean. The key, however, is to differentiate small and large things recursively. This is what underlies head/tail breaks as a classification scheme (Jiang 2013) and visualization tool (Jiang 2015) for data with a heavy-tailed distribution. Given a series of values for measure \(x\) with a heavy-tailed distribution, head/tail breaks help to derive hierarchical levels of the measure. For the sake of simplicity, we employ the Koch curve to illustrate the head/tail breaking process. The arithmetic mean of the 21 triangles is:

\[
m_1 = \frac{1 \times \frac{1}{3} + 4 \times \frac{1}{9} + 16 \times \frac{1}{27}}{21} = 0.07
\]

The first mean of 0.07 split the 21 triangles into two unbalanced parts: five above the mean (about 24%, a minority called the “head”) and 16 below the mean (about 76%, a majority called the “tail”). The average of the five triangles above the first mean is:

\[
m_2 = \frac{1 \times \frac{1}{3} + 4 \times \frac{1}{9} + 5}{5} = 0.16
\]

The second mean of 0.16 further split the five triangles into two unbalanced parts: one above the second mean (about 20%, the “head”) and four below the mean (about 80%, the “tail”). The head/tail breaking process eventually leads to three hierarchical levels that we have seen already – that is, the ht-index of three.

Once the hierarchical levels have been derived, line simplification simply involves keeping those with large values or removing those with small values. Those with large values are characteristic points, which help retain the essential shape of a cartographic curve. The unique feature of the line simplification principle is that the levels of detail are automatically or naturally determined according to the scaling hierarchy of a cartographic curve. This immediately raises the question of how the levels of detail can be associated with different map scales. Another question is how to determine the levels of detail when multiple geographic features are involved in a single map or database. These two issues warrant further research in the future.

Further discussion

A very large body of literature on line simplification has been created over the past few decades (Li 2007). Previous studies on line simplification are strongly guided, and dominated, by Euclidean geometry in developing measures with which to characterize the essential shape of a cartographic curve. For example, over 30 measures have been developed for assessing the performance of line simplification algorithms (McMaster 1986). Fractal geometry
did stimulate many applications and research on line simplification, but without a great deal of progress (Buttenfield 1985; Muller 1986). The research was overly constrained by the notion of fractal dimension and failed to recognize that the essence of fractal geometry is the recurring scaling pattern of far more small things than large ones. In the spirit of fractal geometry, or fractal thinking in general, this section provides further discussion on two algorithms: the Douglas and Visvalingam algorithms (Douglas and Peucker 1973; Visvalingam and Whyatt 1993), which bear some fractal thinking.

The Douglas algorithm is probably the most widely used line simplification algorithm, since it can effectively detect critical points that reflect the essential shape of a cartographic curve. It starts with the straight line that links two ends of a curve and checks which point in between the two ends is farthest away from this line. If the farthest point is closer (measured by \( x \)) than a given threshold, it removes all in-between points; otherwise, the curve is split into two pieces around the farthest point. The above process continues iteratively for each piece until all of the farthest points are within the preset threshold. This is what is called the top-down approach, that is, starting from a curve as a whole and splitting and continuing splitting until all pieces are within a given threshold. The Visvalingam algorithm works the other way around and is bottom-up in nature. It starts with the individual point and checks which point has the smallest triangle with the point’s immediate neighboring points; that point is eliminated first. This process continues progressively until all points with the small triangles (smaller than a given threshold) have been eliminated. This idea of iterative elimination of the smallest triangles is very similar to the Bendsimplify function (Wang and Muller 1998) that is embedded with ArcGIS.

As elaborated, distance \( x \) and triangle area \((d \cdot x/2)\) in the two algorithms both exhibit a heavy-tailed distribution, which implies far more small \( x \) than large ones, or far more small effective areas than large ones. This scaling pattern provides new insights into line simplification. A cartographic curve is simplifiable because of its recurring scaling pattern. In this regard, the cartographic curves show no difference from the Koch curves. The only difference between the cartographic and the Koch curves is that the recurring scaling pattern is defined statistically for the former, but strictly and exactly for the latter. For either the cartographic curves or the Koch curves, head/tail breaks provide an effective means to derive an inherent scaling hierarchy for line simplification. Essentially, the Douglas algorithm is used to progressively select vital and critical points, while the Visvalingam algorithm is used to progressively eliminate trivial and redundant points. With the help of head/tail breaks, selection and elimination are applied respectively to the heads and the tails, again in the progressive and iterative manner. Both algorithms keep a cartographic curve as a whole in mind during the progressive processes of selection and elimination. It is in this sense that both algorithms share a certain spirit of fractal thinking, although both algorithms were developed without guidance of fractal geometry.

While keeping critical points, or equivalently removing redundant points, it is inevitable that convoluted curves will create crossings or self-intersections. A simple way to avoid crossings is to add a few more trivial or redundant points. However, some researchers tend to use the crossings to criticize a line simplification algorithm. The crossings are not a problem and should not be used as an indicator for line simplification performance. For an especially flourishing tree, crossings of branches are often...
LINE SIMPLIFICATION

seen in reality. For the Koch curve, if the scaling ratio is raised to a high value, it will also create self-intersections. Guided by the fractal thinking, the best way to assess the performance of a line simplification algorithm is to determine whether it retains the scaling pattern of far more small things than large ones.

The geographer Perkal (1966) studied the conundrum of length, that is, the issue of undefined curve length, for the purpose of measuring things on maps. However, it was the mathematician Mandelbrot (1967, 1982) who seized the opportunity and developed the new geometry of fractals. Despite many research efforts to apply fractal geometry into line simplification, our mindset still tends to be Euclidean rather than fractal. We see geometric details such as angles, lengths, and shapes, but miss the whole – the recurring scaling pattern of far more small things than large ones; in other words, we are used to seeing things linearly and individually rather than nonlinearly and holistically. Therefore, current line simplification, or map generalization in general, is very much (mis)guided by Euclidean geometry. It is time to change the mindset.

Further reading

Until quite recently it was possible to recount the history of literary geography as a subfield of human geography in a relatively straightforward manner, with geographical work with literary texts following the shifts and turns of research trends in human geography quite closely. For example, early use of descriptive literary passages as data for regional geography was modified and complicated by a growing humanistic emphasis on the subjective experience of place. That shift was in turn challenged by more radical and critical approaches; and then, under the influence of the cultural turn, literary geography became more explicitly influenced by literary and cultural theory.

In the last few years, however, rapid development in three areas has complicated the definition of literary geography. First, work at the intersection of literary studies and geography has become more actively interdisciplinary, and as a result literary geography today appears to be moving into an era of greater cross-disciplinary collaboration. Second, and partly as a result of this first development, it has become more difficult to identify what should be included within the interdisciplinary configuration of “literary geography.” Third, bibliographic efforts to record the history and present range of work combining literary studies with geography have made a wider range of relevant material visible and accessible, and this has complicated the understanding of the history, spatial distribution, and multidisciplinary range of the field. While these developments make coherent overview and collaborative consensus more difficult to sustain they reflect the currently energetic state of work in literary geography and cognate areas.

The origins and early stages of geography’s literary geography have been well documented, with works from the mid-twentieth century on the role of the imagination in geography and on regional literary geographies such as Hardy’s Wessex and Faulkner’s Yoknapatawpha County most commonly cited as marking the establishment of the field. In these early stages of literary geography, emphasis was commonly placed on the depiction of setting in fiction and the relations between fictional and lived regions. Related work in literary studies that would in time become significant for literary geography from the same era includes M.M. Bakhtin’s argument for the connectedness of literary time and space in his theory of the chronotope and Joseph Frank’s introduction of the concept of spatial form. Where Bakhtin was interested in how distinctive literary space-time configurations shaped and characterized particular genres, such as nineteenth century French realism, Frank drew attention to the nonlinear structure of works in which the narrative is distributed spatially throughout the text.

Although the first comprehensive review articles would not appear until the 1990s, as a sub-field within human geography literary geography was already gaining coherence in the 1970s, partly as a result of the emergence of humanistic
LITERARY GEOGRAPHY

geography. Within human geography, literary geography in this era was performed in the context of an increased interest in human perception of the environment and a new approach to the idea of place as location invested with cultural and personal meaning. Humanistic literary geography tended to look to literary texts, usually fiction, for universal truths, and to literary authors for particularly acute and well-written descriptions of place and landscape. Not yet a combination of geographical and literary studies, literary geography turned to literary texts for geographical evidence while maintaining a disciplinary distance from the “complementary field” of literary criticism. Meanwhile in literary studies “landscape in literature” or “literary landscapes” remained an established theme.

In the same way that humanistic literary geography had emerged in reaction to positivist and quantitative geographies, over time it became subject to critique itself from various lines of work associated with more critical and radical geographies, as attempts were made to add a more socially critical and political dimension to the field. The 1970s and 1980s also saw the beginnings of work on the inclusion of maps in literary works and on the use of fiction in the geography classroom. In this period, even as debates continued over the extent to which literary texts could be understood to constitute geographical data, early work began to appear in various areas that would later become major themes for literary geography: literary tourism, for example, science fiction, children’s geographies, regionalism, empire, and postcolonialism.

Literary geography from 1994 to 2005

The appearance of Brosseau’s 1994 review essay in Progress in Human Geography marks an important moment in the development of literary geography for two reasons. First, Brosseau argued for a literary geography methodology built around close reading techniques characteristic of literary studies, criticizing the redirecting of attention toward the ways in which literary texts generate “particular modes of readability that produce a particular type of geography.” Second, because he was familiar with both French and English language literary geography and published in both languages Brosseau initiated early moves toward a greater internationalization of the field. If the period before 1994 could be characterized as the era in which literary geography was primarily focused on description and as a result, typically, realist description and recognizable settings, Brosseau’s work added a focus on the space-generating aspects of narrative as a second major stream in geographical literary geography.

Another new line of work in geographical literary geography beginning to appear in the 1990s emphasized the social, cultural, and political contexts of literary creation and reception. This new emphasis on reading and consumption developed from Sharp’s reminder (2000) that not all readers are trained in literary criticism and that in literary geography the reader-response of nonprofessional readers cannot be ignored. Meanwhile work on literary tourism continued to develop, as did work on the fictional representation of historical places, children’s literature, and the mapping of literary settings. Science fiction first emerged as a significant genre for literary geography in the late 1990s, with the collection Lost in Space (Kitchin and Kneale 2002) marking an important moment in literary geography’s expansion of range, as an interest in the textual production of imagined worlds was added to the conventional emphasis on realistic description and representation. Major themes in human geography in this era which influenced
work in literary geography included the post-colonial, feminist geographies, and geographies of identity and positionality.

Beyond the discipline of geography, the late 1990s and early 2000s saw an increase in work that combined literary studies with geography and spatial theory in established interdisciplinary fields such as American studies. While this work was not formally presented as “literary geography” its themes and methodologies were compatible with the geographical work with literary texts that was emerging in response to the new cultural geography. In contrast, Franco Moretti’s *Atlas of the European Novel* (1998) brought quite a different idea of a literary geography, disconnected from any existing tradition within human geography, to a wide audience. According to Moretti, a specialist in comparative literature, literary geography involved the identification of suitable textual features (such as settings), the collection of data, the cartographic reformulation of that data, and finally the use of the resulting maps to generate new insights into literary history: “this is what literary geography is all about,” he argued. With no reference to work by geographers, or to existing definitions of literary geography, Moretti launched a separate tradition with the *Atlas* that only later began to reconnect with academic geography, for example, in the literary cartography project at ETH Zurich, *A Literary Atlas of Europe*. With the development of GIS and the push to merge qualitative and quantitative methods in literary geography, this kind of work is now an important element in the field. In terms of interdisciplinary connections, this line of work in literary geography – which tends to focus on the mapping of settings – docks quite comfortably at present with work in narratology, which generally assumes a hierarchical container-space metageography and which, as a result, is difficult to integrate with lines of work in literary geography more interested in rethinking the nature of space and in relational and network geographies.

The so-called spatial turn in cultural studies and the cultural turn in geography of the late 1990s and early 2000s generated an increase in the interdisciplinary exchange of ideas and theories. Blair’s “Cultural Geography and the Place of the Literary” (1998), for example, which appeared in *American Literary History*, concentrated on the overlap between the new cultural geography and work in American studies on literary texts, history, and historiography. This line in American literary studies later produced work on the literary production of scale, on fiction and maps, and on literary metageographies. Despite referring to the work of Lefebvre, Harvey, Massey, Soja, Smith, and other spatial theorists, however, Blair’s article typically made no mention of geographical work in literary geography. Work on literary texts, geographies, and spatial theory – even as similar themes and methodologies were being taken up in various disciplines – in this way remained quite fragmented.

**Literary geography after 2005**

The 2004 conference of the Royal Geographical Society/Institute of British geographers included a significantly interdisciplinary session on “Textual Spaces, Spatial Texts” that brought together geographers and literary critics, with papers being published in *New Formations* the following year. While the conference session and subsequent publication represented a new move toward interdisciplinarity in literary geography, the contributions also highlighted the way in which the invention of new variants of literary geography also sustained disciplinary boundaries. The literary critic Andrew Thacker’s
article (2005), for example, calls for the establishment of a “critical literary geography,” based on the practice of “reading and interpreting literary texts by reference to geographical concepts.” Thacker’s question – “What would such a ‘critical literary geography’ look like?” – suggests the extent to which the literary-critical and the geographical strands in literary geography at this point remained disconnected.

To some extent, even today, work at the more literary end of the spectrum tends to focus on the ways in which geographical methods and spatial theory can illuminate critical readings, while work at the more geographical end tends to focus either on the analysis of map data or on close reading employed in the discussion of issues such as the literary production of space and geographies of writing and reading. Remaining differences in purpose and emphasis notwithstanding, however, there has been a notable increase in the interdisciplinarity of literary geography in the past decade. Collections of essays and journals are today much more likely to include work by both literary critics and geographers, and there are an increasing number of collaborative projects underway involving combinations of disciplines. The new open-access online journal Literary Geographies, for example, was jointly established in 2013 by geographers and literary critics collaborating in an attempt to reduce the disciplinary sorting and distancing effects associated with conventionally distinct literary and geographical journals.

Sorting work on literature and geography

One of the major questions in generating an overview of current work in literary geography is whether or not to limit the scope of the review strictly to work which self-identifies as literary geography, or to consider the whole range of work dealing with literary writing and reading and questions of space, place, and geography. While the distinction between critical literary geography and the more traditionally geographical literary geography is not so clear that the two cannot be understood within the same framework, and while work at the intersection of literary studies and geography within American studies (for example) is often clearly compatible with work produced within human geography, other recently emerging fields such as geopoetics, green cultural studies, ecopoetics, and ecocriticism are less susceptible to inclusion within the broad field of literary geography. This can be ascribed in part to the fact that approaches such as ecocriticism tend to embody specific sociopolitical goals in regard to issues such as globalization, ecology, and human–environment relations.

The relatively new field of geocriticism is commonly presented as an expanded form of the French-language concept of géocritique, a geocentered approach to literary criticism. In its English-language manifestation, geocriticism at present in practice bears many similarities with critical literary geography and in theory with cultural geography generally, but its relationship with literary geography is somewhat difficult to determine because of the way in which it has been presented as a new initiative in studies of literary spatiality and indeed spatiality more generally.

The field of literary cartography is more easily grasped in relation to literary geography, its history and current practices, and the terms are sometimes used interchangeably. While some studies dealing with literary texts and maps follow the Moretti “distant reading” path, relying on the accumulation of large data sets and (increasingly) GIS methods to generate cartographic representations of literary aspects such as fictional settings or author geographies, others take an approach more in line with the kind
of “close reading” typical of literary criticism, focusing in greater detail on single authors or texts. There is also a growing interest in the relationship of mapping to narrative: the use of maps within literary works, the mapping of fictional settings, and (particularly in the context of Web 2.0) the reading of maps as stories.

Bibliographies

One of the most significant developments in recent years in literary geography has been the establishment in 2012 of an open-access online bibliography providing a regularly updated database of work in the field. As of January 2014, the bibliography listed more than 1700 items organized into chronological and thematic lists with a separate bibliography for unpublished MA and PhD theses. Themed lists include literary geography and mapping, literary geography and tourism, poetry, science fiction, graphic fiction, and detective fiction, and there is also a page listing research project websites. Thacker’s (2005) and Hones’s (2008) review essays were able to specify clear limits to their reach, dealing, for example, almost exclusively with critical literary geography or with work on fiction published in geography journals. The pushing back of the horizons of literary geography and the increased visibility of similar work in other disciplines and on a wider variety of genres enabled by the literary geographies website means that this kind of strategic limitation is today much less likely.

The rapid emergence of online search engines and depositories in addition to the digitalization of journal archives has meant that the literary geographies bibliography website has been able to expand the horizons of literary geography by compiling citations for relevant but scattered and in many cases “lost” work, such as past unpublished doctoral dissertations or work published in collections and journals outside the mainstream of human geography. This bibliographic recuperation has rendered visible the very broad range of work in the field, bringing into sight work on such varied textual materials as English-language poetry from Singapore and the Niger Delta and from journals as diverse as Australian Literary Studies and the African Research Review. Taken together with the geographical range of the work included, the global spread of the page view metrics for the website indicate the extent to which even English-language literary geography today extends far beyond its traditional foundations in British cultural geography and literary studies and American studies and literary history.

New directions

In the period before 1994, literary geography was primarily concerned with questions of description and representation; the following decade saw the addition of a new focus on narrative and its role in the literary production of place and space. The shift in thinking that has moved geography from a view of space as a set of external coordinates to a view of space as something more unstable – the product of, not the container of, interrelations and networks – has led not only to a widening of the gap separating literary geography generally from narratological work on literary space but also to a closer relationship between literary geography and the work of textual theorists dealing with the concept of intertextuality, a combination which has introduced into literary geography the idea of literary space as a network of intertextual relations.

With continuing work on description, representation, and narrative in literary geography now including strong initiatives in literary cartography, the addition of a third major focus
means that literary geography today is also concerned with various forms of writing and reading practice. This new emphasis, in part a response to the emergence of nonrepresentational theory, has led to increased interest in studies of the physical and social geographies of inspiration, creativity, and production, of author–text–reader interaction and historical geographies of reader reception (Saunders 2010). The idea that the literary text itself can be understood as a spatial or geographical event happening in the interaction of multiple agents (including authors, editors, publishers, and readers) is an emerging line of research. Progress is also being made in work on the historical geography of the book, on author–editor interactions, and on textual materialities.

Overall, in recent years literary geography and its cognate fields have been characterized by a notable increase in productivity and diversity. The fact that the list for theses and dissertations at the literary geographies bibliography website has 53 citations for the period 1980–2008 but 57 citations for the subsequent four years, 2009–2012, indicates the growing interest in this area. Once focused almost exclusively on nineteenth century realist fiction, literary geography in the last decade has diversified extensively now including work on a wide range of other fictional periods and styles: the modernist and the postmodern novel, for example, short stories, poetry, and drama. The 2013 collection Poetry & Geography: Space and Place in Postwar Poetry (Alexander and Cooper 2013) provides a good example of the way in which the post-2000 line of critical literary geography, grounded in literary criticism, and the tradition of geographical literary geography, which can be traced back to the mid-twentieth century, are converging. With the launch of the new journal Literary Geographies in 2013, it seems likely that literary geography will continue to become more varied, collaborative, and interdisciplinary in the years ahead.

Lithologic discontinuities in soils

Steven W. Ahr

Accurate recording and interpretation of vertical changes within a soil profile are important for pedologists, geomorphologists, stratigraphers, hydrologists, and archaeologists. Describing soils is a fairly standardized process that follows a systematic cataloging of observable properties and their changes with depth. Many soil properties that vary with depth often do so abruptly, exhibiting stark contrasts with the upper or lower horizons. It is not always clear, however, even to those who routinely investigate soils, whether such vertical changes originated from sedimentologic/geologic layering (i.e., two or more parent materials), or from pedogenic processes. Where geologic layering has resulted in the vertical change in the soil profile, the point at which that change occurs is referred to as a lithologic discontinuity (LD); it separates the two layers (Figure 1). Each of the layers is assumed to differ substantially from the other layer in terms of particle size distribution (PSD) or mineralogy, reflecting differences in lithology. Because the sediment above an LD is always younger than the sediment below, LDs also denote age differences in the materials (Schaetzl 1998; Soil Survey Staff 2010). If no discontinuities occur within the soil material, pedogenesis is assumed to have proceeded within a single, uniform parent material.

LDs that separate different sedimentary layers, or strata, form when there is a shift from one depositional system to another (e.g., eolian to fluvial), or as changes take place in an otherwise similar sedimentary system. The former can be related to changes in parent material source, whereas the latter may reflect waning or advancing energies associated within a single depositional system. Loess overlying glacial till, alluvium overlying residuum, and colluvium overlying alluvium are examples of stratigraphic successions containing LDs that originate from different depositional agents and sediment sources. Changes in depositional energy within the same sedimentologic regime (e.g., fluvial) can also result in the formation of LDs, such as a significant shift in particle sizes due to changes in stream competence. For example, medium or fine sand overlying mostly coarse or very coarse sand can be assumed to be two different materials, due to differences in depositional energies, although they are of the same mineralogy (Soil Survey Staff 2010). Within soil-stratigraphic successions, LDs can also point to a chronological unconformity caused by a hiatus in sedimentation (beyond diastems). Such chronological unconformities within alluvial soil sequences are often marked by paleosols that form during episodes of landscape stability. The stratification of buried soils in an alluvial sequence can also be marked by LDs if the geologic materials comprising each alluvial unit are lithologically dissimilar, or if particle sizes between layers are strongly contrasting (Soil Survey Staff 2010).
LITHOLOGIC DISCONTINUITIES IN SOILS

Detection of lithologic discontinuities

Although easy to conceptualize, detection of LDs in the field is not always straightforward. Traditional approaches rely on methodologies designed to identify significant vertical changes in profile properties that have unquestionably resulted from geologic processes. Such approaches attempt to exclude those changes that were caused by additions, losses, transformations, and translocations that may have occurred during pedogenesis. For example, pedologists insist that LD indicators must not have resulted solely from translocation of clay during pedogenesis. The same could be said for any substance that is translocated in soils during pedogenesis. Thus, soil properties that are related to mobile soil constituents, including pH, clay content and mineralogy, organic matter and carbonates, as well as those that are affected by in situ weathering processes, should not be used for the detection of LDs. These vertical changes occur in soils due to pedogenesis, not via geologic processes. However, such properties can and often do abruptly shift at an LD. With this background in mind, we turn to the methods that have been developed to detect LDs, including morphological, textural, and mineralogical indicators.

Morphological and textural indicators

Classic morphological indicators of LDs include abrupt changes with depth that are unrelated to pedogenesis, especially those related to differences in lithology, shape, or distribution of coarse fragments. Significant horizon-by-horizon changes in the degree of weathering of soil rock fragments, rock fragment angularity, and the size and shape of resistant mineral grains observed in micromorphic thin section, can suggest different geologic origins for each layer. In areas where soils have relatively unweathered rock fragments, an LD can be indicated by an uneven distribution of rock fragments with depth. Stone lines, which commonly separate different parent materials, could suggest that a soil has developed in more than one kind of parent material, separated by an LD. Caution must be exercised, however, as stone lines are also commonly formed by pedoturbation in initially uniform materials (Johnson 2008).

In terms of textural indicators, abrupt changes in the depth distributions of sand and silt totals,
LITHOLOGIC DISCONTINUITIES IN SOILS

Mineralogical indicators

The analysis of depth trends in stable soil constituents such as Ti and Zr have long been used for detection of LDs. Both Ti and Zr are considered weathering-resistant when present in stable and insoluble mineral phases such as tourmaline and zircon, respectively. If these minerals can be isolated from the sand or silt fraction, which is normally not considered mobile in soils, the amount of Ti and Zr can be used to indicate the presence of lithologic changes. Nonuniform depth functions in Ti and Zr (and ratios between them) imply inherited layering in the soil profile and point to the presence of an LD. Alternatively, uniform values (and ratios) of these kinds of data point to parent material uniformity (Anda, Chittleborough, and Fitzpatrick 2009; Chapman and Horn 1968).

In some instances, Ti- and Zr-bearing minerals may become chemically reactive and/or mobilized, and as a result, their utility as a stable index element can become problematic. For example, Ti is normally present in ilmenite, rutile/anatase, mica, and biotite. But as these minerals weather, Ti may become incorporated into the fine clay (mobile) fraction, transported or leached, and reprecipitate lower in the soil profile (Taboada et al. 2006). In this case, Ti depth functions may reflect weathering and translocation processes, rather than an LD (Figure 2). Because Zr is found almost exclusively within the weathering-resistant mineral zircon, it tends to be ideal for identifying LDs, so long as it is present in the sand or silt fraction, and in detectable quantities. However, the use of Zr can also be problematic in some instances. For example, eolian additions of small amounts of zircon to the upper soil profile can significantly complicate LD detection. Zr has also been shown to be susceptible to redistribution as well as chemical weathering and leaching in extremely acidic or alkaline soils, and in volcanic soils.
LITHOLOGIC DISCONTINUITIES IN SOILS

Figure 2 A texture contrast soil (Grossarenic Paleustalf) from Burleson County, Texas. Clay-free textural and mineralogical data failed to reveal any LDs within this soil, that is, the textural differences have resulted from mobilization and translocation of fine clay by pedogenesis. Note that there is virtually no change in Zr with depth. In contrast, the slight shift in Ti at the top of the argillic horizon is likely attributable to weathering of primary minerals and incorporation of Ti into the mobile clay fraction, which is 81% correlated. Photo by S.W. Ahr.

Post-depositional factors affecting lithologic discontinuities

Some LDs are so subtle as to raise the question of whether they are even worth noting. In other situations, post-depositional processes such as pedoturbation have blurred the contact between the two materials, making detection (and perhaps importance) of the LD questionable (Schaetzl and Luehmann 2013) (Figure 3).

LDs within a profile are often obscured and blurred by weathering and mixing processes that disturb the original stratification between different layers of parent materials. Such horizionation and mechanical sorting processes include various types of pedoturbation, such as shrinking-and-swelling by smectitic clays, cryoturbation, and bioturbation. These processes are most pronounced in the near-surface zone, implying that LDs are more likely to be preserved at greater depths in the soil where relict bedding can persist through multiple phases of pedogenesis and pedoturbation – even within the highly decomposed and weathered soils of humid regions.

The same processes that obscure pre-existing LDs can, in some circumstances, also transform uniform, near-surface sediments into layered sediment, especially on older upland landscapes. For example, weathering in some soils transforms coarse particles in the upper profile into silt, clay, and fine clay, and moves these particles down the profile. This process often results in the formation of a texture contrast soil, in which coarse textured layers overlie finer-textured layers enriched in clay (see Figure 2). This type of contrast is commonly observed in well-drained Alfisols, as well as Ultisols (Ahr, Nordt, and Driese 2012; Koppi and Williams 1980). The contrasting textures, often separated by abrupt boundaries, can be mistakenly interpreted as geologic layering. Such vertical changes are more appropriately interpreted as pedologic discontinuities that resulted from the pedogenic segregation of mobile soil constituents. Because of these complicating factors, distinguishing between pedologic and lithologic discontinuities should be determined using multiple lines of evidence.
Figure 3  Examples of two different graphical methods that can be used to show LDs in soils. The data in (a) and (b) are from a profile composed of a 40-cm-thick, silt-rich, loess mantle over sandy glacial outwash. This soil has a mixed zone, rather than an abrupt and sharp LD. (a) Traditional depth plots of immobile fractions and ratios of immobile fractions, as well as modal particle size. (b) Continuous textural curves, taken by horizon. Note how these curves more readily show the presence of a distinct mixed zone in this soil, which is manifested mainly as loess mixed into the underlying sand, rather than sand mixed upward into the loess. (c) Similar data for a soil formed in 35 cm of loess over sandy glacial outwash, but with perhaps a more abrupt LD. Adapted from Schaetzl and Luehmann (2013).
LITHOLOGIC DISCONTINUITIES IN SOILS

**Figure 4** Historic-to-modern (1840–1960 CE) coal-rich alluvium, or “coal wash,” overlying a late Holocene alluvial surface. The contact between the two materials marks an LD of both a lithologic and a temporal nature. This soil is located along Nesquehoning Creek in eastern Pennsylvania. Photo courtesy of G. Stinchcomb and M. Stewart.

Impacts of lithologic discontinuities on pedogenesis

LDs are globally widespread, and probably more common than many soils researchers recognize. LDs have been reported in loess and sand covers over glacial tills in relic periglacial environments across Europe, in volcanic soils, in sandy Atlantic and Gulf Coastal Plain soils, in the loess-mantled landscapes in North America, in soil complexes in Australia, and in highly weathered soils of the tropics. Because they are so extensive, and because changes in lithology or mineralogy that are indicated by an LD can influence the trajectory of soil formation and impact pedogenesis, the ability to detect LDs in soils and to distinguish between different parent materials is important for pedogenic studies. For example, the presence of LDs in the subsurface, particularly in fine-over-coarse layering, can influence soil hydrology, and may also inhibit the eluviation/illuviation of mobile soil constituents. Also, identification (or misidentification) of an LD can greatly affect interpretations of soil laboratory data, particularly in terms of gains and losses of soil constituents. For example, mass balance calculations, which are used to quantify soil volume changes and open-system transport of constituents into or out of the soil during pedogenesis, depend on an assumption of parent material uniformity, or absence of LDs.

New research directions on lithologic discontinuities in soils

Although traditional approaches to investigating LDs are important, Lorz and Phillips (2006) suggested that current “top-down” genetic models fail to fully account for a dynamic regolith in soil formation. They point out the need to evaluate both pedological and geological (polygenetic) processes in soil genesis studies. This approach is warranted, particularly when dealing with dynamic soil environments such as those in alluvial or other aggradational settings, areas of dust deposition, and places where historic-era anthropogenic materials have been added to the soil column. Recently, Stinchcomb et al. (2013) integrated the concept of event stratigraphy with the pedologic investigation of lithologically distinct, nineteenth- and twentieth-century alluvial coal deposits in eastern North America (Figure 4). Such deposits are becoming increasingly identified and mapped around the world, which will have important implications for biogeochemical changes to the Earth’s surface, along with anthropogenic influences on deposition and erosion. This research underscores the need
LITHOLOGIC DISCONTINUITIES IN SOILS

investigations. Deciphering the complexity and influence of LDs is critical in soil genesis studies because the trajectory of soil formation is greatly influenced by parent material. Traditionally, identification of LDs has yielded important information about the genesis of “modern soils.” As the realm of pedology continues to expand, investigation of LDs will be instrumental in providing useful data on anthropogenic influences on local geomorphic settings, and in reconstructing ancient geologic depositional histories and soil-forming environments.

**Lithuania: Lietuvos geografin̆ draugija (LGD) (Lithuanian Geographical Society)**

Founded: 1934  
Location of headquarters: Vilnius  
Website: [www.lgd.lt](http://www.lgd.lt)  
Membership: 199 (as of January 1, 2014)  
President: Dovilė Krupickaitė  
Contact: dovile.krupickaite@gf.vu.lt, info@lgd.lt

**Description and purpose**

The Lietuvos geografin̆ draugija is a voluntary, independent, and public scientific organization that unites professional geographers and other individuals and organizations interested in the science and teaching of geography and promoting their progress.

The goal of the society is to enhance the significance of geography as a science through the coordination of the activities of its members.

One of the main objectives of the society is to publicize to the general public the geographical problems faced by the Republic of Lithuania so as to improve decision-making.

Membership has been fluctuating between 100 and 300 members over the years since inception. The members work in a variety of different fields, such as science, teaching, planning, and public administration.

**Journals or major publication series**

**Current activities or projects**

The LGS focuses on representing and promoting the interests of the geography community, promoting geography in society while defining and solving topical problems of geography, and international collaboration.

Principal current projects include the preparation of an academic dictionary of geography and the development of a national landscape management plan (in collaboration with other institutions). Since 1986 the society has focused on the education of young geographers with pupils in senior classes participating in a 3-year learning program. Annual national geographical contests attracting approximately 1000 participants from schools throughout the country have been organized by LGS since 2001.

The Lithuanian Geographical Society organizes an annual congress for the discussion and implementation of tasks and discussion of future goals.

**Brief history**

The beginning of geographical research in Lithuania can be traced to the sixteenth century when the first maps of the country appeared. The best known of these is “Moscovia”, mentioned in the *Cosmographia* of Sebastian Münster. In the seventeenth century meteorological research was started at Vilnius University and the *Compendium geographicae* was published in 1743 in Vilnius. By then many geographical subjects were taught and the first textbooks were published at Vilnius University with geography advancing significantly during the nineteenth century. Until 1917, some geographic research in Lithuanian was organized by the northwest division of the Imperial Russian Geographical Society. Geographical research...
LITHUANIA

intensified after 1922 following the restoration of Lithuania’s independence in 1918.

The LGS was established in 1934 with Professor Kazys Pakštas serving as the first and founding president. The LGS started their participation at the International Geographical Congress in 1938. Membership at the time was about 100. After the occupation of Lithuania in 1940, LGS actively functioned abroad (mainly in the USA).

The geographical society of Lithuanian (SSR) was founded in 1955. It was a subdivision of the All-Union Geographic Society of the USSR. Its scientific periodical *Geografijos metraštis* (Geographical yearbook) has been issued since 1958. The LGS was reestablished on April 26, 1989. In 2007 the LGS had about 300 members.

Livelihoods

Sarah Turner
McGill University, Canada

Livelihoods analysis has become a widely used approach in academic and applied development circles to better understand the numerous components of poverty and marginalization, as well as how people escape such circumstances. Since gaining prominence in the mid- to late 1980s, the term “livelihoods” has been the centerpiece of a variety of approaches, frameworks, and methodologies spanning diverse disciplines and scales. At their most fundamental level, these approaches aim to achieve a holistic, actor-focused understanding of how individuals and households work to create and sustain a means of gaining a living, often set within a context of poverty or vulnerability. At the same time, development discourse has increasingly prioritized environmental protection and the sustainable use of natural resources. Emerging scholarship on sustainable livelihoods thus lies at the interface of poverty studies and research on the environment. Since the terms “livelihoods” and “sustainable livelihoods” and the notions surrounding them are often used interchangeably, this entry discusses both concepts.

Two theoretical debates enhanced the initial appeal of the livelihoods concept within development theory and practice. One was the impasse that emerged in the mid-1980s regarding a relevant way to move forward with development theories. Scholars had become critical of the overly structuralist explanations of uneven development offered by the dependency and neo-Marxist theories of the 1970s and 1980s. While livelihoods perspectives kept attention focused on the unequal distribution of power and resources in society just as these former theories had, the livelihoods approach was argued to be more balanced, emphasizing the role of human agency in coping with vulnerability, poverty, and structural change. Second, the livelihoods approach presented an alternative to the inadequacies of modernization approaches to poverty that chiefly focused on income earnings and consumption levels. Advocates of a livelihoods approach thus argued for a more multidimensional and situated concept that perceived local development through the lens of lived experience, with a focus on households, networks, and communities.

Defining “livelihoods” and “sustainable livelihoods”

At its most basic, a livelihood is a means to a living. Livelihoods are dynamic, relying on emerging opportunities that are embedded within constantly changing social and political contexts. It is difficult – and, many would argue, simplistic – to try to measure complex local household realities by monetary income alone. Livelihoods analysis thus takes a holistic approach, looking at multiple components that contribute to the possible living of a household or individual. A frequently cited definition of a livelihood is “the assets (natural, physical, human, financial, and social capital), the activities, and the access to these (mediated by institutions and social relations) that together determine the living gained by the individual or household” (Ellis 2000, 10).
LIVELIHOODS

Because circumstances and situations change over time, an increasingly common feature of livelihoods studies has been a focus on sustainability. A livelihood is considered sustainable when “it can cope with and recover from stresses and shocks, maintain or enhance its capabilities and assets, while not undermining the natural resource base” (Scoones 2009, 175). Ideally, sustainable livelihoods result in maintainable opportunities for the next generation and contribute net benefits to other livelihoods at the local and global levels and over the short and long terms. Key authors involved in the initial creation of these definitions include Chambers and Conway (1992), Carney (1998), and Ellis (2000).

The sustainable livelihoods approach is particularly successful at conceptualizing livelihoods holistically. From this perspective, livelihoods comprise the capabilities, tangible and intangible resources (assets), and activities (or livelihood strategies) – plus access to these, mediated by social relations and institutions – which individuals or households draw on to gain a living. As Chambers and Conway (1992, 6) have suggested,

A livelihood comprises the capabilities, assets (stores, resources, claims and access) and activities required for a means of living; a livelihood is sustainable which can cope with and recover from stress and shocks, maintain or enhance its capabilities and assets, and provide sustainable livelihood opportunities for the next generation; and which contributes net benefits to other livelihoods at the local and global levels and in the short- and long-term.

Anthony Bebbington (1999) adds that sustainable livelihoods build on the assets people have at hand to provide them with outcomes such as material wellbeing, a meaningful existence, and the capability to shape the larger context in which they live.

The concept of sustainable livelihoods emphasizes the fact that people use a variety of assets and activities to build their livelihoods. By concentrating on the individual or household scale, the approach provides a crucial alternative to the abstract, macroscale discussions typical of sustainable development discourse. Sustainable livelihoods research also sees sustainability as a multifaceted and multiscalar notion, while adding a temporal component to earlier ways of conceptualizing livelihoods. Above all, advocates argue that sustainable livelihoods analysis allows for a comprehensive portrayal of the complex composition of livelihoods, including aspects of vulnerability and meaning, while tackling poverty in a transformative way. More specifically, sustainable livelihoods approaches have been considered to be a set of principles guiding evidence-based development interventions; an analytical framework to help understand what is and what could be done to make livelihoods sustainable as an overall developmental objective.

Livelihoods frameworks

Building on the livelihoods and sustainable livelihoods concepts, different frameworks have been designed as analytical structures to better understand the complexities and components of livelihoods and how interventions might best be made. The most familiar frameworks have been conceived of by the International Development Studies Institute, University of Sussex (Scoones 1998), the United Kingdom’s Department for International Development (DFID 1999), and Frank Ellis (2000). These frameworks focus on analyzing how impoverished people draw on their assets to formulate various strategies for making a living. The proponents of such frameworks suggest that the poor choose from
a range of available livelihood pursuits to meet their needs, within the constraints of their given locality and context. Livelihoods analysis considers how this context shapes people’s access to assets, the strategies they are able to pursue, and the resultant outcomes. In turn, the frameworks aim to depict how people subsist, and envision how contextual constraints to sustainable livelihood goals can be overcome. Although these frameworks all differ slightly, the general building blocks are fairly similar. One difference to note is that the DFID livelihood framework includes feedback loops, highlighting the complex and interlinked nature of livelihood creation and composition.

**Livelihood assets or capitals**

Assets or capitals – and how these may be used, combined, expanded, and reshaped – are at the core of determining the feasible set of livelihood strategies an individual or household can pursue to meet their material and experiential needs and motivations. Scholarship on sustainable livelihoods borrows from economics in seeing these assets as capitals which can be accumulated and invested in pursuit of livelihood outcomes. These capitals go beyond mere livelihood resources, though; they are assets that give people the capability to be and to act, permeating lives (cf. Sen’s (1985) capabilities approach). This broad view illustrates how low monetary incomes do not preclude one from having a range of other assets to provide livelihood options and wellbeing. By calling attention to what people have instead of emphasizing what they lack, the sustainable livelihoods approach, it is suggested, lends an outlook of optimism and individual agency to development discourse.

Five types of capital, together commonly known as the “asset pentagon,” are generally used in livelihoods and sustainable livelihoods frameworks:

1. **natural capital**: the local stock of environmental resources, including both renewable resources (such as water, forests, soil) and nonrenewable resources (such as extractive resources like metals and oil) on which livelihoods can be based;
2. **physical capital**: human-produced capital goods (productive resources), such as infrastructure (including roads, communication networks, irrigation schemes), tools, and machinery that facilitate production processes and market exchanges;
3. **financial capital**: wages, savings, credit, remittances, pensions, and precious metals (often in the form of jewelry) which are valued for their convertibility into other types of capitals or consumption goods;
4. **human capital**: a person’s knowledge base, education level, skills, and health status, and the resultant quantity and quality of labor individuals or households can draw on to fulfill their productive and reproductive duties;
5. **social capital**: heralded by the World Bank as perhaps the missing link of development, this includes the rules, norms, obligations, reciprocity, and trust that are found embedded in social relations, structures, and institutional arrangements and which enable people to achieve individual and community objectives, including gaining resources. Like other forms of capital, social capital is subject to accumulation and depletion.

Although these are the five most commonly recognized livelihood capitals, some authors have advocated for cultural capital to be treated as a separate category (rather than it being sometimes subsumed within social capital). Drawing on the work of Pierre Bourdieu (1984), cultural capital (simply put), relates to the skills, knowledge, education, and possible social advantages...
LIVELIHOODS

a person has that can give them benefits in society. Bourdieu divides cultural capital into embodied, objectified, and institutionalized forms. It is sometimes also argued that political capital should be considered as a separate asset, as discussed shortly.

These capitals are interrelated and affect each other; the acquisition or exploitation of one may hinge on the ability to mobilize or access another. For instance, social capital can mediate access to natural resources, while human capital is required to put natural capital to productive use. When necessary, physical capital (e.g., livestock) can be converted into financial capital (e.g., money). To a certain extent, capitals can be substituted for one another, with different assets demonstrating differing potentials for substitution. Fertilizer (physical capital), for example, can compensate for declines in soil fertility (natural capital) to some degree. Substitutions can also occur within asset categories, such as when labor is reallocated from domestic duties to cash cropping. Studies have demonstrated that the capacity to flexibly substitute and convert between assets is often critical for successfully coping with shocks and seizing new opportunities. Since livelihood strategies rarely draw on or enhance all the capitals/assets at once, their sustainability must be considered in light of the combinations of and substitutions between assets and their overall stock through time.

Access

Access determines how individuals acquire (or miss out on) the capitals needed for their livelihoods. While assets/capitals might be considered the building blocks of livelihoods, access to these building blocks is essential for creating a livelihood that meets current needs and can respond to changing circumstances. The three intricate mechanisms which mediate household and individual access to assets and activities include social relations, institutions, and organizations.

Social relations reveal how different social positionings mediate access, grounded in factors such as ethnicity, gender, kinship, religion, and class. Institutions can be defined as “the formal rules, conventions, and informal codes of behaviour, that comprise constraints on human interaction” (Ellis 2000, 38). Institutions are regularized practices or patterns of behavior, structured by the rules and norms of society, which have persistent and widespread use. Institutions are not absolute, but rather are created through social interactions and negotiations, structuring and regulating how society functions. Examples of institutions include land tenure arrangements, traffic rules, and the custom of marriage. Finally, organizations include government agencies, nongovernmental organizations (NGOs), cooperatives, and so on, organized around a common set of objectives.

Focusing on social relations, institutions, and organizations allows for a multiscalar analysis of access, for instance, revealing how a state policy or NGO can impact a household’s livelihood strategies. Concurrently, it is also important to note how social exclusion can occur through these mechanisms, with specific individuals and households (such as women-headed households) potentially locked out of access and opportunities.

Livelihood strategies and diversification

Livelihood strategies are the ways that individuals and households choose to use, transform, and reproduce their capital stock or resource base in pursuit of livelihood goals. Scoones (1998) suggests three main livelihood strategies that are often available in rural contexts: agricultural intensification, agricultural extensification, and
migration. A fourth strategy, livelihood diversification, may include a mix of these three.

Frank Ellis (1998, 4) defines rural livelihood diversification as “the process by which rural families construct a diverse portfolio of activities and social support capabilities in their struggle for survival and in order to improve their standards of living.” Diversification can occur at multiple scales, such as an individual pursuing a variety of activities such as farming, trade, and contractual labor, or members of a household specializing in particular activities but in aggregate bringing together a diverse portfolio of livelihood strategies. Migration is a common livelihood diversification strategy, making a household’s organization of livelihood activities multispatial. As with assets, the relative importance of different livelihood strategies changes through time, across regions, and even within a given household.

Individuals and households diversify their assets, incomes, and activities for various reasons. Push factors include the need to expand safety nets, mitigate risks, and resist and/or cope with shocks and stresses. Diversifying livelihood strategies in this way (also called “distress diversification”) can allow people to stabilize their income and regulate consumption in case of crises or seasonal shortfalls. Alternatively, pull factors, or “progressive diversification,” can involve the realization of new opportunities. In addition, as noted by Sarah Turner (2007), a strategy of “selective diversification” may result in flexibly engaging with certain livelihood strategies at opportune times and withdrawing from them during other periods, thus moving beyond a dualistic classification of diversification. Crucially, sustainable livelihoods scholarship recognizes that diversification plays a central role in livelihoods, and that the “rural” is not strictly synonymous with agricultural activities.

Examining diversification strategies highlights the importance of taking scale into account when researching livelihoods. Although livelihood approaches tend to be focused on the microscale, one still needs to consider whether the individual, household, or some other grouping should be the unit of analysis. Chambers and Conway (1992) situate livelihoods at the level of the household, which they define as a group of people that eat from the same hearth. Yet this analytical unit may not always be the most appropriate; households can be split by intrahousehold conflict or differentials in capitals and capabilities. As a result, different members will be impacted differently by changing circumstances: gender and age differences within the household, for instance, are likely to affect individual outcomes. Furthermore, the definition of a household is up for debate, since not all contributors to a household’s common livelihood necessarily live under the same roof, and remittances may constitute a significant portion of a household’s financial capital.

Vulnerability context and transforming structures and processes

The livelihoods literature calls attention to how the external environment affects people’s options and strategies for making a living. Some analysts distinguish between an exogenous “vulnerability context,” over which people have little or no control, and sociopolitical aspects endogenous to the norms and rules of society, deemed “transforming structures and processes.” The vulnerability context includes people’s exposure to shocks, trends, and seasonal changes. Shocks include human-induced or “natural” stresses such as natural disasters, droughts, conflicts, crop or animal disease, and death. Trends include fluctuating resource stocks and population growth,
LIVELIHOODS

as well as changes in technology and governance, while seasonality can affect production, prices, health, and employment opportunities.

In turn, transforming structures and processes are composed of structures which include public and private organizations such as the government, NGOs, and commercial enterprises, and of processes such as the laws, policies, cultural norms, and institutions that shape human interaction. Attention to these external conditioning variables, it is argued, links the livelihoods framework's micro and macro elements, providing a launching pad for policy-based interventions.

Livelihood outcomes

One of the key contributions of the sustainable livelihoods approach is its holistic conceptualization of what constitutes a sustainable living, challenging practitioners and researchers to question the desired ends of “development.” These ends, or sustainable livelihood outcomes, can include income, dignity, power, and sustainability; put differently, the approach implies an improved quality of life according to a household’s own criteria (Bebbington 1999). From this perspective, the assets that serve as inputs to livelihood strategies are also livelihood outcomes themselves. This bidirectional notion is a strong point of the sustainable livelihoods literature.

Methods

There is no set group of methods that is drawn on to undertake livelihoods analysis. Often a mixed methods approach is used, bringing together quantitative approaches such as village- or community-level surveys and qualitative approaches such as in-depth conversational and semistructured interviews, oral histories, focus groups, and observations. Participatory approaches are sometimes incorporated, including participatory rural appraisal (PRA) techniques such as participatory video and field-mapping. As with any participatory approach, such methods can raise concerns over representation and the “myth of community.” Particularly when used by development practitioners, a livelihoods analysis can also run into trouble if local interviewees downplay their assets because of taxation or theft concerns, or in order to benefit from possible interventions.

Critique of the sustainable livelihoods literature

Though it presents a dynamic portrait of the relationships between rural livelihoods, poverty, and the environment, sustainable livelihoods scholarship is limited in certain ways. One shortcoming is in its handling of poverty. While the concept of poverty is considered essential for discussing livelihoods, no explicit mention is made of poverty’s place within the notion of sustainable livelihoods, nor are the differences between definitions of poverty properly emphasized. Indeed, a focus on capitals privileges research and developmental interventions among poor people who already have some assets, at the expense of the completely destitute with minimal assets. By focusing on shaping environments that facilitate capital accumulation, the safety nets required to protect people from poverty can also be glossed over.

There is also concern that, since the 1990s, endless livelihood case studies have been amassed, but little research across differing scales has emerged. As such, no generalizable trends have become apparent from which comparative explanatory frameworks can be created or existing theories challenged. Academics such as Leo
de Haan (2012) thus argue for the combination of meta-analysis and comparative research to try to extend livelihoods research.

Critiquing capitals

While it may serve as a useful concept, the notion of capitals is contentious. “Capitalizing” key aspects of a livelihood using the language of neoclassical economics can be argued to be reductionist, as is the use of economic terminology to understand microscale resource use and household subsistence decisions. Often, those working through a human geography or anthropology lens aim to theorize capitals/assets within a relational context, while the language of neoclassical economics tends to remove assets from this crucial context.

Given the way sustainable livelihoods research couches both tangible and intangible resources in the language of economics, it is unsurprising that analyses can often end up ignoring ways in which capital can be drawn on to work toward nonmaterial ends. For instance, seeing human capital in terms of labor alone undervalues the way it enhances people’s capabilities to question, challenge, and transform the world. The same criticism applies to the concept of social capital, which is rarely considered for its intrinsic value, such as giving people voice, stimulating participation, and enriching lived experience. Sustainable livelihoods work also tends to ignore negative aspects of social capital, whereby certain individuals or groups are able to deny others access to resources and opportunities.

The asset pentagon is also subject to criticism since defining, measuring, and calibrating across assets is complex, as is calculating tradeoffs between often incomparable capitals/assets such as tangible resources and ongoing processes. Critics argue that this has weakened the sustainable livelihoods approach by not questioning or engaging the linkages and substitutions between different capitals/assets thoroughly enough. Yet proponents have suggested that these concerns can be overcome by working to understand what specific assets mean to particular groups in certain situations and contexts. For instance, an asset such as land is seldom just a tool to realize financial and material ends, but frequently gives meaning to a person’s world.

Power relations

A common critique of the livelihoods and sustainable livelihoods approaches is that they fail to adequately engage with the role of power relations and politics. According to Toner (2003, 772), the sustainable livelihoods approach provides an “individualized,” “depoliticized,” and “benign” portrayal of how people make a living and manage their resources. Its silence on power issues is puzzling given how power routinely (re)produces poverty. With a few exceptions (e.g., Ellis 2000), sustainable livelihoods frameworks have glossed over how everyday life and poverty are shaped by institutions like gender, property regimes, and power relations. This hides from view a crucial portion of the picture that should be analyzed, and underestimates people’s full potential for action. Some theorists therefore argue for the inclusion of political aspects in the definition of sustainable livelihoods, with political capital analyzed in its own right, as noted earlier. While there is some room in commonly used livelihood definitions for considering political power as part of social relations, institutions, and organizations, it can also be argued to be a capital asset which people accumulate or draw on in pursuing livelihood options. Others have instead turned to actor-oriented approaches to explore and explain how macro forces of change are experienced and negotiated locally, drawing on tools
such as the “social-interface” (Long and Long 1992).

Debating strategy

Another aspect of the sustainable livelihoods approach that scholars have questioned is the assumption that individuals act as strategic managers, rationally selecting from a range of livelihood options within given contextual constraints. Structuralist authors, on the other hand, argue that cultural, historical, and social forces govern human action to the point that individual agency cannot truly explain behavioral patterns. From this perspective, livelihood “strategies” are less the result of rational choices and actions than a reflection of power configurations and structural conditions. Structuralists ask whether selection between extremely limited options – for instance, starvation versus prostitution – truly represents a choice, contending that an emphasis on individual agency turns a blind eye to the historical, institutional, economic, and social conditions that people do not necessarily choose but that shape the ways they build their livelihoods. Analyzing livelihoods as outcomes of rational strategic decisions hence ignores how the factors that condition behavior are often cultural and ideological and not just a matter of individual personality or skill.

In response to such critiques, livelihood authors have underscored that, in order to comprehend livelihood choices and decision-making, it is vital to ascertain how these are framed by people’s own definitions and perceptions of wellbeing and poverty. Some, including Leo de Haan and Annelies Zoomers (2005), have advocated for the use of the term “livelihood pathways” in place of “strategies.” Rather than aiming to attain a preset goal, livelihood pathways highlight the iterative process through which a livelihood is fashioned, with goals, preferences, and assets being continuously re-evaluated.

Defining sustainability for livelihoods

The term “sustainable livelihoods” itself has been critiqued by authors who question whether, despite its title, this approach actually attempts to integrate sustainability with other concerns. The main question regarding the literature’s notion of sustainability is its opacity regarding the relative importance of assets like capital stocks and livelihood strategies. Though the sustainable livelihoods approach lends valuable insights by considering sustainability in terms of combinations and substitutions between the five capitals, some questions – such as the degree to which livelihoods require the conservation of certain environmental features in order to be considered sustainable – remain unaddressed. Some aspects of otherwise sustainable livelihoods may indeed be negative, such as when a stable, “sustainable” form of social organization supports the maintenance of a status quo that perpetuates poverty. Scholars working within the sustainable livelihoods framework also acknowledge that strategies can be sustainable at certain scales and not others, and recognize the tensions between short- and long-term livelihood goals; they do not, however, clearly address how to manage these issues. Likewise, the sustainable livelihoods literature has still not sufficiently theorized the temporal aspects of sustainability.

Concluding thoughts

In considering these critiques, it should be noted that no one model alone can fully capture the totality and complexity of lived experience, poverty, and the environment, yet such research does usefully advance understandings
of livelihoods and sustainability among social scientists and development practitioners. Perhaps using what is gleaned from this important work alongside other approaches (such as political ecology, actor-oriented approaches, and gender studies) is the best way to draw on its strengths while addressing its weaknesses.

Staples, James, ed. 2007. Livelihoods at the Margins: Surviving the City. Walnut Creek, CA: Left Coast Press.
A living wage is the minimum hourly wage required to allow a worker to support her/himself and her/his dependents. Although the household circumstances of each worker will be different, the wage rate is calculated to reflect a locally determined minimum acceptable standard of living. Calculations are made to measure the cost of living, including everyday items (such as housing, food, transport, and the ability to engage in the local community), adjusted for household characteristics, such as the presence of a working partner and the number of children. Once agreed as an hourly wage rate, the living wage is designed to set an ethical standard for wages in a geographical labor market and this can be urban, regional, or even national.

The demand for a living wage first surfaced alongside the organization of workers into trade unions in the English coalfields more than 120 years ago. While the concept of a living wage was largely overshadowed by the implementation of minimum wages and the welfare state by national governments during the twentieth century, the demand has recently resurfaced in the context of growing rates of in-work poverty. In its more recent manifestation, the demand for a living wage arose in Baltimore in the early 1990s and subsequently spread to other cities across the United States. It has also been taken up in Canada, New Zealand, and the United Kingdom with related calls to include living wages as part of ongoing efforts to improve labor standards in international supply chains. In the United States, living wages have been agreed at the urban and county scales, whereas in the United Kingdom the campaign began in London and has subsequently determined an out-of-London rate to apply to the rest of the country. The geographical literature includes documentation of the early campaign in Baltimore (Walsh 2000) as well as the development and impact of the campaign in the United Kingdom (Wills 2009; Wills and Linneker 2014).

The growth of in-work poverty and the associated demand for a living wage have triggered a growing body of social science research that seeks to measure the impact of improved wages at the workplace, community, and national scales. Researchers have explored the impact of improved wages on productivity, worker morale, rates of labor turnover, and standards of service in a variety of contexts. In addition, there is a growing body of research looking at the wider impacts on the health and wellbeing of workers and their families, as well as savings made to the taxpayer in reduced welfare spending (Flint, Cummins, and Wills 2013).

Living wage campaigns have wider salience in relation to changes in social movements and the increased demand for economic justice and reduced inequality. The campaigns have also exposed the wider issue of in-work poverty as well as the related prevalence of subcontracted employment and heavy reliance on migrant and minority labor in the lowest paid jobs. As such, living wage campaigns have been associated with the development of new forms of political activism often led by marginalized migrant communities.

Local development

Costis Hadjimichalis
Harokopio University, Greece

Local development is an explicitly social and territorial approach to development including not only economic aspects but also employment creation, poverty reduction, quality of life, and environmental sustainability. In its ideal conceptualization, local development aims to empower local communities to shape, in a participatory and democratic way, the future of the places where they live. Successful local development depends on complex processes of consensus between local social actors – economic associations, firms, political leadership, unions, institutions and people – interacting in a particular territory, aiming at the welfare of everyone living in that territory or locality, without discrimination based on class, social status, age, gender, ethnicity, race, and sexual preference. Such processes may sound utopian under conditions of neoliberal capitalism but nevertheless may function as prerequisites for progressive local development planning. Application of a local development strategy will usually contain several steps: defining the territory and the problem or development issues under consideration; defining and analyzing the parameters of problems/issues and checking whether they generate from elsewhere; sensitizing local actors; promoting a local forum and organizing participation without exclusion; designing a local planning strategy and securing financial and political support; implementation; and evaluation and monitoring. In reality these steps often tend to feed into each other.

Theoretical background and novelties

Local is often conceived as the lowest scale (from “national” to “regional” to “local”) for framing research and policies. It arrived relatively late into the development repertoire with national development being discussed immediately after World War II, regional development from the 1960s onwards, and local development as an independent concept from the 1980s until today. In early studies, local was not adequately theorized – as was the case with regional – and was simply equated with the lowest available administrative boundaries, where politicians and policies are scrutinized and where statistics are available. The US federal system provides a nexus of formal political power to localities, and local means practically local government, which in turn manages local economic development (LED). A characteristic of the US system, in the absence of a clear regional development framework, is the rise of strong local interests, frequently forming local growth coalitions and the bitter competition among local governments to attract inward investments.

In other parts of the world, local development and its associated concept of endogenous growth came as a reaction to inadequacies of national and regional development frameworks. Since the 1950s and until the crisis of Fordism, dominant models of regional development were based on industrialization via capital incentives or large state projects in growth poles, provision of public infrastructures, and employment creation via inward investments from other regions. It was the period of, what is called, welfare regionalism largely based on Keynesianism and social
democratic political principles, predominant in Europe and beyond at that time. The economic crisis of the 1970s and the many inadequacies of the welfare state, including regional policies, paved the road to major changes and regional top-down welfare planning was hit from all sides.

Empirical investigations in the late 1970s discovered cases of “spontaneous” growth, away from old industrial cores and subsidized backward agricultural regions, without direct assistance from the central state or inward investment, where small firms with strong entrepreneurial spirit initiated a “bottom-up” local growth. Paradigmatic local areas included the Third Italy in northeastern-central Italy, Silicon Valley and Orange County in California, the “M4 corridor” in the south of the UK, and southern Bavaria in Germany, while subsequent research came to include many more examples in other parts of the world. Small firms in these localities successfully combined market opportunities mobilizing locally existing resources (particularly knowledge and learning) and new forms of production organization such as flexibility and networking. These new industrial spaces highlighted the role of competition and cooperation at the local level with the assistance of strong local cultural traditions, local institutions, and associations. Researchers and policymakers agree that a distinctive feature of these places and localities is the embeddedness of certain noneconomic factors such as social capital, trust, and reciprocity based on familiarity, face to face exchange, cooperation, embedded routines, habits and norms, and local conventions of communication and interaction, all of which, in turn, have a key role to play in successful local endogenous development.

Pioneering research on local development came from different directions. First, there was the Italian School of Third Italy’s Industrial Districts (IDs) which since the 1970s provides, mainly by economists, brilliant analyses of networked small and medium size industries in various parts of northeastern-central Italy. The Italian School made several groundbreaking contributions such as the concept of a local flexible productive system, the notion of diffused industrialization, the identification of the importance of small and medium enterprises and their networking, the role of local culture, local social relations and knowledge, and the reuse of Alfred Marshall’s notion of localized external economies. Key figures include G. Becattini, R. Camagni, A. Sforzi, G. Garofolli, G. Dei Ottati, and many more.

Second, there was the French School of Milieu Innovateur (innovative local milieux), developed by the economic Research Group GREMI (Groupement de Recherche Européen sur les Milieux Innovateurs) in the early 1980s. Their hypothesis was based in Philippe Aydalot’s idea that behavior initiating innovations are based on local or regional factors rather than national or global ones. Extending Schumpeter’s ideas on innovation, GREMI combined two French traditions: the older milieu concept from sociology and regional geography; and that of regulation regimes. Apart from Aydalot himself other contributors include M. Quévit, D. Maillat, O. Crevoiser, and, later, C. Courlet and B. Pecqueur.

Third, there was the British industrial restructuring perspective, applied in the mid-1980s in the research program “The Changing Urban and Regional System” (CURS), which studied industrial restructuring in particular areas via local labor market transformation. The program, known also as “locality studies,” focuses on seven localities which were chosen and studied by geographers, sociologists, planners, and few economists for their different experience of decline or growth. Among the protagonists was P. Cooke, later joined in this research perspective
by K. Morgan, A. Amin, and N. Thrift, while other CURS participants, such as R. Hudson and H. Beynon developed a much more critical view. Major findings of CURS include the negative effect of Thatcherism in regional policy, the need to link local to global processes for understanding restructuring, the importance of local proactivity, and the propensity for networking by local actors.

Fourth, in California, again in the 1980s, economic geographers developed innovative research on agglomeration economies and transaction cost analysis. Inspired by the Italian industrial districts and regulation theory, agglomeration and transaction are analyzed quantitatively and qualitatively. A. Scott, A. Saxenian, M. Storper, and D. Walker were among this group of researchers. Although their focus was on particular industrial localities, they underlined the importance of competitive regional economies in general at times of globalization, and they stressed technological learning, based on traded (input–output relations) and untraded interdependencies (labor markets, regional conventions, norms and values, and public or semi-public institutions).

These pioneering analyses, despite important differences among the localities studied, have been used as paradigmatic examples for the introduction of synthetic and policy oriented concepts such as “networked firms and regions,” “industrial clusters,” “learning firms and regions,” and “innovative firms and regions,” forming what has been called by others the “New Regionalism.” According to both theorists and policymakers, while in the past local development took place in a spontaneous manner, now it can be designed to implement a policy “from below,” and international organizations, such as the Organisation for Economic Co-operation and Development (OECD), the World Bank, the European Union (EU) and several national governments initiated programs to promote such policies, using the aforementioned success stories as “best practice.”

Misreadings, omissions, problems

In the 1990s local development became the new catch phrase, and the “New Regionalism” a new kind of analytical and development doctrine during a period of major political changes in the Global North. In the euphoria that followed the “discovery” of dynamic small firms in these paradigmatic industrial districts, several misreadings, omissions, and problems occurred. First, there was a simplistic binary opposition between mass production and flexible-specialization, whereas Fordism was never dominant in the regions in which growth was directed by flexible small industrial production ensembles. Second, a similar binary opposition occurred, with endogenous and exogenous factors guiding development. In reality development is always the outcome of the dialectical tension between the two, while the social and environmental effects of this tension are experienced mainly locally. Third, there was a major confusion of scale: in some cases local development was analyzed with reference to traditional agglomerations of small industrial firms with a few thousand inhabitants, to whole regions with multiple sectors, or to large urban conurbations with several hundreds of thousands of firms, while some cases were identified as “local” simply due to their coincidence with lower scale administrative boundaries. Fourth, and related to the problem of scale, is the study of localities (mainly by economists) as bounded territorial entities and as though they were firms. Fifth, in the relevant literature, a very selective appropriation of the complexity and richness of
local productive systems has taken place in which only certain general economic, organizational, and institutional issues have been taken on board. While others, such as power and inequalities among small firms and within industrial districts, the limitations of networking and learning, the real meaning of cooperation, reciprocity, and “social capital” for firms and labor, conditions of work, the informal economy, gender and ethnicity – to mention but a few – remain unexamined. Sixth, there is a lack of attention to the role of the state and other supranational entities in the introduction of various protectionist and assistance measures. Due to the important role of the devaluation of a national currency, labor legislation, and particular incentives for small firms and international agreements (such as the Multi-Fibre agreement), there was never such a thing as “without assistance from the central state.” Seventh, by looking only at success in the context of competitive capitalism, there was interest in few paradigmatic industrial sectors and few advanced service providers in a limited number of European and North American regions. Finally, eighth, and as result of the above, there has been a remarkable silence/neglect of other sectors such as tourism, trade, and agriculture in areas beyond North America and Europe and those millions of ordinary localities that form the majority everywhere and are in real need of development and prosperity.

Perhaps the most important omission in this research framework and in much of the “New Regionalism” literature, and what really remains unmentioned and unexamined, is the uneven relations among localities, successful and unsuccessful, in other words the hard question of uneven geographical development under capitalism. This omission was evident in the absence of attention to the capitalist crisis that was already visible from the mid-1990s in some IDs of Third Italy and in other emblematic localities and regions due to three interrelated processes: (i) mergers and acquisitions and formation of large, vertically integrated firms and groups of firms; (ii) de-localization of a part of production or of all firms to low labor cost regions and countries; and (iii) extensive replacement of local labor by medium- and high-skill immigrants to compensate for increasing labor cost and/or the lack of skilled native labor. These developments directly challenge grandiose claims about flexibly specialized small firms in IDs as models for the future and about the social and cultural continuity of the paradigm based on trust, reciprocity, and social capital. Just at the very moment that policy prescriptions based upon the assumed bases of success of these localities were being generalized through the design and implementation of regional and urban policies across the globe, the conditions on which success was based in these exemplar regions were being eroded.

Policies for local development

Policies promoting local development were not initiated in the 1980s, nor were they all inspired by the theoretical framework presented above. They have a long history and one can recall cases, among the many existing worldwide, in the northeast of England, in the Ruhr area in Germany, and in the polders of the Netherlands during the late nineteenth to early twentieth centuries, and, since World War II, in socialist Yugoslavia and Tanzania and in communist China. In these cases detailed local policies were implemented (without the intention of “development from below” as such) dealing with different problems in each case, from managing water, to building social housing, linking coal fields to ports, and promoting the decentralization and ruralization of industrial production. In the United States the Local Development
LOCAL DEVELOPMENT

Districts Policy in the Appalachia region has a 30 year long history dating from 1965, while community development policies in urban, working class neighborhoods were precursors of later LED policies in urban areas.

Since the 1990s many countries and major global institutions such as the OECD, the World Bank, and the EU started programs dealing explicitly with local development. In 1991 the EU LEADER initiative was announced for the period 1991–1994 as a Europe-wide experiment, and involved the first 217 local action groups (LAGs) which were representatives from small and medium-sized enterprises, local authorities, non-profit organizations, and other local players from various sectors who agree on a common approach to the interests involved in developing their local rural areas. Three other initiatives also embodied similar principles of local development, especially that of partnership: URBAN for urban areas; INTERREG for cross-border and interregional collaboration; and EQUAL for partnership in social integration, combating discrimination in whatever guise, inequality in the labor market and continued vocational training. In Europe another actor was LEDA, an independent association which brings together organizations, practitioners, research centers, and others who are active in the creation of local employment in EU countries.

The OECD’s involvement with local development dates from the 1970s with various programs and recommendations but perhaps the most advanced framework was initiated in early 1980 with LEED (Local Economic and Employment Development) with three main objectives: to improve the quality of public policy through continuous monitoring and assessment of current practices; to promote innovation in local economic and employment development across the globe; and to support the design, implementation, and evaluation of development strategies to help grow local economies. The OECD gives particular attention to tourism and culture as important pillars for local development, finances particular projects in many countries, and, since 2003, operates the LEED Trento Center for Local Development, in the Autonomous Province of Trento in northern Italy.

The World Bank also promotes local development projects worldwide, particularly in Latin America and Southeast Asia, without any particular spatial reference. For the Bank local development means creating a favorable environment for business success and job creation in urban areas. To do this optimally, LED is undertaken through partnerships between local government, business, and community interests. Finally, the UN in the 1992 World Earth Summit at Rio adopted the Local Agenda 21, which provides guidance to local governments in the preparation of local development plans integrating the principles of sustainable development. Local Agenda 21 introduces explicitly the environmental dimension in LED, such as the concern with the per capita ecological footprint, and, in this respect, is a major innovation and critique to previous models, unfortunately with limited applications.

Beyond recognized and formalized models of local development, however, there is a whole world of informal local development practices in both the Global North and South. These cases are classified by some development specialists as non-“modern” or non-“competitive,” while in reality they constitute the best way to increase wellbeing for particular localities. They include a large variety of productive and non-productive activities and local social actions such as – to mention but a few – the development of locally oriented agriculture and linking of producers directly with consumers, self-help housing, social health centers, associations and co-operatives, time banks, local social currencies, activities
LOCAL DEVELOPMENT

in the arts and culture, and larger scale initiatives such as participatory budgeting, operating through more ethical, gender, and environmentally sensitive processes. Often they are classified under the concept of social economy or solidarity economy, and they share a strong local vision of development and a much broader and socially sensitive approach to what constitutes the economic.

The way ahead

Since the 1980s policy options such as “fostering dynamic regional growth” came to replace the old “reducing regional inequality,” and, under neoliberalism, a transition occurred from integrated, comprehensive, and nationally organized regional welfare planning toward intensely competitive and geographically fragmented processes which may be called “entrepreneurial regionalism.” Local development in this context risks being used to introduce hard competition among localities or to substitute for other policies at times when direct welfare intervention on the part of the central state is discredited. Localities cannot be understood as competitive firms or as bounded administrative territories. Therefore, more nuanced interpretation of development trajectories is needed, using “de-localizing” and “de-scaling” discourses, while keeping the principles of progressive local development. Local development projects can learn from experiences in the Global North and South, both formal and informal, and from theoretical developments since the 1980s, keeping in mind the un-transferability of success and the need for cooperation and solidarity.

Local embeddedness

John Pickles
University of North Carolina at Chapel Hill, USA

“Embeddedness” refers to the ways in which relational, institutional and cultural contexts shape economic and social life. In economic geography, it has two distinct albeit related referents and foundations. The first derives from Polanyi’s *The Great Transformation* (1944) and concerns the changing ways in which the economy is integrated into broader social systems. The second derives from Granovetter’s (1985) attempts to discern the role of social action in economic contexts, and to challenge the undersocialized conceptions of economic behavior found in transaction cost and agglomeration economies.

For Polanyi, economies were historically embedded in social and cultural institutions. With the deepening of capitalist market relations and market autonomy, the economy became progressively disembedded from these social and cultural institutions. Economic sociologists and geographers have responded to the disrupting effects of economic globalization by focusing on the ways in which economic actors are embedded in systems of interfirm relations, or chains and networks, and how these forms of organization and their corresponding forms of governance shape their behavior. For example, Gereffi and Mayer (2006) have drawn on Polanyi to suggest that the process of economic disembedding gave rise to global governance deficits as lead firms in global value chains were increasingly disembedded from national regulatory norms and laws. In response, social forces responded with efforts to create new forms of regulation and rule – norms about the length of the working day, health and safety regulations, struggles over wage rates and levels, consumer demands for product quality, and so on. This, they argued, was the Polanyian double movement.

Granovetter was much more skeptical of the Polanyian view of disembedding as a historical process, instead arguing that “embeddedness” refers to the fact that economies always take place “in concrete, ongoing systems of social relations” (Granovetter 1985, 487). It is these social relations that underlie economic transactions, enable relations of trust, maintain order in economic life, and explain why economic transactions can be normalized in conditions of great uncertainty. These relations are networks of interpersonal relations and attachments and, in order to understand economic practices, it is necessary to understand the networks of social relations that constitute them and have given meaning to them. Drawing on Albert Hirschman’s sociology of economic life, Granovetter (1985, 487) argued that actors do not behave or decide as atoms outside a social context, nor do they adhere slavishly to a script written for them by the particular intersection of social categories that they happen to occupy. Their attempts at purposive action are instead embedded in concrete, ongoing systems of social relations.

In this sense, it was important to avoid two traps. One trap was the undersocialization of the economy by focusing on atomized-actor explanations (such as utilitarian concepts of economic actors), with a corresponding overemphasis...
LOCAL EMBEDDEDNESS

on the utilitarian pursuit of self-interest. The other trap was the oversocialized explanation in which custom, culture, or values were seen to be full and sufficient explanations of why people behave in particular ways. Granovetter saw both traps as functionalist and deterministic. Instead, trust is a fundamentally social process that enriches a firm’s opportunities, access to resources, and flexibilities that are difficult to achieve in arm’s-length market arrangements (Bair 2012; Uzzi 1996).

While economic behavior is always embedded in and shaped by cognitive, social, cultural, and political practices, geographers have argued that such forms of embeddedness are also co-constituted by scalar networks that shape local, regional, and global economic geographies. The result is a spatializing of embeddedness that has informed much of the new regional economic geography over the past three decades. For Dicken and Thrift (1992, 283), the way we understand organizations is deeply linked to notions of “culture” as a set of conventions and intangible socially embedded processes that take particular geographical form, such as in research on Italian industrial districts and clusters. Parallel work on global production networks has similarly argued for a focus on the more complex relationalities of the networks of actors with which firms interact (Yeung 2005, 41). In this context, Yeung suggests that the concept of embeddedness represents “a major shift away from radical political economy’s focus on the social relations and social structures of production towards a focus on the socio-spatial economy organized around network paradigms, associational economies and relational geographies” (Yeung 2005, 41).

More recently, Hess has cautioned against the dangers of “over-territorialized” concepts of embeddedness, stressing the importance of not assuming that embeddedness is always a form of spatial rootedness in place, particularly when it is then used to refer to the “evolution and economic success of regions built by locally clustered networks of firms … industrial districts, creative milieu, learning regions or local knowledge communities” (Hess 2004, 166). For Hess, the strength of “new regionalism” is its focus on local and regional systems of economic relations and the social networks that ground them, but its weakness is that it overterritorializes the varying forms of institutional thickness and thinness and their corresponding levels of competitiveness in the global economy. These arguments bring the earlier sociology of embeddedness closer to actor-network theory, which sees in networks and assemblages chains of weaker and stronger association that produce the concrete places of the economy (see Callon 1998).

Cultural geographers have also developed notions of embeddedness through phenomenological, Marxist, and institutional economic traditions. Central to each have been the arguments of Antonio Gramsci, Jürgen Habermas, and the French school of regulation. For Habermas, for example, the economy is always embedded in lifeworlds of shared, often tacit, meanings and values. These taken-for-granted shared worldviews are not immutable but constantly shaped by economic and administrative logics that colonize the lifeworld in historical and geographically specific ways. Regulation theory similarly foregrounded the social relations in and through which economic life is organized. Here, social norms, codes, and beliefs are an essential component of any analysis of the specific regimes of accumulation and modes of regulation (Burawoy 2003).

Local state

Mark Goodwin  
University of Exeter, UK

The local state refers to a set of state institutions and administrative agencies operating at a local scale. The concept of the local state first came to academic prominence in the late 1970s and early 1980s, following the publication of Cynthia Cockburn’s book *The Local State: Management of Cities and People* in 1977. The book was largely devoted to an empirical study of corporate management and community development in the London borough of Lambeth, in the United Kingdom, but it also set out a theoretical framework that viewed local government as a key part of the wider capitalist state. This was a crucial insight, which sparked a range of academic debates and empirical studies across the disciplines of political science, urban sociology, and human geography.

The usage and application of the concept of the local state have always been somewhat uncertain, and linguistically the term itself could equally well refer to “local institutions of the central state” or to an “autonomous local state.” In practice, where individual studies of any particular local state sit on this spectrum depends on both the theoretical framework employed and the empirical context of the research. The nature of the local state in a highly centralized and unitary political system such as the United Kingdom is bound to differ from that in a more federal and devolved system such as the United States. But in the aftermath of Cockburn’s book, work on the local state coalesced around three main avenues of inquiry, the first seeking to analyze the local state’s form and nature, the second investigating its functions, and the third exploring the relationship between the central and the local state. Sometimes researchers explored one or other of these avenues, but more usually the three were combined, as academics sought to understand what the local state was, what it did, and how autonomous it was.

For Cockburn herself, the local state was part of a whole, where the whole – the capitalist state – seeks to secure conditions favorable to capital accumulation by managing economic and social reproduction. The local state plays its part in this reproduction primarily through the highly gendered management of welfare and families locally; but it is always seen as part of the state in general, subject to central government and an integral aspect of the national state. Cockburn was writing from a Marxist perspective, which emphasized class relations and domination. Two years after her book, Peter Saunders published *Urban Politics: A Sociological Interpretation*, which also contained an empirical and theoretical account of the local state (Saunders 1979). Saunders again looked at a London borough, in his case Croydon, but he did so from a more managerial and corporatist perspective that stressed a degree of autonomy in local state activity. Saunders subsequently developed this work into his “dual state thesis,” which argued that distinct political processes operate at the national and local levels. According to Saunders, state intervention at the national level takes place mainly in relation to processes of production, through corporatist policy mediation (involving government, big business, and organized labor), and is addressed...
to the principle of private property and the need to maintain capitalist profitability. In contrast, local state activity is directed toward consumption processes, such as housing, health, and education, where policies are developed through a plurality of competitive political struggles, and are addressed to the principles of social rights and social needs. Saunders’s work highlighted the specificity of the local level and argued for a conceptualization of the local state based primarily on its uniqueness and on its separation from the center. While for Cockburn the local state was effectively the local arm of the central state, for Saunders the local state was local because it dealt with different issues through a different policy process.

Following the pioneering work of Cockburn and Saunders, the concept of the local state began to be widely used in human geography. Michael Dear, for example, used data from Canada to analyze historical trends in state expenditure on different functions at different levels, and concluded that the local state is primarily involved in providing services to reproduce the labor force. In later work with Gordon Clark he developed these ideas further, incorporating empirical data from the United States, to formulate the idea that the specificity of the local state arises from a crisis-absorbing function, whereby continued electoral legitimacy and local self-determination help to maintain political stability (Clark and Dear 1984). For Clark and Dear, surveillance and social integration of the population are facilitated by a decentralized state structure, and the local state helps to displace and manage structural crises at the local level.

In the United Kingdom, Simon Duncan and Mark Goodwin were developing perhaps the most geographically sensitive theoretical framework for analyzing the local state. For them, local state specificity is rooted in a set of factors that are inaccessible to the central state – namely, local social relations. In their 1988 book *The Local State and Uneven Development*, they trace the connections, both empirically and theoretically, between the uneven development of social and economic relations and the emergence of the local state. Put briefly, because such social relations are unevenly developed, there is, on the one hand, a need for different policies in different places, and, on the other hand, a need for local state institutions to formulate and implement these variable policies. Local state institutions are therefore rooted in the heterogeneity of local social relations, where central states have continued difficulty in addressing and responding to this differentiation. They go on to argue that this is a double-edged sword, for locally constituted groups can then use these local institutions to further their own interests, perhaps even those opposed to centrally dominant interests. This “representative” role of the local state is considerably sharpened by the development of representative democracy and universal franchise, for the extra leverage local state institutions give locally constituted groups is legitimized and even expected. For Duncan and Goodwin, then, local state institutions are at once an agent of, and an obstacle to, central control. Their stress on uneven sets of social relations highlights the fact that local states are more than just a group of locally based institutions and government structures. They are also viewed as a set of social relations themselves, and in this way local state activities contribute to the interpretation of how society works and why. Thus, local states have an interpretive as well as a representational role, and some will use this status to challenge the existing social order, while others reinforce it.

In contrast to the other theories considered, Duncan and Goodwin make no claims about the functions carried out at the local level. Indeed, they note that there seems no historical rationale
for any rigid division between the types of functions and types of politics characterizing local and national states, and point out that local state institutions are involved in activities in support of both production and consumption. They also pointed out that, because the local state is rooted in local social relations and performs both interpretive and representational roles, conflict with the central state is a constant possibility, although it is always an empirical question as to how this is realized locally and addressed centrally.

These theoretical frameworks were then populated by a range of empirical studies from the United Kingdom, North America, Western Europe, and Australia that looked at the operation of various local states in practice. Some of these concentrated on particular policy areas, such as housing or local economic development, while others studied the evolution and activities of the local state in particular places. A key message emerging from this work is that the nature and role of the local state are changing. The regulatory practices of Keynesianism, which relied on the local state to deliver collective public services as part of a nationally negotiated welfare settlement, have been replaced by neoliberal policies emphasizing lower welfare spending, competitiveness, and entrepreneurial governance. The abandonment of national redistributive strategies, and the emerging global mosaic of competitive regional economies, have led to the parallel mosaic of increasingly differentiated spaces of economic and social regulation. Within these new spaces of regulation, local state institutions are increasingly working in partnership with the private and voluntary sectors to promote globally competitive urban and regional spaces and to reorient their welfare provision away from a collective public services toward voluntarism, entrepreneurialism, and individual self-reliance.

Local statistics and place-based analysis

Richard Harris  
*University of Bristol, UK*

Information such as census data, environmental records, and measures of neighborhood crime provide insight about the social and physical characteristics of different places, and about the people who live in them. Place-based analysis is about making sense of this information, through classifications of neighborhood types, by maps, charts, and other visualizations, and by the use of analytical techniques to highlight the prevalence of particular characteristics in some places more than others. Local statistics also look for geographical patterns and variations in a measurement at a subregional scale: for example clusters of diseases, hotspots of crime, or to consider whether the relationship between property price and the size and type of property varies according to where in a city that relationship is measured.

Some introductory examples

Consider a choropleth map showing a set of administrative areas located across a country where each area is shaded according to the local unemployment rate. Just looking at the map will reveal something that the national average unemployment rate does not: it shows variation at a subnational scale. Of course, that variation could be quantified in various ways: by determining the standard deviation of the (local) unemployment rates, for example, or by calculating the variance, the minimum and maximum values, or the interquartile range. However, the map offers something additional and fundamentally geographical: it tells us *where* areas of higher or lower unemployment are found. Knowing where something happens is an aid to understanding why it happens and is useful if we want to target appropriate policy initiatives to the areas of greatest need.

The map allows us to examine geographical patterns in the unemployment rate and to look for geographical differences. One way to make sense of the data is to divide the unemployment rates into quartiles, creating four map classes ranging from the lowest unemployment rates to the highest. The result would be a simple area-based classification, a rudimentary typology based on the prevailing level of unemployment in each place. More specifically, it would be a univariate classification, differentiating types of places on the basis of a single variable of measurement. We could then use the classification to look for associations with another variable. Imagine, for example, that the places with the highest unemployment rates contain 20% of the national population but 27% of a particular ethnic group. In this example, the ethnic group is disproportionately located in the high unemployment neighborhoods by a factor of 1.35 (27/20, sometimes multiplied by 100 to give an index value of 135).

We need to be careful how we interpret this. The co-location of the two occurrences (the ethnic group and unemployment) does not necessarily mean that members of the ethnic group are themselves unemployed. It is possible that they are working but living in areas of high
unemployment. To assume that a correlation between two attributes at a neighborhood scale necessarily applies to the individuals themselves is known as the ecological fallacy. Even so, the place-based analysis can be usefully suggestive; in many countries poverty rates do vary considerably by racial group and by neighborhood.

A second method of analyzing the data is to consider what the map shows for each area. It is, in fact, a local statistic – the unemployment rate at each location – where local means information for a specific part of the map as opposed to a statistic that applies to its whole. For simplicity, let us call these the local averages. We also have a global average, where global means not the whole world but the whole of the study region. Here it is the national unemployment rate. Subtracting the global average from each of the local averages tells us which places have high or low unemployment rates relative to the national benchmark.

Next we could map the places where the local average is highest (in the top quartile, for example) and see if they are regularly distributed across the country, randomly distributed, or, most likely in this case, clustered in some parts of the map more than others. In this way, we could study the map to look at the geographical outcome of social and economic forces that, in a market-based economy, sift and sort different people into different places. Note, however, that differentiating what we observe from what could be the outcome of an entirely random process is not always straightforward. This issue becomes especially salient in medical geography when, for example, an unusual cluster of mortality is statistically indistinguishable from a cluster arising due to chance. Early work in geocomputation (the application of computation to geographical analysis and modeling) considered a cluster of childhood leukemia cases around a nuclear processing facility. The fear was that the two were related. Yet, it could have been coincidence.

The analytical problem is that a random process can still generate what appear as clusters on a map. For example, Figure 1 shows a (simulated) cluster of cases to the bottom right and left of the map (shaded dark red), and an absence of cases elsewhere (shaded light yellow). Clearly the number of incidences is not the same across the map yet the numbers arise by chance: the 75 cases were placed on the map at random.

Third, we could use our choropleth map to look at how the unemployment rate in one area compares with those of other areas nearby. Doing so, we might discover a cluster of areas where above average unemployment is the norm. Alternatively, we might identify islands of high unemployment within regions of otherwise low unemployment. In fact, there are four possibilities: (i) areas of high employment surrounded by other areas of high employment (high–high, a “hotspot”); (ii) areas of low employment surrounded by other areas of low employment (low–low, a “cold spot”); (iii) areas of high employment surrounded by areas of low employment (high–low); and (iv) areas of low employment surrounded by areas of high employment (low–high).

Of the above, (i) and (ii) are examples of positive spatial autocorrelation, where similar values are found in closely located areas, and (iii) and (iv) are examples of negative autocorrelation, where dissimilar (or opposite) values are found together. Dependent upon your point of view, detecting spatial autocorrelation can be substantively interesting or a problem to be avoided. It is interesting where it is suggestive of a geographical process or outcome, or of a localized variation from the norm. Finding it invites the question, “What caused it?” However, it may also be regarded as unexplained variation, the presence of which violates statistical assumptions
of independence. If a map of regression residuals reveals patterns of spatial autocorrelation then those residuals are not independent of each other and that has consequences for how the results of the regression model should be interpreted. Specifically, it is likely that the standard errors for the estimated coefficients are underestimated, leading to an overconfidence in the statistical significance of the predictor variables (and suggesting methods of spatial regression should be used instead). The spatial autocorrelation may also point to the model missing an important explanatory variable, the model therefore being incomplete or incorrectly specified.

Figure 2 illustrates some of these ideas. Figure 2a shows the unemployment rate in and around London, UK, in 2011. The map makes clear that unemployment is highest in East London. Figure 2b reclassifies the map according to whether the local unemployment rate is in the top 25% nationally (highest unemployment), in the top 50% but not top 25% (above the median average), in the bottom 50% but not 25% (below average) or in the bottom 25% (lowest unemployment). The contrasting unemployment rates in London and the more rural areas to its south, west, and northeast are evident. Finally, Figure 2c shows how the local unemployment rates compare with those of surrounding areas. The concentration of higher unemployment rates in London is clear.

Geodemographic, neighborhood, and other classifications of places

Place-based classifications, especially at the finer scales of zip codes or census tracts, are usually referred to as neighborhood classifications, albeit with a rather administrative sense of neighborhood implied. Whether those neighborhoods also map to communities in any meaningful sense depends upon how and why they were designed. Some classifications are produced with a specific purpose in mind. For example, indices of deprivations have been developed in the United Kingdom and used to target regeneration funding to the poorest communities. Other classifications are designed for more general application and include many of the commercial classifications produced by multinational data analytical companies that are referred to as geodemographic classifications or as neighborhood segmentation tools. These have been used in applications as diverse as marketing, store location analysis, public service delivery, resource allocation, educational research, and medical research, amongst other fields of inquiry. Place-based classifications are not limited to social geography. Remote sensing can produce classifications of land use. Soil maps, ecological regions, biomes, and classifications of environmental risk all seek to characterize particular places in some way and to differentiate one type of place from another.
Figure 2  (a) The unemployment rate in and around London in 2011; the boundary of London is shown in green. (b) Showing how the local unemployment rates compare with the rates for all of England and Wales. (c) Identifying “hotspots” and “coldspots” of unemployment (see text for details).
As well as distinguishing between more specific and more generic classifications, we can also distinguish between univariate classifications based on a single variable (as in the introductory example) and those that are multivariate, drawing on a wide range of variables to produce the final classification. Some, like the United Kingdom’s aforementioned indices of deprivation, can be divided into a series of subdomains (income deprivation, employment deprivation, health deprivation and disability, education, skills, and training deprivation, crime deprivation, barriers to housing and services deprivation, and living environment deprivation). That is, there are actually seven different indices that can be chosen for specific tasks, as well as an overall index that combines them all. In this example, the classification is continuous – it assigns values to places but it is up to the analyst whether to split the data into distinct groups. The environmental performance index (EPI) uses twenty measures from national-level environmental data that can be combined into nine issue categories (including health impacts and air quality), into one of two overarching objectives (environmental health and ecosystem vitality) and into an overall index score. In 2014, Switzerland was ranked first of 178 countries, Somalia last (http://epi.yale.edu).

In the case of geodemographic products, they are multivariate classifications that assign neighborhoods into types. These are created by the vendor but the user usually has a choice of how many neighborhood types to analyze. Typically there will be a set of no more than ten different neighborhood types at the most aggregate level that then subdivides into a greater number of subclasses. For example, the UK’s Office of National Statistics (ONS) 2001 classification of census output areas had 8 clusters (neighborhood types) at its supergroup level, 13 at group level and 24 at a subgroup level.

It might be assumed that to use a greater number of classes is always better. However, the difficulty is that a large number soon becomes unwieldy in much the same way that it is hard to interpret a map with 20 map classes but relatively straightforward to interpret a map with four or five. The ONS classification mentioned here is of more than passing interest in that it was similar in construction to a commercial classification yet also an early example of “open geodemographics” – that is, a classification free to obtain and use, with the choice of variables and how the classification was created fully documented and accessible for scrutiny. The same cannot be said of commercial products, where that information is far more protected and the classification more of a black box. An open geodemographic classification has also been produced of the United States, and of London.

The origins of these neighborhood classifications are often attributed to Charles Booth and his 1889 Descriptive Map of London Poverty, the 1898–1899 revision of which can be viewed at http://booth.lse.ac.uk. From this, Booth developed a citywide classification of London’s streets where each was shaded on a base map to indicate the general socioeconomic conditions of the residents. For example, a black shading corresponded to Booth’s Class A, “the lowest class – occasional laborers, loafers, and semicriminals” (quoted in Harris, Sleight, and Webber 2005, 32). Dark blue was used to indicate Class B – “the very poor – casual labor, hand-to-mouth existence, chronic want” – and so forth. This classification was based on broadly qualitative information; specifically, school board records of families with children of school age. However, Booth also went on to devise a classification of London’s subdistricts using 1891 census data, creating a social index based on average percentage of poverty, percentage overcrowding,
birth rate, death rate, and rate of early marriage (Booth 1888, 1902–1903).

Booth’s method of classifying areas according to “type” is a precursor to modern geodemographics. His way of ranking neighborhoods according to domains of deprivation and then summing those to give an overall index foreshadows the UK government’s more recent indices of deprivation.

Viewed from the twenty-first century, the language (“occasional laborers, loafers and semicriminals” etc.) can seem paternalistic and patronizing or merely a product of its time. Unfortunately, the potential to stigmatize places and people remains in present day classifications and their use of labeling such as “claimant cultures,” “struggling estates,” or “shotguns & pickups.” The defense of such portrayals is that they create a vivid and instantly recognizable snapshot of a neighborhood. Critics say they are stereotyping. The classification produced by the UK ONS is again of interest here. No such portrayals were produced for it; to do so was judged inappropriate.

Charles Booth was pioneering in his mapping of area types and in his use of census data to create a multivariate social index. There were four further factors central to the development of neighborhood-based classifications. The first was the influence of the Chicago School of urban sociology and its interest in urban ecology, including the processes that led to the formation of what were regarded as natural neighborhoods – geographical areas within cities physically distinguishable from other surrounding areas and also socially distinct by the demographic and ethno-cultural characteristics of their populations. The second was the increased availability of small area data to measure neighborhoods and their populations, and the computational means to analyze them. In particular, the development of statistical techniques, including factor analysis and principal components analysis, which attempt to eliminate duplicated information in correlated variables and reduce them to their underlying factors or domains; also, methods of cluster analysis and agglomeration that are used to group small areas together on a like-with-like basis. Third, was the growth of geodemographics as a commercial industry from the late 1970s onwards. Fourth, is the periodic political interest in structural causes of poverty, deprivation, and inequality, the concern that these are entrenched and magnified by what people experience growing up in particular types of (low income) neighborhood, and the possibility of neighborhood-based policy solutions. It was political interest in the characteristics of neighborhoods, processes of neighborhood formation and decline, and the possibility of neighborhood-targeted regeneration funding that led to the indices of deprivation in the United Kingdom.

Today, a number of companies sell classifications intended to support place-based analysis. A retailer, for example, may notice that a disproportionate number of its customers reside in a given neighborhood type. Locating sites in similar neighborhoods would, therefore, make sense for future store openings. Alternatively, it may be found that instances of some health outcome, such as diabetes or obesity, are disproportionately associated with particular neighborhoods types. Those neighborhoods could be targeted for a health awareness campaign.

**Spatial analysis and local indicators of spatial association**

Despite the “geo” in its name, geodemographic and related types of neighborhood classification are not spatial methods of analysis. It is true that the input data are geographical – they are
information collected about people in places. It is true also that the results of the classification can be mapped because it is a classification of geographical areas. However, the central step, the methods that create the classification, is blind to geography. It takes the numbers and classifies them. It does not explicitly consider where the data were measured during the process of classification. Geographical data consist of two components, an attribute (the measured value) and a location (where it was measured). The processes creating the classification do not directly consider the second of these.

The same cannot be said of an analysis that compares a value at some location with the values for surrounding locations. Location is now important, specifically knowledge of the places that surround each observation. How we define surround is open to choice. For places represented by polygons on a map, it could be those that share a border. For places represented by points on a map, it could be those within a certain distance of each other. In either case, it could be the 10, 20, 50, 100, or any other number of nearest locations (provided that the number is an integer greater than zero and less than the total number of places measured in the study region).

Having settled on a definition, the places that surround each other — call them neighbors — can be recorded in a spatial weights matrix. If there are \( n \) places in total then this can take the form of an \( n \) by \( n \) matrix with a non-zero value at (row \( i \), column \( j \)) indicating that places \( i \) and \( j \) are neighbors. It is common for the matrix to be row-standardized, so that the sum of each row is equal to one. Row standardization prevents locations with large numbers of neighbors from dominating any subsequent analysis due to what would otherwise be the higher sum of their weights.

Recall the question of how the unemployment rate at one location compares with the rate at surrounding locations. One way of answering this is to consider whether closely located values are, in general, correlated with each other. For this a statistic known as Moran’s I can be used. Assuming we have a row-standardized spatial weights matrix, the formula for Moran’s I is:

\[
I = \frac{\sum_i \sum_j w_{ij} (x_i - \bar{x})(x_j - \bar{x})}{\sum_i (x_i - \bar{x})^2} \tag{1}
\]

where \( x_i \) is the unemployment rate at location (observation) \( i \), \( x_j \) is the unemployment rate at a neighboring location, and \( \bar{x} \) is the unemployment rate averaged across all locations.

There are three things to take from this formula. First, it provides a measure of spatial autocorrelation, usually assumed to range from \(-1\) (perfect negative spatial autocorrelation) to \(+1\) (perfect positive spatial autocorrelation) (this need not be correct: see de Jong, Sprenger, and van Veen 1984). Second, observe the presence of the spatial weights matrix, \( w_{ij} \). It is this that characterizes it as a spatial statistic. Third, note that the numerator (top line) of the formula can be rewritten as:

\[
\sum_j w_{1j} (x_1 - \bar{x})(x_j - \bar{x}) + \sum_j w_{2j} (x_2 - \bar{x})(x_j - \bar{x}) + \cdots + \sum_j w_{nj} (x_n - \bar{x})(x_j - \bar{x}) \tag{2}
\]

where the subscript 1 is for location 1, subscript 2 for location 2, and so on. The importance of this is that the final statistic is a function of what could be viewed as \( n \) local statistics summed together.

The idea that a global measure of spatial autocorrelation such as Moran’s I can be decomposed into a set of local indicators of spatial association (LISAs) was first developed by Anselin (1995). LISAs can be used in two ways: first, to look for local patterns of spatial correlation (e.g., hotspots) that are masked by or deviate from the
global average; second, as a diagnostic tool to investigate whether particular locations act as outliers distorting the global measure. LISAs are examples of localized statistics that measure local spatial clusters and identify spatial heterogeneity (meaning that what is present in one place is not the same as that present elsewhere). This broader class of statistics also includes Getis’ and Ord’s (1992) localized G statistics that are used to identify local clusters of low or high values and have been applied, for example, in research in ethnicity, looking at whether the enclaves occupied by minority ethnic groups have grown during the ten-year period between censuses in the United Kingdom. (They have, implying that the groups are not rooted to particular residences but are migrating outwards with a willingness to live amongst other ethnic groups and creating more mixed neighborhoods (Johnston, Poulsen, and Forrest 2015).)

Such statistics are important for highlighting geographical clusters and identifying spatial variations. Nevertheless, their use raises a number of issues. First, the centrality of the spatial weights matrix within their calculation means that if the matrix changes then so too will the result. Using a matrix where neighbors are defined as within 1 km of each other will not give the same answer as a matrix where neighbors are all locations less than 10 km apart. This suggests that, ideally, there ought to be a theoretical or research-related reason that guides the specification of the weights matrix. For example, if the interest is in whether there are spillover effects between regions that share a border, then this invites spatial weights based on contiguity. In other cases, it may be necessary to undertake a process of calibration, finding the distance threshold that gives the greatest average correlation between a location and its neighbors or, alternatively, the least average variation. Graphical methods including correlograms or variograms can help identify this threshold, plotting the amount of correlation or variation for various distances apart. Computational optimization procedures can also be used to minimize the variation or maximize the correlation.

Second, and as intimated earlier, establishing what is a statistically significant cluster of observed values is not entirely straightforward. There are two problems. First, a conventional statistical assumption that a test result is drawn from a Normal distribution where the observations generating the result are independent of each other may be either inappropriate or lead to the wrong values for determining significance in the presence of spatial autocorrelation. Second, if there are, say, 1000 observations located across the study region, and a local statistic is generated at each of them, then the same test has been repeated 1000 times. Imagine the null hypothesis states that there is no local spatial association and we seek to reject that hypothesis at a 95% confidence. The implication is that we will find about 50 false positives (5% of 1000), incorrectly rejecting the null hypothesis when we do.

A solution to the first of the above problems is to use a randomization procedure. This works by keeping the locations constant but randomly reallocating the data to them (such that the data are now in the wrong locations), before recalculating the local statistics. This is done over-and-over again to create a large set of values. If the local Moran’s value we are interested in is 0.30, then the idea is to determine for what proportion of the set a value of 0.30 or greater arises due only to a random process of allocation. If it is relatively often then the value is not particularly unusual given the geography of the study region and also the data.

In regard to the problem of multiple testing, a potential solution is to make a Bonferroni correction. If we have $\alpha = 0.05$ (a 95% confidence) but there are $n = 1000$ locations at which a local
statistic is generated then, arguably, $\alpha$ should be adjusted to $\alpha/n = 0.05/1000 = 0.00005$ (a 99.99995% confidence). However, as Anselin (1995) notes, this will reveal few if any significant clusters and is, in any case, unnecessarily conservative given that there are not really $n$ separate tests but some number less than $n$ because the neighbors at each location overlap.

Geographically weighted statistics

A final class of local statistics has grown in popularity in recent years. These are geographically weighted statistics. Tobler’s “first law of geography” (Tobler 1970) is often cited as the inspiration for the geographically weighted approach: everything is related to everything else but near things are more related than far things. It is not actually a law in any scientific sense but more a maxim about how patterns of positive spatial autocorrelation often are observed in geographical studies. If the maxim holds, then we can expect greater levels of spatial association between the closest observations in a data set and the spatial weights matrix should be formed accordingly.

With geographical weighting, those neighbors that are closest together receive a greater weighting than those that are further apart. This is described as inverse distance weighting – the greater the distance apart, the lower the weight given, reducing to zero beyond a threshold either chosen by the analyst or determined by a calibration/optimization procedure. As before, that threshold may be at a fixed distance (e.g., all observations within 10 km) or it could be at the distance to the $k$th nearest neighbor, a distance that will vary from one observation to another (unless it happens that the observations are all spaced out equally from each other). The latter is sometimes known as an adaptive approach in the sense of adapting to the local density of observations. It will take a larger distance to reach the $k$th nearest neighbor in parts of the study region where the observations are sparse and, conversely, a smaller distance where they are frequent.

Having defined the matrix, we can calculate a local and geographically weighted mean around observation $i$:

$$\bar{x} = \frac{\sum_{j} w_{ij} x_j}{\sum_{j} w_{ij}} \quad \text{(3)}$$

a local standard deviation:

$$s_i = \sqrt{\frac{\sum_{j} w_{ij} (x_j - \bar{x}_i)^2}{\sum_{j} w_{ij}}} \quad \text{(4)}$$

or even a geographically weighted LISA. These equations simplify if the weights are row-standardized (because in each case the denominator, the bottom line, becomes equal to one). The arguments in favor of row-standardization remain as previously. Note, however, that a consequence will be to disturb the relationship between distance apart and the weight given. For example, observations A and B could be the same distance apart as C and D but receive different weightings. That is because after row-standardization, the final weight of, say, B in relation to A, is not only a function of their distance apart but also the number and distance of other neighbors of A.

Figure 3 shows the geographically weighted (local) means for the unemployment data. They were calculated using a cut–off threshold of the 20th nearest neighbor. Comparing Figure 3 with Figure 2a it can be seen that calculating the geographically weighted means smooths the data – the more neighbors included in the calculation the greater the smoothing. In this regard it operates like a low-pass filter used in remote
sensing. Areas given a black border on the map are those where the local mean is significantly high (at a 95% confidence, determined using the sort of randomization procedure discussed earlier).

The idea of geographically weighted statistics has been taken forward within a regression framework. Geographically weighted regression works by comparing the results of a global regression model fitted to the whole study region to the set of results that are obtained if a local regression model is fitted at each individual location in turn, weighting that local regression to give most weight to the closest other observations. If there are $n$ observations, there are $n$ different regression models to compare with each other and with the global model. The interest is in whether the effects of the $X$ variables upon the $Y$ are broadly constant (the estimated beta values are approximately the same everywhere) or whether the relationships are nonstationary, meaning they vary in nature in different parts of the map. In matrix form, the formula for estimating the beta coefficients of ordinary least squared regression is:

$$\beta = [X^T X]^{-1} X^T y$$  \hspace{1cm} (5)

The equivalent for geographically weighted regression is:

$$\beta_i = [X^T W_i X]^{-1} X^T W_i y$$  \hspace{1cm} (6)

The detail of the mathematics need not concern us. Instead, observe the presence of the spatial weights matrices ($W$), which use inverse distance weighting, and note that what is obtained is a geographically localized set of estimates, as indicated by the subscript denoting location, $i$.

**Conclusion**

There is much to be learned from classifying and mapping data, by considering how the attributes of one place compare to those of its neighbors, by being able to establish where there are common characteristics amongst people, places, ecosystems, and environments, and by being
able to recognize and to understand where those characteristics diverge. Both local statistics and place-based analysis can be used to look for evidence of spatial clustering (shared characteristics of proximate observations) and also spatial heterogeneity (variations in those characteristics from one place to another). Local statistics, in particular, imply sensitivity to geographical difference and an expectation that what is measured in one location will not necessarily be measured in another. Identifying geographical difference is a first stage in establishing the causes of the difference.

Local/global production systems

Godfrey Yeung
National University of Singapore

Production systems (production chains) incorporate different production stages based on research and development (R&D), product design, the exploration of raw materials and minerals, and the manufacture of parts and components, which lead to the final assembly of a product before it is distributed and eventually sold to consumers. The networks of firms, the functions that they perform, and their relative power relationships in the various stages of production in different areas are some of the major focuses of research. The location of specific production processes can have a profound impact on the generation of economic value and local industrial development, as well as on interactions with the globalized world, for example the textile and clothing clusters in the Third Italy.

Local and global production systems

Local production systems focus on production stages conducted within a region while the global production system examines all stages of production across space. Manufacturing industries used to be integrated – either horizontally or vertically – to gain economy of scale and/or scope as well as the secure supply of parts and components. In horizontal integration, a firm incorporates pertinent industrial subsectors in-house, while a single firm (conglomerate) conducts all the processes, from R&D to in-house production, in the case of vertical integration.

The conglomerate mode of production is no longer financially viable in the globalized era when production costs in developed countries are rising and the location of manufacturing activities is becoming footloose, partly due to the international division of labor and the advancement of manufacturing and transportation technologies which allow different production processes to be located in different parts of the world. Under intense competition, conglomerates have to divest and focus on their core businesses through mergers and acquisitions (vertical disintegration). This leads to a massive industrial consolidation in manufacturing sectors, from iron and steel and shipbuilding to the pharmaceutical sector.

The divestment occurring in the chemical industry is a typical example. Traditional chemical conglomerates spanned all aspects of the business, from upstream oil exploration and production, through mid-stream ethylene and chlorine production, to downstream synthetic fibers, plastics, agrochemicals, and pharmaceuticals. The 1990s saw a revolution in these businesses, with most of the world’s leading firms espousing the breakup of the traditional chemical firm to focus instead on life sciences, with pharmaceuticals at their core. The establishment of Novartis from Ciba-Geigy and Sandoz is one such example. In the 1980s, Ciba-Geigy and Sandoz (both of Switzerland) were two of the world’s most powerful chemical companies, each particularly strong in speciality chemicals.
After a series of acquisitions and disinvestment in the mid-1990s, Ciba-Geigy was by then the world’s eighth largest chemical producer and ninth largest pharmaceutical manufacturer. To enhance the competitiveness and synergy of the chemical and pharmaceutical businesses, Ciba-Geigy and Sandoz radically changed the shape of the pharmaceutical industry through a simultaneous merger and demerger that arguably changed the corporate landscape of the world’s pharmaceutical and chemical industries in 1996. The main businesses of Ciba-Geigy and Sandoz combined in a US$27.5 billion merger to form the world’s second biggest pharmaceutical company, Novartis. As part of the transformation, Ciba-Geigy separated its slow-growing, speciality chemicals divisions into a new company, Ciba Speciality Chemicals.

Local-global linkages

World systems theory and dependency theory are grand paradigms for understanding the economic relationships between developed and developing countries; the former maps out such relationships and the latter highlights their power dynamics. These two theories do not fully recognize the importance of firms in the power dynamics. They also have no specific tool to unpack the relationships between actors and industries across space. Economic sociologist Gary Gereffi contributed to this research by developing a method to map out community chains in the 1990s.

Based on the asset specificity of transaction cost theory and the importance of trusts, social networks, power, and geographic proximity in the production network theory, Gereffi (1994, 2) introduced the concept of global commodity chains (GCCs), which incorporated “sets of inter-organizational networks clustered around one commodity or product, linking households, enterprises, and states to one another within the world-economy. These networks are situationally specific, socially constructed, and locally integrated, underscoring the social embeddedness of economic organization.”

He highlighted two specific types of commodity chains: producer-driven and buyer-driven commodity chains. Producer-driven commodity chains are characterized by capital- or technology-intensive manufacturers playing a central role in coordinating production networks, including their forward and backward linkages – computers, automobiles, and aircrafts – while large retailers, marketers, and branded manufacturers play pivotal roles in setting up decentralized production networks in labor-intensive consumer goods industries in buyer-driven commodity chains like footwear, garments, and toys. Gereffi, Humphrey, and Sturgeon (2005) further extended the concept to incorporate five specific governance types of global value chains (market-based, modular, relational, captive, and hierarchy value chains) to reconcile the asymmetrical relationships between transnational corporations (TNCs) in developed countries and their suppliers (local firms) in developing countries.

To highlight the nexus of the interconnected functions and operations of firms and non-firm institutions, where goods and services are produced and distributed globally, Coe et al. (2004, 471) proposed global production networks (GPNs) as a geographically attuned heuristic framework for the understanding of the global economy. This analytical approach highlights the spatial asymmetrical capture of value-added in various manufacturing activities across space as manufacturing activities, core knowledge, and technologies are still ultimately controlled by various TNCs and their first-tied
subcontractors. This reconciles the continuous divergence of growth between developed and developing countries despite the massive relocation of labor-intensive manufacturing industries to developing countries since the 1970s.

The GPN framework accounts for the possibility that selected local firms could reduce the manufacturing capability gaps between local producers and TNCs. Local original equipment manufacturers (OEMs) that sell their products to other companies (normally TNCs) to be marketed under the TNC brand could develop into dominant focal firms and spearhead the global (re-)organization of production networks through their corporate and marketing power as long as there is strategic coupling (linkages) with regional endowments and institutions. Focal firms are those with the capacity to operate major production functions, from R&D to manufacturing and assembly. Notwithstanding the analytical insights from relational economic geography in general, and the GPNs in particular, Sunley (2008, 8) highlighted the overemphasis placed on microscale processes and “ties and networks,” and the difficulty of validating the GPN framework empirically other than through qualitative case studies.

To catch up with TNC technological capacity in the knowledge-based economy, economic agents in developing countries have to absorb knowledge either through the internalization of codified knowledge, with the help of tacit knowledge acquired earlier, and/or through socialization that involves the exchange of tacit knowledge. This uncoded tacit knowledge is what Michael Storper (1995, 1997) termed geographically constrained “untraded interdependencies” where face-to-face exchanges, embedded routines, habits and norms, local conventions, and reciprocity and trust are crucial for its development. These interdependencies are not easily reproduced since they draw on the social properties of networked economic agents.

Localization/delocalization

Yu Zhou
Vassar College, USA

The term “localization” emerged as a response to globalization and thus delocalization. Since the 1960s, global production networks (GPNs) have become increasingly sophisticated and absorbed more and more regions into their networks of production, distribution, and consumption (Coe et al. 2004). GPNs are organized and led by top-tier transnational corporations (TNCs) in advanced economies to provide these companies with quick and low-cost accesses to resources, capabilities, and knowledge all over the world (Ernst and Kim 2002). The proliferation of such networks has not only transformed production processes but also profoundly shaped everyday lives and aspirations of peoples and places. For most parts of the world, localities can have little influence on or expect much accountability from TNCs headquartered far away. This transformation – referred to as “delocalization” – is represented by examples such as indigenous businesses being replaced by national or international chains, domestic factories becoming branch plants of TNCs, and local brands being eliminated by foreign brands. The fear is that, as TNCs standardize global practices, the world will eventually lose cultural diversity, and that power will be concentrated in the hands of the few (Sklair 2001).

It turns out, however, that this fear of homogeneity is overblown. Studies have found that TNCs do not just mold localities according to their desires, but also actively pursue localization by adapting capital investment, management personnel, product design, and marketing methods to localities in order to penetrate deeper into the local markets (Agarwal and Brem 2012; Coe and Lee 2013).

While management literature regards localization mainly as TNC strategies, geographers view localization as the vital means through which localities respond to the challenge of globalization. TNCs are only interested in selective local resources and opportunities. They are also footloose, and can quickly pull out of a region if the conditions become unfavorable. Localization from a regional perspective means that regions can develop local networks to broaden the spillover benefits of external resources and opportunities made available by GPNs. Regions can also deepen the embeddedness of TNCs in local economies to reduce their footloose tendencies. GPN studies, for example, advise regions to engage in “strategic coupling” with GPNs to articulate local resources into the global networks (Coe et al. 2004). Bathelt et al. (2004) use the terms “global pipeline” and “local buzz” to summarize the characteristics of innovative clusters that generate intense local exchanges and also build and maintain knowledge channels with innovative spots around the globe. In short, localization represents the regional strategies to create a codependency with GPNs for the purpose of increasing local leverage and autonomy in the global system. The coexistence of globalization and localization gave rise to the term “glocalization” (Valdivieso 2013).

Location and multiplant firms

Isabel Mota
Università di Porto, Portugal
CEF.UP, Portugal

Economic agents – households and firms – have long tended to concentrate in a few places, cities or industrial clusters. But this raises the questions of what explains these locational outcomes, and whether the location choices of economics agents are influenced by their characteristics.

These questions are at the heart of location theory, which aims to explain the use of a finite resource – space – explicitly recognizing that economic activities consume space and are separated by costly distance. Location theory has a long historical tradition that goes back, for instance, to Adam Smith and David Ricardo, but interest in it has been cyclical. Following some remarkable developments, introduced by Von Thünen, Launhardt, Marshall, Weber, and Lösch, location theory has seen some less enthusiastic phases. Fortunately, in recent decades economists increasingly have come to recognize the relevance of space and location theory. It is possible to identify three main trends in economic geography modeling: the urban systems approach, which builds on externalities to explain the agglomeration of agents (Henderson); spatial competition models, which consider oligopolistic competition between firms (Hotelling); and the new economic geography approach, which assumes monopolistic competition among firms and increasing returns to scale (Krugman).

Notwithstanding this long history, it is surprising how little attention has been paid in location theory to studying the location choices of firms that set up multiplants (or multi-establishments or multistores). Typically, literature focuses on the location choices of single-plant firms. However, there are numerous examples of corporations that set up multiple stores in a city (e.g., Pizza Hut, McDonald’s, or Zara in a typical European city), multiple plants within a country (e.g., Cimpor has three plants (Cimpor 2015) in Portugal to produce cement; Talgo has two plants (Talgo 2015) in Spain to produce intercity, standard, and high-speed passenger trains), or even multiple plants across countries (e.g., the Volkswagen group operates 119 production plants (Volkswagen 2015) in 20 European countries and a further 11 countries in the Americas, Asia, and Africa; Bridgestone has 68 tire plants (Bridgestone 2015) in America, Europe, the Middle East, Africa, Russia, Asia and the Pacific, and Japan; Grohe has six plants (Grohe 2014) in Germany, Portugal, Thailand, and South Africa). Indeed, multiplant firms are not an exception, but rather a widespread feature of industrial economies.

Following Pal and Sarkar (2002), it may be argued that studying the location choices of a single-plant firm is merely a technical simplification, and that results for a single-plant firm can be extended to a multiplant firm. However, each plant’s decision influences the decisions of other plants in a corporate network, implying that the location choices of multiplant corporations are likely to differ from those of single-plant firms. The analysis of multiplant location choices may also be viewed as an extension to the theory of monopolistic price discrimination. Yet if the monopolist is not allowed to locate multiple
plants in different places, the ability to segregate the market is greatly restricted, and the price discrimination in question is in fact rather passive. As such, analysis based upon such a restricted setting has only limited implications.

The context in which single-plant firms and multiplant corporations make their location choices is dissimilar. While both search for the most profitable site, the relative importance of each location determinant differs for several reasons. First, new single-plant firms and new multiplant corporations are born at different phases of the life cycle of firms: new multiplants thus can take advantage of more mature entrepreneurship than new single-plant firms. Second, the birth of a multiplant corporation is frequently motivated by capacity needs or market expansion, implying that the optimization of multiplant locations justifies a distinct behavior. Third, branch plants of large firms are more sensitive to environmental regulation than plants in general. Fourth, given that location decisions involve incomplete information and uncertainty, we might expect multiplants to have access to more information about sites when they make their location choices. For example, multiplant corporations can benefit from economies of scale in conducting site searches. Multiplant corporations also can be less risk-averse than single-plant firms due to their presence in several markets, therefore idiosyncratic risk is null. Finally, multiplant corporations may be more flexible: the location of single-plant firms more likely reflects where the entrepreneur lives.

This entry discusses the location choices of multiplant corporations, examining the literature on this topic. In order to offer a broader overview of this research field, the location decisions of multistore and multi-establishment corporations are also included. The main purpose is to explore theoretical and empirical research focusing on location decisions. This is an important topic to review because, although there are many empirical examples, the scholarly literature on this topic is surprisingly sparse.

The second section discusses theoretical contributions to this topic, the third focuses on empirical studies, and the last concludes.

### Theoretical developments

There are three main trends in economic geography modeling: spatial competition models, new economic geography models, and externalities models.

Most research on the location of multiplant corporations builds on the spatial competition framework. This approach finds its roots in the seminal work of Hotelling (1929), who assumes that consumers are uniformly distributed along a bounded linear market with linear transportation costs. In this context, competition between two firms results in them clustering at the center of the market, a result known in the literature as the principle of minimum differentiation.

Hotelling’s paper catalyzed a large and rich literature on spatial competition. Usually, location models are classified into shopping or shipping models. A shopping (or mill pricing) model assumes that consumers bear the transportation costs, whereas a shipping (or delivered price) model assumes that firms deliver the product and pay for the transportation costs. Yet both models have the same centrifugal and centripetal forces, leading to similar location patterns under similar assumptions.

Spatial competition models may also encompass Bertrand (price) or Cournot (quantity) competition between firms. Under Bertrand competition, agglomeration only occurs if an additional differentiation dimension is allowed: for example, heterogeneity in consumers’ tastes
or brand specifications, or partial price collusion. Cournot competition has generated a relatively small body of location models, usually predicting that agglomeration equilibrium exists when population density is high. Recently, incomplete information has also been introduced as an explanation for spatial agglomeration under price competition by assuming, for example, asymmetric information about marginal production costs, product quality, or consumer preferences. Most work in spatial competition also utilizes the linear city model, although some analyzes location in Salop’s circular city and some introduces a triangular market.

Within this rich and diverse literature on spatial competition, only a few papers deal with multiplant (multistore or multi-establishment) corporate location choices. Teitz (1968) was the first author to study spatial competition among multistore firms. In the context of Hotelling’s linear city with linear transportation costs, he concludes that there is no location equilibrium if firms have multiple stores. Twenty years later, Martinez-Giralt and Neven (1988) considered both linear city and circular city models, assuming quadratic transportation costs (increasing with the square of distance) and mill pricing. They show that even if each firm is allowed to open two stores, its optimal choice in equilibrium is not to do so.

Most research on multiplant location emerged in the late 1990s. Some authors approach this issue by considering quantity competition. Chamorro-Rivas (2000) considers a circular market and a duopoly, with two plants per firm, concluding that in equilibrium all plants are equally spaced and paired around a circle. Li (2006) demonstrates that this result is also valid when one of the duopolists is a welfare-maximizing (public) firm. Pal and Sarkar (2002) study a multistore spatial duopoly in a linear city, finding that both agglomeration and dispersion location equilibria are possible. Extending their analysis to a circular city, Pal and Sarkar (2006) show that two firms with an equal number of plants result in a unique equilibrium location pattern, whereas multiple equilibria arise in most other scenarios. Yu and Lai (2003) study Cournot competition between firms producing goods that are either substitutes or complements. They show that a linear market always yields a central agglomeration, but that this result is not always valid for a circular market. For a circular market, they conclude that if the two goods are complements, there is a unique equilibrium where firms agglomerate at some market point; if the products are substitutes, there is a unique equilibrium where firms locate maximally far apart.

Other authors examine location choices on the basis of price competition. Assuming a two-firm two-plant setting, Pontes (2001) considers firms setting mill prices and making interdependent location decisions between two regions (or countries). He concludes that it is always a dominated strategy to locate a single plant in the smaller country. Dasci and Laporte (2004) make endogenous the number of stores opened by a monopolist through the introduction of a fixed cost, and conclude that the number of stores may decrease or increase with unit transportation cost. Janssen, Karamychev, and van Reeven (2005) incorporate consumer heterogeneity into competition between horizontally differentiated firms, and conclude that there is only one subgame perfect equilibrium where the location decisions of multistore firms are completely independent of each other. Karamychev and van Reeven (2009) adopt a random utility model to explore competition between multistore firms selling horizontally differentiated products and conclude that firms’ location strategies contribute to retail sprawl. Takaki and Matsubayashi (2013) focus on multistore sequential locations between two firms,
with fixed costs, which yield two opposing equilibrium location strategies for the leader: segmentation strategy (the leader monopolizes a market segment by partially deterring the follower’s entry) and equidistant strategy (in which stores are opened at equidistant locations throughout the market).

In the past two decades, new economic geography (NEG) models have become popular, emphasizing pecuniary externalities and merging these into a general equilibrium model of monopolistic competition. The seminal paper by Krugman (1991) combines the Dixit–Stiglitz model with an iceberg-type transport cost to examine the conditions under which a country can endogenously become differentiated into an industrialized “core” and an agricultural “periphery.” Extensions to the original model have introduced more realistic assumptions, including intersectoral rather than interregional labor mobility, positive transport costs for both the traditional and modern sectors, quasi-linear utility functions, and heterogeneous workers’ preferences. Although the details of the agglomeration process vary, there is general support for the emergence of a core–periphery structure for intermediate transportation costs with a tradeoff between transport costs and agglomeration. These conclusions agree with evidence of a secular fall in transportation costs coinciding with an intensified geographical concentration of economic activities.

There have been some attempts to model the spatial organization of multiplant firms within the NEG framework. The first was by Markusen and Venables (1998), although their results rely on numerical examples. The initial NEG model of Ekholm and Forslid (2001) also was rather limited. Neary (2002) focuses on the location choices of a multinational firm and identifies three distinct influences of internal trade liberalization: the tariff jumping that encourages plant consolidation; the export platform that favors foreign direct investment with only a single union plant relative to exporting; and reduced internal tariffs that increase competition from domestic firms. Fujita and Gokan (2005) developed a partial equilibrium model incorporating multiplant firms. Considering a two-region economy with declining communication costs, they conclude that firms producing low-trade-cost goods (such as electronics) tend to concentrate manufacturing plants in low-wage countries, while firms producing high-trade-cost products (such as automobiles) tend to open multiple plants serving segmented markets, even in the absence of wage differentials. Markusen (2002) offers an overview of partial and general equilibrium models with both horizontal and vertical foreign direct investment. He analyzes decisions about whether to build or acquire a foreign plant separately from decisions about where to raise the financing, assuming the interaction of scale economies, trade costs, factor endowments, and imperfect competition. Tsubota (2012) examines the outcomes of organizational choice between single-plant and multiplant strategies for two asymmetric regions. He concludes that a decrease in transport costs induces firms to agglomerate in one region, and also makes firms concentrate their production into a single plant. In addition, he observes that lower establishment costs favor the multiplant strategy, but when fixed export costs decrease, more firms choose single exporting.

Only a few studies consider multiplant corporations and the externalities used to explain urban systems (urbanization and localization economies). Using plant-level productivity data, Henderson (2003) finds that high-technology industries benefit more from localization externalities than do traditional manufacturing industries. He also finds that single-plant firms benefit more from localization economies than
do branch plants of multiplant corporations, which can rely more on corporate information networks. Moretti (1999) examines whether average educational attainment outside an industry affects plant level productivity, controlling for overall location fixed effects. He finds that a one-year increase in average education in the city increases plant productivity for single-plant firms by 7.7%, but has no effect for multiplant firms.

Overall, spatial competition models that assume price competition between multiplant firms focus on the optimal number of plants and mostly conclude that dispersion equilibria emerge. The models that assume quantity competition between firms and linear or circular markets frequently reach agglomeration or dispersion equilibria. Studies that use NEG to explain the location of multiplants typically conclude that a decrease in transportation costs favors agglomeration equilibrium and a single-plant structure. Finally, studies that focus on externalities to explain the location of multiplants conclude that both urbanization and localization economies are relevant for single plants and multiplants, but multiplants benefit more from urbanization economies.

Research on multiplant corporation location choices could particularly benefit from further study within the NEG and urban system approaches. It would be interesting to study differences between single-plant firms and multiplant corporations, in terms of how location profiles depend on different costs (transport, establishment, etc.), the types of good produced by each (final versus intermediate), the size of network externalities (i.e., how the value of a good or service changes with the number of consumers), or the qualifications of the workforce. The influence of multiplant corporation networks on urban systems also deserves further research.

**Empirical findings**

Empirical studies on the geography of multiplant firms are relatively scarce. Most research on the locational behavior of multiplant firms adopts a case study approach, employing survey methods to a specific sector. Case studies benefit from detailed information, but their results are difficult to generalize. Other researchers focus on small samples of firms in particular industries. Recently, however, there has been some research on the location choice of multiplant firms using large samples and econometric methods, allowing for more general conclusions. But econometric analysis faces several difficulties: location choices are not continuous and so standard regression specifications are not adequate; there is a whole range of possible locational determinants, requiring large datasets; and location choices are influenced by both local characteristics and neighborhood characteristics, requiring specific spatial econometric tools.

Early research on firms’ location choices, which assumed that firms were identical in terms of size, entrepreneur’s home base, and so on, has been challenged by authors claiming that the determinants of firms’ locations depend on, for example, firms’ size, industrial activity, or technological intensity (e.g., Arauzo–Carod and Manjón–Antolín 2004; Barrios, Görg, and Strobl 2006). There are few studies that focus on the influence of determinants of multiplant corporations’ location choices. Typically, they establish that the location profiles of multiplant and single-plant firms, and the influence of spatial variables on site selection, are different. It is observed that multiplant corporations are particularly sensitive to urbanization economies, land costs, and market size (Mota and Brandão 2013). Kim, Barkley, and Henry (2000), examining the influence of the number of plants
LOCATION AND MULTIPLANT FIRMS

on plant clustering, concludes that spatial clustering of establishments is positively related to industry average establishment size and labor intensity, but negatively related to multiplant structure and reliance on local product and input markets (Kim, Barkley, and Henry 2000). Other authors state that the clustering of industrial firms influences their birth and growth (Delgado, Porter, and Stern 2010), concluding that industries located in regions with strong clusters (i.e., a large presence of other related industries) experience higher growth in new business formation and start-up employment, while strong clusters are also associated with the formation of new establishments of existing firms, thus influencing the location decision of multi-establishment firms.

Some researchers study differences in the performance of multiplant and single-plant firms, frequently focusing on multinational firms. Usually, they establish that multiplant firms (e.g., multinational subsidiaries) have higher market shares and higher advertising and research and development ratios than single-plant firms (Anastassopoulos 2003).

There is a vast empirical literature on firm survival across different countries and time periods that identifies different variables (internal to firms, specific to the industry, specific to the business cycle, and geographical characteristics) influencing survival as well as different specifications for the survival function. New multiplant corporations are expected to have higher survival rates than new single-plant firms, since the former have better market information and can learn from other plants in the corporation. Multiplant corporations usually are larger firms, with fewer financial constraints; affiliates also can benefit from the potential technological and/or organizational superiority of the mother firm (Audretsch and Mahmood 1995; Mata and Portugal 2004).

A recurrent finding in the literature, however, is that plants owned by multinational multiplant corporations are more likely to close (Kneller et al. 2012). This may suggest that the main advantage of corporate networks of plants ultimately lies in the fact that they are bigger (Disney, Haskel, and Heden 2003). Researchers studying the location of functions within multiplant corporations conclude that proximity to corporate headquarters and to metropolitan areas influences a plant’s performance (Brunelle and Polese 2008; Toshihiro and Eiichi 2011; Cappariello, Federico, and Zizza 2012).

In short, much more empirical research into the location of multiplant firms is necessary, particularly into the influence of spatial variables – urban versus rural areas, agglomeration economies, fiscal policies – on the demography and dynamics of single-plant firms and multiplant corporations. It will also be important to develop large datasets and new tools for econometric spatial analysis that can deal with continuous space.

Conclusions

Notwithstanding the growth of both theoretical and empirical research on location economics, research in economic geography into the location of multiplant firms is sparse. With respect to theory, the majority examines spatial competition among firms, assuming either price or quantity competition, and either a linear or circular market. There are some studies examining multiplant corporations within general equilibrium models or the influence of multiplant corporate networks on urban systems. Empirical research is dominated by case studies or by recourse to small samples. There are attempts to develop large datasets and appropriate spatial analytical tools, but a great deal still needs to be done.

Location-allocation analysis is a process that develops mathematical location models, devises solution algorithms, and applies these methods to real-world decision-making situations that involve placement of facilities in a given space. Facility location decisions arise in a wide variety of public and private sector contexts. Examples of facilities whose locations have been analyzed in the location-allocation literature include schools, hospitals, libraries, post offices, ambulance stations, factories, retail outlets, warehouses, nuclear power plants, hydrogen refueling stations, and sensors for wireless networks.

Locations of these facilities greatly impact the level of services they provide, such as the accessibility of users to libraries and the distribution of market share of retail shops among competitors. Thus, constructing location models and solution algorithms that provide optimal locations of facilities is important. Location-allocation analysis provides a framework for the development of these location models and solution algorithms, and applying these methods to real-world situations is very important in providing successful services at facilities and understanding policy implications of locational decisions.

The modeling process is usually the first step of the location-allocation analysis, which involves identification of quantifiable objectives and constraints that depend on the locations of the facilities for the problem under study. An example of an objective is the minisum objective, which minimizes the demand-weighted total distance between users and facilities, where demands are given by the number of users at each location. Constraints define feasible solutions for location problems. For a factory, for example, these would include the number of facilities to be located, the budget available for locating facilities, and daily production capacity. The next step is to obtain optimal or desirable solutions to the facility location problem. Various algorithms have been proposed to solve location problems either optimally or heuristically. Finally, applications of location models involve collection of geographical data, analysis of solutions obtained, and analysis of policy implications for the problem under study.

Because of their rich set of applications, location models have been studied in such diverse fields as geography, regional science, urban economics, operations research, and applied mathematics. Each application has its own characteristics depending on the type of services provided at the facility. This has led location researchers to develop a large number of different models.

Types of location models

The basic elements of location problems are: (i) demand points, which are fixed in advance; (ii) facilities to be placed; and (iii) the space that
contains demand points and placed facilities. Demand points represent a set of locations where potential users of facilities exist, such as customers for retail shops and warehouses served by factories. Because facilities are small relative to the space in which they are sited, the problem can be modeled as finding a set of points in space.

There are a number of taxonomies to classify location problems. An important taxonomy focuses on the above three elements and classifies models into three types: continuous models, network models, and discrete models.

Continuous models typically assume that demand arises only at discrete points but that facilities can be located anywhere on a continuous plane. Objective functions are expressed as distances between users and facilities, where coordinates of facilities are decision variables. Since most distances are nonlinear functions of coordinates of facility locations (e.g., Euclidean distances), continuous location models are usually formulated as nonlinear optimization problems. Many of the continuous location problems are quite difficult to solve.

Networks are important modeling tools for describing transportation networks, such as road networks and railway networks. Network models assume a network composed of nodes and links. Both demand locations and facilities are restricted to the network, and travel between demands and facilities occurs only on a network. Network location models are further classified into those in which candidate locations are restricted among a set of nodes and those in which facilities can be located anywhere on the links as well as on the nodes. While demands are usually assumed to occur only at the nodes, some models assume continuously distributed demands along links of a network.

Discrete location problems assume that both demand locations and candidate facility sites are given by finite sets, with arbitrary distances between demands and facilities permitted. Discrete location problems are usually formulated as integer programming (IP) problems because location decisions can be represented by a set of binary variables that each indicate whether a facility is located at a candidate location or not. Often, variants and extensions of basic location models can be described as simple extensions of IP formulations of the basic models. Due to the recent development of various solution methods for IP problems and mathematical programming solvers, this approach becomes increasingly useful for a variety of problems.

To illustrate typical situations in which location-allocation models are applied, Figure 1 shows two simple solutions of a discrete location model. In the figure, circles represent both the sets of demand points and candidate facility locations. In general, these two sets may or may not be the same. The number of users residing at each demand point is the same for all locations. In both solutions, two facilities are located as shown by the black disks, and allocation of each demand to the nearest facility is illustrated by the solid lines together with user-facility distances. The sum of the distances for all users to the nearest facility in the solution on the left is 35 and that on the right is 26. Thus, in terms of the accessibility to the service provided at the facility, the right-hand solution is much more desirable than the left-hand one. As the example indicates, developing location models to provide optimal locational decisions is quite important.

Depending on the characteristics of each locational decision-making problem, goals and assumptions may differ greatly. For example, in some situations, instead of minimizing the total distance required for traveling to the nearest facility, minimizing the maximum distance
between all user-facility distances is more appropriate. In another case, the number of facilities is endogenous to the problem and is an output for the model rather than an input into the model considered in Figure 1. Another situation may require considering capacity limit for each facility, and each demand may not be allocated to the nearest facility. Just as real-world problems can be complex, so too can the problem formulation become complicated.

**Historical development of basic location-allocation models**

The historical development of mathematical facility location problems is described here and some of the most basic models are introduced. Location models have their roots in the pioneering work of Weber, who investigated an industrial location to minimize transport cost
LOCATION-ALLOCATION ANALYSIS

(Weber 1909). Weber considered the point that minimizes the sum of the transportation costs from two sources of materials to the facility location and the cost from there to a market. Today, the Weber problem is more generally formulated as follows: find a point in the plane that minimizes the weighted sum of the Euclidean distances from the point to a given number of destination points, where different destination points are associated with different amounts of demand, which determine weight. The objective function employed in this model is called the minisum objective because it minimizes the weighted sum of the distances. The Weber problem is a typical continuous location problem. This model can be solved numerically by an iterative method called the Weiszfeld algorithm (Weiszfeld 1937) or similar variants.

The classical Weber problem seeks to determine the location of only one facility. In many situations, however, locations of multiple facilities are simultaneously determined. There is a significant difference between these two cases. When only one facility is available, the facility provides service for all customers. However, when two or more facilities are to be introduced, decisions on which customer should be served by which facility should also be considered, as well as their locations. This process of assigning each demand to each facility is called allocation.

In the 1960s, more than half a century after the pioneering work of Weber, several important contributions were made that extended the classical Weber problem to deal with the location of multiple facilities. Among these, the multifacility Weber problem and the $p$-median problem are two of the most important location-allocation models, and these have had a significant impact on the development of later models. These two approaches employ the minisum objective (demand-weighted distance between demands and facilities), the same objective used in the Weber problem. This objective can be regarded as the maximization of accessibility when users access facilities directly and the minimization of total transport costs when facilities are source locations of products.

In the first of these models, Cooper (1963) considered the multifacility version of the classical Weber problem. As with the Weber problem, this problem assumes the Euclidean distance metric, known demand points in a plane, and a continuous planar region on which facilities can be located anywhere. The difference between this new formulation and the Weber problem is that the number of facilities to be located is generally two or more, which is why the problem is called the multifacility Weber problem. This problem seeks optimal locations of a given number of facilities and allocation of demands to specific facilities. Because of the strong nonlinearity of the objective, solving this problem is much harder than solving the original Weber one. Thus, heuristic methods are essential. The most well-known heuristic is the alternating heuristic presented by Cooper, which performs location improvement and allocation improvement phases alternately.

In the second of the multifacility extensions to the Weber model, Hakimi (1964) investigated the location of $p$ facilities so as to minimize the weighted distances between nodes on a network and the facilities. This can be seen as a network version of the multifacility Weber problem. This problem is perhaps the most well-known and important problem in location-allocation models; it is now usually called the $p$-median problem (PMP). Hakimi proved an interesting property: in any PMP, at least one optimal solution places the $p$ facility sites only on the network's nodes. Due to this property, which is often called Hakimi's theorem, the search
for optimal solutions can be reduced from an infinite set (i.e., every point on every link) to a finite set comprising only nodes of the network.

A mathematical programming formulation of the PMP was given by ReVelle and Swain (1970), which had a significant impact on the development of location-allocation models. They employed methods in mathematical programming such as integer programming formulation, linear programming (LP) relaxation, and branch and bound methods, whose approaches were later used by many researchers in the study of location models. Per Hakimi’s theorem, it is sufficient to search for the optimal solution on a network among the set of nodes. Thus, binary variables are introduced at each candidate node to site a facility or not.

The formulation of PMP is illustrated as follows. Let \( I \) be a set of demands points and \( J \) be a set of candidate locations on a network. The shortest path distance between demand point \( i \in I \) and candidate location \( j \in J \) is \( d_{ij} \). The weight \( w_i \) is associated with each demand location \( i \in I \). A binary decision variable \( x_j \) is defined at each candidate location \( j \in J \), taking a value of 1 if a facility is located at \( j \in J \) and 0 otherwise. Another binary decision variable \( y_{ij} \) is introduced that takes 1 when demand at \( i \in I \) is allocated to a candidate location at \( j \in J \). Using these notations, the PMP is formulated as follows:

| \( x_j \in \{0, 1\}, \forall j \in J \) (5) |
| \( y_{ij} \in \{0, 1\}, \forall i \in I, \forall j \in J \) (6) |

The objective function is the demand-weighted distance from each demand to facilities. Constraint (2) limits the number of facilities to be located to \( p \). Constraint (3) says each demand is allocated to exactly one facility. Constraints (4) states that a demand cannot be allocated to a given node unless a facility is located at the candidate site. Constraints (5) and (6) stipulate the integrality of variables. This formulation can also be applied to PMPs in which both demands and facilities are given by discrete points on a plane and arbitrary distances between these two sets are assumed.

The LP relaxation of the above problem, which results from replacing binary variables with continuous variables taking values between 0 and 1, often provides an all integer solution that is an optimal solution to the original problem. When one or more location variables take fractional values, branch and bound methods can be applied to obtain an exact optimal solution. The above formulation can be input into mathematical programming solvers directly together with input data for the model. Because of the recent development of such solvers, moderate sized problems can often be solved optimally. Daskin (2013) explains several basic methodological tools for solving discrete and network location models.

**Heuristics methods for \( p \)-median problems**

PMP is known to be \( \text{NP}-\text{hard} \), that is, there does not seem to exist any efficient solution method to solve all instances of the problem.
LOCATION-ALLOCATION ANALYSIS

This makes it difficult to obtain globally optimal solutions for large-scale problems. Thus, a number of heuristic algorithms have been proposed. The drawback of these approaches is that they find locally optimal solutions, which may or may not be globally optimal solutions. These approaches have been successfully applied to PMPs, especially for solving large problem instances. There are three fundamental classes of such heuristics for PMPs: greedy algorithms, neighborhood algorithms, and exchange heuristics. These approaches may also be used for obtaining solutions for variants of PMP and other types of location problems.

A greedy algorithm adds a facility at the best location at each step without considering the impact of the present decision on the final solution. This algorithm is a kind of a construction algorithm. At the $k$th step, with the $k-1$ locations obtained thus far taken as given, this method finds the best location for the $k$th facility that minimizes the total distance for $k$ facilities. After the $p$th step, $p$ facilities have been placed, and this is the final output of the method. The quality of solutions obtained by this method is not always good, but the algorithm is simple and easy to implement. Thus, the method is used to obtain initial solutions for neighborhood algorithms and exchange heuristics.

A neighborhood algorithm repeatedly attempts to improve a given solution. This algorithm is a kind of improvement algorithm. A neighborhood algorithm for PMP consists of two phases, a location improvement phase and an allocation improvement phase, and alternates between these steps until no further improvement is made. Given the locations of $p$ facilities, each demand node should be assigned to the nearest facility. This partitions the sets of nodes so that all nodes in each set are assigned to the same facility. These sets are called the neighborhood of the facility, and there are $p$ such neighborhoods. In each neighborhood, the facility should be located optimally. This can be done by solving the 1-median problem $p$ times by the method of exhaustion (i.e., checking the score for placement of the facility at each location within the neighborhood). This location improvement phase yields a new configuration of $p$ facilities (unless all locations were already optimal solutions to the 1-median problems). In the allocation improvement phase, each demand point is assigned to the nearest facility, and this creates new neighborhoods. These two steps are alternated until no further improvement is made.

Exchange heuristics are a third kind for solving PMPs. The neighborhood algorithm evaluates the impact of facility relocation only within its neighborhood; it does not consider potential improvement that might be achieved by relocating a facility to outside its neighborhood and reallocating demand. By lifting this limit, an alternative improvement algorithm, called an exchange algorithm, is created. Given the locations of $p$ facilities, the exchange algorithm evaluates the impact of relocating one of the $p$ facilities to any candidate node. In evaluating the impact of relocation that best reduces the total distance, the other $p-1$ facilities are fixed. There are several variants that vary according to how the relocation occurs. One common variant is to number each facility, from 1 to $p$, and relocate each facility to its best position in this order. When at least one of the $p$ facilities is relocated, the process is restarted. The algorithm continues until no further improvement can be obtained. Different initial solutions can lead to different locally optimal solutions. It is empirically accepted that the exchange heuristic is likely to produce a high-quality solution when a significant number of randomly chosen initial solutions are applied.
Variants and extensions

PMP has been successfully applied to a number of different planning contexts in both the private and the public sector. At the same time, the need to better describe various planning scenarios often requires modification of the basic model. Some typical extensions are introduced below.

For PMP, the number of facilities to be located is an input to the model. The fixed charge location problem is very similar to PMP, but a fixed cost of locating a facility at each candidate location is introduced. Instead of constraining the number of facilities to be located, the total cost of locating facilities is incorporated into the objective function. The objective function is given by the sum of the total transport costs from facilities to customers and the total facility construction cost. Thus, the optimal number of facilities is endogenously determined in the model. This type of modeling is often used in the private sector for location decisions when one organization both pays the costs and receives the benefits. For example, consider the situation in which a product maker decides the locations of warehouses from which goods will be delivered to retail shops. If the cost of opening a warehouse at each potential site and the cost of sending a unit amount of product from each potential site to retail shops is known, minimizing the construction cost of warehouses plus the total transport cost can be modeled as a fixed charge location problem. Depending on the transport costs, two typical locational configurations may be observed. When transport costs are high, many facilities will be selected, which will reduce the average transport distance. In contrast, when transport costs are low, a smaller number of facilities will be selected, which will reduce fixed charges.

Because PMP seeks to maximize global efficiency, accessibility of each user to the nearest facility often varies widely. Since weights at demand locations contribute proportionally to the minisum objective, areas of high population tend to receive significant benefits relative to areas of low population. As a result of this, less populous areas may be unacceptably far from the nearest facility. To reduce such variability, alternative constraints and objective functions have been suggested. For example, one simple idea is to introduce the requirement that the closest facility to each demand point must be within a specified distance. Another important approach that focuses on equity is the well-known \( p \)-center problem, which seeks to minimize the maximum of distances between each demand point and the facility nearest that point (Hakimi 1964). This objective function is called the minimax objective. Hakimi’s theorem does not apply to the network \( p \)-center problem, and therefore the following two cases should be clearly distinguished: in the first case, facilities can be located anywhere along the links of the network (the \( p \)-absolute center problem); in the second case, facilities are restricted to the nodes of the network (the vertex \( p \)-center problem). Solution methods for both types of problems have been developed.

In many location contexts, service to customers depends on the distance between the customers and the facility. Often, service is acceptable enough if the customer is within a given distance of the facility, and is not acceptable if the distance exceeds a given threshold. Covering location models address this situation. Although allocation is not as explicit in the basic covering problems as it is in the previously discussed problems, covering models are sometimes included among location-allocation models. Covering-based models assume that there is some critical coverage distance or time (e.g., 2 km or 10 min) within which demands must be met. Such models often apply to designing emergency services. For
example, it may be assumed that a given demand for fire-fighting services is covered when the nearest fire station is located within a 10-minute distance of households and businesses.

There are two main types of covering models. The first one is the set covering location problem that seeks to find the minimum number of facilities needed to satisfy all demands (Toregas et al. 1971). In practice, the solutions to the set covering location problem tend to be much larger than economically feasible due to the requirement that each potential demand point (e.g., customer location) must be covered. By using weights to reflect the number of customers at each demand point, the maximal covering location problem, the second type of covering problems, seeks to find the best locations for \( p \) facilities (Church and ReVelle 1974). This means maximizing the number of covered demands. These two basic covering models have been extended in a number of directions. For example, a definition of coverage may be changed so that a given demand is considered covered when at least two services are within a critical distance. This may often arise in emergency services when the nearest vehicle is busy attending other calls.

In PMP, it is assumed that each demand can be allocated to the nearest facility because of the minimization of the demand-weighted distance. In practice, facilities may have finite capacity to handle demands. This may represent, for example, a space limitation or production capacity at a factory. An important characteristic is that some demands may not be allocated to the nearest facility due to the capacity limit. Obtaining optimal solutions for capacitated PMPs is often much more difficult than for basic PMPs. Another well-known variation is the capacitated fixed charge location problem, in which each candidate for facility location is assigned a capacity along with a fixed charge.

A variety of solution algorithms have been proposed for this problem.

Many basic location models assume that all facilities being located are the same kind. Often, however, facilities are hierarchical in terms of the types of services they provide. An example is postal services. There are different levels of postal services: post offices at the lowest level, branch offices at the next level, and central post offices at the highest level. Health-care services and school systems are also examples of typical hierarchical systems. Often, higher-level facilities offer specialized services in addition to the services offered at lower-level facilities. In other cases, services are not replicated between levels. The former system is referred to as successively inclusive; the latter is called successively exclusive. A typical objective in this kind of problem is to find locations for each type of facility to best serve as many people as possible. Often, people can move between different levels of facilities. Thus, both the relative locations of facilities among levels and the locations of facilities within each level are important.

Many basic location models have a single objective, such as the total distance traveled to facilities or the maximum distance between facilities and demands. In reality, however, there may be two or more objectives, which should be considered simultaneously. Multi-objective approaches are commonly employed to deal with such situations. Often, the minisum solution and the minimax solution to a particular problem instance are quite different. Furthermore, the minisum solution is likely to rate poorly on the minimax objective and vice versa. However, there are very often many compromise solutions with good performance for both objectives, and so multi-objective approaches are quite useful in realizing desirable locations from various planning viewpoints. The Pareto optimal solution is an important notion in multi-objective
analysis, which characterizes good compromise solutions in multi-objective optimization problems. Solution S1 is dominated by solution S2 when solution S2 is as good as solution S1 in terms of each of the objectives and strictly better than solution S1 in terms of one or more objectives. When no solution exists that dominates solution S, solution S is a Pareto optimal solution. Obtaining some (or all) Pareto optimal solutions and displaying their performance in the objective space is quite an important approach in comparing different alternatives.

For many services provided at facilities, it is desirable to have them as near as possible to demand. There are, however, types of services in which remoteness should be considered. Waste disposal sites are such examples. Although these facilities are indispensable, most communities would like to have them as remotely located as possible. These types of facilities are called undesirable facilities. Other examples are nuclear power plants, hazardous waste dumps, and landfills. One of the common goals of undesirable facility location problems is maximizing a function of distances between facilities and demand locations. As examples, the maxisum objective seeks the maximization of the demand-weighted distance and the maximin seeks the maximization of the minimum distance between facilities and demand points. Usually, these types of problems have other conflicting objectives, and thus multi-objective approaches are commonly used to deal with the problems. For the example of waste disposal sites, the cost of transporting waste to the facility should also be considered. This cost is usually small when the facility is located near the population center. Thus, this type of explicit tradeoff should be properly modeled.

In many situations, some facilities are already placed, and the problem is to introduce one or more new facilities given the locations of existing facilities. An example of such models requires finding a given number of facilities such that the demand-weighted distance is minimized with the locations of existing facilities fixed. In some situations, relocations of existing facilities are also treated together with the introduction of new facilities. While a relocation policy increases the degrees of freedom, the cost of relocation cannot be ignored. Thus, maximum utilization of available resources and flexible relocation decisions should be balanced. This decision-making situation arises when demands for service change over time. An example is elementary school locations. When population changes occur, relocation and integration of existing facilities and construction of new schools should be considered. A class of competitive location problems is another topic requiring consideration of existing facilities. A basic problem formulation is to capture as much share as possible given the existing facilities of competitors.

**Modeling, data collections, applications**

To build adequate location-allocation models and to solve application instances, there are a number of things to consider. The following discusses some of them.

Usually, the first step in building location models is to identify quantifiable objectives that adequately describe the planning situation under investigation. For example, when planning ambulance station locations within a city, one possible objective function is the minisum objective, which seeks to minimize the total (or average) response time. Another objective may be to minimize variation in service among demands, thereby focusing on equity among people. When equity is more important than global efficiency, the minimax objective may be
an appropriate choice. The primary purpose of ambulance services is to save lives. This may lead to another objective of maximizing the number of people who can survive due to earlier access to medical services. This may, in turn, mean employing a nonlinear survival rate (as a function of access time to a hospital) for the objective function. Multi-objective models considering the above objectives are also very important.

Choosing an appropriate objective function (or functions) for the problem at hand is much more important than obtaining good quality solutions to a selected objective. Approximate solutions of well-formulated problems may have much more value than optimal solutions of problems that ignore important factors. It is important to check whether the model being formulated adequately reflects the real situation under study.

Allocation rules are also very important in location-allocation models. The simplest rule is to assign each demand to the nearest facility. However, when the facilities are capacitated, this allocation rule cannot be applied, because some facilities may have to handle more demands than they can cope with. Because of this, some demands may be allocated to facilities other than the closest facility. In some situations, each demand should be served by a single facility. For example, a retail store should be supplied by a single warehouse to operate effectively. Other situations require more complex allocation rules. In retail situations, good accessibility to a shop is only one of several important factors for customers choosing a particular shop. Often, attractiveness of the shop, measured by, for example, the size of the shop and the number of items at the shop, plays an important role. In medical emergency services, availability of ambulances should also be considered. The nearest ambulance depot may be busy attending to other calls. For such types of facilities, the location of not only the nearest depot but also those of the k-nearest depots should be considered. Other situations may require simultaneous deployment of two or more types of facilities to provide service for demands.

Collection of demand data is a very important factor in location-allocation analysis. Population data is typically used to represent demand. It should be noted that daytime population and nighttime population may differ, especially in urban areas. Thus, these measures should be explicitly distinguished and properly used according to the purpose of the analysis. When both nighttime population and daytime population are important, a bi-objective problem using two different inputs for a single objective function may be appropriate. Also, demand for services strongly depends on such demographic characteristics as age and income. For instance, demand for ambulance services depends on the age distribution, and this information should be considered when demands for ambulance services are estimated. When relocation and restructuring of elementary schools is considered, demands for services should consider not only the present number of elementary school students but also its future trend. As another example, when locations of stores are considered, income groups should be properly examined to estimate demand for services; spatial patterns of demands for luxury cars and groceries are generally different because the frequency of using the two stores differs by income group.

When constructing demand data, data are not always available for each potential demand point. In addition, it may not be computationally feasible to incorporate such detailed data for large-scale problems. Thus, depending on the purpose of the analysis, a level of detail adequate to represent the population of each community should be used. Often, aggregated population
data can be used to reduce the size or number of zones included in the model. Since aggregated data is only an approximation of real demand, there is an inherent tradeoff between accurate representation and amount of data; these should be adequately balanced. The proper level of aggregation may differ among types of facilities. One example is the locations of department stores and convenience stores. Each department store usually attracts customers from a wider area than any one convenience store. For locational decisions about convenience stores, detailed local population data may be quite important, but deciding the location of a department store may not require the same level of detail.

Aggregation of demand generates different kinds of errors that should be considered. For example, distances between facilities and demands are generally different after aggregation. For example, the nearest facility location for a given demand point in the original data may be the second or third nearest facility in the aggregated data. To apply location models to real-world decision-making, the extent and types of possible errors should be estimated, and proposed solutions should be carefully checked for acceptability.

A selection of candidate locations of facilities is an important issue in location-allocation analysis. An optimal solution of location-allocation models cannot be directly applied if the location selected in the solution cannot accommodate a facility. This situation is especially relevant for planar location problems, where a facility is assumed to be located anywhere on a continuous two-dimensional plane. The space required for a facility greatly affects the feasibility of sites. Facilities such as automated external defibrillators do not require much space; in contrast, a department store needs a lot. Regulations on land use and surrounding environments (such as zoning rules and environmental regulations) should also be considered in deciding feasible sites for facilities.

The method of measuring distances and travel times between two arbitrary points within a city is an important issue in location-allocation analysis. Sometimes, distances are measured using mathematical formulations, such as Euclidean distance (the $l^2$-norm) or Manhattan distance (the $l^1$-norm). Shortest path distances over a network are also commonly used. Often, travel times are more appropriate than travel distances. Using real-world data, travel times can be estimated by regression analysis for distances between various points over a network. Some more sophisticated models treat congestion of road networks and time-dependent link lengths (i.e., travel times by time of day). Uncertainty of travel times is also an important element in location-allocation models.

**Outlook**

Nearly half a century has passed since modern location models and methods were proposed by Cooper, Hakimi, ReVelle, and others. During this period, basic location models were modified and extended in a variety of directions, reflecting diverse planning situations. Such models include flow capturing (interception) problems, hub location problems, dispersion problems, and location-routing problems, to name only a few. In addition, various types of heuristic algorithms and exact solution methods have been proposed. These developments allowed researchers to introduce more complex factors into models, such as incorporation of the temporal dimension, stochastic elements, and facility failures and reliability issues, and so on.

Recent developments in the creation of mathematical optimization solvers and geographical
LOCATION-ALLOCATION ANALYSIS

information systems provide a strong framework for conducting applied location-allocation analysis. For example, by using an integer programming framework, students, researchers, and practitioners have easier access to location modeling and analysis of solutions. Integer programming solvers can be used to solve moderate-sized problems with location models formulated as integer programming problems. This approach does not usually require special knowledge about optimization techniques and solution algorithms. Another important factor is that various types of geographical data, such as population data and land-use data, are available to the public and can be used for various applications. Location-allocation analysis will continue to be an active research area for diverse disciplines and contribute to support decision-making in a variety of public and private sector problems.

Location-allocation models

Tom Storme
Frank Witlox
Ghent University, Belgium

Location-allocation (LA) models have been important and widely used instruments for location decisions for over half a century. A location decision typically involves substantial capital investment and the positioning of a facility has considerable consequences, so the decision should be based on firm ground (Badri 1999). A first major advantage of LA models is that they deal with multifacility location decisions, instead of evaluating sites individually (Ghosh and McLafferty 1987). This allows areas that are over- and underserved to be identified. Moreover, they handle two sets of questions: they not only address the question of optimizing location from the perspective of the facilities alone, but also aim to optimize the supply of a given set of demand points. They do so by allocating each demand point to a potential facility location and by continuously evaluating the resulting model in terms of a predetermined objective function. The objective functions maximize efficiency in a particular way. In doing so, the models keep the central place logic of more traditional location models but reject “the adoption of any particular spatial pattern of activities” (Rushton 1988, 99). As a result, and if applied well, LA models offer a valuable contribution to locational decision-making. In addition, the models are not only helpful for supporting location decisions, but they also can evaluate the quality and efficiency of current location patterns and/or diagnose viable alternatives for decision-makers, when conditions change (Rushton, 1988).

Common distinctions between LA models

LA models are mostly applied when planning the provision of public services or the location of development aid facilities (Rushton 1984; Møller-Jensen and Kofie 2001). Numerous examples can be found in the literature where LA models are used for site selection of emergency services, police departments, schools, post offices, museums, health care organizations, and the like within a given area (Murray 2010). However, the models can also be applied for determining the optimal location of private sector companies. For example, Goodchild (1984) applied the model for retail site selection, while Min and Melachrinoudis (2001) used the model in the banking sector. In fact, the often used distinction between public and private ownership is of minor importance, because what matters are the characteristics of the decision-making processes (Bach 1980). Another common distinction between LA models is based on a priori knowledge of potential selection sites. When there are few constraints in terms of potential locations and little a priori knowledge, the model determines the optimal locations across the complete study area, in a continuous plane across space (Wen and Iwamura 2008). Such analyses are more suitable for theoretical or macro-level analyses (Yeh and Chow 1996). In a particular (urban) context and built environment, there often are only a discrete number of candidate sites available, be it
LOCATION-ALLOCATION MODELS

already existing locations or new, potential sites. The model then searches for the best location among a given and discrete number of candidate sites, which is the type of LA model most often applied by spatial planners (Teixeira and Antunes 2008).

Predetermined objective functions

The optimal location pattern of facilities in LA models is subject to the prioritization of objectives or, in other words, the specific problem that has to be tackled. Several objective functions can be calculated. Three such objective functions are given as examples here.

One of the earlier and most popular LA models in operational research is the p-median model (Fotheringham, Densham, and Curtis 1995; Rahman and Smith, 2000), where p sites are chosen from a number of candidate sites to minimize the total weighted travel distance or time between solution facilities and demand points. This specific objective function starts from the assumption that supplier facilities offer a demand at fewer sites than there are points of demand and, as such, those facilities are located somewhere central to the demand points (Bach 1980). Given a set of demand points and transportation costs (per unit of distance, for example), this optimal central location can be determined. The p-median model ensures that the overall impedance for consumers/recipients is at its lowest. Such an objective function is particularly suitable to decide the optimal location of public services facilities, such as museums, schools, or libraries.

A second objective function aims at maximizing spatial coverage, or allocating as many demand points as possible to potential facilities. In the case of determining the optimal location of emergency services (e.g., emergency response service centers or fire departments), it is recommended that this objective function is applied, because it is often determined that these services need to be offered to all demand points within a specific response period. Other applications include, for example, the determination of the optimal location of bike-sharing stations (García-Palomares, Gutiérrez, and Latorre 2012).

Especially suitable for private sector companies are objective functions that maximize profits or market shares. For example, the Belgian case study of Dejonghe (2004) showed that such models can be used for constructing a market-oriented football league with professional clubs that can survive over a longer period of time. In addition, certain LA models take the location and service levels of competing facilities into account to obtain this objective.

Real-world location decisions, especially in an international setting, are nonetheless often complicated and require a well-informed trade-off between objectives. More information on structuring complex problems has been discussed by Badri (1999), who proposes to use hierarchical decision-making processes.

Input data and data challenges

Decision-making processes benefit from large amounts of data, which serve as an input to the algorithms. The models typically include information on elements such as:

1 the location, sets of demand and characteristics of demand points or “consumers,” for example, capacity and willingness to travel, specific consumer behavior;
2 the location, sets of objectives and characteristics of a company or “producer” of services and amenities. Characteristics
include, for example, a supply capacity. Information about current facilities or competing facilities can be included as well; operational and transportation costs, for example, accessibility by road/rail/air/water, travel and congestion times, parking facilities; spatial characteristics, which can include the availability of adequate sites and physical barriers.

To cope with these various and large sets of data, algorithms are often encompassed and run in a geographic information system (GIS) environment, which allows a relatively rapid evaluation of various scenarios.

LA models are also associated with a number of challenges, which can lead to suboptimal location solutions and can seriously cast doubt on the usefulness of the outcomes. It is both a strength and a weakness of the models that they rely on large amounts of data. With respect to the weaknesses, sufficient data are sometimes not easily available (e.g., data on competing facilities or facility capacities) and/or inaccurate or uncertain, which can lead to a considerable number of assumptions being made (e.g., all consumers have similar consumption behavior) or quite complex models (e.g., when applying the models in stochastic or fuzzy environments). Moreover, the modifiable areal unit problem (MAUP) problem, whereby demand points are aggregated in “central” and zonal demand points (e.g., when using census data), can seriously affect the outcomes as well (Goodchild 1979; Fotheringham, Densham, and Curtis 1995). Badri (1999) also stressed the difficulties of adding qualitative criteria to the model, for example, the political situation of a country when solving transnational, multifacility location decisions. It is, therefore, often necessary to perform sufficient research on the demand for facilities to ensure an adequate outcome.

LOCATION-ALLOCATION MODELS

Location-based games

Ola Ahlqvist
Ohio State University, USA

Games and play are part of human life, and in many games space plays a central role in determining the rules and interactions that are characteristic of each game. Location-based games, however, is a relatively new term that emerged from the increasing use of mobile and geospatial technologies in games that are situated in the real world.

Notions of play and games intersect, and many languages, for example German and French, use the same word for play and game (Salen and Zimmerman 2004). As such, games and play are complex concepts and have proven to be hard to define, but many efforts to do so seem to converge on at least some key elements. In an effort to give a comprehensive definition of games, Salen and Zimmerman (2004) propose the following definition: “A game is a system in which players engage in an artificial conflict, defined by rules, that results in a quantifiable outcome.” Using this definition we can identify some key components of games. A game defined as a system means that there are parts (e.g., players, tokens, artifacts) and interactions between those parts. The system is then defined by the characteristics of those parts and the rules that govern how the parts can interact. The conflict or contest emerges from the system and a specification of how the outcome is quantified. As an example, the hide-and-seek game has a natural goal of finding all the participants who have tried to hide and the outcome then generates a conflict around how to best find and use the best locations for hiding. The quantified outcome can then be differently valued to determine, for example, if a player won or lost, or if no clear outcome is possible.

So far, this definition of games has avoided the idea of a game environment, that is, some type of framing or boundary of the game activity in both space and time. For a game like chess, the boundaries are defined by the game board of $8 \times 8$ squares and there are temporal limits, beginning with the start of the game and ending when one of the players wins or the game is tied. Traditionally, games take place either in the real world or in a represented world. Examples of the first category are tag, hide-and-seek, and football. Examples of represented games are chess, where the game board and pieces represent a generic battlefield and fighting troops, and Monopoly which in a similar fashion represents a generic city in which players, represented by tokens, move through and perform a variety of socioeconomic interactions.

Many popular games that are framed by a represented world include some form of a map. Historically, they go back several thousand years and often draw inspiration from war scenarios where players assume some role of an army leader with the goal of engaging in war-like interactions with the opponent in order to win the game. Only as late as the mid-nineteenth century did these map-based games take inspiration from and serve other purposes than warfare and conflict. Educational games and games drawing from current and noteworthy events started to permeate society and a variety of new games have continued to be produced to this day.
LOCATION-BASED GAMES

During the first half of the twentieth century, the industrial-military complex and the introduction of computers developed the foundations for what we know today as location-based games. With the advent of computer technology, many represented games could be translated into computer-based versions of existing real-world or represented games. Computers also allowed for entirely new games to be developed. Based on ideas from military simulations, other forms of simulated environments started to form the foundation for games like Space Invaders, and Pong.

Continued developments in computing and visualization technology allowed for increasingly sophisticated, realistic, and detailed renderings of various game worlds. Game developers continued to situate games in generic or artificial worlds, but as geographic information systems technologies have evolved and geographic data have become increasingly available, computer games have started to incorporate representations of real environments.

Still, games were traditionally either played in the real, physical world, or in a represented, sometimes digital and virtual reality. Only very recently have experimental computer games started to truly blend aspects of reality into a digital game system. However, the idea of combining the real and the represented and fictional is not new and some have argued that it dates back as far as *The Games at Abydos*, as described by Greek historian Herodotus (Ericsson 2004). While that example would probably be referred to as a live-action role-playing game today, contemporary media is increasingly blurring the boundary between fact and fiction, from Orson Welles’s *War of the Worlds* to current TV reality shows (Stenros, Montola, and Mäyrä 2007).

Recent developments and widespread access to mobile information, communication, and geospatial technologies have spurred a flurry of changes, including many variations of games that exploit these technical affordances. Because of their relatively recent nature, with first examples appearing around 2004–2005, there are many suggested terms for these games: pervasive games, ubiquitous games, augmented-, alternate-, and mixed-reality games, mobile games, geogames, and adatrionic games are just a few of the concepts proposed. Among them, location-based games were originally described as games that somehow involved a player’s relative or absolute location in the game play. Like many of the other terms listed above, the label draws from its enabling technology, location-based services for mobile devices.

Walther (2005) held location-based games to be a subgenre of the more overarching concept of pervasive games, which has been described as games that expand the spatial, temporal, and social boundaries of traditional games (Montola 2005; Stenros, Montola, and Mäyrä 2007), and these games are part of a gaming culture that “exist[s] in the intersection of phenomena such as city culture, mobile technology, network communication, reality fiction, and performing arts, combining bits and pieces from various contexts to produce new play experiences” (Montola, Stenros, and Waern 2009, 7).

Two early examples of location-based games are BotFighters and Pac-Manhattan. Players in Pac-Manhattan actually dress up as the yellow Pac-Man and the colored ghosts, run around the street grid of New York City, and while Pac-Man tries to collect virtual “dots” along the streets, the ghosts try to catch Pac-Man before all of the dots are collected. The game uses cell-phone communication, location-based services, and software to track players and broadcast their progress over the Internet for viewers from around the world (http://www.pacmanhattan.com/).
The BotFighters game also uses a portion of the real world as the game environment and mobile phones as a key communication device for game interaction and control. Players assume the role of robots that try to kill each other using text messages to find other robots, engage in battle using a variety of “weapons,” and receive messages about game progress. Integral to the game is the importance of location and relative distance between players to determine the outcome of battles.

Largely driven by continued developments in mobile, location-aware, information, and communication technologies, these and other games are increasingly blurring the boundaries between the game world and the real world. Because of this, it is often hard to draw a line between when a game is location-based and when it is not. Most observers would not consider a regular chess game as location-based, although spatial locations on the chess board are key to the game mechanics. Not even if we turn the board game version of chess into a large-scale, outdoor chess game would we think of it as location-based. Similarly, the game Pac-Man, in its most well-known form on a screen, would not be considered location-based until it is moved into the Pac-Manhattan context described above.

Despite a growing interest from academics to define the various pervasive game genres, including location-based games, they are elusive concepts that are constantly changing, and therefore hard to pin down with any one definition. So far the term has come to bear because of the need to label the types of games that are technically enabled by location aware devices, mobile technology, and information and communications technology in general. But this means that the definition would have to constantly change with changing technology. Better, then, is to characterize and identify location-based games using a set of key dimensions.

- **Location**: the degree to which the location of game entities, such as players, avatars, tokens, or other game objects determine the game system dynamics. Clearly, the location dimension is the first and foremost dimension to be satisfied for any game to be considered location-based. A location-based game, then, should be highly determined by spatial factors such as absolute location, distance, and connectivity. But this criterion alone would most likely include regular board games like chess in the category, and a few other dimensions are generally considered central to the broader category of pervasive games.

- **Spatial expansion**: the degree to which a game expands the game environment to larger spaces than a game board, a room, or a soccer field. Scale itself is not enough to be a determining factor but it helps to describe the spatiotemporal scope of a location-based game, and neighborhood-sized environments are common in existing examples. Another captivating aspect of spatial expansion is the ability to play a game anywhere and everywhere, even when that can introduce uncertainty about where the game space actually begins and ends.

- **Temporal expansion**: as with spatial expansion, location-based games often take on a less determined temporal scope and a common aspect of location-based games is their omnitemporal character; they continue even when you sleep or go to work.

- **Representation**: the way that the game represents (most often digitally) real space and time in an abstract information environment. This could take the form of a map of the neighborhood where the game is played such that
it allows for an overview of the game play. Represented game space and time can also be augmented, scaled, and warped to allow for the addition of virtual game items, and to show particular views, sequencing, jumps, and loops to support particular game rules and dynamics.

- **Pervasiveness**: the degree to which the game allows participants to move between real and represented environments. Wearable computers, head-mounted displays, sensor networks, and other pervasive computing technologies can allow the game to mix in with the real world such that the boundary between what is part of the game and what is not is blurred.

*Rupprecht-Karls-Universität, Germany*

In 2010, a speaker at the Mobile World Congress emphasized that mobile smartphones were the “iconic” device of the moment, acting as an extension of yourself, aware of your location and displacements, and that will have an important impact on daily activities and life in general. Whether through smartphones or through the potentially more embedded devices of the future (which we may have difficulty visualizing today), location-based services (LBS), which are defined as wireless IP (Internet Protocol)-based services for mobile users that rely on geographic data, have definitely entered our reality. According to a recent survey conducted by the US-based Pew Research Internet Project, 74% of adult smartphone users said that they commonly use their phone to obtain information based on their location. Besides basic, well-known services such as discovering nearby restaurants or the whereabouts of a friend, LBS are quickly evolving toward more complex applications. The evolution of LBS is propelled by a unique characteristic: while LBS consume information to deliver it to their users, they also generate volumes of data. This self-contributing pattern today is mainly impeded by a lack of appropriate techniques and technologies to extract relevant information and knowledge from the data being generated, but it is only a matter of time before this issue will be addressed. As will be demonstrated in this entry, the research community from various disciplines, ranging from computer science, cognitive sciences, and law, to economics, geographic information systems (GIS), and sociology, is actively exploring the potential of LBS and the opportunities to improve it. In the meantime, other emerging paradigms such as so-called big data and the Internet of Things will converge with LBS to further stimulate their development. This entry reviews the historical development of LBS through an explanation of its initial enabling technologies, and provides an overview of the categories of existing LBS applications. Then, it analyzes the main impacts of LBS that have been discussed in the literature, whether at the economic or the social level. The current and future challenges related to the evolution of LBS are also discussed.

Historical development of LBS

A decade ago, official and commercial data producers and mapping agencies were virtually the only geospatial data producers. In addition, official and commercial data was available to experts, such as urban planning officials, but, in practice, not to “ordinary” citizens due to its high cost. In other words, geospatial data was data produced by experts for experts. Traditionally, the official or commercially produced data has been aggregated according to
LOCATION-BASED SERVICES

Figure 1  LBS-enabling technologies.

administrative units, which can be quite large (e.g., district-level). This constraint limits the possibility to conduct analysis and make decisions at a finer level of spatial precision. Moreover, traditional data update processes are lengthy, limiting access to up-to-date and real-time, or near-real-time, data.

Technological advances have changed the way in which data is being produced today, and have enabled the emergence, and ubiquity, of LBS. In the introduction to the 2013 review Progress in Location-Based Services, Gartner wrote that the first stage of LBS development was mainly driven by technology, as opposed to social, economic, or other considerations.

The technologies that have enabled the advent of LBS are illustrated in Figure 1. On the one hand, the core technologies underlying LBS include positioning techniques and technologies; broadband Internet access and web technologies that enable the sharing of location-based data; and mobile and web GIS. On the other hand, propelling technologies contribute to making LBS relevant and reliable: namely, the technologies, techniques, and paradigms that support the generation of publicly available location-based data; the increasing processing capacity that supports dealing with volumes of location-based data consumed and produced by LBS; the development of context awareness; and the standardization of LBS interfaces. Some of these enabling technologies are discussed in further detail below.

Positioning techniques and technologies

The evolution and availability of positioning technologies have played a major role in enabling
LBS. Various positioning techniques have been developed, with different costs and deployment scenarios:

**Global Positioning System (GPS).** GPS is a satellite-based localization system and probably the most well-known positioning technology. The majority of mobile devices are equipped with GPS chips that enable their position to be determined with relative accuracy. The uncertainty can be as little as 10 m or less (US Federal Communications Commission 2012). GPS can calculate the location of the device independently; the calculation is performed offline, which is an advantage when the connectivity of the device is limited or when privacy needs to be ensured for certain applications that are handling confidential information. However, a line of sight to at least four satellites is needed to calculate the device’s position. Therefore, it is unreliable in so-called “urban canyons,” as well as inside buildings. As a result, it is often used in conjunction with other positioning technologies.

**Network-based localization.** Wi-Fi technologies in mobile devices scan the surrounding area to find Wi-Fi networks, which include a wide variety of stations such as residential and business networks. The mobile device retrieves the coordinates of the Wi-Fi networks it found, and these coordinates are used to triangulate its current position. In contrast to the GPS system, network-based localization is generally conducted on a remote server operated by a third entity: for example, the Android localization system relies on Google’s Wi-Fi database, while iOS devices rely on Apple’s servers to compute coordinates based on incoming Wi-Fi signals. One main advantage of this technique is that it does not require building a costly infrastructure for the purpose of positioning itself, since it relies on existing networks.

**Cellular Sector/Base ID.** Cellular devices are constantly registering their presence with the nearest base station. The network operator has the exact location of each base station, so the cellular device’s location is computed through triangulation. The radius covered can vary by a significant amount, depending on the density of cells. For example, the coverage of a cell may vary from approximately 10 km to 30 km, depending on the urban density of the area. One of the drawbacks of this method is that since some networks for cellular devices have a quite wide coverage, the positioning may lack accuracy by a significant amount (e.g., more than the coverage of a cell).

**Other indirect positioning techniques.** Also worth mentioning are techniques to indirectly position a device through its user’s action. For example, check-in is an indirect way to determine one’s location and it is mostly used by applications that allow users to share their location with other users on the web. For a given place where the user has checked in (e.g., a restaurant), inverse geocoding can be used to retrieve the coordinates of the user at this time. Position can also be determined when a user scans a Near Field Communication (NFC) tag or a QR (Quick Response) code for which the location is known.

In addition, there are a number of hybrid techniques that combine two or more existing techniques, such as the Assisted Global Positioning System (A-GPS) technique, which refines GPS positioning with Cellular Sector/Base ID. While positioning techniques have reached a relatively satisfying level of spatial accuracy for most outdoor applications, today’s challenges with respect to positioning relate to indoor localization.
Concerning the mathematical models used for calculating a position, the most common ones are the following:

**Lateration:** the position of a point $A$ is calculated based on its distance to at least three other different points. The distance is usually calculated using signal runtime difference or received signal strength (RSS). The technique is also referred to as trilateration or multilateration, depending on the number of positions used.

**Triangulation:** the position of a point $A$ is calculated based on the angles $\alpha$ and $\beta$ between the segment that connects two points $B$ and $C$ and the segment that connects $A$ to $B$ and $A$ to $C$, respectively.

**Centroid localization:** the position of a point $A$ is calculated based on the location of origin of signals received by a mobile device. It is assumed that these locations are known. The position of $A$ corresponds to the centroid of a polygon formed with the origin of signals.

### Generation of publicly available location-based data

The other category of technologies that has enabled the advent of LBS is technologies that allow the collection of various types of data in a user’s surroundings, which can be called “location-based data.” Positioning technologies themselves are major tools in enabling the collection of such information. As today’s smartphones are equipped with positioning technologies, they allow so-called citizens-as-sensors, a term coined by Goodchild in 2007, to “sense” data about their environment and share it through collaborative web platforms or online social networks, generating huge volumes of data. Social network sites have been playing a significant role in the indirect generation of volumes of data, since they attract billions of users throughout the world. For instance, Facebook — probably the most well-known social network site — had more than 1.5 billion users in 2015. While social network sites are basically meant to support online social activities, due to their ability to localize users, the content generated through these sites is increasingly enriched with geolocated information. Also, location-based capacities of social network sites have been gradually improved to take advantage of this new trend, in addition to making some of this data available through Application Programming Interfaces (APIs). This has resulted in the labeling of these sites as geosocial or location-based social network (LBSN) sites (Roick and Heuser 2013). Examples of LBSN include Facebook Places, where users can visualize a list of nearby places and other points of interest (POIs) and can share their location with friends through check-ins, or Foursquare, where users are encouraged, through rewards, to check in frequently at the same place.

Emerging geosensor networks, which are increasingly accessible and cheaper to produce thanks to the miniaturization of sensing components and data storage, are also another major contributor of location-based data. In addition, data generated through geosensor networks are increasingly available online, especially due to the development of the concept of Sensor Web (Liang, Croitoru, and Tao 2005). The Sensor Web Enablement (SWE) initiative of the Open Geospatial Consortium (OGC) has contributed significantly to the online availability of sensor data through the development of interface and specification standards, such as the Observations and Measurements (O&M) data model and the Sensor Observation Service (SOS), to access sensor data through standardized protocols. Examples of Sensor Web platforms implementing SWE standards include the 52° North platform, mostly known in Europe, and the
GeoCENS platform, mostly known in North America. Such platforms can be leveraged to collect data on an LBS user’s environment, although concrete projects and experiments in this direction are still at an early stage due to limited ability to process and exploit real-time data streams, and to merge several semantically heterogeneous data streams.

Open data policies adopted by several governments, often put in place to foster economic opportunities, have also contributed to make official location-based data available to the public for location-aware services. While geospatial data have traditionally remained in the hands of experts (like governments and mapping agencies), paradigms such as open data, social media, and collaborative mapping projects make it possible for an increasing proportion of these data to be virtually available to anyone who has Internet access, with the potential to benefit businesses, civil society, and individuals in general (Bakillah et al. 2014a).

Context awareness

Context-aware applications take into account the physical environment or situation, and react proactively based on such knowledge. Research on context-aware applications started in the 1990s. Interestingly, several early context-aware systems were indoor services; in contrast, current LBS applications and associated context-aware services are mostly outdoor services, with a re-emerging trend to develop indoor services.

Context awareness technologies has played an important role in making LBS more intelligent and user-oriented (Anagnostopoulos, Tsounis, and Hadjiefthymiades 2004; Bakillah et al. 2014b). The notion of context as a component of ubiquitous and mobile computing has been studied for more than a decade, with some of the most prominent work being Dey’s (2001). Context is not an objective and comprehensive representation of reality, but rather an abstraction for which the degree of accuracy varies, and which may focus on different aspects of reality, depending on factors that include the users’ intentions and the perception of the real world. While Dey describes the context as “anything that can be used to characterize the situation of an entity,” there is no agreement on the definition of context, and a significant number of more specific definitions have been provided in relation to context awareness that depend on the application at hand. The elements that compose context can generally include the location of the user, his or her preferences, his or her neighbors in a social network, the most recent places visited and events that he or she attended, websites that he/she visited, and so on.

For the purpose of LBS, context can be acquired using two different approaches: explicitly, whereby the user manually specifies the context-related information, or implicitly, whereby technologies such as sensors are used to gather contextual information.

Standardization

Achieving the interoperability of LBS with various types of mobile devices and web services is critical for the potential of LBS to be fully exploited. Therefore, standardization has contributed and is likely to continue contributing to the development of LBS, even if existing standards are not necessarily widely adopted yet. More particularly, the OGC’s Open Location Services (OpenLS) initiative has been developing open specifications for LBS. The current official version 1.2 is dated 9 September 2008. The OpenLS core services are embedded in a service layer called the Geo Mobility Server (GMS), the role of which is to broker between the physical network and the service providers. LBS
LOCATION-BASED SERVICES

applications can be implemented either directly into the GMS or at the service providers. The OpenLS specification includes various interfaces that enable service providers to leverage existing services for their specific application. The interfaces, as described by the OGC specification, are the following.

- **Directory Service**: provides clients with access to a web directory that enables them to find a place, product, or service, often within a certain radius.
- **Gateway Service**: acts as an interface between the GMS and the Gateway Mobile Location Center (GMLC) or Mobile Positioning Center (MPC), which provides the position of the device.
- **Location Utility Service (Geocode/Reverse Geocode)**: when provided with a place name, street address, or postal code, this service returns geographic coordinates (geocoding). It also performs the inverse conversion (reverse geocoding).
- **Presentation Service**: this service enables the mobile terminal to display geographic information, such as the map of a selected area with selected data layers.
- **Route Service**: this determines a route between a starting point and a destination point. A navigation application is required to use this service.

The OpenLS standard specifications have been increasingly adopted in recent years, due in part to the efforts that were made to align them with other existing OGC standards. Still, more effort is required to increase their dissemination.

Categories of LBS applications

Today’s range of LBS applications is very diverse. The speed of innovation and market penetration has notably increased with the convergence of mobile communication, mobile Internet, Web 2.0 technologies, and new mobile devices such as smartphones, in addition to being driven by economic opportunities.

A categorization of LBS applications can help to visualize the spectrum of available services, but also services that are yet to come. Here, a categorization that is based on the applications’ purpose is offered (Figure 2).

![Categories of LBS applications](Image)
• *Monitoring and tracking applications* enable objects to be located in real time, often for business and management purposes, such as fleet management or parcel location. Applications also include systems that enable people, such as children and the elderly, to be tracked for safety purposes.

• *Entertainment applications* include location-based games such as real-life scavenger hunts.

• *Social networking applications*’ main purpose is to connect people online and enable them to share interests and location-related information, among others. Examples include applications where users can share places of interest through “checks-in,” such as Foursquare and Facebook Places. Social network sites that enable location-based information to be shared are also called “Location-Based Social Networks” (LBSN), and are reviewed in Roick and Heuser (2013). In their paper on the convergence of GIS and social media, Sui and Goodchild (2011) state that LBNS include check-in sites, social review sites, and social scheduling/events sites. LBNS are an important source of crowdsourced location-based data that could benefit a large variety of LBS.

• *Business applications* are meant to support and improve business processes and provide services such as targeted advertising based on a user’s location (e.g., PayPal Media Network, SkyHook, and go2 Media).

• *Information applications* are meant to deliver news and information that take into account the users’ location, and are often provided by traditional news services (e.g., The Weather Channel).

• *Traveling services* mainly include routing, navigation, and wayfinding services. Traditionally, the digitization of existing streets required to support routing and navigation services was performed by commercial services (such as Nokia’s HERE, formerly Navteq, and TomTom, formerly TeleAtlas). Later, with the emergence of Volunteered Geographic Information (VGI) platforms such as the OpenStreetMap (OSM) project, open and free routing services were developed. For example, the OpenRouteService.org uses OSM as a source of data. Also, initially available as car devices, an increasing number of applications are being developed for multiple transportation modes and pedestrians, as well as particular groups such as people with limited mobility (e.g., Rollstuhlrouting.de).

An analysis of the categories of LBS applications shows that at the moment, most of them offer services to individuals, but few support collaborative tasks that go beyond the activity of sharing data with no further commitment. In addition, most of them are based on a limited dataset and lack the capacity to use heterogeneous data that come from a variety of sources.

### Social and economic impacts of LBS

LBS have the potential to enhance people’s ability to make their environment more interactive and customized, their workplace more efficient, and their surroundings searchable, in addition to creating new economic opportunities. Still, LBS can also exacerbate social and environmental problems in an already crowded, polluted, and urbanized environment.

#### Economic impacts

Various sources emphasize that LBS have significant potential for economic growth. For example, Resch (2013) reported that in 2010,
the potential for economic opportunities generated by LBS was estimated to be US$20 billion. According to a 2012 report by the US Federal Communications Commission’s Wireless Telecommunications Bureau, revenues generated by LBS are expected to triple between 2012 and 2017. A review of location-aware applications from the iPhone, Blackberry, and Android Application Stores indicates that in July 2009, about 3300 LBS were offered, and that this number went up to about 7200 in February 2010 (Skyhook Wireless 2010). At the end of 2015 Foursquare’s website indicated that it had over 50 million users across the world and 8 billion check-ins, with several million new ones every day, and that more than 65 million companies were registered with them (https://fr.foursquare.com/about). With such numbers, it is likely that the LBS markets and opportunities will continue to grow in size and diversity.

Social impacts

As LBS are a relatively new technology that became available to the public only in the last decade, studies on their social impact, supported by experiments, for example, on analysis of social interactions through LBSN and analysis of human behavior in space and time as captured by LBS, are only starting to emerge. The main areas of concern relate to the impact of LBS on individual and collective behavior, privacy issues, and the threat or benefits associated with remote surveillance of people.

Regarding the impact of LBS on human behavior, in 2002, in *Smart Mobs: The Next Social Revolution*, Howard Rheingold predicted that mobile communication and instant access could result in disruptive social effects in various areas of life, ranging from political activism to intimate relationships and corporate management (Rheingold 2002). However, other authors, such as Miller, suggest that social media’s capacity to support many-to-many communication instead of the traditional one-to-one (through written correspondence, telephony) and one-to-many (through broadcasts and webpages) modes is also likely to foster collaborative behavior through the formation of groups (Miller 2013). This contrasts with the traditional social organization paradigm, where top-down, hierarchical organizations are created to support the achievement of a common, complex objective. As a result, scientists think that social media are likely to enable a new way of achieving complex objectives through technology-supported cooperation (Shirky 2008; Miller 2013). Still, it is not obvious that technologies such as social media and LBS will be sufficient to foster collaborative behavior. Several current problems are caused by behaviors that aim at optimizing an individual’s benefit but that, when adopted by a majority, lead to outcomes that are not beneficial for the society as a whole. Transportation is a common example of this type of problem: individuals use the shortest path from a starting point to a destination, as computed and recommended by some routing or navigation service. However, the large number of people relying on the same recommendation generates further congestion and pollution, which is the opposite of the expected result. LBS can contribute to this problem, unless LBS applications that take into account collective behaviors and outcomes are promoted and adopted by a majority. With regard to this concern, some LBS applications that aim to improve public transportation may be instrumental in achieving this goal – for example, the WaitLess bus tracking device, which allows users to locate buses. Other applications also reward users for environment-friendly behavior, like the TrafficPulse application (GeoSensor 2012). The TrafficPulse application provides subscribers with real-time updates on traffic conditions.
The application relies on GPS traces provided by volunteer smartphone users. Citizens are encouraged to provide updates through a reward system that emphasizes their contribution to reducing traffic. However, apart from such rare examples, as of today, most LBS applications are intended to benefit individuals first and foremost.

With regard to privacy and the remote surveillance of people, the tracking capacity of LBS obviously generates concerns regarding its potential use for monitoring individuals, as emphasized by Michael and Michael (2011). Some existing tracking services seem beneficial to their users, such as child safety location services that enable parents to track their children, or remote health monitoring services. LBS applications can also be used to make sure that people comply with certain rules; for example, employers can use them to supervise the displacement of their staff and verify if they have been engaged in work or in unpermitted activities. Even more controversial is the GPS Spouse Tracking service to check that partners are not being cheated on. Other emerging applications include vehicle monitoring devices in cars to assess how people are driving, which are used by insurance companies to evaluate risks and adjust prices accordingly. Authors argue that data gathered through LBS applications can be used to conduct profiling, since they can uncover a large spectrum of user patterns and behaviors. Concerns about the ability to track people through LBS are also exacerbated by the upcoming convergence between LBS and biometric recognition systems (remote iris scanners, facial recognition technologies, fingerprinting, etc.) (Michael and Michael 2011). Privacy concerns are therefore of utmost importance for the future development of LBS.

The disclosure of geographic information about individuals on the web can be a threat to personal privacy. A person’s location can be revealed in a variety of manners: someone can intentionally share their location with “friends” in the context of social networking activities, while an individual’s location can also be disclosed on the web by another user (Roick and Heuser 2013). The fact that users lose control of the information they share online, whether it relates to their location or their absence from a particular place, their identity, or their relationship with other users, is often itself considered a privacy threat.

Roick and Heuser (2013) report that users of location-based social networks experience difficulties in setting their privacy preservation rules. Researchers have attempted to address this issue, for example by developing systems that enable users to change their personal privacy settings when a location request is received (Xu et al. 2012). However, such a system is not yet common. Other strategies that were developed to protect privacy include cloaking algorithms, which generalize an individual’s current location (e.g., at a city level) or delay the publication of the individual’s location, and encryption protocols to prevent individuals and service providers from accessing geographic information on the user, as explained by Jonker, Mauw, and Pang (2012) in “Location-Based Services: Privacy, Security and Assurance.”

Current and future LBS-related research challenges

Developing LBS still poses several challenges to the research community in general and to the GIScience community in particular. The research challenges related to LBS include technological challenges for improving LBS themselves (core technologies), such as the need to develop better indoor positioning techniques, and research challenges related to the development of other
technologies that have an impact on LBS, such as big data and the Internet of Things.

Enabling indoor LBS

Indoor LBS is a relatively new trend, although it can be traced back to the early 1990s. Their relevance can be fully appreciated if we consider that, as reported by Li and Rizos (2014), human beings spend on average 90% of their time indoors, sometimes in complex environments like airports, large office buildings, huge shopping malls, university campuses, and so on. In addition, because they lose track of outdoor environmental markers, people lose orientation more quickly within buildings than in outdoor environments. As a result, at the moment, the most discussed applications of indoor LBS are routing, navigation, and wayfinding services, as Huang and Gartner (2010) reported in their survey of mobile indoor navigation systems. Indoor LBS are also needed for some groups of individuals, such as people with limited mobility, who must be able to find their way in indoor environments that are not always accessible (due to lack of access ramps, elevators, etc.). Providing indoor LBS requires very accurate positioning techniques, as the potential applications often have to detect in which room a user is located, for example.

While the accuracy of the GPS can reach approximately 4 m, which is suitable for the majority of applications, the GPS has major drawbacks for indoor positioning. The radio waves that are transmitted by satellites to mobile devices are mostly blocked by walls and roofs of buildings. As a result, other positioning techniques are required to enable indoor LBS. In their introduction to a 2014 special issue on indoor positioning and navigation published by the Journal of Location Based Services, Li and Rizos (2014) indicate that indoor positioning technologies can be classified into three categories:

- **Technologies based on pre-deployed signal transmission infrastructure**: the most common examples of such technologies include infrared signals, ultrasonic signals, and other radio frequency-based systems. Of note is that the first indoor positioning system was in this category: in 1992, Want and associates created the “active badge location system,” which used infrared emitters and receivers installed within a building to determine the position of people, who had to carry infrared emitting badges. A direct line of sight was required for the system to function, which is true for more recent infrared systems as well. Of note as well is that the latter system was able to achieve a 16-cm accuracy, but only within an area of 100 m². More recent technologies also include Bluetooth, which can be used to determine in which room a device is located and can achieve an accuracy of 98% for this task. The major drawback of this approach, however, is that the mobile device must not move for 3 minutes. This is hardly suitable for most of today’s contexts. Overall, while such a system can achieve good accuracy, systems that are based on a local infrastructure are costly to deploy over large areas.

- **Technologies based on signals of opportunity**: these systems exploit radio frequency signals and infrastructures that are not necessarily dedicated to positioning. Examples of such signals include Wi-Fi and mobile telephony signals. Wi-Fi in particular is seen as an interesting indoor positioning avenue as its wide use has turned it into a common standard today. For example, indoor positioning techniques based on WiFiLoc, which relies on the signal distribution of the widely used Institute of Electrical and Electronics Engineers (IEEE) 802.11 Wi-Fi networks, were developed. Such a system
has the capacity to position devices within rooms of a building. Still, for some indoor applications, such as navigation services for people with limited mobility, a higher level of accuracy is required. As another example, Laoudias, Piché, and Panayiotou (2013) state that Received Signal Strength (RSS) fingerprinting with wireless local area network (WLAN) is an interesting alternative for indoor positioning because WLAN access points are widely available and WLAN-enabled mobile devices can easily monitor RSS measurements. Fingerprinting is a technique where a reference device is employed to generate a radiomap within a given area; one drawback of this technique is that the positioning accuracy can be affected if the user has a different type of device than the one that was used for generating the radiomap (Laoudias, Piché, and Panayiotou 2013). Ongoing research aims at improving the accuracy of fingerprinting through calibration methods.

- **Technologies not based on signals**: these technologies are independent of any infrastructure and use embarked sensors to locate a device. Common approaches are based on inertial sensors, such as accelerometers and gyroscopes that measure changes in distance and speed, or camera systems. An active area of research is based on the improvement of the Inertial Navigation System (INS), which is continually adding changes detected by embarked sensors to the previously calculated position. The main drawbacks of this technique include many sources of errors, such as the fact that the accuracy of the computed position depends on that of the initial position and direction; the noisiness of accelerometer measurements; the angular deviation over the traveled distance (known as the Abbe error); and the uncertainty of the step length. Among the solutions proposed to improve accuracy, “map matching” is currently an active area of research. The idea of this technique is to compare the measured movement trajectory of the monitored device with the geometrical constraints indicated on an (indoor) map. An example of a recent approach within this area is the work of Kaiser, Khider, and Robertson (2013). Another technology in this category of positioning technique gave birth to so-called vision-based localization and navigation systems, where the comparison of images captured by an embarked camera with a pre-existing collection of images or maps enables the device carrying the camera to be located. A recent example of such an approach is given in Li and Wang (2014). As one can expect, this technique is computationally demanding.

In addition, a certain number of hybrid approaches exist that combine technologies from these different categories. Hybrid approaches are employed since, currently, there is no overall standalone solution to indoor positioning that would balance cost, coverage, and accuracy in a satisfying manner.

Another challenge related to the development of indoor LBS is the lack of solutions for indoor mapping. In particular, floor plans are usually not made available for open applications. The solutions being explored include the generation of indoor maps through the reconstitution of trajectories within buildings.

**Extracting implicit location-based information and knowledge**

As the huge volumes of data produced through mobile devices and disseminated through the web is an emerging, relatively recent phenomenon, research on how these data could be
exploited and used to improve LBS is still at an early stage. Nevertheless, LBS will become increasingly relevant to a large spectrum of activities when mature technologies to extract knowledge from data become available.

Nowadays, the research on extraction of implicit information focuses on the geolocation of features. Such techniques are needed since an explicit geographic reference is not always available for all features. For example, a message posted on a social media platform, such as a review about a specific venue or event, may not be associated with actual coordinates or a nameplace that can be automatically interpreted and processed. This limits the ability of location-aware services to use this information. Techniques that are currently being investigated to identify the geolocation of features include various text analysis and processing techniques, such as Named Entity Recognition, which enables the identification of a city, street names, or names of buildings within a text, such as in Twitter messages. It is worth noting that more research is needed in this area, as studies have generally resulted in low accuracy.

Besides text messages, keywords associated with photographs (for example, in Flickr) can also be used to extract location names, including colloquial names of geographical areas. Another related technique is to model the probability that a group of tags is associated with a location. Social media feeds can also be gathered and analyzed in order to locate social hotspots or to map social networks in a given geographical area.

The geolocation of users whose position is not made available is another active research field. For this purpose, researchers have employed similar techniques to those being used for geolocating features in general, such as using probabilistic methods applied on social media postings. Still, in this experiment, only 50% of users were located accurately. “Friends” in social networks like Facebook can also be relied upon to determine the location of users.

Besides geolocation, other efforts are being made to extract various types of location-based information from data, which we can refer to as “situational information.” Most of these efforts focus on geosocial networks. For example, situational information can be extracted from social media postings to coordinate responses to emergencies, while tourists’ preferences can be uncovered from pictures they have posted on social media, using data mining techniques. Experiments to extract the structure of geolocated events and patterns of real-world activity were also conducted with microblogging sites like Twitter. A well-known example of recent research is the use of social media to monitor natural disasters, where algorithms have been developed to calculate earthquakes’ epicenters and typhoons’ trajectories based on Twitter data. Twitter was also used to monitor the occurrence of particular diseases at a given location and detect the location of outbreaks, or predict the time and place of outbreaks. Landmarks and events can also be inferred from geotagged photo collections. Spatiotemporal analysis of check-in data can also reveal information on categories of POIs, based on a certain number of assumptions, such as the time of day when the number of visitors at a given type of venue is likely to be higher. Of note is that several of these approaches rely on domain-specific assumptions, and therefore are not readily applicable to other problems. In addition, they are mostly based on a single source of data, and do not tackle the problem of merging data from several sources.

Basically, due to these current limitations, most LBS applications use simple data of one type at a time – for example, finding POIs of a certain category within a given distance from the user – but the capacity to rapidly merge heterogeneous data from multiple sources in
order to generate value-added knowledge is still very limited, despite considerable research work, since current data conflation approaches include several steps that have to be performed and validated manually.

**LBS and “big data”**

Recent technological advances in data production and dissemination have enabled the generation of unprecedented volumes of geospatial data, giving rise to the concept of “big data.” In 2012, it was reported in *The Age of Big Data* that the global volume of data was growing at a rate of 50% per year (Lohr 2012), due to the increasing dissemination of digital sensors, smartphones, GPS-enabled devices, crowdsourcing applications, and social media, among others. VGI, that is, geographic information produced by volunteer contributors (Goodchild 2007), also contributes to big data, and is often produced through LBS.

“Big data” is a loosely used term that refers to either the huge volume of data itself, which no longer fits traditional database structures, or, perhaps less frequently, to the set of techniques that are being developed to deal with such volumes of data.

As for many applications, big data both raise challenges and open up new opportunities. Indeed, the possibility of exploiting massive datasets raises new opportunities to improve LBS with even more data on users’ environments. While traditional data storage and management approaches are not suitable for dealing with big data, the range of techniques and technologies dedicated to big data is already wide.

Meanwhile, storage technologies are reported to have significantly improved, and storage issues have largely been addressed through cloud-based platforms. Rather, major difficulties are related to the extraction of relevant information from massive datasets. Traditional data mining algorithms, such as spatial clustering techniques or classification algorithms, are inefficient when dealing with massive datasets. As a result, as reported by Russom (2011), ongoing research is being conducted to improve existing knowledge extraction techniques, such as Structured Query Language (SQL) queries, data mining, statistical analysis, clustering, natural language processing, text analytics, and artificial intelligence, so that they can deal with massive datasets. These analytic techniques, among others, could be deployed to improve social media analysis, change detection algorithms for high-resolution images, and improve complex object recognition, which would all help to enrich LBS. In particular, the ability to deal with massive datasets is supported by underlying technologies such as Google’s MapReduce, a programming model that supports the development of scalable parallel applications for big data. MapReduce is based on a distributed file system where data is represented according to key-value pairs. It is then partitioned in several machines before being processed. An increasingly popular open source implementation of MapReduce is Hadoop, which is now considered by some as the de facto standard in industry and academia. MapReduce can enable data mining algorithms such as clustering, frequent pattern mining, classifiers, and graph analysis to be parallelized to deal with massive datasets. Research is being conducted to further improve MapReduce, such as developing methods to improve join algorithms and indexing techniques. Research on big data could be highly beneficial for feeding LBS applications with more relevant knowledge on their users’ environments, such as data on road conditions to support efficient routing services.
Dealing with data quality

Data quality, while being a concern for most applications, is a special concern for LBS because an increasing part of the data used by LBS applications comes from volunteers who contribute through crowdsourcing applications and social media. Researchers have highlighted the value of crowdsourced data to enrich or update existing geospatial datasets (Goodchild 2007). This advantage is especially useful considering that traditional geospatial data producers may lack the capacity to generate datasets with comprehensive coverage and level of detail. In addition, the fact that crowdsourced data can be provided and disseminated in a timely, near real-time fashion suggests that it can help to provide a dynamic picture of the environment. Still, problems concerning the credibility, reliability, and quality of VGI and crowdsourced data in general have been reported by several researchers, as indicated by Elwood (2008) in a review of future directions for research on VGI. The lack of quality affects the ability to interpret data, to extract relevant knowledge from it, and to integrate it with other data, among other problems (Bakillah et al. 2013).

Crowdsourced data may lack credibility and reliability because it is produced in a context that differs from the “structured institution-initiated and expert-driven contexts” (Elwood 2008). For instance, in contrast with official or commercial data producers, who are expected to generate data with a certain level of accuracy, volunteer contributors are not obligated to do so. In addition, there are no standard formats and languages for collecting crowdsourced data and formalizing the context around it (Bakillah et al. 2013). Crowdsourced data is produced using natural language, rather than the agreed-upon terminology often employed by professional data producers. As a result, the terminology used by contributors is ambiguous. The lack of standardization, combined with the diversity of users’ experiences, suggests that the heterogeneity affecting crowdsourced data is more problematic than that of traditional geospatial data. In addition, the profile and motivation of contributors are often unknown. Still, while this remains to be thoroughly demonstrated, one can expect that the socioeconomic, sociological, and cultural background of contributors could have an impact on the quality of contributions. Being aware of the relevant characteristics of contributors could help to assess the quality of crowdsourced data.

A common method for assessing data quality is to compare it with reference data, whether commercial or administrative datasets. With respect to the quality of VGI, such an attempt has been made, for example, by Haklay (2010), who compared OSM data with ordnance survey datasets. However, accessibility to high-quality reference may be limited for crowdsourced data since, as mentioned, its coverage may be different from official data. Alternative solutions include methods for measuring intrinsic data quality indicators based on an analysis of the history of the data. Another approach consists of classifying contributors into categories such as “beginners” or “experts,” and using this categorization in the assessment of contributions. When the profile of a contributor is characterized, this contributor can be assigned a “level of trust” that can help predict the quality of his or her future contribution. Systems where contributors review each other’s contributions have also been developed and coupled with learning algorithms to improve their relevance. A contrasting paradigm was adopted by Foody (2013), where the focus is on extracting relevant information. Foody provides an alternative quality assessment method where crowdsourced contributions are considered as “imperfect indicators of the actual phenomenon under study”; a latent class analysis method is employed to extract underlying
information and to estimate the quality of the contributions.

“Preventive” approaches can also be implemented to try to prevent quality issues from arising by controlling the data production process. Some crowdsourcing applications use editors with templates to control data production. However, other authors report that a clear correlation between data accuracy and the use of editors has not been observed. For example, Yaari, Baruchson-Arbib, and Bar-Ilan (2011) have conducted a study that supports this claim, but it was conducted in Wikipedia. Further research is therefore needed to establish whether this statement holds, and if it holds specifically for VGI. Indeed, editors supporting the production of VGI must differ from those that could be used in Wikipedia. In addition, difficulties arise because of the need to reach a balance between the freedom and flexibility that is given to contributors and the necessity to improve the data production process. Therefore, further research is needed to determine how data production and control mechanisms can be successfully implemented within crowdsourcing applications. Some other VGI applications, such as OSM, recommend that contributors document and share with others the terms they use to describe geographic features, where terms are afterwards organized into a folksonomy. However, communities had difficulty in reaching a consensus regarding terminology; in addition, there are generally few mechanisms in crowdsourcing applications for checking adherence to the agreed-upon terminology.

The research on crowdsourced data quality is still at an early stage. According to Roick and Heuser (2013), the quality of crowdsourced data is one of the issues that has been the least studied so far. In addition, the suitability of quality management approaches for LBS has not been thoroughly explored yet.

LBS and the Internet of Things

Nowadays, users can produce geographic information via a variety of Internet applications. As a result, a “global digital commons of geographic knowledge” can be created without having to rely solely on “traditional” geospatial data production processes. In addition, it is expected that in the near future, smart devices that will be embedded in a variety of objects (vehicles, clothes, appliances, plants, buildings, etc.) will continue to blur the line between the virtual and real worlds (Liang, Croitoru, and Tao 2005). The upcoming availability of this data through the Internet of Things (IoT) infrastructure will create new opportunities to develop LBS applications that could better integrate information on the current state of the environment. In fact, we can consider that LBS are a building block of the IoT, since they both generate and consume location-based data that will be made available through IoT infrastructure.

Sui and Goodchild (2011) have put forward the idea of a generic data service that would retrieve, store, and provide access to geospatial data from LBSN, in addition to assisting users in the discovery of relevant information. Similar services are required to make the IoT a reality. However, before such a global data service can be implemented and before data from LBSN can be fully exploited and applied to different use case scenarios, several issues need to be addressed, such as enabling collaboration between applications and devices without human intervention, supporting the extraction and automatic formalization of context information so that applications can properly interpret the data, handling the IoT heterogeneities in an automatic manner, processing the IoT data streams with smart algorithms, and so on.

Today, some of the solutions that have been suggested for the development of the IoT rely
on existing standards and technologies for Sensor Web, such as OGC’s Sensor Web Enablement specifications, as well as on the Service-Oriented Architecture (SOA) principles.

Towards LBS of the future

While authors writing in “Location Matters: LBS 2030” explain that the first development phase of LBS was mainly driven by technologies such as positioning technologies and the Internet, they expect that coming development phases will be driven by data and users (Gartner 2013). Notably, the big data paradigm and related advances will stimulate the development of LBS applications that are based on the exploitation of important volumes of data, whether generated through sensors that will be widely disseminated in our environment, or crowdsourced applications. Then, while in the first decade of existence users of LBS were constrained by available technologies, once the main technological challenges have been addressed, the development of LBS will focus on users’ needs: for example, how to make LBS more useful to support collaborative work. Still, emerging technologies that have not been considered yet may challenge this vision of a “smooth” evolution where all technological challenges are behind us. For example, LBS may have to adapt to more embedded devices such as Google glasses in the future. One could also add that the legislation and regulations that will be adopted in relation to the use of LBS (privacy, data exchange, etc.) will have an impact on LBS evolution.

Whether the dissemination of information through LBS will benefit society and individuals from an economic, social, or environmental perspective will depend on how scientists, businesses, governments, civil society, and individuals address the challenges and opportunities created by LBS. The analysis presented in this entry reveals that the successful development of LBS will require integrated interdisciplinary approaches from a large variety of research fields that include computer science, GIScience, human–computer interaction, cognitive sciences, social sciences, and economics, to name only a few.

Still, the current advances suggest that, regardless of their impact on society, LBS will become even more widespread, until they eventually become part of the fabric of our daily life; so deeply integrated that it will become invisible.

Socioeconomic change and the modernization of logistics

Logistics includes the process of planning, implementing, and controlling the efficient, cost-effective, and synchronized flow and storage of raw materials, inventory, finished goods, and related information from point of origin to point of consumption for the purpose of fulfilling customer needs. Flows are also increasingly directed up-stream, from the point of sale or customer backwards to the supplier or producer, for example, in the case of vessels (e.g., empty containers) or reverse logistics, and also generally concerning data and information. While logistics initially emerged from the preparation and organization of military procedures, it is now used to optimize the functions of production, distribution, and consumption for serving businesses and households. Moreover, logistics was a major requirement for global trade to evolve to today’s volume, and it is a vital part of transportation operations of any kind.

Logistics once belonged to the three sciences of military operations, besides strategy and tactics. It emerged particularly during World War I, when large numbers of troops had to be moved and the supply of materials, vessels, and munitions had to be organized. It remained significant for any warfare until today, as recent experience for example, in the two Gulf wars in the early 1990s and 2000s, has revealed. The offspring of modern logistics goes back to the modernization of the capitalist economy, most notably the transformation of the modern corporation and the evolution of a networked economy. The development and constant improvement of industrial production and the emergence of a rather sophisticated division of labor across space and time would not have been possible without logistics. Particularly, the rationalization of production required an effective supply with materials and components. As a consequence, integrated supply-chain approaches were developed, including distribution and marketing. The practice of modern management, as described by Alfred Chandler (1977), started to integrate the flow of materials into overall managerial operations. However, logistics did not receive notable attention for long. In the early 1960s, management writer Peter F. Drucker called it “the economy’s dark continent,” still far from any particular consideration. Meanwhile, things changed significantly, due to both technological changes and innovations in organization. This change is also expressed by the move from the “visible hand,” as emphasized in Chandler’s treatise on management, towards the “vanishing hand,” as Langlois (2003) put it. The latter term refers to the discrete function logistics plays nowadays at various stages of the value-creating process, where a multitude of practices is conducted by an equally broad variety of actors and institutions (Table 1 indicates the major stages in the development of logistics).

The recent development of logistics and physical distribution was particularly triggered by a complex set of structural economic changes to which corporations had to respond. These

changes comprise the rise of service economies, the increasing share of goods with high value and low weight, the upcoming high-tech and knowledge-based sectors, and certainly globalization, most importantly the rise of countries such as China or India to become the manufacturing center of the world. The rise of logistics became intensified by an accelerated competition among firms on increasingly open, deregulated markets. As a consequence, much of the storage, forwarding, and trucking activities of the firms that were previously organized in-house became outsourced to logistics subcontractors. The growth of these services helped in establishing specialized networks of freight forwarders (sea, land, air), of courier, express, and parcel services, and also of warehousing firms that were operating their own facilities on behalf of their customers.

Probably one of the most important catalysts of logistics development was the introduction of new information and communication technologies (ICT). They allowed for the truly integrated management and control of information, finance, and goods flows. Features like electronic data interchange, the automatization of product flow in dedicated warehouses, and distribution centers (DCs), computer-based tracking-and-tracing systems or radio-frequency based identification (RFID) of single items have changed corporate practice in logistics and physical distribution significantly. They are also the source of enormous productivity gains over the last two decades, as they permitted the operation of a completely new mode of inventory management, by adjusting materials management according to customers’ demand, thus reducing inventory costs substantially. The standardized container did the same; it made trade and transport more efficient, and thus much less expensive, from its very first introduction by a sea–land freight forwarding company in North America in 1956. The enormous growth of world trade, of which more than 90% of the volume is seaborne, would not have been possible without the economies of scale achieved by the efficient handling of containers. The throughput of containers via largely automatized terminal operations, their movement by ever-larger ocean carriers, and the challenge of maintaining access into and out of major seaport regions are among the most important challenges of the maritime economy due to logistics changes.

The Internet accelerated the application and distribution of new ICT in logistics firms, with research having some difficulties in properly assessing related impacts. Features such as the bar code and electronic data interchange (EDI) had already been practiced in logistics businesses since in the late 1970s/early 1980s. However, the advent of the web changed the situation dramatically. Now, data-handling technologies have become affordable on a general level, standardization of web appliances made the Internet a common feature, and corporations were able to establish interfaces with their customers. Now the web has become a major tool for rationalization, not only for individual firms and their subsidiaries, but for managing the entire producer–customer relationship and more complex networks. The accelerated pace of technological innovation contributed to further changes, for instance by introducing global positioning systems (GPS) that allow for identification and routing of vehicles (such as lorries, container ships) in a way that was not possible before.

As a consequence of these developments, corporate management has been switching to a flow-oriented mode of operation. Its core component is the supply chain, the time and space-related arrangement of the flow of goods, information, and capital between the stages of
supply, manufacturing, distribution, and consumption. These changes do result in an overall vertical fragmentation of the value added process, in modular manufacturing, worldwide sourcing, and big-box retail operations. The underlying generic idea of spatiotemporal fragmentation has to be compensated for by logistics integration. In order to describe the transformation or deconstruction of the firm in the context of fragmentation and networks, Suarez-Villa (2003) coined the term “techno-capitalism.” It is used as an interpretative scheme for analyzing structural changes that are primarily driven by new technologies and globalization. Network building, devolution of spatial hierarchies, and the reliability and speed of flows are its main characteristics. Thus, transportation costs and the supply of infrastructure lost their significance for explaining spatial differentiation, compared to corporate organization, institutions, and, particularly, the newly emerging logistics networks.

The geographical dimensions of logistics

When logistics is considered the art of managing and re-structuring material space–time relations, then it becomes clear that it has a substantial impact on geographies at various spatial scales (Hesse and Rodrigue 2004). Altogether with the expansion of infrastructure systems, logistics enabled regionally bound economies to further dissociate in terms of space, time, and organization. (In turn, the more complex and distanced the related corporate networks and trade systems were becoming, the higher was the demand for specialized logistics and freight distribution services.) On a global scale, logistics allowed for the structural rearrangement of value chains, production networks, and distribution channels. Astonishingly, logistics has received little attention by the pundits of global production networks (GPNs) so far – although the economic and social integration of regions into global economic relationships and interdependencies is hard to imagine without the properly designed flow of goods; the same applies for the increase in global trade rates that has been observed. As logistics and freight distribution are carrying the physical “load” of operating GPNs and trade flows, their significance is undoubted, however. Most notable is the emergence of major gateways alongside the trade routes, particularly large seaports and airports that offer the capacity to handle large portions of incoming or outgoing commodity flows. These gateways are bundling various flows oscillating between global, regional, and local scales, and provide connectivity with the larger hinterland regions (O’Connor 2010). As they concentrate major portions of national and international goods flows and related handling activities, they are subject to both positive and negative agglomeration externalities; ensuring the seamless flow of vessels through gateway regions still remains a costly and contested issue. Steering these regions is rather difficult due to an institutional fragmentation, consisting of corporations as diverse as shipping lines, carriers (of all modes), operators of warehouses, airfreight and container terminals, freight forwarding firms, receivers of goods (manufacturing, retail chains), and representatives from various public policy interests.

With respect to the landside movement and handling of consignments, the establishment of large distribution centers (DCs) is an important feature of current dynamics. This issue found significant coverage by geographical research recently. DCs have been developed in order to synchronize or buffer the materials flow between the scheduling of the supplier and the demand-side activities (sales, ordering) at wholesale or retail markets. They have replaced the old warehouses, as inventory has been diminished
until almost zero on both sides (production and wholesale/retail). DCs are often situated within regional logistics clusters, and big-box distribution centers have developed, as they offer advantages due to internal economies of scale. In locational terms, DCs and logistics parks have been subject to a significant sub- and exurban drift, with a certain preference for areas surrounding metropolitan cores that offer benefits for both long-distance haulage and regional distribution. Size, however, also tends to maximize the negative impact of related activities on neighborhoods and the environment. Besides traffic conditions in core city areas, land costs and policy pressure against a disturbing, locally often unwanted land use have pushed the movement of DCs out of the cities further.

DCs and logistics clusters also became the subject of regional development concepts and policies, particularly in the context of their localization as so-called transportation hubs. The innovation of the hub-and-spoke concept by airlines and freight shipping companies was based on an indirect routing of transport flows via major nodes. As a consequence, hubs were dislocated and got on the screen of regional development policies. Now, even places that lack any agglomeration potential could qualify for becoming a hub. Policy practices thus aimed at territorializing the dynamics of logistics, both locally and also in the context of state strategies (e.g., The Netherlands’ or Dubai’s attempt to create a global hub and “logistics city”). It was also argued that logistics corporations offer entry-level jobs, so this compensates for the loss of employment due to deindustrialization. However, research and practice are still challenged to make local sense of global flows in the context of emerging network dynamics, as hubs tend to be far more fluid, volatile, and fragile, compared to the traditional gateways. What they do have in common with gateways is that they were established on the ground of positive externalities of agglomeration (by routing and bundling flows), and they offer the same degree of negative externalities in terms of congestion, environmental, and neighborhood burden caused by the circulation of vehicles, aircraft, and the like.

In order to better understand the transformation of the logistics sector, research interest turned to the single corporation – particularly since large firms bundle a critical mass of flows and are proactive in using new technologies or organizational concepts. Such companies take advantage of a growing level of integration of services, finance, retail, manufacturing, and distribution. A good example of these powerful actors is the US retailer Wal-Mart, the largest corporation in the world, judging from relatively recent editions of the Fortune 500 list. Wal-Mart has already been coined the “template” for late-modern capitalism (Lichtenstein 2006). The company achieved this position by linking newly emerging places that provide the production and supply of cheap goods (e.g., in China) with serving major customer markets in North America. Wal-Mart thus successfully implemented a fine-tuned geography of retail outlets, distribution centers, and delivery concepts, with which it achieves an optimal coverage of markets and territories. This case also provides certain evidence that, besides the efficient management of financial resources, the core reason for its rapid success as a truly global company results from its ability to manage its supply chains and networks extremely efficiently (Brunn 2006). It combines minimum inventory with rapid turnover, fast and reliable supply chains, and a geostrategic know-how that helps in exploiting resources at the best possible level.

Whereas Wal-Mart has been considered a template for late-modern capitalism, the online retailer
Amazon.com might soon be regarded as the template for its digital version. At least it offers excellent empirical insight into the various ways that the material and the digital intersect. Again this feature coincides with the logistical capabilities of the firm and also its enormous rate of innovation. Within a time-span of about 15 years, Amazon became the world’s largest online store, investing massively in efficient logistics systems and optimal market coverage through a series of carefully placed distribution centers. Even more so, digital technologies are essential, allowing for not only the seamless flow of information, money and, last but not least, commodities, yet also the total control of assets, workforce, and customer behavior. The corporation is now seeking to further automate handling processes (e.g., by testing robots in DCs, planning delivery by drones) and also decentralizing distribution in major metropolitan regions. This may make same-day deliveries cost efficient on a regular basis. Hard to overlook is the impact that the further dominance of online retailers such as Amazon.com already have and will have in the future on stationary retail. It seems obvious that the rise of e-commerce severely affects one of the historical properties of towns and cities: to provide households and corporations with goods and services nearby. Will retail migrate into the back-end DCs of digital mail-order companies? The urban and societal consequences would be substantial.

**Future issues with respect to logistics**

There is a series of future issues that will raise further interest in logistics from a geography perspective, each including certain methodological challenges. First and foremost, an important issue will be energy and the related transportation cost. The circulatory economy is quite sensitive to the oil price, and the current rationale, for example, of locational concepts is very much based on the given cost of fossil fuel. If such limits are exceeded, the system will have to adjust, and it will be interesting to see how far and where this will go. Second, technological innovation will continue to develop. As projects such as the Amazon-drone or the Google-car already indicate, autonomous objects, robots, predators, and the like will take over an increasing array of functions within various supply chains. Spatial consequences are likely to occur, even though hard to break down at this point. Third, and this takes us back to the origins of logistics as warfare, there is an increasing “market” for security, surveillance, and intervention, secretly intersecting with geostrategic, economic interests. In the aftermath of 9/11, and with the NSA/GCHQ spy affairs not yet resolved, states and private agents will further use and thus revolutionize the management of flows. Logistics is becoming a core tool for regulating access and controlling mobilities of various kinds. In this respect, it seems most critical for the idea of an open society and has the potential to affect citizen rights severely (Cowen 2010). The astonishing degree and speed of change incorporated in recent developments has helped to create not only newly emerging material “logistics landscapes” (Waldheim and Berger 2008) but also a secret web of surveillance and control that deserves critical reflection.

**References**

The Los Angeles School refers to a conceptual approach to understanding contemporary patterns of urbanization based on Los Angeles. The Los Angeles School emerged during the 1980s when a loosely formed group of predominantly Marxist urban scholars – geographers, planners, and urban historians – from the University of Southern California and the University of California, Los Angeles, turned to Los Angeles as, then, a comparatively understudied site for empirical and theoretical urban analysis (Davis 1990). While there has never been an official list of members, prominent commentators have been Michael Dear, Edward Soja, Mike Davis, Allen Scott, and Michael Storper. The work of these scholars is wide-ranging and presents numerous influences, objects of inquiry, and conceptual disagreements. Yet, the creation of the Los Angeles School was based on an understanding that Anglo cities were developing in new ways (post-1970), which rendered the classic modernist theories of the city increasingly obsolete (Dear 2000). The biggest critique was levied against the centralized, concentric-ring model associated with the widely known and influential Chicago School.

Based on dense empirical work on Chicago, the paradigmatic modernist city, the Chicago School was formed by sociologists at the University of Chicago during the 1920s and 1930s. Robert Park, Ernest Burgess, and Louis Wirth were its leaders. The Chicago School presented a theory of urban growth and change – often referred to as “urban ecology” – based on a central core surrounded by rings of distinctive zones. The concentric-ring diagram and model of 1920s Chicago is perhaps the best-known visual feature associated with this school of thought.

Los Angeles, conversely, was observed as a city void of a central core or of concentric rings even remotely reminiscent of the Chicago model. This observation led to the claim that the Chicago School was ill equipped to understand emerging trends and patterns of development that marked the post-Fordist, or what some Los Angeles School scholars called the “postmodern” metropolis. As most forcefully argued by Dear (2000), the polycentric, decentralized, and disorderly character of Los Angeles reflected what was unfolding across urban America and beyond, which formed the basis for claiming Los Angeles as the new prototypical urbanized landscape. Bluntly summed up by Joel Garreau in Edge City: Life on the New Frontier (1991, 3), “every American city that is growing, is growing in the fashion of Los Angeles.” As echoed particularly by Dear and Soja, Los Angeles epitomized what was happening across Sun Belt metropolitan regions and represented a new historical layer of development unfolding in many older, postindustrial cities, including Chicago.

The first explicit mention of a Los Angeles School is often attributed to Mike Davis in his landmark text, City of Quartz (1990). But it was not until Dear and Flusty’s (1998) article “Postmodern Urbanism,” published in the Annals of the Association of American Geographers, that the existence of the Los Angeles School gained widespread attention. On the basis of the dramatic departure of Los Angeles from the
LOS ANGELES SCHOOL

Chicago School model, Dear and Flusty argued that Los Angeles represented a “radical break” from modernist urban forms and that new epistemologies were needed to make sense of these changes. Modern industrial cities were supposedly being overwritten by a new hyperdifferentiated, “kaleidoscope” layer of development. And, to adequately understand this transformation, a new lexicon and taxonomy of postmodern urbanisms based on southern California was presented. For example, concepts such as “keno capitalism” were used to capture the perceivable lack of order or single driving force underpinning this emergent urban form. Dear subsequently became the primary spokesperson and most ardent promoter of the Los Angeles School.

This embrace of the postmodern movement, however, also marked a conceptual division within the Los Angeles School. Dear and Soja, notably influenced by Henri Lefebvre, Michel Foucault, Jacques Derrida, and Fredric Jameson, were among the earliest scholars to incorporate postmodern insights into human geography (Dear 2000; Soja 1989; 1996). But Dear and Soja were somewhat at odds in their approach to this incorporation. Soja’s postmodernism was based more on invigorating the role of space and spatiality in critical social theory, long subsumed beneath the dominance of time and temporality. Dear, in contrast, embraced a notably deeper, more epistemological basis for his postmodernism, criticizing Soja for still adopting a classic Marxist (and therefore) modernist metanarrative to structure his analyses and interpretations (Dear 2000).

But there were also more fundamental divisions within the group, with Davis rejecting postmodernism and Scott and Storper avoiding it altogether. Scott and Storper, for instance, rather than directly engaging with postmodernism, have tended to situate their work in industrial location patterns, flexible specialization, and the “regionalization” of contemporary metropolitan areas within the broad transition from Fordist to post-Fordist modes of production observed in advanced economies since the 1970s (e.g., see Storper 1997; Scott 1998).

Numerous criticisms have been levied against the Los Angeles School, notably the claims of this city as paradigmatic and that this new postmodern urbanism represented a radical break with the past (e.g., see Harvey 1989). This debate is now extensive, with the entire inaugural issue of City & Community (2002) covering the topic. A central criticism is that the Chicago School’s dominance was overstated, notably by Dear, to bolster the relevance of the Los Angeles School, as, by this time, the Chicago School was already considered by some as a relic of the past. Although Dear continues to advocate for the Los Angeles School (e.g., see Dear and Dahmann 2008), these debates have notably subsided. But, regardless of where one stands, the Los Angeles School stimulated significant and important critical debate in urban studies at the time, with many insights now generally accepted, such as the increasing polycentric patterning of metropolitan regions and obsolescence of the urban/suburb dichotomy.

Description and purpose

The institute’s objectives are the development of theoretical bases and methodology for physical, human, and regional geography studies on spatial processes and interrelationships; temporal and spatial surveys of the interaction between humans and environment; assessment of factors of the geographical environment with special reference to natural and socioeconomic resources and to the emerging socio-economic issues in the Carpatho-Pannonian area; international cooperation; and documentation and dissemination of research achievements through the publication of studies and periodicals in Hungarian and foreign languages.

Journals or major publication series

Current activities or projects

From 2012 scientific work has been organized into eight scientific project groups supervised by the director. These project groups are: National Atlas of Hungary; Geomorphology and Quaternary Studies; Loess and Quaternary; Recent Physical Geographical Processes and Landscape Studies; Lithosphere-Biosphere Interactions; Ethnic and Political Geography; Spatial Mobility; and Metropolitan Regions and Urbanization Processes. The project groups are supported by three functional groups: Cartographical Group, Laboratory for Sediment and Soil Analysis, and a Geographical Library.

Machine learning

Ningchuan Xiao
Ohio State University, USA

In his 1950 paper “Computing Machinery and Intelligence,” Alan Turing posed a provocative question: can machines think? To further understand the meaning of thinking and machine, Turing developed an imitation game, now more popularly known as the Turing test, to determine whether a computer can act as a human via a conversation with another human. Turing predicted that computers equipped with the ability to learn will pass the test. Tom Mitchell (1997) later defined the meaning of learning in a more specific context: “A computer program is said to learn from experience \( E \) with respect to some class of tasks \( T \) and performance measure \( P \), if its performance at tasks in \( T \), as measured by \( P \), improves with experience \( E \).” Examples of tasks in machine learning include recognizing spoken words, playing chess, identifying objects (e.g., houses, trees, parks, and roads) from an aerial photograph, and identifying places for ecological habitats.

For a computer program to learn, past experience must be presented to the program, which often takes the form of a set of data collected for the task. A machine learning method can be broadly categorized as being either supervised or unsupervised. A supervised method needs the desired result to be labeled or identified in the data, while an unsupervised method uses unlabeled data to uncover the structure in the data. A performance measure must be developed to indicate how well the machine or computer program has learned from the data. For example, if the machine is expected to identify housing styles from aerial photographs, then the performance measure will score how well the machine performs this task. To produce unbiased and robust learning results, the data are often partitioned into a training set that is used to calibrate the parameters of the learning program and a test set for evaluating the learning results.

Machine learning spans, and draws from, a number of different academic fields. Within computer science, machine learning is a special branch of artificial intelligence. Many methods used in machine learning are also derived from statistics. A closely related field to machine learning is data mining, which shares many common theories and methods with machine learning. However, data mining has a focus on the discovery of unknown patterns in the data while machine learning is more about prediction: using learned patterns to understand new data. For example, data mining approaches are useful in diagnosing the problems of a car; machine learning methods can be used to automatically drive an autonomous vehicle. Machine learning results must be generalizable, so that the result can perform under circumstances that are not necessarily reflected in the training data.

Clustering

Given a dataset, \( w \), each observation or data entry can be assigned to a cluster using a similarity or distance measure. In this way, observations assigned to the same group are similar to each other, while observations in different groups are dissimilar. A geographical example would
be classifying pixels in a remote sensing image as being one of several different land-use and land-cover classes (e.g., forest, agriculture, and water). The training data are denoted as $x = (x_1, x_2, \ldots, x_n)$, where $x_i (1 \leq i \leq n)$ is a $d$ dimensional vector. It is assumed there exists a set of $k$ mean (or center) data points $(\mu_1, \mu_2, \ldots, \mu_k)$ that is used to define a set of $k$ clusters $(s_1, s_2, \ldots, s_k)$ such that a data point $x_i$ belongs to cluster $s_j$ if, and only if, the distance between $x_i$ and $\mu_j$ is the nearest among all the $k$ center data points. The goal of solving the clustering problem is to find a set of center points such that the total distance between each data entry to its nearest center is minimized. Finding the exact solution to the problem is computationally intensive and the commonly used $k$-means method is an algorithm that can be used to return a good, though not necessarily optimal, solution.

The $k$-means algorithm has two steps. In the first step, $k$ data points in the $d$ dimensional space are randomly determined as the initial center points and each observation in $x$ is assigned to its nearest center based on the distance between the observation and the center. In the second step, observations assigned to the same center are used to calculate a new center as

$$\mu'_i = \frac{1}{|s_i|} \sum_{x_j \in s_i} x_j$$

If the new centers exhibit significant differences from the current centers, the new centers will be used to replace the current ones and the assignments of observations in $x$ will be updated. This step is repeated until no significant gain in the total distance can be achieved.

**Decision tree learning**

A decision tree represents a step-by-step classification process in which a question is asked in each step and, depending on the answer to each question, a decision can be made or more questions will be asked before a decision. For example, to decide on whether one should bring the umbrella today, one may first ask, “Is it raining now?” If it is raining now, then the decision will be yes (will bring umbrella). If it is not raining, one may further ask, “Will it rain later today?” If weather forecasting shows a high likelihood of rain, then the answer will be yes. Otherwise, the umbrella will not be brought. In this simple example, each question relates to an input variable or attribute (e.g., raining), which forms a node of the decision tree. When the answer to the question leads to the target (e.g., if raining is yes, then bring umbrella), the target answer is a leaf of the tree. The first question to ask is the root of the tree. Figure 1a shows the formation of a tree that captures the flow of decisions and questions in this simple example. In a more complicated situation, it is critical to determine which question will be asked first and the order to ask all the questions.

Decision tree learning is an example of the supervised machine approach that requires a training set where each data entry is labeled with a given classification. A learning algorithm is developed to associate the attributes of training-set members with the known target. The association will be represented in a series of decisions that can be illustrated as a tree. Different from the above example, where the sequence of questions seems to be straightforward, the training dataset can be more complicated and it is often difficult to know which question to ask first. The first question becomes the root of the tree.

To determine which question to ask first, it is necessary to identify which attribute best gives insight into choices. Assume there are $k$ target decisions to make (for example, in the above example, $k = 2$). Let $p_j$ be the probability for decision $j (1 \leq j \leq k)$ to occur in the data. The
The impurity of the data can be measured using an entropy measure

\[ H = -\sum_{j=1}^{k} p_j \log_k p_j \]

In information theory, entropy has been used to measure the disorder in the system. When only one class exists in the data, \( H = 0 \), indicating no further learning is necessary. When the \( k \) decisions are equally divided in the data, \( H = 1 \), indicating the highest level of disorder.

Suppose the question about an attribute takes \( m \) answers. By answering this question, the data can be divided into \( m \) subgroups and it is assumed that there are \( N_i \) data entries in subgroup \( i \) \((1 \leq i \leq m)\). The probability for the data to fall in class \( j \) in the subgroup is \( p_{ij} = N_j / N_i \), where \( N_j \) is the number of data labeled as decision \( j \). The total impurity of answering question \( v \) is

\[ H(v) = -\sum_{i=1}^{m} \sum_{j=1}^{k} p_{ij} \log_k p_{ij} \]

The information gain can then be calculated as \( H - H(v) \), which indicates how well attribute \( v \) can be used to classify the data. The attribute with the highest gain is then used as the root of the decision tree. For each of the subgroup, if the data in that subgroup contain more than one decision, a new node must be created and the data in that subgroup will undergo the same process described above to choose the attribute for the node. This process continues until the tree only has leaf nodes at the end of each branch, or all the attributes are used.

**Figure 1** Decision trees. (a) A simple decision tree to decide whether to bring an umbrella. (b) A decision using the sample data about likability of cities. The overall answer in the Like column has four yes answers and six no answers, which gives a total entropy of:

\[
-\frac{4}{10}\log_{2}\frac{4}{10} - \frac{6}{10}\log_{2}\frac{6}{10} = 0.53 + 0.44 = 0.97.
\]

At the root level, job opportunity has the highest information gain (0.97 − 0.32 = 0.65) and is chosen as the root of the decision tree.
Decision tree learning can be illustrated with an example dataset (Table 1) about the likability of 10 cities with three attributes: living costs, jobs, and air quality. The resulting decision tree (Figure 1b) is essentially a set of rules that can be used to determine the likability of a new city. For example, for any city with high (or low) job opportunities, according to this model it would be predicted that its likability will be yes (no). For a city with medium job opportunities and low air quality, it will not be likable. This example also shows some limitations of this method. For example, the model will not tell the likability of city with medium job options, high air quality, and low living cost, because this combination of attribute values is unknown in the training dataset.

Artificial neural networks

Artificial neural networks (ANNs) are inspired by the advances in animal central nervous system research. In essence, ANNs are meant to mimic how biological brains operate by representing how neurons are connected together in the brain. A typical ANN has three layers and each layer has a number of nodes that represent neurons in real biological brains. The input and output layers have the same number of nodes as the input and output variables of a problem. The third layer is called a hidden layer and each node in this layer is called a perceptron. Each perceptron takes the input from each input node and algorithmically transforms them into the values of the output variables. Figure 2a shows...
Table 1 A sample dataset. For each attribute, the values of H, M, and L refer to as high, medium, and low. Air quality only has two values: H and L. The Like column only has a binary value of Yes (Y) or No (N).

</table>

The layout of an ANN with three input variables, two outputs, and a hidden layer of four nodes. Each node in the hidden layer is a perceptron that sums a set of weighted input information and converts it to a standardized value between 0 and 1 (Figure 2b). Formally, the output from a perceptron can be written as

\[ s_j = \sum_{i=1}^{n} w_{ij} x_i \]

where \( w_{ij} \) is the weight between the \( i \)-th input node and the \( j \)-th perceptron, and \( x_i \) is the input from the \( i \)-th input node. A sigmoid or “S”-shaped function can be used to convert \( s_j \) to a standardized value

\[ o_j = \sigma(s_j) = \frac{1}{1 + e^{-s_j}} \]

a step function can also be used for this purpose. A node in the output layer uses another set of weights to yield the estimated value:

\[ o_k = \sum_{j=1}^{m} w_{jk} s_j \]

where \( w_{jk} \) is the weight between the \( j \)-th hidden node (\( 1 < j < m \)) and the \( k \)-th output node.

A critical characteristic of a neural network is its learning ability, which it gains by virtue of adjusting the weights used in the above computation in order to minimize the overall difference between the estimated values \( (o_k) \) and the known target values (denoted as \( y_k \) for the \( k \)-th output) in the training set. For each entry in the training data, an error at an output node can be calculated as

\[ E = \frac{1}{2} (y_k - o_k)^2 \]

The partial derivative of \( E \) over the weight is

\[ \frac{\partial E}{\partial w_{ij}} = \frac{1}{2} \frac{\partial}{\partial w_{ij}} (y_k - o_k)^2 = (y_k - o_k) \left( -\frac{\partial o_k}{\partial w_{ij}} \right) = -(y_k - o_k) \frac{\partial o_k}{\partial s_k} \frac{\partial s_k}{\partial w_{ij}} \]

For the sigmoid function

\[ \frac{\partial o_k}{\partial s_k} = \frac{\partial \sigma(s_k)}{\partial s_k} = o_k(1 - o_k) \quad \text{and} \quad \frac{\partial s_k}{\partial w_{ij}} = x_i \]

Therefore for the output nodes, the error gradient is

\[ \frac{\partial E}{\partial w_{ij}} = -(y_k - o_k) o_k(1 - o_k) x_i \]

The weight can then be adjusted using a rate proportional to the error gradient. Based on this error correction principle, a back-propagation algorithm (so named because it operates from outputs back to the inputs) can be developed.
to systematically adjust the weights until the overall error is reduced to an acceptable level (Box 1).

### Box 1 Back-propagation algorithm.

Assign random values to all the weights

Repeat

Randomly pick an entry from the training data and compute the outputs

For each output node, compute

\[ \delta_k = (y_k - o_k) o_k (1 - o_k) \]

For each hidden node, compute

\[ \delta_j = o_k (1 - o_k) \sum_{k=1}^{m} w_{jk} \delta_k \]

For the entire network, update each weight as

\[ w_{ij} + \Delta w_{ij}, \] where \( \Delta w_{ij} = \eta \delta_j x_i \)

Until the termination conditions are met

In this algorithm, \( \eta \) is a small constant called the learning rate. The algorithm typically terminates when the error at the output layer is lower than a predefined level, or when the number of iterations reaches a predefined number.

### Genetic algorithms

Genetic algorithms (GAs) belong to a family of computational methods that is inspired by the biological theory of natural selection. To use a GA as a classifier that returns a class assignment to an input, it is critical to represent classification rules as an individual in the GA. Extending the example of the training data in Table 1, living costs and job opportunities can be encoded using three-digit binary strings, where values of H, M, and L are encoded as 100, 010, and 001, respectively. Value combinations can also be represented using this method. For example, a binary string of 011 indicates a value of M or L. For air quality, a two-digit binary string can be used and values of H and L are encoded as 10 and 01, respectively. A string of all 1’s is used to represent a condition when the corresponding input variable does not affect the classification result. Finally, a single binary digital can be used to encode likability of yes (1) or no (0). Table 2 lists a set of rules and their encoding in the GA.

A classifier often has multiple rules (see the result from the decision tree on the training data), which can be constructed by cascading across multiple binary strings. With such a representation strategy, a classifier genetic algorithm contains a population of \( P \) individual classifiers. Here, a single rule classifier is used as an example. An initial set of classifiers are randomly generated and then each classifier is evaluated by a fitness function that is often based on the number of data entries the classifier can correctly match. For example, the last rule listed above can match three instances in the data, while a rule of 001111111 does not match any instances.

The core mechanism in GA is that the individuals are selected to create new individuals on the basis of how well they solve the problem, with better ones being more likely to be

<table>
<thead>
<tr>

<td>IF Jobs = H THEN Like = Y</td>
</tr>
</tbody>
</table>
selected. After evaluation, each individual is assigned a selection probability as the ratio of its fitness value (a measure of how well it solves the problem) and the total fitness values of the population. Individuals with high probabilities will have a high chance to be selected to create the next generation of the population. Specifically, $\frac{P}{2}$ pairs of individual will be selected and, for each pair, a cross-over operation is used to produce two new individuals. For example, when two individuals of $H_1 = 010010100$ and $H_2 = 001111111$ are selected, the GA randomly decides a cross-over point, say, at after the third digit of each rule. Then the first part of $H_1$ is combined with the second part of $H_2$ to form a new individual of $H'_1 = 010111111$. Similarly, the first part of $H_2$ can be combined with the second part of $H_1$ to form $H'_2 = 001010100$. The cross-over operation will create a new population that is used to replace the previous one. Finally, a mutation operation can be carried out on each individual, on a rare and random basis, to flip a randomly selected digit in the individual. For example, flipping the seventh digit of $H'_2$, gives 001010000. The new population subsequently undergoes the selection, cross-over, and mutation operations to generate the next generation. The process continues until a predefined condition, such as the maximum fitness value or maximum number of generations, is satisfied.

GA performance can be significantly improved by controlling the pace of convergence. Because individuals are selected based on their fitness values, highly rated individuals may dominate the selection process and, therefore, take over the population at the early stage of the GA process. This may trap the entire population into a local optimum because individuals at the early stage tend to be inferior to the global optimal classifier. To prevent a GA from being premature in choosing its final solution, it is important to increase the diversity of the GA population so that individuals with low fitness values can be maintained in the population.

Though the fitness values of these individuals may be low, they may still contain useful binary blocks that can contribute to the overall search when they are selected and combined with other individuals.

**Support vector machine**

Support vector machine (SVM) is a relatively new development in machine learning. Here, a training data entry is denoted as $\{x_i, y_i\}$, where $x_i$ contains $d$ attributes and $y_i$ is the output that has two values of $-1$ or $+1$, representing two classes. Assume there is a $d$-dimensional hyperplane that can separate the data into the two sides of the hyperplane where all the $y$ values of $-1$ are on one side and $+1$ on the other. When $d = 2$, a straight line can be drawn to separate the data in a 2-D plane. The hyperplane can be denoted as $w \cdot x + b = 0$, where $w$ is the normal vector of the hyperplane and the operation ($\cdot$) means the dot product. The data points that are closest to the hyperplane are called support vectors and it is necessary to find a hyperplane such that the distance between the support vectors and the hyperplane is maximized. In Figure 3, the two points on the dashed lines are support vectors and the solid line between the two points is the optimal hyperplane. Given a hyperplane, there are a pair of planes that are in parallel with the hyperplane and cross the support vectors (as the two dashed lines in the 2-D case). The distance between the hyperplane and one of these parallel planes is called the margin of the support vector machine and can be computed as

$$\frac{1}{||w||}$$
To find the optimal hyperplane with a maximized margin, a specific optimization problem is designed that minimizes

$$\frac{1}{2}||w||^2$$

subject to $$\gamma_i(x_i \cdot w + b) \geq 0 \ \forall i$$. The constraints ensure any point $$i$$ in the training data is on one side of the dashed line. This problem can be converted to a convex quadratic problem that can be solved efficiently with well-known methods.

In many applications, the different classes in the data may not be separated by a linear function but instead by a more complicated one. In order to apply the linear separation approach, the data can be mapped into a higher dimension so that the linear separation can be applied. It is also possible to enforce a so-called soft margin on the training data, such that a few data points are allowed to be on the wrong side of the hyperplane. When multiple, instead

of two, classes are necessary, various approaches have been developed to convert the multiple classes into a number of binary classification problems, essentially taking a divide and conquer approach.

**Discussion**

A challenge that all machine learning methods face is overfitting, a phenomenon by which the results found from the training data turn out to be overly tailored to the training set at the cost of being generally applicable. These results, when used on test data or other new data, may yield errors higher than in the training dataset. The decision tree example described here, for instance, derived from the training data is perfect in the sense that it can correctly match every entry in the data. However, it would easily go wrong on a new data entry with the values of H, H, L, and N, respectively, because these values are not well represented in the training set but are still a reasonably likely combination. There are many ways to address the overfitting issue in learning. Penalty methods, for example, add a complexity penalty into the evaluation of each alternative, where the penalty is proportional to the complexity of the result. In a decision tree, a simple way to measure the complexity is the size (or number of branches) of the tree, where complex trees with many branches will be penalized by having a reduced evaluation score. Another method is called hold-out or cross-validation because it utilizes a smaller training dataset by holding out a subset of the training data to be used as experimental test data. While this method creates a smaller training set for learning, the subset that is held out can be used to test the performance of learning and, therefore, can prevent overfitting. The bootstrap method
handles overfitting by repeatedly drawing random subsets of data with replacement from the entire dataset. The statistical distribution of learning performance can be used to test the robustness of the result coming from the training dataset.

The machine learning methods described so far represent some important advances in the field. Other methods, such as Bayesian learning, instance-based learning, reinforcement learning, and analytical learning, are also important. Machine learning methods have been used in a wide range of application fields, such as speech recognition and computer vision. In geographic research, machine learning has been a focused area in remote sensing and geographic information science, for tasks such as land cover classification and spatial pattern analysis.

Mainstream and shadow banking

Simon Xiaobin Zhao
Nam Hee Kim
University of Hong Kong, China

Mainstream banking

Mainstream banking can be defined as a system of commercial and retail banks that are closely regulated and supervised by government banks commonly referred to as central banks. Commercial and retail banks are privately owned institutions that serve as financial intermediaries for the safeguarding, transfer, exchange, and lending of money. Central banks are government entities tasked with supervising the safety and stability of the money supply and the banking system.

Commercial and retail banking

Commercial and retail banks accept deposits from businesses and households and pay an interest on the deposits. The banks then use the deposits to fund longer-term loans directly to borrowers. The activity of transforming the risk and timing of cash flows between savers and borrowers is called financial intermediation. An important aspect of financial intermediation is maturity transformation, which is the use of short-term liabilities, such as deposits, to fund long-term assets such as mortgages. This maturity transformation creates liquidity risk, which is the risk that it will not be able to raise cash to meet demand from depositors withdrawing their money or short-term creditors demanding repayment. Liquidity risk creates the possibility that an institution may be forced to sell its long-term assets at distressed prices in order to meet its short-term liabilities.

Another key function of banks is the provision of credit. In providing credit, banks accept and manage credit risk, or the potential that the borrower fails to repay the money that the bank lends. Through financial intermediation, banks transform savings into long-term sources of capital that allow individuals, corporations, and governments to engage in economic activity.

One of the most significant trends in mainstream banking since the 1990s has been consolidation. Some of the acquisitions were cross-border, resulting in a few large banks controlling more and more of the world’s money. The ultimate outcome of the wave of mergers in the 1990s and the globalization of banking has been a geographical concentration of banking decision centers and strategic functions. According to data compiled by Forbes in 2015 using the banks’ reported assets under their respective accounting regimes, China, United States, and Japan had the largest number of big banks, with, respectively, 13, 12, and 9 of the 100 largest banks by assets being headquartered there. The top 18 largest banks controlled assets of $40.2 trillion, which represent just over half of the total assets controlled by the top 100 banks. The top 30 banks were all located in North America, North Asia, the European Union, or the United Kingdom. Outside of those regions, Australia had the largest number of banks in the top 30 list, with five banks holding just over $3 trillion
of assets, followed by Brazil with three holding combined assets of $1.4 trillion. Only one bank from Africa, the Standard Bank of South Africa, made the top 100 list with assets of $182 billion under management.

Geography of mainstream banking

The role of geographical distance in banking activities is most often attributed to its effect on transportation and information costs (Elliehausen and Wolken 1990). Transportation costs include both the time and money spent by either the bank or its customer to facilitate in-person transactions. Several studies have examined how distance affects a consumer’s choice of depository institution and shown that consumers are more likely to choose banks based on geographic proximity (Chiappori, Perez-Castrillo, and Verdier 1995; Dell’Ariccia 2001; Villas-Boas and Schmidt-Mohr 1999). Information costs include the cost of advertising and maintaining relationships with existing and potential customers. Lenders who are geographically closer to customers may also gain a competitive advantage since they should be able to gather information about borrowers during the approval process as well as monitor the loans throughout the life of the loan at lower expense.

Automated teller machines (ATMs) have the potential to reduce the transportation costs for both customers and the banks that serve them. If consumers view ATMs as an effective substitute for bank branches, banks can compete for customers in geographic areas where they have few or no branches by providing services through an ATM. While this is unlikely to play any role in lending, ATMs may allow banks to expand their geographic reach at lower cost. However, using data on banks in Italy, Hester, Calcagnini, and de Bonis (2001) find that the number of ATMs in a province is positively related to the number of branches a bank has in that province, a result that appears contrary to the idea that ATMs are deployed by banks as substitutes for branches.

Not only does the distance between the bank and the customer matter in banking, but the distance between the branch (or location) and the headquarters (HQ) where the lending decision is made also impacts on banking relationships and decisions. Credit availability and innovation adoption have been found to be inversely related to functional distance (Alessandrini, Presbitero, and Zazzaro 2009). A large bank is, on average, subject to greater functional distance between its HQ and its branches and is less able to produce soft information; therefore it is less inclined to make relationship loans to small and medium enterprises (SMEs) compared to small banks which, in theory, are subject to a smaller functional distance (Berger, Rosen, and Udell 2007).

Banking activities vary greatly regionally and nationally because, perhaps more than any other industry, they are shaped by government-imposed rules and regulations distinct to each territory. Government regulation impacts the spatial distribution of mainstream banking across jurisdictions. In the United Kingdom the five “major” banks – Royal Bank of Scotland (RBS), HSBC, Barclays, Lloyds, and Standard Chartered – account for over 90% of bank deposits. These large banks maintain a network of branches primarily for the purpose of collecting deposits, but grant fewer loans to local SMEs. In Germany, by contrast, banking is dominated by almost 2000 small, locally headquartered banks distributed throughout the country whose activities are geographically restricted by law to the local area. These small, local banks in the regions account for 70% of bank deposits, while the larger, major banks account for only 13% of bank deposits.
In Islamic countries, banks and financial institutions have created financial contracts that conform to Islamic, or sharia, law, commonly termed “Islamic finance”; such banks do not pay or receive interest, or *riba*, on banking products. In lieu of *riba*, prohibited by the Quran, banks share in the profit generated from the use of funds that it loans to its customers. The depositors also share in the profits of the bank at a predetermined ratio. Most Islamic banks are headquartered in the Middle East including Iran, Saudi Arabia, United Arab Emirates, and Kuwait. Outside of the Middle East, Malaysia is home to several Islamic banks.

With increasing globalization and cross-border flows of capital, firms and households can choose not only between banks within their local area or jurisdiction but also make deposits and use the financial services of banks based in foreign jurisdictions, sometimes thousands of miles away. Many mainstream banks offer “offshore” banking to take advantage both of the absence of a global legal framework and of disparate tax structures. Although there is no precise definition of an offshore jurisdiction, significant offshore financial centers (OFCs) around the world include Bermuda, the Cayman Islands, the Channel Islands, Hong Kong, and Singapore (Roberts 2009). Onshore governments argue that regulatory efforts in banking are undercut by competition from offshore financial centers.

An increase in regionally concentrated imbalances may also be a by-product of globalization, creating a more uneven distribution of financial access. Access to mainstream banking services varies between both countries and communities within a country. A two-tier banking system has developed in the United States, with mainstream finance in most places but financial exclusion, predatory lending, and fringe banking (pawnshops, payday lenders, etc.) in certain communities (Caskey 1994; Dymski 1999; Immergluck 2009; Leyshon and Thrift 1997; Squires 2004). Predatory lending can increase the likeliness of loan default and housing foreclosure, which in turn can spiral into housing abandonment at the neighborhood level. Foreclosure rates vary widely between communities, especially during times of crisis. Smith (2008) finds that areas in Chicago that are over 80% minority exhibited more than five times the rate of foreclosures of areas with less than 10% minority during the Great Recession.

Central banks and international governance

Central banks are the government banks that manage, regulate, and protect the money supply and banks themselves. Central banks perform the role of lender of last resort (LOLR), providing loans to a financial institution when the market refuses to do so, possibly avoiding default caused by the lack of liquidity. In the nineteenth century, after the collapse of a major London discount bank, Overend and Gurney, the Bank of England became the first central bank to perform this role. As the role of central banks evolved through the twentieth century, macroeconomic stability, including a focus on inflation targeting, became one of their essential responsibilities. In some developed countries, the supervision of financial institutions was transferred from central banks to other agencies.

In the United States, the Federal Reserve System performs this central banking function and supervises banks, as well as acting as crisis manager with the authority to oblige banks to monitor their risks. In the European Union, the European Central Bank (ECB) has primary stability responsibilities when it comes to the payment system but not the explicit task of preserving the stability of the financial system in general. That responsibility falls on the national central banks, which also have the LOLR role.
The debate over the role of central banks persists, with some arguing that central bank interventions encourage banks to take more risks on the assumption that they will be bailed out. In times of crises or when an individual bank is in distress, bank runs can occur: a rapid loss of deposits that causes the bank to fail from lack of liquidity. Many countries address this problem by providing government guarantees for deposits or deposit insurance. According to the International Association of Deposit Insurers, nearly 100 countries offer government guarantees on deposits. Holding sufficient liquid assets also reduces the chance that investors would become concerned enough to cause a bank run. In most jurisdictions, regulatory requirements are in place for banks to hold sufficient reserves.

Established in 1930, Bank for International Settlements (BIS) is an international organization based in Basel, Switzerland, commonly referred to as the “central bankers’ bank.” Its aim includes fostering the cooperation of central banks and international monetary policymakers. Situated within the BIS, the Basel Committee on Banking Supervision (BCBS) was established in 1974 by the G10 central banks, Switzerland, and Luxembourg to supervise the activities of commercial banks. Committee membership now also includes Argentina, Australia, Brazil, China, Hong Kong SAR, India, Indonesia, South Korea, Mexico, Russia, Saudi Arabia, Singapore, South Africa, and Turkey. In 2004 the committee developed the capital adequacy framework, commonly referred to as Basel II. In response to the financial crisis of 2007–2008, an enhanced set of rules named Basel III was introduced in November 2010 at the G20 summit in Seoul. Excessive leverage and insufficient liquidity buffers in the banking sector are believed to have precipitated the financial crisis of 2007–2008, and Basel III standards are intended to safeguard against a similar crisis by requiring banks to maintain lower levels of leverage – the ratio of capital to assets – and higher amounts of cash than required under Basel II (BCBS, Basel Committee on Banking Supervision, 2015). The Basel process has gained focus among geographers as one of the first truly “glocal” institutional responses that coordinates the multilateral efforts of central banks, regulators, and market participants in an attempt to foster and maintain global and local financial stability (Bieri 2009; Christophers 2014).

While BCBS’s efforts may lead to an increased adoption of regulatory and supervisory best practice around the globe, this does not necessarily mean that local compliance with such standards is uniform. Regional variations in the quality of banking regulation and institutions persist, only some of which can be explained by differences in economic development (Bieri 2009).

Shadow banking

Broadly, shadow banking is defined as bank-like financial activities that are conducted outside the traditional commercial banking system, with little or no regulatory oversight. Some market participants prefer to use terms such as “market-based financing” rather than “shadow banking” to describe nonbank financial intermediation. Shadow banking institutions differ from mainstream banking institutions in that they cannot take deposits and do not benefit from deposit insurance. Notwithstanding widespread disagreement over which entities constitute the shadow banking system, it includes financial intermediaries that serve as proxies for traditional banks, such as investment banks, finance companies, money market funds, hedge funds, private equity groups, structured investment vehicles, payday lenders, and insurance firms.
A study of 23 jurisdictions by the Financial Stability Board (FSB, Financial Stability Board, 2014) estimated that shadow banking assets stood at $34.9 trillion at the end of 2013, up from $34.0 trillion in 2012. The United States had the largest shadow banking sector in terms of US dollars, followed by the United Kingdom and China. Brokerage or investment banks, accounting for $9.3 trillion of shadow banking system assets, are concentrated in the United Kingdom (39%), United States (28%), and Japan (21%). Structured finance or securitization vehicles, accounting for $5 trillion at the end of 2013, are concentrated in the United States (35%) and the United Kingdom (13%). Finance companies and money market funds made up $4.1 trillion and $3.8 trillion of total shadow banking assets, respectively. Money market funds are mainly concentrated in the United States and the euro area. The FSB study found that hedge funds accounted for an insignificant portion of shadow banking assets. However, the majority of hedge funds are domiciled in offshore jurisdictions such as the Cayman Islands, which were not included in the FSB study.

Brokerage and investment banking

Brokerage refers to bringing together parties interested in making a transaction such as buying and selling shares of stock, for a fee charged to brokers. Investment banks operate brokerages, assist in the issuance of securities such as bonds and stocks, and trade securities and derivatives for their own accounts. Investment banks have large holdings of securities that they generally plan to hold only for short periods, and fund a large portion of their balance sheets with repurchase agreements, in addition to commercial paper and long-term debt.

During the Great Depression in the United States, bank failures and investment losses nearly destroyed the banking system and the national economy. In order to safeguard against such bank failures, the Glass–Steagall Act of 1933 prohibited banks from owning or affiliating with brokerage firms. The intention of the law was to create a “firewall” between speculative businesses and banking institutions. Even as banks became deregulated in the United States in the 1980s, the prohibition of direct securities trading and insurance underwriting continued. In 1999, however, the Gramm–Leach–Biley Act (GLBA) allowed banks to pursue insurance and securities businesses directly, essentially repealing the Glass–Steagall Act and eliminating legal barriers that had separated the securities, insurance, and banking industries. By the 2000s, several commercial bank holding companies in the United States, such as Citigroup and JPMorgan Chase, had significant investment banking subsidiaries. Today, many of the largest investment banks globally are part of commercial bank holding companies. On Bloomberg’s 2013 list of top 20 investment banks globally by fees, only four (Goldman Sachs, Morgan Stanley, Jefferies Group, and Lazard) were not affiliated with a commercial bank.

Finance companies

Finance companies supply credit to businesses and consumers, but they do not take deposits. Instead, they raise funds by issuing commercial paper and bonds. While they securitize some of their loans, some finance companies also hold assets on their balance sheet, in a similar way to a traditional bank. Finance companies’ business activities may include providing business loans secured by assets of the firm, making consumer loans for purchase of appliances or furniture, and offering credit cards. In the years leading up to the financial crisis of 2007–2008, finance companies in the United States were also offering mortgages.
Securitization

Securitization is the process by which a pool of assets, mainly loans including credit card debt, mortgages, and student loans, are repackaged into securities, mainly bonds. The interest and principal payments from such a pool of assets are used to pay the debt service on the securities. Securitization began in the 1970s, when home mortgages were pooled by US government-backed agencies Freddie Mac and Fannie Mae. Other income-producing assets began to be securitized in the 1980s, and in recent years the market has grown dramatically. Shadow banking entities are critical players in markets for securitized products. The shadow banking system facilitates the securitization of a substantial fraction of consumer and business credit, including mortgages, auto loans, student loans, and credit cards. Finance companies fund loans prior to securitization, in many cases through short-term lending markets, while the investment banks structure and sell securitized products. Commercial banks or their investment banking affiliates often participate in the origination and trading of securitized products, supplementing their traditional banking business revenues. Higher-risk tranches of these securities are purchased mostly by hedge funds and special purpose entities.

Money market funds

Money market funds (MMF) are mutual funds that invest in short-term securities such as government securities, commercial paper, certificates of deposit, and repurchase agreements. MMF appear similar to deposits at commercial banks, and investors can even write checks using the funds in the MMF. MMFs attempt to maintain a stable $1 net asset value (NAV). Sometimes a parent company will provide support in order to avoid the NAV declining below $1, also known as “breaking the buck.”

MMFs began appearing in the United States in the early 1970s, following regulatory limits on the interest payable on bank deposits. In the 1980s the first MMF was created in Europe for similar reasons: French asset managers offered the product with similar returns and characteristics as bank deposits, avoiding restrictions on interest paid. The MMF sector is an important funding source through their investment in short-term debt issued primarily by banks. Many banks in the United States and Europe obtain a substantial proportion of their funding from MMFs and rely on them for rolling over short-term debt.

Hedge funds

Hedge funds are investment companies that manage funds for high net worth individuals or institutions. Global estimates for the size of the hedge fund industry vary. Hedge Fund Research estimates that $2.6 trillion of capital was managed by the global hedge fund industry at the end of 2013. However, regulators in the United States and the United Kingdom, where the greatest number of hedge funds are believed to be domiciled, have reported $470 billion and $5 trillion, respectively, of hedge funds assets under management.

Hedge funds originated in the United States. US-based managers manage approximately 70% of global hedge fund assets while European and Asian managers hold 21% and 5% respectively. Hedge funds are major trading partners with the large commercial banks and investment banks. These relationships form yet another link from the shadow banking system to the traditional banking system which could spread a crisis to the mainstream banking sector.
Peer-to-peer lending

A variety of peer-to-peer lending sites have emerged around the globe, using the Internet to facilitate the borrower and lender matchmaking. Although specifics vary, common characteristics of peer-to-peer lending include using social networks to facilitate connections, allowing lenders to earn interest by participating as part of a larger loan, and selecting borrowers to finance on the basis of their personal narrative in addition to their credit ratings.

Mainstream and shadow banking
interdependence and the 2007–2008 financial crisis

Systemic risk can arise from the relationship between shadow banking entities and the mainstream banking sector. This interconnectedness can take many forms. Direct linkages are created when shadow banking entities form part of the bank intermediation chain, are directly owned by banks, or benefit directly from bank support (explicit or implicit). Funding interdependence is another form of direct linkage, as is the holding of each other’s assets such as debt securities. Indirect linkages also exist, when the two sectors invest in similar assets or are exposed to a number of common counterparties. These connections create a contagion channel through which stress in one sector can be transmitted to the other, as occurred during the 2007–2008 subprime mortgage crisis and the ensuing financial crisis.

When the shadow banking entities came under pressure in 2007 and 2008, under agreements that were triggered by disruptions in the market, major US and European commercial banks were required to provide funds to these entities. As the commercial banks themselves came under funding pressure, even commercial banks that had not provided such backstop agreements reduced their lending in the interbank and other money markets. Banks began to hoard cash, which further froze the funding markets.

In late 2008 a US investment bank, Lehman Brothers, came under funding pressure which eventually pushed it into bankruptcy. The failure of Lehman Brothers had repercussions for both mainstream and shadow banking systems. Withdrawals increased from money market funds, and hedge funds and funding markets were in turmoil. On September 25, 2008, a commercial bank, Washington Mutual Bank (WaMu), filed for bankruptcy in the largest bank failure in US history, the result of a run on WaMu that began on the day of Lehman’s bankruptcy. The failure of Lehman Brothers had repercussions across Europe and throughout the world as a contagion effect started to spread through the entire banking system.

The Federal Reserve established a series of funding facilities in 2008 in an effort to restore investor confidence and liquidity in the shadow banking system, effectively extending its LOLR role (traditionally reserved for commercial banks and savings institutions) to the shadow banking system. The US government also offered temporary insurance for money market fund investments in 2008, which was necessary to restart financing in the many nonfinancial sectors that depended on the shadow banking system. In 2010 the Dodd–Frank Wall Street Reform and Consumer Protection Act was enacted, prohibiting banks from owning, investing, or sponsoring hedge funds, private equity funds, or proprietary trading operations. This provision, also known as the Volcker Rule, is aimed specifically at reducing commercial banks’ shadow banking activities in an attempt to weaken the interconnectedness of mainstream and shadow banking.

The evolution and impact of the Great Recession have been spatially uneven. A myriad of geographic research focus includes the nature of the governmental responses to bank failures (e.g.,
Grossman and Woll 2013) and geographical differences in experiences of the crisis (e.g., Aalbers 2009; Hadjimichalis 2011; Schafran 2013).

**Regulating shadow banking**

Regulators around the world have stepped up their oversight of nonbank institutions since the 2007–2008 financial crisis, recognizing that entities from money market funds to private equity firms can have a big impact on economic stability. The increased globalization of financial markets, the deepening of financial integration, and the rapid pace of financial innovation have created a global financial system that transcends national boundaries, resulting in increased capital flows, lower borrowing costs, and better price discovery. However, the system has also created and strengthened a network transmitting negative shocks simultaneously to different regions and markets. The worldwide Great Recession served as a wake-up call for the risks of a globalized financial market, highlighting the challenges for international regulation.

There is an ongoing international effort to improve the global financial architecture and to ensure more coordination and information sharing between national and international regulators. In most economic or financial crises, national governments have reacted in isolation from each other by introducing new national regulatory rules. Unless an integrated global framework is successfully implemented, market participants will continue to bypass national rules through cross-border regulatory arbitrage. A study by the International Monetary Fund (IMF) found that the 2007–2008 financial crisis has “revealed important flaws in the current global architecture” (IMF, International Monetary Fund, 2009, 1), identifying four areas in which reforms are needed: (i) surveillance of systematic risk; (ii) international coordination of macro-prudential response to systematic risk; (iii) cross-border arrangements for financial regulation; and (iv) funding for liquidity support or external adjustment.

The emergence of the G20 as a forum to deal with the Great Recession has been a major development toward such global coordination in regulating both mainstream and shadow banking sectors. The G20 communiqué from London in April 2009 agreed to replace the Financial Stability Forum (FSF) with a new supranational Financial Stability Board (FSB). In collaboration with other international institutions such as the IMF, this board is responsible for safeguarding global financial stability. Its mandate, as stated on its website, includes the following: “assess vulnerabilities affecting the financial system and identify and oversee action needed to address them; promote coordination and information exchange among authorities responsible for financial stability” (FSB, Financial Stability Board, 2015). The establishment of the FSB as a supranational board, combined with an enhanced role for the IMF, and the close collaboration of these two institutions with the BIS are among the efforts made to improve the international financial architecture and to contribute to the process of global financial stability.

Within Europe, the European Systemic Risk Board was established in December 2010 to provide an early warning to national regulators and to ensure that they take joint responsibility for the supervision of major banks. It is tasked with developing a common set of quantitative and qualitative indicators to identify, measure, and monitor systemic risk, and with recommending remedial action in coordination with international financial organizations, particularly the IMF and FSB.

The highly interdependent nature of the twenty-first-century global financial market, with assets that can instantaneously move from
MAASTREAM AND SHADOW BANKING

one country to another or from one country to
an OFC, means that rules set out by international
institutions such as the FSB or the IMF must
be fully supported by national legislation and
laws throughout the world to be effective. There
remain challenges for the FSB in collaborating
with all OFCs as a way of removing regulatory
arbitrage. The policy debate following the Great
Recession has highlighted the role of OFCs, and
the need to limit the shadow banking sector’s
ability to channel money through these lightly
taxed havens. However, the concern
over OFCs should not detract from how the
long-standing rivalry between New York and
London for dominance in both mainstream and
shadow banking was a major factor behind the
2007–2008 financial crisis (French, Leyshon, and
Thrift 2009). Despite the perceived competition
from OFCs, mainstream and shadow banking
institutions, including hedge funds, are still tied
to a location (Wójcik 2013; Sennholz-Weinhardt
2014), with disincentives preventing them from
relocating to another jurisdiction in order to
benefit from looser regulation. Reforming regu-
lation in the long-standing international financial
centers of London and New York should there-
fore be the highest priority, even if uniform
regulation can’t be achieved across regions.

Although the literature on mainstream and
shadow banking continues to expand following the
Great Recession, some areas for further
research remain. With the emergence of global
banks such as HSBC and Barclays, which have
multiple global headquarters (Hong Kong and
London in the case of HSBC; London and
New York in the case of Barclays) and branches
across continents, alternative and comprehen-
sive measures of banking activity, beyond assets
under management and market value, should
be explored in different countries and in inter-
ationally comparative ways. Although China
now hosts the four largest banks as measured
by profits (Chen 2015), research on banking is
still focused on New York and London. Further
investigation should be performed on the finan-
cial, spatial, and social implications of the growth
of Chinese banks and its regional and global
implications. It is also important to focus on all
dimensions of banking. The Great Recession
has focused the research spotlight on subprime
mortgage lending, but other sectors of credit
intermediation (including small business, stu-
dent, auto, and personal loans) have significant
societal implications. Geographers and other
social scientists also should not ignore the study
of spaces that seem peripheral, such as markets
that fall under the generalization of “emerging”
despite each having unique attributes. These
include alternative banking activities such as
microcredit and Islamic finance, which mainly
serve households and firms in the Middle East,
South Asia, and Africa. Qualitative and discursive
analyses, including case studies, could add to the
body of existing research given the dissonance
in scale and spatiality. Finally, the relationship
between mainstream and shadow banking and
the state is also an important avenue for future
research. Academic discourse on the regula-
tion of both mainstream and shadow banking
has increased since the Great Recession, but
empirical research on the interlinkages between
banking and government is relatively lacking.

sis.” Area, 41: 34–42.

Manufacturing industry

Chun Yang
Hong Kong Baptist University, China

Does manufacturing still matter?

An essential component of the industrial sector of an economy, “manufacturing industry” refers to processes involving the transformation of raw materials into finished goods for sale, or intermediate processes involving the production or finishing of semifinished products. Unlike agriculture and mining, manufacturing takes place under human-made and controllable conditions. Unlike service activities, manufacturing provides vital material inputs into the continuation of human life.

For nearly three centuries, since the Industrial Revolution, manufacturing industries have helped drive economic growth and rising living standards; they continue to do so in developing economies. Global manufacturing value added grew from $5.7 trillion in 2000 to $7.5 trillion (in 2000 prices) in 2010, which represented 16% of global GDP. Both advanced and developing economies have experienced growth in manufacturing value added. Nevertheless, the role of manufacturing in global and national economies has evolved over time. Empirical evidence shows that as economies become wealthier and reach middle-income status, manufacturing’s share of GDP peaks (at 20–35% of GDP). Beyond that point, consumption shifts toward services, hiring in services outpaces job creation in manufacturing, and manufacturing’s share of GDP begins to fall along an inverted “U” curve. It is evident that manufacturing will continue to matter a great deal to both developing and advanced economies. However, the way manufacturing contributes to national economies and competitiveness changes over time as economies grow.

Moreover, the definition of manufacturing is changing. Manufacturing employs a rising number of workers in nonproduction jobs, and service inputs represent a rising share of manufacturing output. Manufacturing industries are increasingly large users of service inputs and employ many workers in service roles. Service-like activities – such as R&D, marketing and sales, and customer support – have become a larger share of what manufacturing companies do: 30–55% of manufacturing jobs in advanced economies are service-type functions, and service inputs make up 20–25% of manufacturing output (McKinsey 2012, 7). The distinctions between manufacturing and services have blurred.

Globalization of manufacturing industry

Over the past several decades, manufacturing industry has experienced significant changes as rapid globalization shifted a substantial proportion of manufacturing capacity from developed economies to the “newly industrializing economies”: that is, Hong Kong, Singapore, South Korea, and Taiwan, in the 1960s, and then to developing economies, for example, China and Malaysia in Asia and Mexico in Latin America, in the 1970s and 1980s. In consequence, global production has become increasingly fragmented and different stages of
production are now regularly carried out in different countries. This great unbundling of tasks, also known as fragmentation, offshoring, or vertical specialization, has implications for the organization and coordination of manufacturing activities around the world. Through the trade of intermediate goods and services, global production networks developed quickly in manufacturing industries such as textiles, automotive, and electronics. Traditionally, the global technologies/innovators group has been led by companies from advanced economies, such as Apple and Hewlett-Packard in the United States, Fujitsu, Hitachi, and Toshiba in Japan, and Ericsson, Nokia, Philips, and Siemens in Europe. Advanced economies contribute 70% of the global value added, and the United States retains the lead, with 27% of the group’s global value added in 2010. It is, however, worth noting that South Korea, with companies such as LG and Samsung, and Taiwan, with Acer and AsusTek, also have strong positions and have changed from followers to market leaders (Yeung 2007).

Globally, manufacturing output (measured by gross value added) continued to grow: between 2000 and 2007, by 2.7% annually in advanced economies and by 7.4% in large developing economies. Economies like China, India, and Indonesia have risen into the world’s top 15 largest manufacturing economies, according to their share of global nominal manufacturing gross value added (Table 1).

In order to reflect the increasing fragmentation of global manufacturing, the World Trade Organization (WTO) launched “Made in the World” in 2011. For a number of electronic products (iPods and laptops) manufactured in China, less than 3% of the export value actually goes to the manufacturers/assemblers in China, for example, Foxconn (Dedrick, Kraemer, and Linden 2010). The major part of the value is captured by firms in the United States, Japan, Korea, and Taiwan through the delivery of sophisticated intermediate inputs.

The future of manufacturing industry

Today’s global landscape of manufacturing is more complicated than that of a few decades ago. Although there are clear elements of continuity, dramatic changes have occurred. The overall trajectory of global manufacturing has become increasingly volatile. Within this uneven trajectory there has been major geographical reconfiguration. As claimed by Dicken (2011), a relatively simple global geographical division of labor has been replaced by a far more complex and multiscalar structure. The dominant factors that shaped the disaggregated supply chains today will not be the same as those through the next several decades, because the global environment is changing. On the one hand, many emerging economies used by transnational corporations (TNCs) as locations of low-cost labor have developed significant manufacturing and innovation capabilities, which allow them to produce increasingly advanced manufactured products. On the other hand, these economies have begun to experience a corresponding escalation in wages and costs, following in the footsteps of their developed nation counterparts decades ago. Greater prosperity and higher wages are helping to drive an increased ability and desire to consume by the growing middle classes, making them an exciting market of new consumers: for example, China and India.

Until the past decade, globalization of manufacturing was driven largely by cost arbitrage – essentially the search for low-cost production locations. Today, however, a more important driver for multinational manufacturing companies is to match production footprints to patterns of demand growth. At the same time,
Table 1  Top 15 manufacturers (% of global nominal manufacturing gross value added).

Italics show the rising positions of India, Indonesia, and China (see text).

an increasingly diverse global customer base creates a demand for a broad set of localized, tailored products, also driving the need for proximity to customers. These shifting demand trends affect all manufacturing industries, although to differing degrees and on different timelines, and conventional policy is not adequate to deal with them. Demand is shifting to emerging markets at an accelerated rate and is becoming more fragmented. According to McKinsey’s (2012) research, consumption by developing economies could rise from $12 trillion annually in 2010 to $30 trillion in 2025. By 2025, it is estimated that developing economies could account for nearly 70% of global demand for manufactured goods. Demand shifts to emerging markets are being driven not just by large economies such as those of China and India, but also by economic growth in Indonesia, Kenya, Vietnam, and other smaller emerging markets.

Rising wage costs are most likely to affect industries in the labor-intensive tradable group and the assembly steps in global technologies/innovators’ businesses – where labor is a relatively large fraction of compressible costs. From 2005 to 2010, wage hikes averaged 10% per year. In 2010, the giant contract manufacturer Foxconn, which employs 920,000 people in China alone, doubled wages in its Shenzhen plant. Companies typically respond to rising wages by moving to lower-cost locations. This presents opportunities for “next frontier” developing economies to capture any labor-intensive work from countries with rapidly rising wages, such as China. Countries such as Bangladesh, Cambodia, Indonesia, Vietnam, and other developing economies are already experiencing
growth in labor-intensive industries because of their cost advantages. While the manufacturing of some goods will shift from China to nations with lower labor costs, these nations’ ability to absorb the higher-end manufacturing will be limited by inadequate infrastructure, a lack of skilled workers, scale, and domestic supply networks, as well as by political and intellectual property risks. Lower worker productivity, higher corruption, and greater risk to personal safety are also concerns for the relocation of manufacturing to these nations.

The future of manufacturing is unfolding in an environment of changing dynamics and greater risk and uncertainty than before. An exciting new era of global manufacturing is ahead – driven by shifts in demand and by innovations in materials, processes, information technology, and operations. The prospect is a more “global” manufacturing industry (Dicken 2011), in which developing economies are the source of new customers as well as the source of low-cost production. However, these opportunities arise amid a global shift in the cost and availability of factor inputs (e.g., labor and natural resources) and rising complexity, uncertainty, and risk. As manufacturing evolves, policymakers must adjust their expectations and look at manufacturing not only as a source of mass employment in traditional production work but also as a critical driver of innovation, productivity, and competitiveness. In the aftermath of the 2008 global financial crisis and world recession, the restructuring of global manufacturing is taking place. The new era of manufacturing will unfold in an environment in which old assumptions, strategies, and policies no longer suffice. Both manufacturing leaders and policymakers need to think and act in new ways, and develop new strategies.

Map algebra

C. Dana Tomlin
University of Pennsylvania, USA

Map algebra is the language of cartographic modeling. Introduced in the early 1980s (Tomlin 1983), it is a computational pseudocode intended to represent the concepts, conventions, and capabilities of that methodology in terms that are concise, consistent, and comprehensive yet legible to a wide range of users. The result is a form of notation resembling that of assignment statements in imperative programming languages.

The capabilities represented by map algebra are common to fields ranging from remote sensing and geoprocessing to spatial statistics and digital photography. Map algebra expresses these capabilities by relating them to a coherent data-processing framework intended to make them more readily understood, more easily combined, more creatively utilized, and more likely to be extended. Among its extensions to date have been versions specifically oriented toward binary images, linear networks, areal features, vector fields, volumetric conditions, temporal phenomena, and relational data models.

The general nature, structure, and role of map algebra are introduced in this volume’s entry on cartographic modeling. By building on that foundation, the present entry offers more detailed descriptions of individual functions and their implications. To do so, it introduces the basic set of elementary functions and then illustrates how these can be used to generate a variety of compound functions and, thereby, perform more sophisticated and more specialized tasks.

The elementary functions of map algebra were initially implemented and are most fully developed for use in conjunction with geospatial data that are encoded in a raster format. Each operates on variables that are organized as shown in Figure 1.

Every function accepts one or more layers as its input variable(s) and generates a single new layer as its output. Since the output of any one of these functions can therefore be used as input to any other, functions can be easily combined, and

![Figure 1 Map algebraic variables. All of the map algebraic functions operate on variables in the form of “layers,” each of which depicts a geographical area as a bounded plane on which every “location” is defined by a particular pair of planar coordinates. Each location is also associated with exactly one of a set of a “zones” that are uniquely represented by numerical “values.” The zones of any given layer generally depict variations on a single geographical characteristic such as soil type, population density, or proximity to home.](image-url)
none of them therefore has to be complex. The elementary functions are, in fact, deliberately designed to minimize duplication and to avoid undue complexity.

The result is a set of some fifty functions that are associated with three major groups termed “local,” “zonal,” and “focal.” Among the focal functions, which operate on locations within a specified vicinity or “neighborhood” around any given location, four subgroups can further be distinguished according to whether those neighborhoods are “lateral,” “visible,” “accessible,” or “local” in nature. As indicated in Figure 2, this gives rise to three (or, more precisely, six) major types of map algebraic function.

![Map Algebra Functions](image)

**Figure 2** The major types of map algebraic function. Each of the map algebraic functions calculates new values for all locations (depicted as dots) such that the new value at any given location (red dot) is computed from the existing values of a particular set of locations (yellow dots). Local functions compute each location’s new value from its own existing value(s). Zonal functions use the values of locations sharing a common attribute. Focal functions consider the values of neighboring locations in one of four types of neighborhood. Lateral neighborhoods are defined by distance and/or direction to each neighborhood center or “focus” (red dot), while visible neighborhoods also require that neighbors lie within sight. Accessible neighborhoods are defined in terms of travel costs, and local neighborhoods only encompass immediately adjacent neighbors.
Local functions

Each of the local functions generates a new layer on which every location is set to a value computed from the value(s) of that same location on one or more designated layers. Local functions are specified as:

\[
\text{NEWLAYER} = \text{LocalFUNCTION of } \text{1STLAYER} \text{ and NEXTLAYER}
\]

where

- **NEWLAYER** specifies the new layer to be generated;
- **1STLAYER** specifies an existing layer of values to be processed;
- **NEXTLAYER** specifies another existing layer of values to be processed (in a phrase that may be used repeatedly);
- **LocalFUNCTION** specifies that new values are to be computed as follows:
  - **LocalSelection** sets each location to a value of 1 (for true) or 0 (for false) that indicates the verity of one or more specified statements asserting that the value of that location on one existing layer is greater than, less than, and/or equal to its value on another existing layer;
  - **LocalRating** sets each location to a value explicitly specified (either as a numeral representing that value or the name of an existing layer from which the location’s new value is to be drawn) according to the value(s) of that location on one or more existing layers;
  - **LocalMix** sets each location to a value that identifies the particular combination of its values on **1STLAYER** and one or more **NEXTLAYERs**;
  - **LocalVariety** sets each location to a value indicating the number of dissimilar values associated with that location on **1STLAYER** and one or more **NEXTLAYERs**;
  - **LocalMajority** sets each location to the most frequently occurring of its values on **1STLAYER** and one or more **NEXTLAYERs**;
  - **LocalMinority** sets each location to the least frequently occurring of its values on **1STLAYER** and one or more **NEXTLAYERs**;
  - **LocalAmount** sets each location to a value that indicates how often its **1STLAYER** value matches that of a **NEXTLAYER**;
  - **LocalRank** sets each location to a value that identifies the interval containing its **1STLAYER** value when its **NEXTLAYER** values are divided into a specified series of interval;
  - **LocalMean** sets each location to the average of its values on **1STLAYER** and one or more **NEXTLAYERs**;
  - **LocalMaximum** sets each location to the highest of its values on **1STLAYER** and one or more **NEXTLAYERs**;
**MAP ALGEBRA**

- **LocalMinimum** sets each location to the lowest of its values on 1STLAYER and one or more NEXTLAYERS;
- **LocalCalculation** sets each location to a value computed by subjecting its values on a specified set of existing layers to one or more standard mathematical functions;
- **LocalInteger** sets each location to a value computed by rounding or truncating its 1STLAYER value to integer form;
- **LocalBitSelection** sets each location to a value computed by subjecting its values on a specified set of existing layers to one or more standard bitwise operations.

An example of the LocalCalculation function is presented in Figure 3.

**Figure 3** The LocalCalculation function. DistanceInBetween is a layer on which each location’s value indicates the total distance from one destination to another (red dots) through that location. This layer was created by subjecting layers of planar distance from those two destinations (Distance and MoreDistance) to a function specified as follows:

\[
\text{DistanceInBetween} = \text{LocalCalculation of Distance} + \text{MoreDistance}
\]
Zonal functions

Each of the zonal functions generates a new layer on which every location is set to a value computed from the values of all locations that share its zone on a designated layer. Zonal functions are specified as:

\[
\text{NEWLAYER} = \text{ZonalFUNCTION of} \quad 1\text{STLAYER} \quad \text{within} \quad 2\text{NDLAYER}
\]

where

- **NEWLAYER** specifies the new layer to be generated;
- **1STLAYER** specifies an existing layer of values to be processed;
- **2NDLAYER** specifies another existing layer defining the zones within which **1STLAYER** values are to be considered;
- **ZonalFUNCTION** specifies that new values are to be computed as follows:
  - **ZonalRating** sets each location to a value explicitly specified (either as a numeral representing that value or the name of an existing layer from which the location’s new value is to be drawn) according to the set of **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalMix** sets each location to a value that identifies the particular combination of **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalVariety** sets each location to a value indicating the number of dissimilar **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalMajority** sets each location to the most frequently occurring of the **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalMinority** sets each location to the least frequently occurring of the **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalAmount** sets each location to a value indicating how often its **1STLAYER** value matches that of another location within its **2NDLAYER** zone;
  - **ZonalRank** sets each location to a value identifying the interval containing its **1STLAYER** value when all of the locations within its **2NDLAYER** zone are divided into a specified series of intervals by **1STLAYER** value;
  - **ZonalMean** sets each location to the location-wise average of **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalMaximum** sets each location to the highest of the **1STLAYER** values within its **2NDLAYER** zone;
  - **ZonalMinimum** sets each location to the lowest of the **1STLAYER** values within its **2NDLAYER** zone;
MAP ALGEBRA

**Figure 4** The $ZonalMinimum$ function. $DistanceToEachHill$ is a layer on which each location’s value indicates the distance from a particular destination (red dot) to the hill, if any, containing that location. This layer was created by subjecting a layer of distance from that destination ($Distance$) and a layer of individual hills ($EachHill$) to a function specified as follows:

$$DistanceToEachHill = ZonalMinimum\ of\ Distance\ within\ EachHill$$

$ZonalSum$ sets each location to the location-wise sum of $1STLAYER$ values within its $2NDLAYER$ zone.

An example of the $ZonalMinimum$ function is presented in Figure 4.

**Focal functions of lateral neighbors**

Each of the focal functions generates a new layer on which every location is set to a value computed from the values of its neighbors within a designated neighborhood. Lateral neighborhoods encompass locations that lie at specified planar distances and/or directions from each
neighborhood focus. Focal functions of lateral
neighborhoods are specified as

\[
\text{NEWLAYER} = \text{FocalFUNCTION of}
\]

\[
\text{1STLAYER at DISTANCE by DIRECTION}
\]

where

\text{NEWLAYER} \quad \text{specifies the new layer to be generated;}

\text{1STLAYER} \quad \text{specifies the existing layer of values to be processed;}

\text{DISTANCE} \quad \text{specifies the distance(s) bounding each neighborhood (which can vary from one location to another);}

\text{DIRECTION} \quad \text{specifies the direction(s) bounding each neighborhood (which can also vary from one location to another);}

\text{FocalFUNCTION} \quad \text{specifies that new values are to be computed as follows.}

\text{FocalRating} \quad \text{sets each location to a value explicitly specified (either as a numeral representing that value or the name of an existing layer from which the location’s new value is to be drawn) according to the set of 1STLAYER values within its neighborhood;}

\text{FocalMix} \quad \text{sets each location to a value identifying the particular combination of 1STLAYER values within its neighborhood;}

\text{FocalVariety} \quad \text{sets each location to a value indicating the number of dissimilar 1STLAYER values within its neighborhood;}

\text{FocalMajority} \quad \text{sets each location to the most frequently occurring of the 1STLAYER values within its neighborhood;}

\text{FocalMinority} \quad \text{sets each location to the least frequently occurring of the 1STLAYER values within its neighborhood;}

\text{FocalAmount} \quad \text{sets each location to a value indicating how often its 1STLAYER value matches that of another location within its neighborhood;}

\text{FocalRank} \quad \text{sets each location to a value identifying the interval containing its 1STLAYER value when all of the locations within its neighborhood are divided into a specified series of intervals by 1STLAYER value;}

\text{FocalMean} \quad \text{sets each location to the location-wise average of 1STLAYER values within its neighborhood;}

\text{FocalMaximum} \quad \text{sets each location to the highest of the 1STLAYER values within its neighborhood;}

\text{FocalMinimum} \quad \text{sets each location to the lowest of the 1STLAYER values within its neighborhood;}

\text{FocalSum} \quad \text{sets each location to the location-wise sum of}
MAP ALGEBRA

1STLAYER values within its neighborhood;

FocalProximity sets each location to its distance from the nearest of a set of neighbors identified by their 1STLAYER values;

FocalBearing sets each location to its direction from the nearest of a set of neighbors identified by their 1STLAYER values;

FocalNeighbor sets each location to the value of the nearest of a set of neighbors identified by their 1STLAYER values;

FocalConvolution sets each location to a position-weighted average of 1STLAYER values within its neighborhood;

FocalInterpolation sets each location to a distance-weighted average of the 1STLAYER values within its neighborhood;

FocalDistribution sets each location to a value computed by summing contributions from selected neighbors when each of those neighbors distributes its 1STLAYER value to surrounding locations in distance-weighted proportions;

FocalInsularity sets each location to a value that distinguishes it as part of an insular (or near-insular) group of locations that share the same 1STLAYER value.

Examples of the FocalBearing and FocalProximity functions are presented in Figure 5.

The Distance layer shown in Figures 3 and 4 was generated with a similar function specified as follows.

\[ \text{Distance} = \text{FocalProximity of Destination} \]

where

\text{NEWLAYER}, \text{1STLAYER}, \text{DISTANCE}, \text{DIRECTION}, \text{and FocalFUNCTION}

\text{SURFACE LAYER}

\text{specifies an existing layer on which each location's value indicates its elevation on an opaque (usually topographic) surface;}

\text{are all as described for focal functions of lateral neighborhoods (except for the absence of FocalConvolution)}

\text{Visible neighborhoods encompass locations that lie at designated planar distances and/or directions from each neighborhood focus and also within visual contact of that focus. Focal functions of visible neighborhoods are specified as:}

\text{NEWLAYER}

\text{= FocalFUNCTION of 1STLAYER at DISTANCE by DIRECTION radiating on SURFACE LAYER from TRANSMISSION LAYER through OBSTRUCTION LAYER to RECEPTION LAYER}
Figure 5  The *FocalBearing* and *FocalProximity* functions. *Direction* is a layer on which each location’s value indicates the compass direction from that location toward a particular destination (red dot). This layer was created by subjecting a layer depicting that destination (*Destination*) to a function specified as follows:

\[ \text{Direction} = \text{FocalBearing of Destination} \]

*TRANSMISSIONLAYER* specifies an existing layer on which each location’s value indicates the height above *SURFACE LAYER* at (or below) which that location is visually opaque; *RECEPTIONLAYER* specifies an existing layer on which each location’s value indicates the height above *SURFACE LAYER* at (or below) which that location is able to establish visual contact with other locations.

*OBSTRUCTIONLAYER* specifies an existing layer on which each location’s value indicates the height above *SURFACE LAYER*.
Visibility is a layer on which each location’s value indicates the distance to that location from a particular destination (red dot) but only if the location lies within visual contact of that destination. This layer was created by subjecting a layer depicting the destination (Destination) and a layer of topographic elevation (Elevation) to a function specified as follows:

\[
\text{Visibility} = \text{FocalProximity of Destination radiating on Elevation}
\]

If any of SURFACELAYER, TRANSMISSION-LAYER, OBSTRUCTIONLAYER, or RECEPTIONLAYER is unspecified, the layer assumed is one on which every location’s value is set to 0.

An example of one of the FocalProximity radiating function is presented in Figure 6.

Focal functions of accessible neighbors

Accessible neighborhoods encompass locations that lie at designated distances from each neighborhood focus, but where distances are measured in terms of travel cost. Focal functions of accessible neighborhoods are specified as:

\[
\text{NEWLAYER} = \text{FocalFUNCTION of 1STLAYER at DISTANCE by DIRECTION spreading in FRICTIONLAYER on SURFACELAYER through NETWORKLAYER}
\]
where

**NEWLAYER**, **1STLAYER**, **DISTANCE**, and, **FocalFUNCTION** are all as described for focal functions of lateral neighborhoods (except for the absence of **FocalConvolution**);

**FRICTIONLAYER** specifies an existing layer on which each location’s value indicates the amount of travel cost per unit of physical distance at that location;

**SURFACELAYER** specifies an existing layer on which each location’s value indicates its elevation on what is usually a topographic surface such that the physical distance between that location and any of its adjacent neighbors accounts for their vertical as well as their horizontal positions;

**NETWORKLAYER** specifies an existing layer on which each location’s value indicates which of its adjacent neighbors are directly accessible from that location.

If any of **FRICTIONLAYER**, **SURFACE-LAYER**, or **NETWORKLAYER** is unspecified, the layer assumed is one on which every location’s value is set to 0.

An example of the **FocalProximity spreading** function is presented in Figure 7.

**Focal functions of local neighbors**

Local neighborhoods encompass only those locations that lie on or adjacent to each neighborhood focus, and focal functions of these neighborhoods use them to characterize their foci as parts of larger geometric forms. Those forms may be 1-, 2- or 3-D in nature, and the value computed for each location within a given form generally indicates its unique contribution to the overall measurement of a geometric characteristic such as length, area, or volume. Focal functions of local neighborhoods are specified as:

\[
\text{NEWLAYER} \cdot \text{FocalFUNCTION of } 1\text{STLAYER} \quad \text{on } \text{SURFACELAYER}
\]

where

**NEWLAYER** specifies the new layer to be generated;

**1STLAYER** specifies an existing layer depicting 1- or 2-D forms;

**SURFACELAYER** specifies an existing layer depicting 3-D form (assumed to be flat if this layer is unspecified);

**FocalFUNCTION** specifies that new values are to be computed as follows:

- **FocalLinkage** sets each location to a value identifying the configuration of linear connections occurring at that location on **1STLAYER**;
- **FocalLength** sets each location to the total length of all linear connections occurring at that location on **1STLAYER** when projected onto a **SURFACELAYER** surface;
**Figure 7** The *FocalProximity spreading* function. *TravelCost* is a layer on which each location’s value indicates the cost of travel required to reach to that location from a particular destination (red dot). This layer was created by subjecting a layer depicting that destination (*Destination*) and a layer indicating the rates at which travel costs are incurred (*CostPerStep*) to a function specified as follows:

\[
TravelCost = \text{FocalProximity of Destination spreading in CostPerStep}
\]

- **FocalPartition** sets each location to a value identifying the configuration of areal boundaries occurring at that location on *1STLAYER*; that location’s portion of *1STLAYER* when projected onto a *SURFACELAYER* surface;
- **FocalFrontage** sets each location to the total length of all boundaries occurring at that location on *1STLAYER* when projected onto a *SURFACELAYER* surface; sets each location to a value indicating the surficial steepness at that location on a *SURFACELAYER* surface partitioned into *1STLAYER* zones;
- **FocalArea** sets each location to the surface area associated with that location’s portion of *1STLAYER* when projected onto a *SURFACELAYER* surface; sets each location to a value indicating the compass direction of surficial descent;
The *FocalDrainage* function. *TravelDirection* is a layer on which each location’s value indicates the direction of the minimum cost path to that location from a particular destination (red dot). This layer was created by subjecting a layer depicting the cost of travel from that destination (the *TravelCost* layer presented in Figure 7) to a function specified as follows:

\[
TravelDirection = FocalDrainage \text{ of } TravelCost
\]

An example of one of the *FocalDrainage* function is presented in Figure 8.

Also shown for comparison is a layer that was created as follows from the *Elevation* layer presented in Figure 6.

\[
DownhillDirection = FocalDrainage \text{ of } Elevation
\]
Convexity is a layer on which each location’s value indicates the degree to which a topographic surface is convex or concave in the vicinity of that location. This layer was created by subjecting a layer of topographic elevation (the *Elevation* layer presented in Figure 6) to a sequence of functions specified as follows:

\[
\text{MeanElevation} = \text{FocalMean of Elevation at } \ldots 100
\]

\[
\text{Convexity} = \text{LocalCalculation of Elevation} - \text{MeanElevation}
\]

The *EachHill* layer shown in Figure 4 was then created as follows:

\[
\text{AllHills} = \text{LocalSelection of Convexity} > 30
\]

\[
\text{EachHill} = \text{FocalInsularity of AllHills}
\]

**Compound Functions**

While it is easy to argue for additions to the elementary map algebraic functions, it is often more useful to note how such functions can be composed from those already available. Consider, for example, how elementary functions might be used to create general-purpose compound functions with names like *LocalAbsoluteValue*, *ZonalRange*, or *FocalStandardDeviation*. Of course, more specialized sequences of
elementary functions can also be composed, stored, and invoked as compound functions.

To demonstrate the power of these functions and the kind of thinking involved in their creation, consider a contrived example. It begins as described in Figure 9 by generating a layer of hills. As illustrated in Figure 10, it then goes on to indicate which of each hill’s internal locations is (or are) closest to a specified destination. Finally, as illustrated in Figure 11, each location is set to a value indicating whether or not any of those selected hill locations lie upstream on a 3-D surface of travel-cost proximity to that destination.

The technique used here to delineate minimum cost paths effectively drains those selected locations over the 3-D surface of travel costs just as rainfall might be drained over a 3-D surface of topographic elevation. Much of the power of map algebra relates to this sort of connection.

Figure 10  A ZonalLowPoint function. HillPoints is a layer that identifies the location (black dot) within each of a set of (tan) hills that is closest to a given destination in terms of travel cost. This layer was created by subjecting a layer of hills (the EachHill layer described in Figure 9) and a layer of travel cost (the TravelCost layer presented in Figure 7) to a sequence of functions specified as follows:

$$
\text{HillCost} = \text{ZonalMinimum of TravelCost within EachHill}
$$

$$
\text{HillPoints} = \text{LocalSelection of TravelCost == HillCost}
$$
Figure 11  A FocalRouting function. Paths is a layer delineating the minimum cost routes (red lines) from a set of origins (black dots) to a particular destination (red dot). This layer was created by subjecting a layer of those origins (the HillPoints layer described in Figure 10) and a layer of directions (the TravelDirection layer presented in Figure 8) to a sequence of functions specified as follows:

$$\text{Traffic} = \text{FocalSum of HillPoints spreading through TravelDirection}$$

$$\text{Paths} = \text{LocalSelection of Traffic} > 0$$

between seemingly unrelated phenomena. By transcending particulars and focusing instead on the general nature of geospatial variables and functions, it is often possible to grasp concepts and develop insights more effectively than might otherwise be likely.

Consider again, for example, the apparent similarity between those surfaces of elevation and travel cost. Applying the FocalGradient function to a layer of topographic elevation would yield a layer of topographic steepness. Applying it to a layer of travel costs would yield a layer very much like the FRICTIONLAYER layer from which travels costs were computed by using FocalProximity spreading. The reason for this reflects on the fundamental nature of the FocalProximity spreading.

Also consider again the apparent similarity between layers of travel cost and planar distance. In Figure 3 is a layer of ellipses between two
Figure 12 The cost of traveling from here to there at locations in between. \( \text{TravelCostInBetween} \) is a layer on which each location’s value indicates the total cost of travel from one destination to another (red dots) through that location. This layer was created by subjecting layers of travel cost from those two destinations (\( \text{TravelCost} \) and \( \text{MoreTravelCost} \)) to a function specified as follows:

\[
\text{TravelCostInBetween} = \text{FocalCalculation of TravelCost} + \text{MoreTravelCost}
\]

destinations that was generated by adding each location’s distances from those destinations. In Figure 12 is the travel-cost equivalent: a rather different pattern but one that also arises from the measurement of in-betweenness.

Reasons for generalizing

The ambition

Many tasks require the use of maps (whether in digital or paper form). They range in scale from the highly detailed (1:500), through the commonly used midscale topographic range (1:50,000), to the world maps found in atlases (1:50 million). There is increasing thematic diversity across those scales, fueled by an expectation that anyone can collect their own data, integrate it with others, quickly produce their own map (a “mashup”), and share it across the web. Now everyone is a cartographer (the so-called democratization of cartography) and can participate in solving the challenges of the world (cybercartography).

In reality it is difficult to source and integrate data at appropriate levels of detail (scale); users have poor cartographic knowledge and risk producing dreadful maps that mislead rather than inform. Whilst the default symbology of geographical information systems (GIS) might go some way to facilitating the creation of maps, GIS cannot deal with the notion that map design is a complex decision-making process – very much one of finding compromise among a competing set of constraints. The complexity of this design task was why large teams of highly trained and experienced human cartographers were required in order to produce series mapping at a wide range of scales; their manual solutions reflected a deep knowledge of the map generalization process and the ways and means by which geographic entities might best be illustrated at different scales. In the computer age, the human cartographer was seen as something of an anachronism and an impediment to high levels of automation. People sought ways to reduce the involvement of humans in the map generalization process by trying to capture and embed their “know how” within automated mapping systems. Thus the question became: Can we capture the map requirements of the user, automatically select appropriate contextualizing data, integrate those data and visualize them, at an appropriate scale, with clarity, taking into consideration aesthetic considerations, whilst concealing the complexity of this task from the user? This ambition very much defines map generalization research today. Can map generalization automatically produce maps at a range of scales with minimum human intervention (Figure 1)?

A definition

The opportunities and challenges of automated mapping first became apparent in the 1960s. The initial focus was on scanning and digitizing paper maps produced by national mapping agencies (NMAs). For example the Ordnance Survey, the NMA of Great Britain, completed this task in the 1970s. Typically, NMAs produced map series
at specific scales and each series had its own production environment independent of other map series. This “silo” approach to map production was echoed in the digital environment but it was quickly realized that there was huge redundancy in this approach. The question became: Could we not capture and represent the world at the finest scale, and from this fine scale derive more generalized representations? For example, could algorithms be developed whereby the streets, pavements, gardens, and individual houses could be grouped and represented as suburbs? Could these in turn be combined with representations of the commercial districts and green spaces in order to represent cities, which in turn might eventually be represented as labeled dots on a map showing an entire country? In such a context, changes made at the finest scale would be automatically reflected at the coarse scale. Free of the shackles of paper-based, map series production, that vision has been further expanded, reflecting a context of “scale-free” web-based mapping, in which the user can interact with the data in real time, pinch and swipe (zoom and “slide”) across the map using any device.

Early research into map generalization had topographic mapping as its focus in anticipation of an NMA’s paper-based requirements. Nowadays that context lies more with exploratory analysis and in anticipation of users who have limited appreciation of map production and design. It seeks to embrace the open source vision and accommodate the ambition of being able to mix together multiple sources of data (both formal and user-generated), captured at fundamentally different scales. The definition given by the International Cartographic Association in 1973 is that map generalization is concerned with “the selection and simplified representation of detail appropriate to the scale and/or the purpose of the map.” At its heart, map generalization is about the process of abstraction, conveying patterns and associations among a set of geographic phenomena. The context of use has changed dramatically but the ambition remains the same – namely, to efficiently communicate a particular geography of the world.

**Reasons for automating the map generalization process**

The first motivation for automating generalization comes from the need to produce maps quickly, and at low cost. For decades, manual generalization was used to produce topographic or more thematic maps, but this was time-consuming (expensive) and the typical 5–10-year update cycles were no longer compatible with current standards of data currency and productivity constraints (Duchêne *et al.* 2014). Automating the
generalization process seeks to ensure cartographic quality whilst reducing costs. Flexible automated generalization tools enable customizable integration of topographic data (backdrop data) with thematic map data (salient data). This is particularly relevant in the context of maps made by nonexperts in web-based environments – where the absence of generalization functionality can lead to maps of very poor cartographic quality (Gaffuri 2011; Figure 2).

Another motivation for automating generalization is the opportunity for data producers or integrators to improve geographic database management, by capturing the initial data at a fine level of detail and automatically deriving both coarser databases (referred to as digital landscape models) and maps at different scales (digital cartographic models). This improves consistency and data quality by making explicit the route by which different maps were derived.

Automated generalization helps both with data management and with derivation of customized databases and maps in the context of spatial data infrastructures (SDIs). SDIs are infrastructures that, via geoportals, provide access to institutional geographic datasets stemming from diverse sources and services. In the context of SDIs, an important process is the integration of datasets from diverse sources (e.g., different national agencies) into a seamless dataset that enables cross-border geographic studies. Whenever the levels of detail of the input datasets are different, automated generalization is used to homogenize the data as a first step to integration (Stanislawski and Savino 2011). Figure 3 shows pan-European data from EuroGeographics (via www.geoportail.gouv.fr) and reveals uneven hydrographic detail reflecting the varying definitions of what constitutes a “major river.” Generalization can be used to even out such differences.

Modeling the generalization process

Generalization operators

From observation of the human cartographer, it is possible to identify a set of discrete activities that collectively lead to the creation of a generalized map. For example, the line work representing rivers might be simplified in its form, the polygonal field data might be merged, or more generic text labeling might help reduce clutter. Much effort has been invested in creating a taxonomy of these operators (Figure 4 is an example), in the development of algorithms, and evaluative frameworks that enable assessment of the quality of any given solution. The difference between an operator and an algorithm is that an operator articulates how the cartographer conceptualizes the cartographic design decision while the algorithm articulates the execution of that decision (Roth et al. 2011). The taxonomy comprises a range of operators that can be loosely classified into one of two types of operator; those...
addressing the modeling of data (selection and reclassification) and the rest that seek to bring clarity to the map (model generalization and cartographic generalization). Some algorithms are specific to a particular feature type, whilst others can be applied more generically.

The subtle and complex epistemic nature of cartography is reflected in the many attempts to create a comprehensive taxonomy of generalization operators (Roth, Brewer, and Stryker 2011). Different taxonomies reflect various conceptualizations of the cartographic process and the difficulty in differentiating between outputs arising from various algorithms applied in varying degree. For example selection and elimination are conceptually similar while aggregation can be further differentiated into fusion of two connected objects or the merging of disjoint objects. Whilst the problem is often rationalized (and implemented) at a geometric level, the essence of the problem is a semantic one – namely, how to transform semantic information at one level to information at another. For this to happen, we need to take into account the underlying geography that we are seeking to visualize at the geometric level. For example, the simplification of lines representing streets is very different from the simplification of lines representing the outlines of buildings.

Generalization algorithms

The wide diversity and number of generalization algorithms reflect the breadth of feature classes, their different representational forms, and how they are stored within the database. Though algorithms have been developed to generalize data in raster form, the dominant focus is on vector-based algorithms. This entry first considers those algorithms that manipulate individual objects, and then those able to take a more

**Figure 4** A taxonomy of generalization operators.
contextual approach by taking into account their spatial and topological relationships with respect to other map features. Space prohibits exhaustive review. Instead, a subset of algorithms is considered under the following three headings.

**Generalization algorithms for isolated objects**

Early forays into automated generalization focused on the simplification of individual lines using geometric transformations parameterized by tolerance values (e.g., the line simplification algorithm of Douglas and Peucker (1973)). The algorithm starts with a straight connection between the first and the last point of the line, followed by a recursive subdivision in which points are retained based on the largest perpendicular distance between the original line and its straight line connection (Figure 5). The storage within a hierarchical data structure provides fast and ordered access to the points describing the line, from the smallest critical set down to the finest level, depending on the tolerance length required ($\varepsilon$).

Another approach for line simplification was proposed by Visvalingam and Whyatt (1993) with elimination of points based on the smallest triangles created by successive triplets of points along the line. Both algorithms provide a sorting of points according to their importance. Whilst these algorithms reduce the number of points used to represent a line, a different class of algorithms was developed for the smoothing of isolated lines. A distinction can be made between the use of spatial filters (e.g., moving average filter, Gaussian line smoothing, Perkal’s $\varepsilon$-circle rolling), curve fitting (e.g., least squares fitting, spline interpolation), and application of frequency filters (e.g., Fourier or wavelet transformation). Algorithms can be applied to a variety of object classes, though problems arise.

![Figure 5](image.jpg)  
**Figure 5** The Douglas–Peucker algorithm: (a) pseudo code; (b) iterative point reduction; (c) a binary line generalization tree of the corresponding hierarchical data structure.
through the creation of self-intersections or changes in topology with respect to neighboring objects. These same algorithms can be applied to lines representing natural polygonal features such as woods and lake boundaries. However, a different class of algorithm is required for anthropogenic features such as buildings with their orthogonal shapes and sharp edges. The fitting and rotation of a minimum bounding box is one approach to simplifying such forms. Different algorithms are required for natural polygonal features (for example, a combination of dilating and eroding buffers can be used to merge and create simplified forms). Algorithms have also been developed for area elimination or for the collapsing of area objects to a linear or point representation (effectively reducing the dimensionality of the data). A center of gravity calculation is a simple way of representing an area as a point. More complex skeletonization algorithms are required to simplify areas to linear features (for example, reducing a detailed representation of a river down to a single linear form). Typical application cases are the derivation of large-scale topographic maps at a scale of 1:10,000 with streets and rivers modeled as lines, or the creation of network graphs from cadastral data at 1:1000 scale where streets and rivers are modeled as polygons (Figure 6).

**Generalization algorithms for connected objects**

Two types of algorithms exist for handling connected objects – those that generalize networks, and those that generalize polygon mosaics (or polygonal networks). Networks are modeled as graphs comprising segments connected by nodes. Polygon mosaics are modeled via the shared edges between the polygon boundaries. Algorithms for the transformation of network graphs (such as rivers or stream networks) utilize hierarchical ordering schemes based on branching complexity such as those proposed by Strahler, Horton, or Shreve. The Strahler stream ordering begins with numbering the unbranching streams with the value one. At the confluence of two branches with the same order the number will be increased, otherwise the higher number is taken (Figure 7). Selective omission can then be carried out through elimination of lower-order river objects followed by line simplification and smoothing operations.

Figure 6  Roads modeled as polygons within cadastral data (a) and skeleton algorithm applied on polygons (b) resulting in roads modeled as lines (c) for overview maps. Haunert and Sester 2004. Reproduced by permission of ICA Commission on Generalisation and Multiple Representation.
Algorithms for the simplification of transportation or road networks apply selective omission based on the road classes, topological constraints, and the good continuation grouping principle (Thomson and Brooks 2007). At each intersection the angles between connecting segments are calculated and pairs of segments are concatenated into “strokes” based on the analysis of that angle. A ranking of the strokes is achieved by considering geometric, thematic, and topological information and this provides an ordering by which the network can then be pruned.

Polygon mosaics which represent, for example, administrative boundaries or land cover data require the topological encoding of shared boundaries. Various criteria govern the merging of adjacent polygons including shape compactness and semantic similarity. One example of such topological data encoding is the variable scale representation of area partitions using topological generalized area partitioning (tGAP) developed by Van Oosterom (2005). The tGAP provides real-time access to a representation at a broad range of scales (Figure 8). Line simplification algorithms and skeletonization algorithms have been additionally utilized in mosaic generalization.

Generalization algorithms for contextualized objects

A third group of algorithms exist that are capable of analyzing the surrounding spatial context of an object. This is required where the generalization of an object is likely to impact on surrounding objects. For example, we might displace a group of objects in order to make them less ambiguous, but this approach is only possible where there is sufficient space to accommodate the displacement. Another example might be to retain the alignment of a group of features during displacement. Thus a range of cartometric techniques are required that measure changes in qualities such as the distribution, pattern, topology, and distances between a collection of features.

The process of typification seeks to reduce the number of objects whilst preserving their distribution pattern. A range of techniques have been developed that are based on clustering methods, neural networks, or mesh simplification techniques. Using hierarchical clustering methods such as single-linkage or nearest neighbor clustering enables individual objects to be sequentially combined in a hierarchical structure. Delaunay triangulation is an example of an auxiliary data structure that makes explicit information about neighboring objects; such information can be used in the process of typification, for example (Figure 9).

Selecting and combining generalization algorithms

Map generalization methodologies are generally reactive in nature. By this we mean that design
conflicts only become apparent once the data are symbolized. For example, consider how the symbolization of a road, river, and railway running through a gorge might result in overlapping and confusing symbology. Some remedies might be to remove a feature class; to simplify the shape of the features; to locally displace some of the feature classes; or to amalgamate some of the feature classes. Invariably, a combination of algorithms are used to resolve such conflicts, which raises the question, how do we select and combine these algorithms, and when is their application deemed to have resolved the conflict? Measures of content linked to changes in scale have been proposed as one approach. For example, a power law distribution between the ratio of source and target scale denominators \( M_1/M_2 \) and the number of objects before \( (n_1) \)

![Figure 8](image-url)

and after \( n_2 \) generalization was empirically developed by Töpfer and Pillewizer (1966) and provides a guiding principle of selection:

\[
 n_2 = n_1 \sqrt{M_1 / M_2}
\]

However, knowing the proposed number of objects for a given scale does not help us to decide how best to combine and variously apply these many algorithms. For this task, four approaches are possible: human interaction models; condition-action modeling; constraint-based modeling; and flowline modeling (service chaining). In human interaction modeling the expertise of the user is drawn upon to select the data and the scale and theme of the map, to decide on the generalization strategy, and to assess whether the final map output is adequate. The focus is very much on an interface design that supports the intuitive execution of all these tasks. The anticipated environment of use is within NMAs in which there is a clear understanding of the map specification requirements. All the decisions are made by the human.

A second approach is condition-action modeling. The earliest attempts at automation used a rule-based approach, typically of the form: IF <this situation arises in the map> THEN <apply algorithm \( x \) to feature object \( y \>). For example, IF the building symbology overlaps the road THEN displace the building footprint away from the road. It was envisaged that such condition-action modeling could readily be distilled from detailed map specifications associated with topographic mapping, and that rules of thumb (heuristics) governing the ordering of algorithms could be derived from observation of the human cartographer at work. For example, it was noted that the process began with modeling (selection and classification of data), followed by graphical considerations focused on clarification of the data (aggregation, smoothing, and displacement). In reality, it proved hard to formalize these condition-action pairings and such systems proved inflexible in dealing with the various mixes of features comprising any given conflict. A third and more fruitful approach has been to use constraint-based modeling. In this approach various internal and external constraints are defined (e.g., minimum separation between features; minimum changes in area and distortion of shape; minimum loss of locational precision; and maintenance of distribution patterns). The idea is that various actions associated with each constraint are then triggered. An optimization engine is used to determine the maximum number of constraints that can be satisfied. Such an approach has been incorporated within agent-based methodologies in which the behaviors and interactions among map features can be modeled as a key component to constraint-based modeling (Ruas and Duchene 2007).

The fourth approach is referred to as flowline modeling or service chaining. It involves the sequencing (and possible iteration) of map generalization algorithms based on parameter values derived from research in constraint-based modeling. It has proved popular among NMAs because of its relative simplicity, transparency, and repeatability, thus ensuring consistency and quality control throughout the map production process. In effect it involves the hard wiring of the values derived from the optimization engine within a constraint-based approach. These four approaches are not mutually exclusive; one can readily envisage a hybrid approach and a sliding scale of dependency upon the decision-making capacity of the human. Different contexts and different levels of expertise will govern which mix of approaches is most appropriate in any given context.
Evaluation in generalization

The final generalized map reflects a compromise in terms of clarity and truthfulness: clarity in conveying the relationships among the various features (both metric and topological), and truthfulness in conveying the reality of what is actually there. The omission of something, or its displacement, makes the map less truthful, but improves its clarity. The question becomes: Are the distortions of truth acceptable given the context of use?

To measure any change in truth, and to assess the clarity of the map, we first need to apply a range of cartometric techniques that inform us of the properties of the features. Metric and topological measures can be applied at the micro scale (the individual feature or its parts), at the meso scale (examining local groups of features), and at the macro scale (all occurrences of a particular feature across the map). Thus we can measure changes internal to a feature (its shape, length, area), as well as changes relative to other features (their topology, density, and distribution). A range of techniques can be used to make explicit properties that are implicit in the arrangement of those features. For example, graph theory can be used to model changes among network features and Voronoi diagrams can be used to create surfaces that define neighborhoods.

But it is one thing to measure, and another to know the significance of any given measurement in terms of the generalized map. Beyond these many geometric measures, it is imperative to make explicit the semantic relationships inherent among a set of features (Touya et al. 2014). For example, if we no longer wish to show a river, then perhaps it is not meaningful to show the bridge by which the road crossed that river. If we model the semantics of this relationship, it provides the basis for this type of cartographic decision-making. Space precludes exhaustive review of these methods of geometric and semantic enrichment, suffice to say that they are critical to the detection of conflict and to the measurement of the degree of success in their remediation. In the absence of such data enrichment techniques (making the implicit explicit), our capacity to automate is curtailed and we must depend upon the eyes of the user to detect and resolve such conflicts.

Implementations and operational environments

One can argue that the veracity of these approaches is evident in their operationalization within NMAs and their incorporation within commercial off-the-shelf GIS systems and web-based services. Here some operational use cases are briefly reported on.

Automated generalization in national mapping agencies

In the 1980s, research into automated generalization was mostly driven by the needs of NMAs. Yet it was the early 2000s before we began to see automated cartographic generalization methods being comprehensively incorporated within production environments – an endeavor that depended on massive in-house developments based on research results. One example of this was work at IGN France with the production of the 1:100,000 map. The time allocated for manual generalization for one map sheet had typically been 1200 hours. As a result of automation, this reduced to 50 hours of automated processing and 100 hours of manual corrections per sheet (Lecordix et al. 2005; Figure 10).

More recently there has been a surge in adoption of automated techniques among a number of NMAs (Duchêne et al. 2014). For the first time, three NMAs have produced maps in fully automated environments: Kadaster Netherlands with their 1:50,000 map, and Ordnance Survey...
Figure 10 Results obtained in production with automated generalization at IGN France: production of the 1:100 000 map from the “BDCarto” database. Lecordix et al. 2005. Extracts of maps © IGN.

Great Britain and IGN France with their simplified versions of their standard 1:25 000 map (Figure 11). Two factors have contributed to their success, both reflecting an ability to industrialize results from map generalization research. First, the incorporation of customizable map generalization modules within commercial GIS software, and second, being able to draw upon in-house expertise to develop additional generalization functionalities. Fully automated environments produce meaningful and acceptable results. Where high-quality solutions are required, some manual intervention is still needed.

The traditional emphasis on paper maps is being replaced by a focus on delivery of maps via web-based geoportals. In these cases, a series of outputs are stored. Each output is bound by a minimum and maximum zoom level. Thus, as the user zooms in (or out), the initially displayed map is replaced with a map at larger (or smaller) scale. NMAs have begun harmonizing the symbols used on maps across scales for display via the web in order to smooth the transition from one zoom level to another. As a result of using vector digital cartographic models (DCMs) instead of raster maps, some NMAs also enable customization of the displayed maps, by interactive selection and deselection of layers, a case in point being the NMA of the United States, the US Geological Survey (USGS), with its multiscale “National Map” (produced semiautomatically). The associated web viewer enables the user to choose which layers to display. The USGS has placed great store by its focus on web-based delivery – providing more advanced kinds of customization, including the ability to integrate thematic data provided by the user. As NMAs become more confident, they are making increasing use of cartographic generalization techniques in the updating of their digital landscape models (DLMs), with the “capture once, use many times” model in mind.

Online generalization for web and mobile maps

Traditionally, the emphasis has been on the production of maps “offline” which are then
Fully automated cartographic generalization was first achieved in production in 2013, in three NMAs: Ordnance Survey Great Britain (left), IGN France (middle), and Kadaster Netherlands (right). Top left image reproduced by permission of Ordnance Survey. © Crown copyright and/or database right 2016 OS. Bottom left image contains OS data © Crown copyright and database right. made available online as passive images and in vector format. The complexity of production (and processing time) necessitates this approach (i.e., it has not been possible to deliver generalized maps in real time). However, it binds the user to a predefined set of outputs. Therefore a number of research studies have tried to address this issue through a hybrid approach that creates a number of precomputed levels of detail (offline generalization) that can be subsequently modified in real time by the user based on (i) the zoom level, (ii) the addition of their own thematic data (perhaps also obtained in real time), and (iii) their location.

Figure 12 shows examples of such maps obtained via advanced prototypes stemming from three studies. The first example is from a European project named WebPark which focused on the real-time delivery of touristic and recreational information to national park visitors based on their location. In this context, Edwardes (2007) proposed on-the-fly selection and aggregation methods to generate real-time views of fauna locations at different abstraction levels (Figure 12a). Depending on the zoom level, a pie chart shows the proportions of species that can be observed from a given location (top), or a small image shows the majority species and their relative numbers (bottom). The second example is from the European project GiMoDig (geospatial info-mobility service by real-time data-integration and generalization), which sought to deliver data from different European NMAs to mobile users by means of real-time data.
integration and generalization. In this context, Harrie, Sarjakoski, and Lehto (2002) proposed a cartographic display where the area around the user’s position is emphasized by a circular “fisheye” lens (Figure 12b), while the rest of the area is generalized on-the-fly by simple selection and simplification algorithms. The third example is from work done as part of INSPIRE (infrastructure for spatial information in the European Community) – a European directive, which envisages the creation of a European spatial data infrastructure supporting the online publication of NMAs’ vector data and associated on-the-fly services. In this context, Gaffuri and Tóth (2014) have proposed a system that transfers the relevant portion of a vector dataset to the web client of the user based on pan and zoom “requests.” Simple cartographic methods are then applied on the client side to obtain a more synthetic representation (in Figure 12c, a density map is computed from a point cloud). Having the vector data on the client side enables quicker interactivity with the representation.

**Evolving contexts**

The value of a map lies in its abstraction of geography. A map is a caricature – a compromise between clarity and truthfulness. The overarching ambition of map generalization is well understood – requiring as it does the modeling of user requirements that results in a map specification, a choice of remedying algorithms, process modeling that sequences and variously applies those remedies, and map measurement and evaluation methodologies to assess the quality of the final design. As a complex decision-making process, it requires us first to model the underlying geography being visualized, and based on that to make explicit the knowledge used in that decision-making process.

Advances in technology have raised the expectations of the user; they now wish to interact with data in real time, through infinitely zoomable maps that reflect their own data gathering efforts, in both web and mobile environments. Thus there...
has been something of a shift towards utilizing map generalization methodologies in exploratory data analysis contexts. There is an expectation that, beyond the focus on topographic mapping, map generalization methodologies should be relevant in the context of thematic and even schematized maps and that they should be applicable over very large changes in levels of detail (or scale). In such contexts, we may need to find alternate paradigms, though ultimately the ambition will remain the same.

Ultimately, map generalization outputs seek to support human decision-making. From this perspective, map generalization methodologies should be built around a paradigm of efficiency in communication. In such contexts, it remains very challenging when it comes to measuring the information content of a map, or the effectiveness of our design in the communication of that information. As our view of the world becomes more generalized at smaller scales, it is not that we see less information, but that we see different information. How we model those changes in information content with respect to map generalization methodologies remains a key area of research.

One way to conceptualize the process of making a map is to view the flow from Earth observation to map as a sequence of transformations. These are the scale transformation that resizes the Earth to a geodetic model, the projection transformation that changes the spherical or ellipsoidal Earth into a flat surface, and, lastly, the symbolization transformation in which objects are selected, generalized, and converted into points, lines, areas, and text on the map. Of these, the projection transformation is critical. Map projection is the oldest form of cartography, having formed a major part of Claudius Ptolemy’s foundational work Geography. A map projection is an operation that has the geographic coordinates of features on the Earth or other mappable object as input, and as output creates a new coordinate space that is Euclidean. In converting a 3-D surface into one with only two dimensions, some of the geometric properties of the globe must be sacrificed. This takes the form of distortions of scale, shape, and direction at multiple locations on the map.

Controlling and minimizing the distortion has been an elusive goal of map projection science. This is especially the case when designing projections for standard coordinate systems. Coordinate systems are ordered systems that use one or more numbers to uniquely determine the position of a point within a Euclidean space. Standard coordinate systems have been developed for mapping and geographical application, such as the Military Grid Reference System (MGRS) and the State Plane Coordinate System. These systems can cover all of the Earth (a global grid) or part of it. Coordinate systems are suitable for positioning, the recording of a place’s location as a coordinate, and for navigation to a place. As the numbers underlying digital maps and geographic information systems (GIS), it is the coordinates that facilitate plotting and allow cartometry and analysis. Without coordinates, geography would be entirely descriptive and nonscientific. Deriving and using coordinates, therefore, and understanding their projective geometry, underlie all science within geography.

Map projections: a history

It is possible that projections date from about 200 BCE or earlier (Snyder 1987). However, in Claudius Ptolemy’s (90–168 CE) book Geography, he described four new projections for the first time. The book is centered around instructing the reader on how to make their own maps. It details methods in the first part, then assigns coordinates to all known geographical places and features on a global grid. This grid counted latitude from the equator, measuring off the length of the longest day rather than degrees. Parts 2–7 used a zero meridian at the Canary Islands. The remainder of the book includes instructions on drawing the four map projections, and topographic lists with map annotations for features and places throughout the known world of the time. While the maps did not survive, during the fifteenth century when Geography was translated into Latin from the Greek and Arabic, editions...
reproduced these four projections, sparking new interest in world mapping (Campbell 1987).

The ages of enlightenment and discovery led to a boom in the devising of new map projections. This was especially true after the first circumnavigations of the Earth and the discovery of the Americas, Australia, and Antarctica. Using as a source Snyder and Voxland’s (1989) Album of Map Projections, which catalogs the principal projections in use today, dates of creation were obtained for 93 map projections (Table 1). Eight projections date from before 1500 CE, then, other than the seventeenth century, the number increases rapidly. Important early additions were the Mercator projection (1569), the Sinusoidal (1570), and the Ruysch (1508) modifications to the equidistant conic. These projections were frequently used in maps showing the new discoveries in Asia and America.

During the eighteenth century, the work of Johann Heinrich Lambert linked the map projection transformation to mathematics and geometry. Lambert was the first to discuss the properties of conformality and equal area preservation and to point out that they were mutually exclusive (Snyder 1983). In 1772, Lambert published seven new map projections in Anmerkungen und Zusätze zur Entwerfung der Land- und Himmelscharen (Tobler 1972). Of these, three have been highly influential (the Conformal Conic, Transverse Mercator, and the Azimuthal Equal Area). During the nineteenth century important contributions came from Karl Brandan Mollweide, Heinrich Christian Albers, George Siddell Airy, and Ferdinand Rudolph Hassler’s Polyconic projection. Additional notable projections in the twentieth century were those by Robinson, Snyder’s Space Oblique projection and GS-50, Tobler’s Loximuthal Projection, and those by Osborn Maitland Miller. Snyder’s book on twentieth century projections remains a definitive survey (Snyder 1997).

### Classifications of map projections

Early classifications of map projections were based entirely on their mechanical means of construction. Prior to digital maps and computer programs, projected maps were generated by applying geometrical rules to the base graticule, and then filling in the Earth’s coastlines, political boundaries, and features by manual interpolation. In the early period this led to some significant geographical errors. Mechanical aids for projection drafting became quite sophisticated during the nineteenth and early twentieth centuries, including splines and projective ray geometry.

Largely inherited from this early era was the classification by the major “developable form,” that is, the surface onto which the maps were to be projected. Azimuthal projections, such as the gnomonic and stereographic, went straight from the Earth to a flat surface, either using projective geometry or the hemisphere at a time in the globular projections. Cylindrical projections projected onto a cylinder either tangent or secant to the ellipsoid or sphere. The cylinder was then unrolled, making straight parallels and usually straight meridians. Lastly, the projection could be
onto a tangent or secant cone, usually covering one hemisphere. The unwrapped cone made for a conic projection, in which the meridians were straight lines radiating from a common point, and the parallels formed concentric circles.

Variants on this simple schema included the “pseudo” projections, pseudo-azimuthal, pseudocylindrical, and pseudoconic. The pseudo designation is because one condition of the form can be preserved, while another is varied. For example, classic cylindrical projections such as the equirectangular, Mercator, and Miller projections have straight vertical meridians, while the Molleweide and Sinusoidal have only a straight central meridian, the remainder being curves that converge at the poles. Classifications that have extended the projection types to pseudo variants often add polyconical, “other,” and space map projections as categories (Yang, Snyder, and Tobler 2000).

There are many other ways to classify map projections. Bugayevskiy and Snyder (1995) simplified the types to those with straight parallels, those with parallels forming concentric circles, and those with parallels forming nonconcentric circles. These authors note that classifications have also been based on (i) distortion properties (conformal, equivalent, equidistant), (ii) the shape of the graticule, (iii) the aspect of the projection, (iv) the form of differential equations describing the projection, and (v) the method of construction. Snyder’s 1987 survey of US Geological Survey (USGS) projections used five categories: cylindrical, conic, azimuthal and related, space map projections and pseudocylindrical, and miscellaneous. Another classification is by the degree of interrelation of the projection coordinates: \( x = f(\lambda), y = f(\phi) \) (mostly cylindrical); \( x = f(\lambda, \phi), y = f(\phi) \); \( x = f(\lambda), y = f(\lambda, \phi) \); and \( x = f(\lambda, \phi), y = (\lambda, \phi) \). In general, the more traditional methods of classification of map projections based on methods of construction are yielding to classifications based on mathematical, distortion, and functional properties, largely influenced by the incorporation of projections into software packages and GIS.

### Map projections: methods

Map projections start with a vector of geographic coordinates on the sphere or ellipsoid \((\lambda, \phi)\) and end with Cartesian coordinates \((x, y)\). The transformations are embedded within computer mapping and GIS software, where the database is usually held in geographic coordinates. All transformations involve a scale factor \(s\), the radius of the Earth \(R\), and assume a central meridian for the projection, \(\lambda_0\). The simplest projections involve independent transformations from the spherical Earth model of \(\lambda\) to \(x\), and \(\phi\) to \(y\). The Plate Carrée or equirectangular projection (Figure 1), for example, sets \(x = R_s(\lambda)\) and \(y = R_s(\phi)\). More complex projections build algebraic geometric transformations; for example, the Mercator projection (Figure 2) sets \(x = R_s(\lambda - \lambda_0)\) and \(y = R_s \ln \tan (\pi/4 + \phi/2)\), but still with independent transformations on each axis. More complex projections use both \(\lambda\) and \(\phi\) to compute \(x\) and \(y\). For example, the Molleweide projection (Figure 3) first computes and solves for an intermediate variable \((\Theta)\) using \(2\Theta + \sin (2\Theta) = \pi \sin \phi\). This allows solving for \(x\) as: \(x = 2(2^{1/2}) R_s(\lambda - \lambda_0) \cos (\Theta) / \pi\) and for \(y\) as: \(y = 2^{1/2} R_s \sin \Theta\). So \(x\) is a function of both latitude and longitude, but \(y\) is a function of just latitude. Many projections make parts of the world unplottable, for example, the high latitudes on the Mercator. When lines cross the map edges or interruptions, special case corrections are necessary.

Other complexities with map projections involve using different scale factors for \(x\) and \(y\) (which change the proportions of the map),
rotating the axes by some angle, combining two or more projections by averaging or mixing, using different interruptions and central meridians, and doing any of these transformations on an ellipsoid rather than the sphere. As a result, some map projections are numerical approximations, so cannot be analytically inverted. Inverse transformations exist for most projections, that is projection formulas that start with \((x, y)\) and yield \((\lambda, \phi)\). Inverse transformations are necessary

**Figure 1** Plate Carrée projection showing seven days (February 26 through March 3, 2012) of Aquarius V1.2.3 SSS data collected during the ascending (evening) portion of each orbit. Reproduced from NASA.

to capture data that has been mapped on a particular projection.

Variants for projection include aspect, interruptions, form, and tangency. Aspects can be equatorial, oblique, or transverse (Figure 4). The formulas simply apply an affine transformation to the computed $x$ and $y$ values. In equatorial aspects, the North Pole is customarily placed at the top and the equator runs horizontally across the middle of the map. Oblique aspects are rarely used, other than in the family of space projections, such as the Space Oblique Mercator, as they allow satellite ground tracks to be shown as continuous strips. Transverse aspects have the poles in the center, and a single meridian and its anti-meridian form a straight line across the map. Interruptions are where “seams” in the transformation are applied. Adding more breaks can reduce distortion, but makes the map more discontinuous. Interruptions can be chosen to fall in the oceans or on land, depending on the map’s purpose.

Forms of projection are the equivalent surfaces onto which the projection is made. The classic forms are the plane (azimuthal), cylinder (cylindrical), and cone (conic). Azimuthal projections can cover half or the whole Earth. Many sixteenth- and seventeenth-century projections chose two circles for the hemispheres, the globular projections. Cylindrical projections are common, have the advantage of being rectangular, and may or may not include the poles. Conic projections project first onto a cone, which is then interrupted and flattened. These projections have straight meridians that radiate out from the cone’s peak, and parallels that form arcs of circles. Tangency is the degree to which the 3-D globe and the form meet directly. For example, a cylinder can be scaled so as to wrap around the equator, with all other points being projected out onto the surface. This has the advantage of zero distortion, but only along the equator. Alternatively, the projection can be made secant. In this case the scale is set
so that the equivalent tangent line becomes two lines at parallels in each hemisphere. The lines of zero distortion are now at “standard” parallels, reducing the overall distortion. The parts of the map inside the secant cylinder are projected out, and those now outside are projected in. Many maps are made secant along a central meridian by changing scale to reduce distortion, such as the Universal Transverse Mercator (UTM).

Map projections: distortion properties

In the transformation from a 3-D surface to a 2-D one, properties of the surface must be distorted. Other than the obvious distortions at interruptions and map edges, in general one or more of four interrelated properties of the surface are distorted: scale, distance, shape, and direction. Projections that preserve scale across the map are called equivalent or equal area. For each point on the Earth’s surface, a small circle when transformed should have the same area at all points on the map. Differences in scale as a function of direction create different distances across the map. Generally, distances can only be preserved from a point on an equidistant projection. For shape, it is important that features on the globe, such as a county, should still be recognizable as the same features on the map. Shape can only be preserved locally, as only a globe can preserve shape completely. Such maps are called conformal. Conformal maps also preserve direction, but only over short distances. Conformality is desirable because compass directions are preserved locally, making them useful for navigation. Only a gnomonic projection can preserve directions, and only then for one point. Conformal projections have been used extensively since the twentieth century as the basis for standard coordinate systems for surveying and mapping. Projections that achieve neither conformality nor equivalence are termed compromise projections, but even maps that are equivalent or conformal do not preserve distortion at all points on the map.

It is possible to compute and display on a map the degree of each distortion (Mulcahy and Clarke 2001). First to do so was Nicolas Auguste Tissot in 1859 and 1871 in the form of his ellipse of distortion or indicatrix. Placed on the map at increments of longitude and latitude is a repeating small circle that results from projecting a circle of infinitesimal radius from the globe onto the map. Tissot proved that an ellipse whose axes indicate the two principal directions along which scale will be maximal and minimal.
at that point on the map. The ellipses show scale distortion by their size, shape distortion by their degree of lengthening, and direction by their angle (Figure 5). They are a highly effective visual aid in understanding projection distortion.

Lastly, many have attempted to optimize projections so that all distortions fall below a threshold, at least for a particular area. The Winkel tripel was an early example. The equal area Goode’s Homolosine joined two projections (Molleweide and the Sinusoidal) to improve conformality. Others have attempted to create the average of coordinates across multiple projections with each property. Snyder’s GS–50 was designed to be conformal, but to keep scale distortion below 2% over the land areas of the 50 United States (Figure 6).

In addition, recent scholarship has moved toward creating intelligent decision-support systems that assist in making choices about which projection to use for a given application. One such system is the “Decision Support System for Map Projections of Small Scale Data” from the USGS (USGS 2013).

Coordinate systems

Once a map has been projected into a Euclidean space, it is possible to use the mathematics of geometry and trigonometry to perform a large number of operations. Two technologies, however, favor systems that formalize the 2-D referencing into standardized coordinate systems. These are positioning, usually via a global navigation satellite system such as the global positioning system, and navigation, including web-based map use. Navigation needs coordinates both in the analog and digital sense, for display on aids to navigation and to create grids on maps. Tasks such as location-based services, search and rescue, point-to-point navigation by vehicle, and many others demand and use standard coordinates.

In some cases, geographic coordinates themselves can be used as coordinates. Many software packages store raw geographic coordinates in various forms and do map projection and coordinate conversion on the fly. However, the nature of the shape of the Earth makes the use of geographic coordinates difficult. An alternative is three axis (x,y,z) coordinates called Earth centered Earth fixed, as is common in geodesy, space geometry, and computer graphics. Mapping applications, however, favor flat map transformations so that the grids can be printed or drawn directly onto the maps. This implies two things: first a suitable
projection must be chosen and, second, the system must establish units, axes, and a point or origin.

Comparisons have been made of the properties of “good” global grid systems (Clarke 2002). Desirable properties are universality (fitting into existing alternative Earth models such as geodetic and astronomical models); authority (being supported by a permanent and credible agency, standard, or law); being succinct (using as few codes as possible to ensure location); definitiveness (providing reference to one and only one unique location); exhaustiveness (applying to the whole Earth); being hierarchical (allowing references to multiple scales depending on the desired level of detail); intuitive (easy to understand and use); and tractable (able to be used computationally). Not all grids in common use share all of these properties and, consequently, there exist multiple grid systems, in spite of national efforts at standardization around “National Grids” as in the United States and the United Kingdom.

Among the many global grid coordinate systems in common use are different versions of the UTM coordinate system (UTM, MGRS, the US National Grid), a referencing system for satellite imagery (Georef: The World Geographic Reference System), and various systems based on tesselated triangles and hexagons (e.g., QTM). There are also national grid systems for many countries, such as the Map Grid of Australia, the British Ordnance Survey National Grid, the Irish National
Grid, the QND95/Qatar National Grid, and in the United States the State Plane Coordinate system. Many national grid systems, though obviously existent, have little publicly available information about their details. At a third level, there are a host of special purpose grids such as the Maidenhead Grid Square system (amateur radio), the US Public Land Survey system, and the Canadian Dominion Land survey (cadastral), and the Universal Polar Stereographic, which completes the military and civilian versions of the UTM system for the two polar regions.

Covering all these systems is beyond the scope of this entry (see Cartesian coordinate systems). The reader is referred to Clarke (2015), Maling (1992), Goodchild and Kimerling (2002), and the other sources referenced in the Further reading section. Notable is that most online mapping systems and geobrowsers support only a subset of the systems: typically UTM and geographic coordinates, and some nonstandard grids. Many of the systems are based on the properties of the Transverse Mercator (or Gauss–Kruger) projection, usually made secant along the central meridian. Others mix projections, such as the United States State Plane Coordinate system, which uses the Transverse Mercator, the Lambert conformal conic, and the Oblique Mercator. The choice of projections and liberal use of zones and false origins is testimony to the difficulty of removing map distortion during projection. Therefore, global grids that extend across the whole planet or most of its surface by necessity introduce significant error due to scale and directional divergence. Projection distortion is always least on grid systems that are local, use conformal projections, and use local secancy or controlled extent to minimize distortion, strategically surrounding a particular mapping region of interest.

Cyberspace from imagined to real

“Cyberspace is real” claimed President Barack Obama in his speech concerning American cyber infrastructure security in 2009 (White House 2009). In other words, cyberspace might be surreal, thus the president was obliged to make such an unmistakable statement about the existence of cyberspace. However, the uncanny thing is that cyberspace is a neologism coined by a science fiction writer through popular science fiction, which evokes massive public imagination about a future virtual digital space. The science fiction writer is William Gibson and the novel is *Neuromancer* published in 1984. So, what turned cyberspace from merely an imagination of the general public into an existence whose safety is fundamental to the security of a nation in less than two decades? More importantly, in order to map cyberspace in a meaningful way, there should be a clear understanding about the materiality of cyberspace.

Before striving to understand the materiality of cyberspace, it is useful to briefly review the concept of cyberspace, a virtual world, as it was envisaged by William Gibson. The original imaginative representation deserves a mention not only because it became a symbol in popular culture, but also because scholars and technicians were so fascinated by the idea to eventually bring forth the creation of the real cyberspace today (Bell 2007). In *Neuromancer*, cyberspace is “a consensual hallucination experienced daily by millions of legitimate operations. … A graphic representation of data abstracted from the banks of every computer in the human system.” (Gibson 1984, 67).

Nonetheless, although Gibson (1991) pointed out later that the neologism of cyberspace was suggestive and without concrete semantic meaning, the imagination of a virtual cyberspace had profound influence upon its subsequent materialization (Bell 2007). Gibson coined the word by borrowing the prefix “cyber-” from cybernetics and connected it to the suffix “-space,” whose combination pointed to an imaginary “datscape.” To a great degree, in the virtual world depicted by Gibson, the spatial dimensions of the cyberspace were implied. For the Greek stem of the word cybernetics, *kubernites*, means steersman (Wiener 1954). It was Benedikt, who orchestrated a spatial environment to spatially contextualize the constellation of immaterial data. According to Benedikt, the cyberspace is “multisensory, three-dimensional, involving, richly textured and nuanced virtual world converting oceans of abstract data and the intelligence of distant people into perceptually engaging, all-but-firsthand experience.” (Benedikt 1991a, 1991b) Thus, the cyberspace could be navigated in a way similar to geographical navigation in the real world, and a set of rules about discerning space, time, and objects could be fancied. That is to imply that, in Benedikt’s cyberspace, the virtual world could be mapped in the similar way to the way our physical world is mapped.

The goal of this entry is to introduce geographical knowledge regarding crafting maps of cyberspace. While cyberspace is beyond
humans’ direct perception, its skeleton, which is the modern day Internet, is as concrete as any other physical objects on the Earth’s surface. The rest of this entry is organized by first briefly overviewing the evolution of the Internet then in the second section focusing on the definition and categorization of many types of webs, such as the World Wide Web and other specific webs. After the third section, which gives a brief description of a cyberspace model, different mapping methodologies and maps of cyberspace are introduced. The entry concludes with a brief summary about the materiality of cyberspace.

Internet as the skeleton of cyberspace

In order to map cyberspace, the first step would be to investigate cyberspace about its constituent components. By carrying out a search in Google Scholar for articles containing the exact phrase “what is cyberspace,” the engine would give about 233 entries in less than 0.06s. Scanning through these entries you would realize that the definition of cyberspace is multifaceted by people’s perspectives. If you read them in detail, then you would discover that Benedikt (1991b)’s definition about cyberspace has been popularly cited. According to Benedikt, cyberspace is “a globally networked, computer-sustained, computer-accessed, and computer generated, multidimensional, artificial, or ‘virtual reality’.” In this article, Benedikt’s vision about cyberspace is adopted, and it was from this vision that we started to demonstrate the project of mapping cyberspace by first examining the evolution of cyberspace.

The progenitor of the present-day Internet, the ARPANET, was initiated 45 years ago in the shadow of global nuclear war. The motivation for the project of the Advanced Research Projects Agency (ARPA) within the US Department of Defense was to share the limited computing resources of powerful large research computers with users at geographically dispersed locations at that time (Leiner, Cerf, and Clark 2012). The first generation of ARPANET was launched in 1969 connecting hosts at four US universities: Stanford Research Institute, University of California at Los Angeles, University of California at Santa Barbara, and the University of Utah. ARPANET grew rapidly to have 23 hosts connecting universities and research centers in the United States by 1971. It became international in 1973 with two connections established to University College in London, England and the Royal Radar Establishment in Norway. The first commercial version of ARPANET was constructed by Bolt, Beranek and Newman (BBN) in 1974, called the Telenet. It is from the Telenet that the public started to vaguely savor the possibilities of networked computers. From the 1970s to early 1980s, more computer networks for specific usages were constructed, for example, BITNET for electronic mail and UUNET for Unix users. The dominance of ARPANET gradually faded out during this period, until the operation was permanently terminated in 1989 and the system was retired in 1990. Through its life cycle, ARPANET pioneered the research and development in global communication network construction, and left many legacies to its successors, such as the transmission control protocol/internet protocol (TCP/IP), which became the only endorsed information communication protocol for the future Internet.

While various networks were built in the 1980s, one gained extraordinary importance, since our present-day Internet was a spin-off of the original network, the NSFNET, which was funded by the US National Science Foundation (NSF). The initial NSFNET was constructed to support sharing precious supercomputing powers among
MAPPING CYBERSPACE

scientists at different locations of the United States. The first generation of the NSFNET initiated operation in mid-1986 and connected NSF-funded supercomputing sites. The sites comprised San Diego Supercomputer Center, University of Illinois at Urbana-Champaign, Carnegie Mellon University, Princeton University, which were all newly built out-of NSF funds, and the then-existing supercomputing facilities at the National Center for Atmospheric Research. It was also called the NSF backbone network, or simply the Backbone. Around this backbone network, many regional networks were deployed to connect countless local area networks (LANs). LAN was the first layer in the hierarchy of the layered NSFNET architecture. In the early days of the NSFNET, LANs were more likely to connect computers on university campuses, called campus networks. NSF called the NSFNET “inter-net,” because it was a net of networks. The structure of the Internet that the NSFNET adopted was developed by the Defense Advanced Research Projects Agency (DARPA), renamed from ARPA. Eventually, NSF decided to initiate the backbone service transition from a NSF-controlled Internet to a commercially operated Internet. The transition concluded in 1995, and the NSFNET backbone was decommissioned, which denoted the end of an era in the Internet history. As part of the solutions to decommission the NSFNET backbone, four network access points (NAPs) were established to enable information exchange among different networks. The four NAPs were deployed at four sites: New York, Washington DC, Chicago, and San Jose. At each NAP, peer Internet service providers (ISPs) connected with each other based on standard agreements. Business companies or individual persons can purchase connection services to Internet from ISPs. Soon NAP was replaced by Internet exchange points (IXPs), which gave the interconnected networks advantages of direct connectivity instead of via third-party networks.

With the Internet moving to the mode of ISP with IXP, the operational model of the modern Internet was formed. As ISPs dominate the accesses to the Internet, they may deny users’ connections to destinations. Thus, geographical proximity does not necessarily equal to cyberspace closeness. Recently, the development of wireless communication technologies has realized high-speed Internet connections on mobile platforms, which has fostered the nascent and fertile field of mobile networking. Grassroots organizations have been implementing wireless networking technologies to construct private communication networks at small areas, such as in Portland, OR. With many privately constructed networks mushroomed, there are efforts to connect them, and hopefully form an alternative Internet, independent of the current Internet and its supervision. In geography, there has been a persistent interest in mapping the Internet and the virtual space that was carved out of the bricks and mortar of the physical servers and routers. However, it is a daunting task. With the invention of the World Wide Web (WWW) and search engines as well as the growth and evolution of the Internet, the entire Internet has gradually developed into many types of networks, such as surface web, deep web, darknet, or dark Internet.

The virtual worlds of cyberspace

There are virtual worlds of cyberspace as different types of webs, either surface web or deep web. The web can be deemed an application that runs on the Internet. Although sometimes the Internet and the web are treated as the same thing, practically they are quite different. The Internet refers to the interconnected physical servers, and the web consists of networks of hypertext documents that can be accessed through the Internet.
Tim Berners-Lee invented the World Wide Web (or the web) when he worked at the European Organization for Nuclear Research (known as CERN). The original proposal was to improve the effectiveness of CERN’s communication system. But soon, Berners-Lee realized that the same design could be applied throughout the Internet, and thus the web was born. Inside the web, the hypertext document is identified by the uniform resource locator (URL) or the uniform resource identifier (URI). Hypertexts are formatted using the hypertext markup language (HTML) as web pages, which can be interpreted by web browsers. The exchanging and transferring of hypertext document follows the hypertext transfer protocol (HTTP). With hyperlinks embedded inside the body of HTML web pages, the conglomeration of hypertext documents forms another level of interconnectivity on top of the Internet. One fact that deserves to be pointed out is that although Berners-Lee proposed the universal authorship of the web, it actually took a very long time to realize fully the universal authorship for the majority of web users.

According to Morris and Ogan (1996), there are four types of relationships between information producers and receivers on the Internet. The first is one-to-one asynchronous information exchange, such as found with using email. The second is many-to-many asynchronous information broadcasting, and online public forum is the typical example. The third is synchronous communication, in modes from one-to-one, one-to-few, to one-to-many; for example, two users chatting via Skype. The fourth is synchronous information seeking, such as in the scenario when web users search and receive information from a website. For a very long time, the web was read-only, especially for multimedia contents, to the vast majority of web users, and the right to broadcast web content was held by a small group of producers that had the suitable skills for manipulating multimedia contents and the necessary computing resources for holding them. The producer's privilege was gradually transferred to the majority of web users after the emergence of search engine companies, such as Google, and social media companies, such as Flickr, Twitter, and Facebook. The web with universal authorship has been termed the web 2.0, in order to distinguish it from the first generation of web, or web 1.0, which was mostly read-only for the majority.

Indeed, the generational evolution of the web marked not merely the shift of power, but the web in a much deeper entanglement with the general public’s daily lives. In recent years, with the fast evolution of computing power of mobile platforms, such as smartphones and tablets, a new mode of web usage rises significantly, generally called the mobile web, which refers to the phenomenon of web surfing via mobile devices. It has been predicted that soon the use of the mobile web would surpass the use of the traditional web on fixed-line computers. The increasing fusion of the web 2.0 technologies and the mobile web has triggered dramatic socioeconomic and technological changes in both developing and developed countries. In developing countries, the use of mobile phones and social media has become a way to facilitate humanitarian operations by the United Nations. In developed countries, mobile social networking has gradually become the lifestyle of the younger generations. If the web 1.0 cyberspace was somehow like a detached virtual space from the geographical space where we live, then the emergence of the web 2.0 applications and the mobile web has indeed blurred the once distinctive boundary between the virtual and physical spaces.

The web is not the only application on the Internet, although it is one of the most popular applications and gives an immediate impression
about the Internet for general web users. There are many other Internet applications, some of them date back to the early days of the Internet, such as electronic mail (e-mail) application, Telnet, file transfer protocols (FTP), multiple user domain (MUD), and so on. E-mail has been the most popular application of the Internet. Telnet turns a user’s desktop into a terminal to a remote server, and enables the user to work remotely on files stored on the server. FTP lets users connect to remote servers without offering them capacities to work on it beyond browsing and transferring files. Also, there is multiple user domain (MUD, originally multi-user dungeon), which is a real-time virtual environment for users to explore. In a MUD world, a user imagines the world by reading the textual description. Meanwhile, the user can interact with peers through text messages. It is a very primitive role-play video game. But not all MUDs were games, some MUDs were contracted for educational and research purposes. Different from the MUD, virtual reality (VR) strives to visually create a mirror world of the physical world or an imagined world on the Internet. Google Earth is the most well known example of the mirror world, and World of Warcraft (WoW) is one of the most popular imagined online virtual worlds.

Just as the web is not the only application on the Internet, computers are not the only terminals that have the capacity for Internet communication. Things like the Internet phone, online fax, or Internet printer can all connect to the Internet. Actually, with the Internet communication functions built into more and more daily appliances, the web has gradually dissolved into humans’ daily life and the Internet communication technology becomes invisible. It has been envisioned that in future, with implementation of the Internet of Things (IoT) technology, which refers to the communication networks of material objects (e.g., clothes, food stocks), the webs of machines will greatly shift human societies towards more intelligent and autonomous.

Thus on the Internet, there are humans who interact with each other, machines which interact with each other, and humans who interact with machines. Different spaces were formed because of these activities. That is to say there exists not a single universal cyberspace, but many cyberspaces that can be defined at different levels of the Internet and with different types of terminals. In terms of mapping cyberspace, this complexity is significant and profoundly influences how we map cyberspace and why we map cyberspace.

The ways to spatially anchor cyberspace

The task to map cyberspace implies that the virtual space has spatiality and spatial geometry. Otherwise, there would be nothing to be measured and orchestrated to allow a space to be depicted on a map. Hence, an immediate question would be what defines the spatiality and spatial geometry of a cyberspace. Socially produced space is termed “spatiality,” which differs from the spatial geometry that is physical existence (Soja 1985). If the spatial geometry of cyberspace is somewhat obvious to us – the physical infrastructure of the Internet (for a comprehensive map about the global Internet between cities worldwide, see: http://global-internet-map-2012.telegeography.com/) then the spatiality of cyberspace is very obscure. In order to understand the spatiality of cyberspace, we must understand that the infrastructure of the Internet only provides the skeleton, on which information is transmitted. The operation of the Internet is dictated by software at various levels of the Internet. At the backbone level, the connection of information transmission conduit is regulated by the autonomous system (AS).
MAPPING CYBERSPACE

ISPs use AS policies to restrict the connectivity between different destinations of computers. The AS can be modified according to requirements. Hence, although the physical topology of the Internet is more stable, the information topology of the Internet is dynamic and ever changing. On top of the ISPs, companies or individual persons receive Internet connection services to satisfy their communication needs. These needs are fulfilled by leveraging all kinds of software. Indeed, it is through the utilization of software that humans interact with the information sphere of the Internet, and together they bring space into being. The socioeconomic studies of software have pointed out that software is not merely a technology product, it is also social constructions, which represent the idealisms of their creators (Kitchin and Dodge 2011). Thus, the being of cyberspace is socially constructed, which is the spatiality of the Internet.

Batty (1997) conceptualized the assembly of different types of hardware on the Internet with the different spaces they initialized in the following model. First, personal computers are the entrance to the Internet, and the interactions between humans and the Internet via the use of software on the computer create “cspace.” Therefore, individual cspaces exist locally in the geographical world, and the distributed networks of connected cspaces form cyberspace. In order for cyberspace to occur, it needs to be supplemented with the functioning physical hardware of the Internet. The interconnection of the physical hardware of the Internet forms the cyberplace. Batty further stated that the use of cyberspace created demands for extending the boundary of cyberplace to new geographical territories. The establishment of the Internet infrastructure modifies the socioeconomic relationships of geographical space. For companies, these modifications bring business advantages, and entice them to move towards increasing creation of cyberspace inside of the geographical space. Regarding mapping cyberspace, Batty’s model has provided a solid foundation for mapping cyberspace as the physical infrastructure, which is through measuring the topology of the hardware. However, it is much too complex to map cyberspace in terms of an information sphere, as hypertexts are mostly nonspatial, which indicates the fact that information in cyberspace lacks explicit spatial characteristics that belong to material things in the real world. Thus, spatialization is the first step for mapping the information sphere of cyberspace. Spatialization builds theoretical spatial forms of information in cyberspace.

Meanwhile, the evolvement of the information and communication technology (ICT) has mobilized Internet access. People can access the Internet from their mobile devices such as smartphones or tablet computers. Consequently, cyberspace at the physical level becomes dynamic as well. As the availability of global positioning system (GPS) technology, which is a satellite-based navigation system providing real-time location and time information, increases on mobile devices, it is much easier and accurate to pinpoint the geographic location of Internet accessing points by leveraging the GPS coordinates that have been inserted into the contents transmitted by the devices. Satellite technology not only supports versatile GPS applications that are widely demanded in situations where accurate geographical location matters, but also provides a way to observe the Earth’s surface by means of high resolution remote sensing imagery. These high resolution Earth surface images have been applied to create web-based virtual globes. One of the most popular virtual globes is Google Earth/Map. In the history of the Internet and cyberspace, a few companies stood at pivot points. Google is one of those companies and with its Google search engine, Google Earth/Map, and many other products changed users’ experiences
about the Internet and cyberspace. The Google search engine largely made obsolete the requirement for a comprehensive online catalog about webpages. Google Earth/Map really revived the public’s interests in geography. Using Google Earth/Map for virtual geographical discovery indeed becomes a fad, such that online forums and user communities were formed for sharing experiences and discoveries. The public’s enthusiasm about web-based mapping has been one form of a broader phenomenon of an increasing fusion of the Internet and people’s daily lives.

The web from 1.0 to 2.0 gives mapping cyberspace multiple meanings and methods. Firstly, mapping cyberspace can be done by approaching the ethereality of cyberspace via its material skeleton, the Internet. Secondly, mapping cyberspace can also refer to the activities such as building navigation map of the information sphere. Thirdly, mapping cyberspace can also broadly mean mapping in cyberspace and is a significant phenomenon. Web-based geographical information systems have become a major technological development trend for GIS, with companies like ESRI gradually moving its products into cyberspace. Google Earth/Map extended the means and applications of mapping in cyberspace. They have been one of the driving forces behind the volunteered geographical information (VGI) phenomenon (Goodchild 2007). VGI, or more broadly web 2.0, represents a new phase in the Internet and cyberspace evolvement.

Exemplar mapping cyberspace applications

There have been multiple ways to anchor digital information in the real world. Jiang and Ormeling (1997) among a few others started early attempts to adopt cartographic methods of creating maps for the geographical world, to plot maps for cyberspace. The maps were termed cybermaps. Cybermaps suggested solutions for questions such as how to map cyberspace and what to map. As cybermaps developed, they divided cyberspace into two parts: a physical part and an information part. More focus had been put on mapping the information part rather than on the physical part of cyberspace. Here, cybermaps provided several methodologies, with some still widely implemented in all kinds of tasks today. For example, using the last part of a domain name (e.g., www.google.com), the part after the last period (e.g., .com), is used to assign an organizational role to a website, indicating whether it is situated in the commercial domain (.com) or in the educational domain (.edu). Also, the last part of the domain name can indicate the geographical region, if the domain name ends with a country abbreviation, such as .uk or .us. Domain names, for example, google.com (no www), are purchased from registrars, such as Go Daddy Company. Once a customer owns a domain name, he/she can create as many subdomains as wanted. Each subdomain then can be allocated to a host machine. The allocation information is stored in domain name servers (DNS) in a form that connects the subdomain to the IP address of the host machine. Each host machine has a unique IP address on the Internet. Barrett Lyon initiated the Opte Project to map the Internet by using a tool called traceroute to record the route of data packets across an IP network. Maps produced by him have been collected by the Museum of Modern Art (MoMA) in New York City (for an example of IP maps, see: http://www.moma.org/collection/object.php?object_id=110263). The allocation of IP addresses is handled by regional organizations. Therefore, by examining the numerical numbers of an IP address, there is great chance to rightly estimate the geographical location of a host machine at the country level. For example, IP addresses between
The block from 3.0.0.0 to 3.255.255.255 are more likely to belong to host machines in the United States. There is software to convert domain names or IP addresses to the geographical locations (i.e., longitude and latitude) of the host machines. Thus, it has created a way to map the geographical dimension of cyberspace by using domain names or IP addresses. By estimate of the total numbers of hosts connected to the Internet, another type of cybermap was created to show the number of hosts per capita in different regions, such as in the United States. On the Internet, each access to a host machine is captured and recorded in a log file. By analyzing information kept in the log file, maps can be plotted to show the frequency of access as well as the geographical distribution of requests. By capturing the geographical existence of host machines, domain names, and IP addresses, cybermap managed to materialize the ethereal nature of cyberspace in geographical fashions.

The above methods portray cyberspace from a point that is close to Batty’s model about cspace and its assemblage. When getting inside cyberspace, that is, entering the information sphere of the cyberspace, the geographical location of the host machine does not provide much clue for navigating such an entirely virtual landscape. Cybermap used the networks of hyperlinks to indicate the position inside the information sphere. Thus, in order to reach a hypertext document, for example a home page at the end of a connection, a predefined passage of hyperlinks had to be followed. The assembly of passages and nodes created a network-like representation of cyberspace. The vast and ever expanding scope of networks of hyperlinks made the navigation a daunting task, even for someone familiar with the information sphere. Yahoo! has been one of the Internet companies that has achieved great success by cataloging these messy home pages according to their themes. A cybermap thence can be crafted by treating catalogue information captured by Yahoo! as a proxy of the structure of the cyberspace’s information sphere; and by representing such hierarchical structure in cartographical language, namely points and lines, the information sphere of cyberspace can be mapped. Such a cybermap is an indispensable compass for cyberspace navigation. Potentially, a cybermap can serve three types of functional purpose; navigation is the first functional category. The other two functional categories are cyberspatial analysis, which quantifies information flows on the Internet; and persuasion, which provides situational snapshots about the Internet.

For cyberspace of web 1.0, Dodge and Kitchin (2001) provided one of the earliest comprehensive surveys and illustrations about ways to map cyberspace. In the book, they presented methodologies about mapping cyberspace from different perspectives, from socioeconomic to art. Zook (2005) mapped the .com type of domain names about their geographical distributions in several US cities. The maps demonstrated the comparative effects of cyberspace on geographical distributions of socioeconomic developments. With Euclidean distance becoming ethereal and symbolic in cyberspace, the possibilities to map cyberspace is only confined by imagination. Tamara Munzner and Paul Burchard leveraged the multidimensions of hyperbolic space, which mathematically is a non-Euclidean geometry, to construct a navigable 3-D information sphere of cyberspace. Online forums and discussion boards normally adopt a hierarchical information organization strategy for displaying different topics. The method is that a new topic becomes the topmost entry of a conversation tree, and has all responses to the original topic listed as leaves. One drawback with this arrangement is that for a long conversation it becomes difficult to trace the threads between conversations. Xiong and Donath (1999) invented the PeopleGarden tool...
to visually portrait relationships between different conversations. Besides the various methodological depictions about cyberspace, there were artists who illustrated their imaginations about cyberspace in animated film and deconstruction views of webpage and its hidden codes.

Technically, hardware and software behind web 2.0 has mobilized Internet implementations, which resulted in greater fusion of cyberspace and geographical space, creating a type of hybrid space (Couclelis 1996). Inside hybrid space, there is in situ user experience of cyberspace. That is to say, users’ geographical location has been part of the criteria for an information search in cyberspace. Meanwhile, instant response from the cyberspace communities enables users to make real-time decisions that have concrete links to the real world. This technological trend is accelerating, with wearable technologies, such as Google Glass, and implantable technologies, such as neural implants, becoming realistic and affordable, which is a highly controversial trend (McGee and Maguire 2007). The emergence of hybrid space has generated new challenges for mapping cyberspace. One effect with the availability of hybrid space is that ideas or rumors can travel far more broadly as well as in greater speed through cyberspace, and impact people’s behaviors in the real world. For example, social media tools such as Twitter and Facebook have been commonly used for emergency responses or organizing protection. Scholars have started to study the new phenomenon and produce new methodologies, for example, for capturing the geographical footprints of real-world transitory events through pinpointing digital traces they left in cyberspace (Tsou et al. 2014).

The invention of search engines dramatically changed the way of information seeking in cyberspace. Automatic crawlers constantly navigate the accessible Internet and build an index of the information sphere. Keywords have to be properly designed for accurate search results, which are listed according to their relevancy to the keywords. From web 1.0 to 2.0 rendered it almost impossible to create catalogs for web contents that keep growing as web users continuously post new blogs or upload new photos. Search engines can better capture the evolving and changing information landscape, which can potentially be implemented for assessing public opinion about, e.g., presidential candidates (Tsou et al. 2013). The method starts with keyword searching that find the most relevant webpages on a subject. As each webpage has to be hosted by a computer that has an IP address, the location of the webpage can be approximated by the geographical location of the hosting server and generate a geographical point that can be put on a traditional map. The aggregation of webpages on the subject thus creates a density map that reflects the geographical distribution of the webpages. As webpages contain ideas that spread throughout the Internet, the method suggests a new way to study information diffusion in cyberspace.

Compared to webpages, social media are nowadays preferred for gauging public opinions. Part of the difficulty with mapping cyberspace using social media data is caused by the discrepancy between geographic locations of content creators and content hosts. There are explicit and implicit methods to inferring the geographical locations of the social media contents. If tweets or photos posted to Twitter or Flickr are from devices with geo-enabled technologies available, such as GPS or wireless triangulation, then explicit geographical locations can be easily gotten by reading the longitude and latitude coordinates. However, due to privacy considerations or the availability of geo-enabled technologies, explicit geographical locations are only contained by a small percentage of total public social media contents. Methods have been designed to indicate geographical locations from hints embedded
Mapping cyberspace reveals spatiality and geometry of cyberspace at different levels of the Internet. In his effort to explain the rearrangement of socioeconomic relationships in the digital information age, Castells (2011) defined two types of space, namely the space of places and the space of flows. The space of places refers to space that consists of physical places in the real world, where daily lives take place. The experience of space of places is confined by locality; therefore, the conduct of different socioeconomic activities has distinct geographical places. Through cyberspace, certain types of locality have been annihilated. Geographically distributed places can coexist inside of cyberspace, which forms the space of flows. New space, such as space of flows, expresses the spatially transformed society (Castells 2004).

Cyberspace maps convey the changes in a more understandable means, which provides indispensable support for decisions regarding future development of societies or cities. Finally, through the pursuance of mapping cyberspace at different levels from the Internet, the TCP/IP system, and to the virtual hypertext documents, the materiality of cyberspace has been revealed, which comprises human, code, software, and infrastructure (Kinsley 2014).

Mashing and mapping

A map mashup is a genre of mashup in which two or more pre-existing data sources gleaned from the Internet, via either data scraping or querying an application programming interface (API), are combined in a web map to create a novel, online cartographic representation. The original data sources can be either used directly (e.g., mapping a list of objects with latitude and longitude coordinates or addresses) or (dis)aggregated into new spatial categories. Originally termed a “Google Map mashup” (see Dalton 2013), the map mashup is a subset of a larger category of social practice associated with creativity and artistic endeavors including collage and musical remix, such as the methods used extensively in hip hop music (Butler 2006; McConchie 2008).

In addition to their connections to artistic practice, map mashups are also closely associated with the advent of user-generated data and social networking, often lumped under the category of Web 2.0 (O’Reilly 2005), which provided novel data sources to map (Zook and Graham 2007). While map mashups are not limited to this kind of volunteered geographic information (Goodchild 2007) – reuse or combination of non-crowdsourced datasets would also be included – the availability and variety of volunteered geographic information (VGI) data has featured prominently in these efforts.

An additional key element tied to the rise of map mashups was the unscrambling of civilian global positioning system (GPS) satellite data by President Bill Clinton in 1996, paving the way for an explosion in the use of GPS in consumer electronics, including the rise of location-aware mobile services and social networking. These applications leverage the new sources of geotagged data produced by Web 2.0 activities with handheld GPS-enabled devices to enable users to both create and consume map mashups, from relatively simplistic wayfinding (directions to a party) to spatial search (location of restaurants, apartments, etc.) to social and political commentary (historical tours, political protests, and geotagged Wikipedia entries). The flexibility and versatility of map mashups also means that they have become a widely adopted practice.

Ten years of map mashups

Arguably the most remarkable aspect of map mashups is how quickly they have faded into the background consciousness of daily life. They are used by hundreds of millions people every day in a matter-of-fact manner, and yet the origin of these remarkable and powerful cartographic artifacts only traces back to 2005.

Paul Rademacher is credited with creating the first mapping mashup, and it was in reference to his original mashup, Housingmaps.com, that the term “Google Map mashup” was first coined (Dalton 2013). In April 2005, Rademacher, who at the time worked as a software engineer at Dreamworks, reverse engineered the then...
unpublished Google Maps API so that he could map rental housing information gathered from Craigslist to aid him in his search for a new apartment. Google quickly discovered Rademacher’s unauthorized use of their map data, but rather than prosecute him for the data breach, they hired him. This choice by Google not to sue Rademacher – and moreover to publish the Google Maps API and actively encourage third-party applications – represents a key moment in the spread of mapping mashups.

In May 2005, Google Maps API went live for official use, with the proviso that users had to register their use with Google, a requirement which provided Google with greater control. This launch also created just enough changes in the API setup to effectively render pre-existing map mashups useless (Dalton 2013). This was followed by the release of map APIs from other online companies, including those of Yahoo!, Bing, and MapQuest. It also set the stage for OpenStreetMap, then in its infancy, to eventually adopt an open API as well. The availability of these online mapping tools and data sources attracted a number of individuals without formal cartographic training – the so-called neogeographers (Turner 2006). Many of these neogeographers come out of the field of computer science due to their familiarity with the tools used to create map mashups, namely APIs, data scraping, and coding.

As the number of APIs increased, so did the breadth of topics dealt with by map mashups. Expanding beyond the relatively simple first mapping of Craigslist apartment listings, map mashups have expanded to topics ranging from the mundane to the enchanting and the downright creepy. While a full accounting is well beyond the scope of this entry (for more examples see ProgrammableWeb.com, which tracks mashups by genre and API utilization, and googlemapsmania.blogspot.com, which highlights a range of online maps), examples to provide some sense of the range of mapping mashups include the following.

- Taxiwiz provides information on the cost of taxi fares for specific trips in about a dozen cities.
- Healthmap.org uses World Health Organization data to provide maps of contagious disease surveillance.
- Donor2Deed traces charitable donations to on-the-ground actions.
- Trulia lists properties for rent, for sale, and recently sold to create a house-hunting map.
- Goocam searches out and maps unprotected webcams connected to the Internet.

A key characteristic shared by all of these map mashups is the creation of cartographic products that make new patterns visible that were not as easily found in the data’s previous form or use. This often includes providing users with the ability to explore spatialized data in a highly individualized and granular manner (Elwood and Leszczynski 2013). Moreover, this listing illustrates the wide variety of data sources and uses (in particular the ability of Goocam to make unsecured webcams more visible) and reminds us that map mashups, like any technology, are deeply imbedded in the societal practices from which they emerged. As Castells (2001, 6) notes, “Neither utopia nor dystopia, the Internet is the expression of ourselves.” In the case of map mashups, this expression manifests across all aspects of society and begins with selecting data to be mapped.

**Getting data for map mashups**

In addition to using pre-existing and organized spatial datasets – often drawn from governmental sources such as the Census but also including directories and other online sources – mashups also build new datasets via online interfaces. For
example, one can obtain a listing of store locations from company websites that provide a store locator feature by conducting a series of queries by state or zip code (Zook and Graham 2006). Generally, there are two ways of building such datasets for use on a map mashup, data scraping and APIs, and both require a certain level of skill with computers and programming. Data scraping pre-dates APIs, which have emerged more recently to help the owners of data control access to their data; many data owners see usefulness, for either ideological or financial reasons, in sharing data more widely.

Data scraping (a.k.a. screen scraping) allows a skilled user to obtain data from a website by using computer code to simulate a user’s action and access websites or web-based databases to get data such as address listings, home sales, and so on and save it into a format that can be easily sorted and analyzed. It is an early Web 2.0 technology, but still widely used for pulling data from portable document format (pdf) files and non-API websites which do not offer an easier alternative. Because data scraping is a potentially illicit activity, data scrapers are often intentionally written to avoid raising red flags, for example, by limiting the number of requests sent to a server in a given amount of time.

In addition to being reliant on the technique of data scraping, map mashups rely on APIs for their base map content, and often for their secondary data sources. APIs are a set of commands or instructions through which users can request data from particular websites, for example, various social media services such as Twitter, Flickr, and Instagram. Depending upon the goals of a website, APIs can be documented, undocumented, partially documented, public, or not public. Public and well-documented APIs make it easy for mapping mashup to provide an up-to-the-minute reflection of a website’s content. Nonpublic, undocumented, and partially documented APIs can be accessed by users, but it requires the sort of reverse engineering of the site’s code that Rademacher initially employed with the Google Maps site.

A key issue facing map mashups is that the remixing of data – particularly in ways not originally envisioned by the creators of the data – can give rise to legal and ethical issues. As a result, data pulled via APIs are governed by the generating website’s terms of service or terms of use, and the more encompassing AUP (acceptable use policy), the code of rules set up by a website that a user is expected to abide by when using the site’s data. For example, Google (as do Bing, Yahoo!, and MapQuest) reserves the right to advertise on webpages where maps created via their map API are being used (Li and Yan 2010), while OpenStreetMap has a Creative Commons attribution license allowing for free reuse of their data. While somewhat of a grey zone – as aptly shown by Rademacher’s experience with Google – misuse of data could conceivably lead to prosecution, although a more common result is simply the cutting off of access – a death warrant for commercial applications. The use of user-supplied data is particularly complicated; as Li and Yan (2010) note, “In general, service providers do not hold the copyright but claim for free, non-exclusive rights to use, reproduce, modify, translate, publish, publicly perform and display, distribute, etc., the content.”

Challenges facing map mashups

While mashups have empowered individuals to create new and exciting maps, they have also led to the creation of maps that are problematic in various technical aspects, the result of little to no exposure to cartographic techniques and conventions. For example, a common failing of map mashups is related to projections – especially
the web standard of the Google Mercator projection. While this greatly distorts the size of continents at the global scale – the well-known “size of Greenland” problem – it has been adopted by Google since the company sees the primary use of Google Maps as a service for navigation, and the Mercator projection preserves angles and compass directions at the local scale. Of course, this distorts area, which can be extremely problematic for choropleths and other maps at the global scale. In the case of the “Gaza Everywhere Map,” a mashup which superimposes the outline of Gaza onto any zip code directed location in the world (see Nasri 2014), it is problematic given the area distortion inherent in the Mercator projection, which was completely unaccounted for in this map. To be sure, the goal of the map – to illustrate the size of this territory relative to an area familiar to a user – was likely achieved; nevertheless, it highlights how basic mapping knowledge, such as the distortion brought by projection, is often lacking within map mashups.

A second issue to arise with map mashups is the often naive approach to normalization of data, especially through the creation of heatmaps or interpolation of data that often is not appropriate given the type of phenomenon being mapped. As a result, non-normalized data about societal phenomenon are converted to heatmaps and presented as meaningful results despite the fact that these exercises primarily show population density rather than any real social phenomenon. This issue has become prevalent enough within amateur mapping that there’s even a famous Internet cartoon about it (Monroe 2014).

A third problem facing mapping mashups relates to the often underdeveloped sensibilities toward how mapping – particularly data drawn from Web 2.0 sources contributed by individuals – impacts privacy. The power of visualizing spatial data is that it allows a viewer to see patterns in the data that may not have been visible in the raw data themselves and to put the data to new uses (Elwood and Leszczynski 2011). The novelty of many map mashups is that they aggregate and map spatial data that have not previously been visualized; this is also what has led map mashups to occasionally run afoul of concerns surrounding privacy and surveillance. Examples of this include the website Rotten-neighbor.com, where individuals were invited to call out their neighbors for less than neighborly behavior, and the Girls Around Me app that culled public social media data of individuals checking in to a location via FourSquare to allow other users to surreptitiously view the social media profiles of women in their immediate geographic vicinity. While FourSquare check-ins were publicly available data, the aggregation of it and deployment via a map mashup upset many people, leading FourSquare to terminate their use of data and to the removal of the App from the Apple App Store (Bilton 2012).

These issues, however, are not simply limited to Web 2.0, as various map mashups using official government data have run afoul of privacy concerns – for example, the Connecticut Gun Ownership map published in a Connecticut newspaper following the Newtown School Shootings that showed the exact location of the home addresses of gun owners in Connecticut. While the information was already publicly available, it was available in table form and not as a map in which a user could zero in on a specific address (Maas and Levs 2012). The public outcry following the publication of the map surprised the newspaper publishers and ultimately led to the map’s withdrawal. A related example (FloatingSheep 2011) was the release of crime data in the United Kingdom that allowed for searches at the postcode level with returned results mapping these aggregated results to a specific point, perhaps the centroid of a road.
segment or postcode polygon. Concerns about this approach were that users of this search and mapping function would assume that crimes were taking place at specific points – rather than in an aggregated area – with repercussions for neighborhood perceptions and real estate values.

A fourth challenge relating specifically to map mashups drawing upon geotagged social media turns on questions of who is producing the data and how representative it is of the larger population. The claims to democracy on the Internet have time and again been discredited (Haklay 2013), with the majority of data being created by a small number of individuals (Stephens 2013). While these issues do not render geosocial media irrelevant (Crampton et al. 2013), they highlight the need for creators of map mashups to be cautious in how they are presented, a practice that is often downplayed. This mindfulness includes the recognition that “going beyond the geotag” – that is, considering nonspatial dimensions of social media data such as relationalities, temporal change, or qualitative measures – is important in understanding what map mashups might or should be visualizing (Crampton et al. 2013).

Conclusion

This entry highlights the history, data gathering techniques, and challenges associated with map mashups. Although a relatively recent phenomenon, the availability of new consumer mapping technology – including GPS and online tools – has resulted in the widespread creation and use of map mashups (Arnaud et al. 2010). In turn, location-aware mobile applications and social media have created new and more abundant sources of spatial data that can be gathered and funneled into new map mashups. This abundance, however, does come with a cost, particularly in new challenges in the way things are represented and the privacy of individuals and groups. As a result, map mashups are one of these most exciting, intriguing, and troubling spatial practices in the world today.

**MAPPING MASHUPS**

Maritime transport

Jean-Paul Rodrigue  
*Hofstra University, USA*

The geography of maritime transport

The geography over which maritime transportation operates is unique, with its combination of physical, strategic, and commercial imperatives. Physical issues are obviously stable across time, but strategic, and especially commercial, considerations continually shift with the ebb and flow of globalization. The physiography of maritime transport is composed of oceanic and river systems of circulation, which are well defined by criteria such as depth, currents, winds (historically significant), and the configuration of coastlines and passages. Although oceans account for 71% of the Earth’s surface, maritime transport mostly takes place only along specific routes that are regularly used in shipping itineraries. These routes are a function of obligatory points of passage, which are strategic locations, of physical constraints (coasts, winds, marine currents, depth, reefs, ice), and of political borders.

The configuration of the global maritime network is relatively simple and is organized along a circum-equatorial corridor linking North America, Europe, and Pacific Asia through the Suez Canal, the Strait of Malacca, and the Panama Canal (Figure 1). Limited use is made of the northernmost parts of the Atlantic, as well as the southernmost parts of the Atlantic, Indian, and Pacific oceans, because of hazardous navigation conditions (mainly ice) and their remoteness from the centers of economic activity. During the summer monsoon season (April to October), navigation may become more hazardous in the Indian Ocean and the South China Sea. Climate change may also provide maritime transport with shorter shipping routes through the Arctic, but such prospects remain limited at this point.

For obvious reasons, maritime routes try to follow the great circle route, a pattern that is readily observable on the configuration of transatlantic and transpacific routes. Core routes are those that are most used because they service major markets, while secondary routes are mostly connectors between secondary and main markets. Maritime transportation remains dominated by longitudinal (east–west) interactions, which are considerable. The advantage of maritime transport is not speed but continuity (regular services) and the capacity to handle large amounts of cargo. Rail and road transport systems are simply unable to support such a scale and intensity of traffic.

In part because of physiography, geopolitics, and trade, specific locations play a strategic role in the global maritime network. These locations are labeled as strategic passages and can be classified into two main categories. Primary passages are the most important since, without them, there would be limited cost-effective alternatives that would seriously impair global trade. Among these are the Panama Canal, the Suez Canal, the Strait of Hormuz, and the Strait of Malacca, which are key locations in the global trade of goods and commodities. The expansion of the Panama Canal, which is projected to come online in 2016, is an attempt to provide additional capacity, both in ship size and as a whole, to a strategic passage that has
been operating for 100 years. Secondary passages support maritime routes for which there are alternatives that would still involve a notable detour. These include the Magellan Passage, the Dover Strait, the Sunda Strait, and the Taiwan Strait. Historically, these passages have been subject to contention and the risk of closure, such as for the Suez Canal (which was closed between 1967 and 1975) and the Strait of Hormuz. More recently, maritime piracy has experienced a resurgence in light of the growth in the volume and value of trade, particularly in the vicinity of the Strait of Bab-el-Mandab, which links the Indian Ocean to the Red Sea.

However, several technical changes have transformed maritime transport in terms of its capacity and reliability. The first and most obvious is that most ship classes have become bigger, which has substantially improved the economies of scale that were always to the advantage of maritime shipping. The only remaining constraints on ship size are the capacity of ports, harbors, and canals to accommodate them. Second, the speed of ships has marginally improved, as containerships are faster than the conventional ships they have replaced. These slight speed improvements mean that, over transoceanic distances, a few days can be gained, which is important. Third, ships have become increasingly specialized, with many solely designed to carry one type of cargo such as containers, petroleum, vehicles, or liquid natural gas. Fourth, ship design has improved, enabling the construction of larger ships that are more energy-efficient. Fifth, automation has enabled ships to be manned by smaller crews while improving safety standards.

Like any transport activity, maritime transport is a derived demand supporting trade relations. These trade relations are also influenced by the existing maritime shipping capacity. There is thus a level of reciprocity between trade and maritime shipping as supply (maritime transport) and demand (trade) interact. Maritime transport
has been adapting to a number of commercial trends. A conventional trend is the growing demand for fossil fuels, raw materials, and grains, a process that is correlated with regional economic development. However, with the outsourcing and offshoring of manufacturing, it is the growth of the trade of parts and finished goods that has been the most common driver of change in maritime transport. The outcome has been far from uniform in the geography of maritime transport, with some locations better connected than others.

Not every location is directly connected to maritime transport, with landlocked countries facing the challenge of accessing global trade. The development of transnational infrastructure such as highway and rail corridors granting access to a port is of prime importance in facing this challenge. Being landlocked does not necessarily imply exclusion from international trade, but in many cases it does mean substantially higher transport costs, which may impinge on economic development. On average, landlocked countries have 50% higher transportation costs. These costs vary depending on the level of economic integration. For example, landlocked European countries have supportive trading agreements with their neighbors while agreements between landlocked African countries are much less effective.

Fluvial transportation is limited to the path of navigable rivers and canals and is slow and inflexible, but it still offers a high capacity and low costs. Ports are less relevant to fluvial transportation, but fluvial hubs are increasingly being integrated with maritime and land transportation, particularly with containerization. In regions that are well supplied by hydrographic networks, such as Western Europe, fluvial transportation can be a privileged mode of shipment between economic activities. In fact, several industrial regions emerged along major fluvial axes, as this mode was initially an important vector of industrialization.

The dominance of freight in maritime shipping

Maritime shipping has traditionally faced two disadvantages compared to transportation modes such as road and rail, even if such a comparison may be considered fallacious since they service different markets. The first is that maritime shipping has slow speeds, averaging 15 knots for bulk ships (26 km/hr) and over 20 knots (37 km/hr) for containerships. The second disadvantage is related to delays and time performance, particularly at ports where loading and unloading take place. This can involve several days of handling, particularly when break-bulk cargo is carried. Maritime transport is thus not attractive to shippers requiring rapid, reliable deliveries.

Maritime transportation is dominated by freight because there is no other means to move large amounts of cargo over long distances at a low cost. Maritime transport also used to dominate long-distance passenger transport, such as the North Atlantic liner ship trade, but this ended in the 1950s with the establishment of intercontinental air services. Passenger traffic is now a small niche market for maritime transport, mostly supplied by cruise shipping. There is, however, an active short-distance passenger market serviced by ferries, particularly in Western Europe (mostly in the English Channel and the Baltic Sea), Japan, Indonesia, and the Philippines. The dominance of freight in maritime transport has particularly been favored by:

- Energy and mineral cargoes: The rapid industrialization of developing economies has fueled additional movements of energy
(e.g., coal and petroleum) cargoes. These flows supplement the traditional north–south trade such as petroleum flows from the Middle East to the advanced economies of Europe, North America, and Japan.

- **Globalization:** The establishment of global supply chains has led to the maritime transport of a growing number of parts and finished goods.

- **Technical improvements:** Ships and maritime terminals have become more efficient and thus able to support long-distance sourcing. For instance, they are able to handle an impressive array of goods and commodities, particularly with containerization.

- **Economies of scale:** Ship and terminal facilities have become bigger, enabling a reduction of the unit cost of what is being transported. This was particularly the case for container shipping, a sector that has recently seen a rapid growth in the size of containerships.

There are two main types of maritime freight:

- **Bulk cargo:** freight that has not been packaged, such as minerals (oil, coal, iron ore, bauxite) and grains. These are dry or liquid bulk products that rely on the use of specialized ships such as oil tankers or ore ships and on specialized port and storage facilities. Bulk cargo usually has a single origin and a single destination, with services that are prone to seasonality, with the exception of energy transport. It supports the heavy manufacturing sector.

- **Break-bulk cargo:** general cargo that has been packaged in bags, boxes, drums, and particularly containers, which now represents the dominant break-bulk use of maritime transport. Break-bulk cargo usually has several origins and destinations. It supports manufacturing and retailing.

Technical improvements have blurred the distinction between bulk and break-bulk cargo, as both can now be unitized on pallets and also loaded into containers. Shipping grain and coal, which are bulk cargoes, in containers is becoming increasingly common.

About 100,000 registered commercial vessels are supporting global maritime transport. There are four major categories of these vessels. The first is the passenger vessels such as ferries and cruise ships. Passenger vessels used to be important conveyances for long-distance transport (liners), a role that has now been relegated to cruise ships. Still, the cruise industry has experienced a remarkable growth, particularly in the Caribbean and the Mediterranean, with about 20.3 million passengers taking a cruise in 2012.

A major category of cargo ships consists of bulk carriers, both liquid (particularly for petroleum) and dry (particularly for ores) bulk carriers (Figure 2). As a result of the propensity for economies of scale for this type of cargo, bulk carriers are the largest ships in existence. General cargo ships carry nonbulk cargoes and, prior to containerization, tended to be relatively small because the loading and unloading were done manually. These vessels have now been replaced by containerships that can be loaded and unloaded much more efficiently now that the cargo is in standard load units. Roll-on roll-off (RORO) vessels are designed to carry vehicles that can be directly driven on board. These specialized forms of transport were initially used as ferries but are now also extensively used as vehicle carriers. They transport vehicles (mostly cars and small trucks) from assembly plants to major consumption markets.

Maritime traffic is commonly measured in deadweight tons (dwt), which is the maximum amount of cargo that can be loaded on a ship without exceeding its operational design limits.
Between 2000 and 2012, the world deadweight tonnage almost doubled, propelled by a surge in global trade. Bulk ships tend to support regular services between two ports and may be used for specific trips depending on fluctuations in demand. The demand for maritime transport is often seasonal, as is the demand for grain transport and project cargo (e.g., construction material). General cargo vessels are commonly allocated to liner services whereby vessels will call at a series of ports according to a schedule.

Figure 3  Types of maritime routes.
Maritime transport networks

Maritime transport is an international industry, particularly in terms of ownership and the flagging of ships. The distinction between ownership and flagging is important: the corporations of developed countries remain the main owners of ship assets, but the flagging of the ships may involve different countries. While there are still many ships registered under national registries, the growth of the use of “flags of convenience” has been significant. A flag of convenience enables an owner to pay lower registration fees and lower operating costs, and be subject to fewer restrictions. Maritime transport is a highly deregulated industry, with open registry ships operating under fiscal shelter states such as Panama and Liberia. As of 2011, 68% of the global maritime transport tonnage was registered under a flag of convenience, up from 55% in 1995.

Maritime transport networks are designed to use the shortest route while being able to service the main markets. This leads to various compromises between the number of ports of call and the number of ships to allocate to specific trades. Containerization had a far-reaching impact on the configuration of maritime routes, particularly since, prior to containerization, loading or unloading a ship was a very expensive and time-consuming task; a cargo ship typically spent more time docked than at sea. The trend has now been reversed, and containerships spend more time at sea than in port, constantly on the move between ports of call. Therefore, containerships gave rise to a new network structure: what used to be mostly port-to-port has now evolved toward a more complex structure covering multiple markets. Maritime routes are organized according to the commercial services they support. These services can be divided into three main categories (Figure 3):

- **Port-to-port** represents the conventional service structure which concerns regular calls between two ports. Commonly ships move back and forth with a full load in one direction and an empty backhaul in the other. This low connectivity network structure is typical of raw material flows such as oil, minerals, and grains. These markets are usually serviced by chartered ships loading in one port (next to a major resource extraction area) and discharging their cargo in one to three ports.

- **Pendulum services** are typical of container shipping with regular itineraries covering a set of ports calls that are sequentially serviced. The sequence of these ports is obviously selected to maximize the load factor of the ships. The term “pendulum” refers to the shipping service moving back and forth between two maritime ranges (some pendulum services cover three maritime ranges). The most significant pendulum routes are between East Asia, North America, and Western Europe, the three main poles of the global economy.

- **Round-the-world services** also relate to container shipping and involve calling at a sequence of ports, often in both directions, such that the sequence involves a trip around the world. A limited number of ports per continent are serviced, but those ports are either major gateways or trans-shipment hubs. Thus, round-the-world services are an attempt to better connect longitudinal and latitudinal trade flows.

Historically, maritime transport was organized according to conferences, which are formal agreements between shipping companies operating over specific routes. Although they have the appearance of an oligopoly, they are designed to provide a level of rate stability in a context where rates have been subject to a
lot of variations, and to offer regular services. In view of the rising costs of ships due to their larger sizes, alliances have also been established. These alliances involve competing shipping companies pooling their vessels along major, and highly competitive, commercial routes with the expectation of higher utilization of their ship assets. This process has been taking place alongside a growing concentration of ownership and the emergence of a few very large shipping lines. As of 2013, the 20 largest shipping lines control 81% of the global container slot capacity, up from 42% in 1992.

Maritime transport is the linchpin of the global economy, acting as the physical support of its flows of freight. Although containerization was an important driver of change in maritime shipping, bulk cargo such as petroleum, minerals, and grains are fundamental and enduring trades, supporting large industrial sectors. Physical constraints have played an important part in the structure and organization of maritime transport. Such constraints have been partly mitigated by the construction of transoceanic canals, particularly the Panama (which is being expanded) and Suez canals. Climate change may also have an impact on maritime transport, with the opening up of Arctic routes, but such prospects remain speculative. It is the commercial factors related to the demand of energy, food, raw materials, parts, and finished goods that drive the dynamo of maritime transport. The fates of globalization and of maritime transport remain closely intertwined: maritime transport supports commercial flows, and more efficient maritime transport is also conducive to improved trade.

Marxism – a global phenomenon with its own geography

Marxist geography, like Marxism, is named after one individual, the German thinker Karl Marx (1818–1883). This may sound like some kind of personality cult, but nothing could be more contrary to Marx’s own thinking, which focuses on how society as a whole functions and develops, and how capitalist societies are characterized by a mode of production based on exploitation. Academics and activists working within the Marxist tradition have become especially cautious when it comes to personality cults. Throughout the twentieth century, Marx’s name and ideas were exploited as a state ideology in the Soviet Union, Eastern Europe, and China, for example, in order to legitimize political regimes of highly problematic and sometimes outright dictatorial character that had very little in common with Marx’s own ideas.

During his lifetime, Marx’s work was adopted by thinkers and activists in many places all over the world to understand and to criticize both grievances caused by capitalism and capitalism itself. In the twentieth century, Marxism has become a global phenomenon, reflecting the spread of capitalist social relations and the struggle against their many different forms. Depending on historical epoch, national and language context, and strand within the discussion, there are numerous understandings of what Marxist thinking entails. While many of these understandings are closely related, there are cases where different strands of Marxism have little in common. Especially in the second half of the twentieth century, “Western” Marxists struggled to come to terms with Marxism–Leninism or Maoism, both of which drew on Marx but tended to portray his thinking as rather mechanical, as opposed to relational. Today, cleavages and disagreements within the Marxist tradition remain, but clearly take a back seat to the common goal: the comprehensive analysis of the functioning and steady development of capitalist society and the work toward alternatives. It was the latter that Marx famously called for when he wrote in the “Theses on Feuerbach” in 1845: “The philosophers have only interpreted the world, in various ways; the point is to change it.” On the most general level, the contribution of Marxist geographers to these endeavors lies in bringing to the fore the relevance of spatial differences in the analysis of capitalism and its alternatives, using concepts such as uneven development, geopolitics, urbanization, territory, place, region, landscape, and scale.

Marxist geographers are not particularly interested in defining a certain version of the academic discipline of geography. The division of academic labor into disciplines is mainly the result of struggles and exclusions within academia (with geography often having a hard time justifying its specificity vis-à-vis other disciplines) and, to a much lesser degree, a reasonable division of labor between academics. Just as Marx’s own work cannot be assigned to one academic discipline, the work of Marxist geographers is closely linked and sometimes indistinguishable from that of Marxists working in other disciplines.
Marxist Geography

Nature and metabolism

In volume 1 of his major work, *Das Kapital* (published in 1867 and revised in 1890), Marx makes reference to the “original sources of all wealth – the soil and the labourer” (Marx 1996, 508). Note that “the soil” is the translation for “die Erde,” which is more accurately translated as “the earth,” referring to nature in general. For Marx, as for geographers in the nineteenth century, nature forms the basis for all social processes. But, unlike the environmental determinism of nineteenth-century geography, he is very clear that the natural world – soil, air, water, minerals, plants, animals, and so on – does not determine culture but that human societies live in a complex relationship with nature which he terms *metabolism*, and which makes it difficult to even distinguish the border between the two spheres. It is through labor, understood as the “process in which both man and Nature participate” (Marx 1996, 187; note that Marx originally used the term “Mensch,” which is more accurately translated as “human being”), that this metabolism works. On the most general level, “arms and legs, head and hands” are themselves “natural forces” of the body, and through their use the human being “at the same time changes his [or her] own nature” (Marx 1996, 187). Marxist geographers have further developed this line of thinking by arguing that nature is actually produced in and through the metabolism with human societies, and that the production of nature under capitalism follows the imperatives of capital (Smith 1990). In another strand of the discussion in Marxist geography and in common with feminist literature, the human body, which was traditionally thought of as something merely natural, is discussed as produced in and through labor processes (Callard 1998).

Commodity production, value, and uneven development

The capitalist way to organize the metabolism between nature and society, and therefore the labor process, is marked by *commodity production*. In *Das Kapital*, commodities are the point of departure for Marx’s discussion of the capitalist mode of production. Commodities (including services) are useful things that are produced solely because they can be sold to others for a profit. The usefulness of things – the qualities that make up their *use value* – is reduced to a means to an end: it is only their quantitative *exchange value* that the capitalists who produce them are interested in. The exchange value is the amount of money that can be exchanged for the commodity because somebody else finds it useful and is willing and able to pay for it. It is only in the marketplace, in competition with other producers, that capitalists find out if they can realize an exchange value, and this is why it seems as if the value of a commodity is determined by what is going on in the marketplace: that is, supply and demand. But Marx argues that the exchange value is only the form in which the value of the commodity appears in exchange. *Value*, he argues, is inherent in the commodity prior to its entering the marketplace where it is realized. Following what is called the labor theory of value, he argues that the value of a commodity is determined by the average amount of socially necessary labor time that goes into its production. New value is produced in the labor process, not in exchange. Capitalists buy the commodity labor *power*: that is, the mere ability to work, in an exchange of equivalents for a certain price (the wage), and organize the labor process in a way that labor *time* is spent producing more value than is covered by the wage. This is how *surplus value* is produced and how capitalist
exploitation works: through the specific form in which the labor process is organized.

Marxist geographers have emphasized that capitalist production necessarily results in uneven geographic development (Harvey 1982; Smith 1990), since capitalists strategically use spatial differentiations to minimize costs (of means of production and/or labor power), to profit from the proximity to markets or to other capitalists such as suppliers, to create a spatial monopoly, or to use location as a competitive advantage (Harvey 1982). Spatial (re)location and organization thus play an integral role in the way in which production and exploitation develop, and result in a “spatial division of labor” (Massey 1984). In capitalism, uneven development is sometimes organized though spatial scales like the global scale of the world market, the national scale of the state, and the local scale, where production sites and labor power are concentrated (Smith 1990). Within labor geography, Marxist geographers look into the spatial strategies of laborers, such as how they mobilize their struggle for better working conditions and wages using spatial strategies, for example by organizing on a larger geographical scale (Herod 2001).

Classes, the state, and reproductive labor

The capitalist mode of production as described so far presupposes two classes: capitalists, as private proprietors of the means of production, and laborers, who have nothing to sell but their labor power. The existence of these two classes is the result of an (ongoing) history of “conquest, enslavement, robbery, murder, briefly, force” (Marx 1996, 705). Class struggle, enclosures, urbanization, colonialism, imperialism, geopolitics, coups d’état, police power, and wars were necessary, and are still used, to produce and reproduce these two classes. In Das Kapital, Marx emphasizes how wealth is produced and circulates in capitalism as a result of the distinction of these two classes with antagonistic interests. He further identified several more classes with particular interests, as well as other groups and institutions playing fundamental roles in the capitalist mode of production.

In “The Eighteenth Brumaire of Louis Napoleon,” first published in 1852, for example, Marx identifies the “small-holding peasantry” (Marx 1979, 187; emphasis original) as the class that would-be French ruler Louis Napoleon represented in his coup d’état in 1851. These small farmers were, as a result of the French Revolution, free from direct rule by their former overlords, but as they were not able to live off their land they ran up debts that made them unfree in a new respect. This economic position formed the basis of their particular interests that Louis Napoleon was able to represent. The proprietors of the banks to which they owned money, the “urban usurers” (Marx 1979, 190) as Marx calls them, are an example of yet another class: financial capitalists who lend money to other capitalists, laborers, and states. Their main concern is to secure the return of their credit with interest, for which reason they support the profit-making industrial capitalists and tax–collecting states while at the same time struggling with the former over the share of social wealth and the latter over the burden of taxation, banking regulations, and so on.

In the same work, Marx also mentions “the rivalry between capital and landed property” (Marx 1979, 128). Landowners who receive ground rent from capitalists or others for the permission to use a piece of land for a certain time constitute a class of their own, with interests that conflict with those of the renters. As landed property was discussed as a relevant source of wealth in the realm of agriculture in Marx’s time, he identifies the aforementioned rivalry with
“the old contrast between town and country” (Marx 1979, 128). Marxist geographers have contributed to an understanding of the role of private property over land, with a focus on the urbanization process that has shaped the world so fundamentally since Marx’s time. In order to understand the spatial structure of cities, the housing question, and gentrification, they emphasize “the co-ordinating functions that [ground rent] performs in allocating land to uses and shaping geographical organization in ways reflective of compensation and amendable to accumulation” (Harvey 1982, 333).

Also in the same work, Marx makes important contributions to an understanding of the state in the capitalist mode of production. On the one hand, he shows how the multitude of interests of various classes is represented within the state in an indirect manner, through parties, their campaigning, and propaganda, and through elections. On the other hand, he qualifies the state bureaucracy as “an artificial caste” (Marx 1979, 192) that is necessary to organize all other classes and that develops an interest of its own: the “maintenance of [the] regime” (Marx 1979, 192). Marxist geographers, often in close collaboration with Marxists from other disciplines, have made important contributions to our understanding of the state under capitalism and the way in which indirect rule, mainly in the interest of some classes over the vast majority of the population, is organized through coercion, but more importantly through hegemony, power relations, and the selectivities of state apparatuses. Geographers have tackled the following issues, among others: the way in which political coalitions of (parts of) different classes with competing interests form in places of different scale (cities, regions, nation-states), putting their common interest in the protection of value embedded in the land and the capitalist activities in these places on a similar level as their particular interests (Harvey 1982); how and why capitalist states are organized spatially in territories and scales, and how groups and classes try to strategically influence the scalar organization of states in their own interest (Smith 1990); and how states use their powers of policing, punishment, and incarceration to order spaces and populations in socially selective manners, such as along racial lines (Wilson Gilmore 2007).

Large groups and many activities seem to stand outside of the economic and political relations discussed so far, especially reproductive work and housework, which are mainly done by women. While Marx never explicitly engaged in a discussion of women’s role in capitalism, feminists in the Marxist tradition have highlighted the role of women in the biological reproduction of laborers (i.e., giving birth) and the social reproduction of capitalist social relations in general by guaranteeing the reproduction of the (often) male “breadwinner’s” labor power. Marxist geographers have contributed to these discussions by, for example, deciphering the way in which reproductive labor is hidden from sight in urban spaces and by showing how reproduction differs between places (Katz 2004).

Pathways of Marxist geographies

Marxist geographies, while based on the work of Marx, differ in time and space, reflecting different economic and political situations and emancipatory struggles in which Marxists in general, and Marxist geographers in particular, were engaged. In the anglophone world, Marxist geography was central to the theoretical development of geography in the 1970s and 1980s, before being challenged on a variety of levels by phenomenology, structuration theory, and especially poststructural and feminist theories that constituted a “critical geography” that
wanted to overcome the perceived shortcomings of Marxist radical geography. Building on the work of authors such as Michel Foucault, Judith Butler, Ernesto Laclau and Chantal Mouffe, many contributions of anglophone critical geography in the 1990s seemed to place a wedge between their endeavor and the Marxist tradition (sometimes ignoring the close relation of poststructuralist authors to the Marxist tradition). This development is rather specific to the anglophone context, though. It reflects, among other things, the political upheaval at universities in the late 1960s, the sometimes problematic relationship of Marxist political organizations to feminist movements and movements of people of color, and the specific “publish or perish” environment at British and American universities since the 1990s which gave an incentive to authors to focus on the novelty of their contribution. By contrast, in Latin America the work of Brazilian geographer Milton Santos (1926–2001), who included the category of race in his Marxist work, remains a central point of reference. Following his example, and as a result of the close relationship of Marxist geographers to social movements and their existential struggles, a far more open exchange between different kinds of critical theories has evolved. In France, important geographers such as Pierre George (1909–2006) were members of the Communist Party (a relevant political force between the 1950s and 1980s), but little Marxist theory is reflected in their work. In Japanese economic geography, Marxism was present from the 1920s and especially strong in the 1970s, following the country’s rapid industrialization after World War II and its negative impacts on Japan’s social and natural environments. In the Soviet Union and Eastern Europe, Marxism–Leninism functioned as a state ideology, but it also made possible an early and radical critique of traditional geography as well as interesting attempts to build an applied Marxist geography with a strong focus on territorial planning in the service of “real existing socialism.” In the current conjuncture, with English being the lingua franca of global academia and very few translations from other languages into English, and with excellent Marxist work being produced in English-language geography, anglophone Marxist geography has become hegemonic within Marxist geography (as reflected in the references of this entry).

The relational thinking of Marxism allows us to understand these different pathways as appropriations of Marx’s basic contributions to the understanding of capitalism and its alternatives in different economic and political contexts. In this sense, the development of Marxist geography illustrates one of Marx’s strongest phrases, which also captures nicely the inherently political nature of Marxist thinking: “Men [originally ‘Die Menschen,’ i.e., ‘human beings’] make their own history, but they do not make it just as they please; they do not make it under circumstances chosen by themselves; but under circumstances directly encountered, given and transmitted from the past” (Marx 1979, 103). Building on the insights of Marx and the tradition he founded allows us to understand the ways in which human beings make their own geographies in varying circumstances and to contribute to progressive attempts to change them.

MARXIST GEOGRAPHY

Mass movement processes and landforms

Francesco Dramis
Roma Tre University, Italy

Mass movements may be defined as “downslope movements of rock (hard rock), earth (soft clayey rocks) or soil (loose debris) masses occurring when their resisting forces cannot resist gravitational stress.” They include a large variety of phenomena that mobilize with different modalities (type of displacement, type of movement, speed, run-out distance, etc.) masses of extremely various dimensions. Similarly to other geomorphological processes, these phenomena may heavily interact with human settlements and activities, being responsible for loss of human lives and damage to built-up structures and properties.

From the definition, mass movements are favored by conditions and processes causing either an increase in gravity stress and/or a decrease in shear strength in the involved material.

An increase in gravity stress may be induced by: (i) long lasting heavy rainfall causing higher groundwater levels in the slope materials and a related increase in their specific weight (the same effect is produced by water leakage from water pipes or sewers); (ii) earthquake shocks, which may increase (even if for a short time) the downslope stress component by the transitory addition of seismic acceleration (up to more than 0.5 g in high magnitude earthquakes) to the gravity acceleration; (iii) transient or permanent co-seismic oversteepening of slopes; (iv) oversteepening of volcano flanks during eruptions; (v) removal of lateral support because of valley incision, coastal erosion or glacial oversteepening of valley slopes followed by glacier retreat; (vi) removal of basal support due to underexcavation of the slope foot by streams, sea waves or human activity; (vii) slope overloading due to debris accumulation by other mass movements, running water, or pyroclastic fall. Comparable effects are produced by artificially constructed embankments and constructions, or by the growth of big tree forests.

The main parameters controlling the shear strength of a geologic material are cohesion, internal friction angle, and normal stress. Friction is the force that resists the sliding movement of a material over a surface. Its value depends on different parameters, the most important of which are the roughness of the potential sliding surface and the extent of the contact area. The internal friction angle is the threshold angle above which the material is unstable and moves down by failure. Cohesion is the tendency of the particles that compose the material to be linked; it depends on several factors, such as compaction, cementation, chemical bonds, and plant root networks. Normal stress corresponds to the weight of the material overlying the potential sliding surface.

Shear strength \(s\) is quantitatively defined by the Coulomb–Terzaghi equation:

\[
s = c + \sigma' \tan \varphi
\]

where \(c\) is the cohesion, \(\sigma'\) the normal stress, and \(\varphi\) the sliding surface angle. When water fills the pores, a part of normal stress is supported by it, resulting in a reduced shear strength. In this case, the Coulomb–Terzaghi equation is:
where $u$ is the neutral pressure, defined as the water pressure within the material interstices (pores). When air fills the pores, the neutral pressure is zero.

The strength of geological material is mainly dependent on its composition, permeability, and pore pressure. In the case of hard rocks, the following factors should be taken into account: rock composition and structure; weathering degree; joint spacing, orientation, width, continuity, and infill; and groundwater flow within joints.

A decrease in strength of the slope materials may be induced by different causes, including: (i) an increase in pore pressure because of infiltration of rain and snow melt or pipeline/wasteway leakage (this effect is significant where expandable clay minerals, such as montmorillonite, are present); (ii) seismically induced expansion/compression cycles of pore pressures in water-saturated granular sediments (in fine sands and silt, the material structure may break down (liquefaction)); (iii) seismically induced ground faulting and fracturing; (iv) progressive weathering; (v) gravity-induced enlargement of joints; (vi) joint enlargement by tree roots; (vii) climate-induced melting of permafrost ice and related high water pore pressures in ice-cemented debris; (viii) climate-induced warming of permafrost ice filling potential detachment/yielding surfaces (Davies, Hamza, and Harris 2001).

The stability conditions of a hillslope may be expressed by the safety factor ($F$), corresponding to the ratio between resisting forces and driving forces: with $F < 1$ if the slope is unstable; with $F > 1$ if the slope is stable. The safety factor of natural slopes commonly ranges between 1 and 1.3. The steepest slope angle that a cohesionless material can keep without losing its stability is called the angle of repose.

Gravity-driven masses may be displaced downslope through some basic mechanisms: (i) detachment from the slope by a newly generated fracture or shear surface; (ii) fall in free air; (iii) sliding over a newly generated shear surface whose shape is controlled by the mass structure; (iv) spreading of a subhorizontal layer over a softer material along a non-defined basal shear surface; (v) flow over the slope surface or in a preexisting slope incision; (vi) creep, an extremely slow gravity-driven deformation of slope material.

Mass movements may be distinguished in four main groups: (i) generalized near-surface slope wasting; (ii) landslides; (iii) deep-seated gravitational deformations; (iv) subsidence.

**Generalized near-surface slope wasting**

Generalized near-surface slope wasting includes two widespread gravity-driven processes: soil creep and solifluxion.

Soil creep is the slow (a few centimeters per year) movement of eluvial/colluvial material induced by several different actions (such as rain splash, shrinking/swelling, plant rooting, burrowing by worms or other animals) displacing the single grains in different directions but with the result of shifting them downslope. All the single grains make up a unique mass, involved in a continuous deformation of the creep type. Frost creep, a particular type of soil creep, commonly occurs on debris slopes affected by seasonal freeze/thaw cycles. Winter freezing pushes upward the debris fragments at a right angle to the slope; subsequently, the spring thaw of ground ice causes their vertical fall and downward displacement. The surface indicators of soil creep are hook-shaping of sedimentary layers, curved upslope tree trunks, bent walls and fences, inclined poles, offset roads, walls, and fences. Soil creep often forms long
narrow steps called terracettes, especially where animals walk across the slope.

Solifluction is the slow downhill flow of the soil layer saturated by rainfall or snowmelt. Gelifluction is a particular case of solifluction affecting the permafrost active layer: affected by seasonal freeze/thaw cycles, the meltwater cannot penetrate the ground because of the presence of permafrost ice, thus inducing high pore pressure in the soil particles and making them flow downward as a cohesive mass. Sometimes, the underlying permafrost table may act as a sliding surface for the saturated soil. Solifluction landforms include slope surface undulations with water ponds, lobes, sheets, and turf-banked terraces. Plowing boulders are large blocks that move slowly downslope pushing a soil rampart ahead of them, leaving a furrow behind.

**Landslides**

Landslides are the fastest geomorphic processes by which gravity tends to re-establish the disequilibria induced by tectonic uplifting on the Earth’s surface. The term includes a large variety of downslope movements that involve masses of various dimensions, ranging from small blocks to entire slopes and hills (large-scale landslides). Due to the large masses involved, large-scale landslides are occasionally characterized by scale effects, such as rock melting, carbonate dissociation, and fluid vaporization along the shearing surface (Goguel 1978). Landslides of different types and dimensions (up to several tens of cubic kilometers) also commonly occur in subaquatic environments as a result of earthquake shocks. They can affect the offshore areas near the coast and can extend backward to the coastal belt or the sediments accumulated on the edge of the continental scarp. Landslides are also common on the slopes of submarine volcanoes. The aquatic environment facilitates the movements and enables the displaced materials to travel considerable distances. Large-scale submarine or coastal landslides may generate catastrophic tsunamis.

Landslides are classified in different ways. The most generally adopted scheme, based on the types of movement and the nature of involved material, is that proposed by Varnes (1978) and more recently improved by Dikau et al. (1996). The landslide types shown here primarily refer to this scheme. As recognized for all classifications, the list is only a simplified representation of the real phenomena that, in many cases, may include more than one landslide type or may change downslope from one type to another. Different types of landslides are locally associated to form landslide systems, in which each component moves with a different mechanism and recurrence time. In some cases, landslides are superposed to deeper levels, the lowermost of which is reactivated only by major triggering events.

**Falls**

A fall is the detachment of a block of solid rock (rock fall), soft clayey–sandy rock (earth fall) or unconsolidated/poorly consolidated debris (soil fall) from a cliff, along newly generated or pre-existing rupture surfaces (joints, layering, fractures, etc.) progressively enlarged by gravity stress, recurrent earthquake shocks, frost shattering or plant-root wedging. The detached mass may move rapidly in free air or roll and jump on the slope surface. When impacting the ground, the fallen mass commonly breaks into smaller fragments that are deposited at the base of the cliff giving rise to a talus slope, an accumulation belt of debris whose slope gradient is controlled by the internal friction angle. The size of the falling mass may range from decametric blocks to single small fragments (commonly not considered as true landslides).
Toppling is the detachment of a prism of rock (rock toppling), earth (earth toppling), or soil (soil toppling) from a cliff, along a pre-existing subvertical surface. After detachment, the mass rotates clockwise on its base and tips over the slope foot or falls in free air, breaking into rolling or jumping fragments. The landslide heaps are similar to those produced by falls.

Rotational slides

Rotational slides are downslope movements of rock, earth or soil along newly generated, concave upward subcircular shear surfaces. Rotational earth slides (Figure 1) are commonly characterized by a step-like evolution, alternating short-lived reactivation phases with long periods of quiescence that may range from seasonal to multi-annual, decadal or centurial, up to more than 1000 years. There are different types of rotational earth slides: (i) single slides, which may enlarge upslope (retrogressive slide), downslope (advancing slide) or laterally (enlarging slide); (ii) multiple slides, made of more than one sliding units, each of which has a sliding surface intersecting a common, basal yielding surface; (iii) successive slides, consisting of a series of individual rotational slides one above the other. The main scarp is concave valley-ward and is commonly bordered upslope by tension cracks. Scarps and steps are often present also along both landslide flanks. The body of a rotational earth slide often consists of an almost undisturbed mass whose surface is less inclined than the original one or is
even inclined upslope, resulting in a topographic depression. This latter formation may host superficial water, causing concentrate infiltration into the ground and further slope destabilization. Transverse fissures, steps, trenches, and uplifted blocks on the landslide surface indicate the occurrence of minor shear planes. The landslide foot (the portion of the landslide beside the lower limit of the sliding surface) often shows transverse pressure ridges and compressional shear planes. The landslide toe (the lower margin of the landslide) often evolves to earth flow. Rotational soil slides, also known as soil slips or slumps, usually occur on steep slopes. They move quickly and may be extremely dangerous. Rotational rock slides are characterized by extremely large depth (up to several hundred meters) and involved volume (up to several thousand cubic meters). They commonly form on very high slopes and represent the final collapse of deep-seated gravitational deformations, which are described later.

Translational slides

Translational slides are downslope movements of rock, earth, or soil masses along a newly generated planar shear surface, emplaced over pre-existing (predisposed) “weak” structural elements, such as layers, faults, and fractures, that are inclined less than the slope. The detachment surface is subvertical in the upper part (main scarp) and less inclined (up to subhorizontal) in the lower part. Tension cracks are often present upslope of the main scarp. Low diverging downwards scarps commonly border the landslide body. On high steep slopes, translational rock slides move down with extremely high speed as rock avalanches impacting the ground and disintegrating into fragments that climb over the opposite valley-side (Figure 2). Occasionally, the landslide debris dams the valley bottom, causing the formation of a temporary lake. Translational earth slides frequently show a step-like evolution. The landslide bodies commonly consist of single (or a few) undisturbed units crossed by tension fractures. Also in this case, the landslide toe may evolve to earth flow. Translational debris slides on high steep slopes may change to extremely rapid, dangerous debris avalanches that can travel for great distances even along very low gradients.

Soil spreads

The term of soil spreading describes the gravity-driven translational movement of a soil mass over a softer material along a non-defined basal shear surface. This results from a loss of strength (liquefaction) in the upper layer (commonly quick clay soils) induced by prolonged periods of heavy rainfall/snowmelt or earthquake shaking. The expanding soil mass breaks off into tilting, subsiding, heaving, and overthrusting blocks that produce a typical hummocky topography. The movement starts in the lower sector of the slope and rapidly extends upslope and laterally, giving a pear shape to the failure area. Because of their rapid evolution, soil spreads may be extremely dangerous.

Flows

Flow is a fluid-like movement of loose sediments that have a velocity which ranges from extremely slow to extremely rapid in relation to the slope angle, grain size, and water content. Almost all flows move with a non-Newtonian behavior (their viscosity increases with an increasing applied stress), except for materials with high water contents. Debris flows are characterized by very high speed and frequently cause destruction and death. With increasing water content, debris flows gradually develop into torrential flows. Their typical geomorphic features include:
Deep-seated gravitational deformations

Deep-seated gravitational deformations are complex phenomena whose genesis and evolution are controlled by several factors, among which structure, relief, tectonic, and seismic activity play a primary role (Dramis et al. 1995). The most recurrent typologies are sackungs, rock spreads, and deep-seated block slides.

Sackungs

Sackungs, also known as gravity sags or rock flows, commonly develop in hard rocks over a high slope. They are characterized by the following morphological features (Dramis et al. 1995): (i) surface extension generally more than 1 km²; (ii) thickness of deformed mass ranging from tens to hundreds of meters; (iii) displacement reduced with respect to the involved mass volume; (iv) absence of a continuous shear surface; (v) extremely slow evolution with long periods of inactivity or reduced activity alternated with short-lived activations, often triggered by earthquakes; (vi) deformational mechanism of the creep type, with accelerations and ruptures; (vii) kinematics often influenced by active or residual tectonic stress; (viii) reduced influence of...
topography in respect to structure in controlling the deformation location and typology; and (ix) surficial landslides affecting the deformed slope. The upper part of the deforming slope shows high-angle extensional shear planes giving rise to graben-like depressions (trenches) and counter-slope scarplets. In contrast, the lowermost slope portion often presents compressional features such as bulging and low-angle shear planes. Smaller surficial landslides often affect the deforming slopes. Sackungs may be considered as preparatory stages for large-scale rock slides even if, usually, they may not complete their evolution (Dramis et al. 1995).

Rock spreads

Rock spreads are characterized by horizontal extension of the relief, balanced by shear or tensile fractures. They may occur in the following ways: (i) bilateral spreading without any shear surface or basal flow causing the formation of double ridges on top of high elongated reliefs in stiff homogeneous rocks (Jahn 1964); (ii) bilateral spreading associated with both trench-like summit depressions and shear planes at the base (Beck 1968); (iii) tectonic-gravitational spreading (Dramis and Sorriso-Valvo 1994) affecting morpho-structural reliefs produced by active thrusting (spreading starts because of tectonics...
but then evolves because of gravity); (iv) lateral rock spreading involving thick rocky masses horizontally overlying softer layers on top of a high relief (Cruden and Varnes 1996). The upper mass induces squeezing and expansion in the lower layer, which causes, in turn, the fragmentation of the hard rock into blocks, bordered by progressively enlarging fractures. These blocks may subside, translate, rotate, or tilt, giving origin to counter-slopes, steps, and trenches. The edges of the expanding mass are commonly affected by minor landslides.

Deep-seated block slides

Deep-seated block slides (Figure 4) are characterized by relatively small displacements of thick rocky blocks overlying gently sloping, less competent layers (Dramis et al. 1995). Their surface effects are large scarps and trenches in the upper and intermediate portions of the slope, and bulging associated with compressive shear planes in its lowermost portion.

Subsidence

Subsidence may be defined as a ground surface lowering or failure due to removal of underlying support. It may occur at different rates from extremely slow movements to sudden collapses that may result in subcircular cavities (sinkholes). In the latter case, catastrophic effects may be induced to buildings, infrastructures, and human lives. The possible causes of subsidence include both natural and anthropic actions. Among the first, the most common are: natural compaction of sediments; removal of fine sediments by circulating groundwater; collapse of near-surface roofs of karst caves in calcareous/gypseous rocks; dissolution of salt deposits; thermokarst in permafrost areas; upwelling artesian groundwater; seismic liquefaction; co-seismic ground lowering. The main anthropogenic causes are mining; extraction of gas, oil, and water; and overloading of the ground surface by buildings.

Figure 4  A deep-seated block slide near San Mango, Calabria, Italy. Note the large detachment scarp across the ridge (photograph by F. Dramis).
Gravity tectonics

Gravity-driven movements may also involve masses at the geological scale giving rise to imposing tectonic structures such as thrusts and nappes. These features may involve any rocks, including hard rocks, which move at an extremely low rate by creep deformation and sliding. During geological times, these phenomena have repeatedly affected orogenic structures, causing the removal of enormous masses of overlying rocks (tectonic denudation).

Further reading

At present, the level of confidence is high that the global average temperature of the past few decades was warmer than at any comparable period during the last 2000 years (IPCC 2013). Current evidence also suggests that temperatures during the last 25 years were higher than at any period of comparable length since BCE 900 for many, but not all, regions. The Intergovernmental Panel on Climate Change (IPCC) also reports that most land regions of the world show an increase of high temperatures for the past 50–100 years, usually expressed as the 90th or 95th percentile of the long-term record, such that the frequency of hot days has almost tripled in Europe since 1880. Based on simulation runs forced with different greenhouse gas emission scenarios, the IPCC (2013) also concludes that the rate of warming until the end of the twenty-first century is likely to be faster than ever recorded from historical or proxy records. In high-mountain regions, the evolution of mean and extreme temperatures will likely be comparable to what has been described above; however, studies specifically focusing on trends at high elevations have not been published so far.

The capacity of air to hold moisture is a function of temperature. As a consequence, global warming is likely to lead to an overall greater frequency and magnitude of heavy precipitation events. An increase in the frequency and intensity of extreme precipitation events has been identified in different sets of observational data from several regions of the world (IPCC 2013). For the future, projections likewise suggest decreasing return periods of extreme rainfall events.

Changes in temperature and precipitation are considered likely to have a range of secondary effects, including on the extent of glaciers, the distribution and duration of the snow cover, and on the temperature and 3-D distribution of permafrost. While there is a theoretical understanding for increased mass-movement activity as a result of predicted climate change in mountain environments, changes in activity can hardly be detected in observational records. Uncertainty also remains considerable as a result of error margins inherent in scenario-driven global predictions, and due to the lack of spatial resolution of downscaled projections.

This entry aims to document the role of climate variability and change on mass-movement processes in mountainous regions through the description and analysis of selected, recent mass movements where the effects of global warming and the occurrence of heavy precipitation are thought to have contributed to, or triggered, events. It addresses possible effects of future climatic changes on the occurrence of future mass-movement processes and speculates about possible consequences of climate and mass movements on hazards and risks.
Glacier downwasting and the formation of new ice-marginal lakes

One of the most obvious consequences of climate change at high-elevation sites is the widespread retreat and disintegration of glaciers (Zemp et al. 2007). The consequences for natural hazards are multiple and include the formation of ice-marginal lakes, ice avalanches, and mass movements originating from the recent debuttressing of previously glacierized landscapes.

A prominent phenomenon associated with glacier retreat and changes in glacier geometry is the formation and growth of ice-marginal lakes. Hazards related to glacier retreat and the formation of glacial lakes have been recognized for several decades. Indeed, severe disasters have occurred in the past as a result of outburst floods from glacial lakes in various high-mountain regions of the world (Worni et al. 2014). Rapid lake formation and growth has accelerated in recent years. Many of the current lakes have typically formed within the past decades and are often located at the terminus of glaciers, where subglacial topography has been overdeepened by the glacier. Lower Grindelwald glacier (Figure 1a), for instance, has been in strong retreat since its maximum glacier extension during the Little Ice Age around 1860. Downwasting of the glacier in its terminal part resulted in a loss of between 60 and more than 80 m of ice thickness between 1985 and 2000. In recent years a glacial lake started to form in the terminus area of the glacier (Figure 1a). In 2004 and 2005, the lake had a limited volume but has subsequently continuously grown in the spring and early summer seasons, resulting in lake volumes of 250 000 m$^3$ in 2006, 1.3 million m$^3$ in 2008, and 2.5 million m$^3$ in May 2009, and the occurrence of a glacier lake outburst flood in 2008 (Worni et al. 2014).

Glacier debuttressing and the occurrence of rock slope instability

The combined effects of glacier downwasting and debuttressing on rock and moraine slopes, permafrost degradation, rockfalls, and...
debris-flow activity, all interacting with the formation and growth of glacier lakes and further glacier decay, are often remarkable. At the Lower Grindelwald glacier, the rock slope failure above the glacier terminus (Figure 1b) is a textbook example of the effects of glacier retreat, downwasting, and associated debuttressing effects on rock slope stability, and could, in fact, serve as a model case for increasingly destabilized future high-mountain environments. The response of a rock slope to glacier downwasting has been reported to potentially result in (i) large rock avalanches, (ii) large-scale, progressive and slow rock mass deformation, and (iii) frequent rockfall events (Ballantyne 2002). The three modes of response are all consequences of stress redistribution and release and may act in a combined way. Rock slope failure thereby often represents the result of slope steepening by glacial erosion and unloading or debuttressing due to glacier retreat.

Examples that may be related to glacial oversteepening or debuttressing include the Brenva and Troiet rock avalanches in the Mont Blanc massif in the eighteenth and twentieth centuries, the Sherman glacier-rock avalanche in 1964 in Alaska (although earthquake-triggered), a significant number of rock avalanches in the Karakorum, and several rock avalanches in British Columbia, Canada, just to name a few. The nature, timing, and scaling of rock slope failures due to glacial debuttressing is strongly conditioned by geology, in particular by lithology and structure, that is, rock mass strength, orientation and inclination of discontinuities, and density and depth of joint networks. The timescale of failure and its delayed response in relation to glacier retreat has been much debated (Ballantyne 2002). Recent advances in geochronology have helped to better constrain the ages of many rock slope failures in alpine environments. The picture that evolves from the different studies and approaches is one of a varying response of rock slope failures to glacial retreat and downwasting. Failures can occur on timescales of $10^1$–$10^4$ years, depending on the glaciation history, topography, or geology.

**Temperature increase and permafrost degradation**

Important effects of climate change on mountain slope stability are, furthermore, related to warming and thawing of permafrost. Permafrost exists in many steep rock slopes in high-mountain environments and its degradation due to global warming can affect slope stability. Although this link might be intuitively clear, the mechanisms of permafrost degradation and related slope stability are rather complex, and the corresponding research field is relatively young. As a result, many aspects and links remain uncertain to date because of the complexity of interacting processes.

Evidence comes from a number of recent slope failures in permafrost areas, including mass movements at scales that range over several orders of magnitude from block and rockfall to rock avalanches (volumes of about $10^2$–$10^7$ m$^3$), observed predominantly in the Alps but also in other mountain regions. Several studies have demonstrated that the heatwave in the summer of 2003 and the related excessive thawing of the active layer of permafrost bodies have resulted in an unusually high number of rockfalls at high-elevation sites in the European Alps (Gruuber, Hoelzle, and Haeberli 2004). An increase in large rockslide failures has been observed in the Swiss Alps and neighboring areas for the past two decades as compared to the twentieth century, and more particularly in the Mont Blanc area, for which a detailed study exists.

Examples of large rock failures in the Alps include the 2004 $2.5 \times 10^6$ m$^3$ rock avalanche
from Punta Thurwieser, Italy; the 1997 $2–3 \times 10^6$ m$^3$ Brenva rock avalanche, Mont Blanc region, Italy; the 2006 about $10^6$ m$^3$ rockslides from Dents du Midi and Dent Blanche, Switzerland; the 2007 rock avalanche from Monte Rosa east face, Italy; and the December 2011 $2–3 \times 10^6$ m$^3$ rock avalanche at Piz Cengalo, Val Bregaglia, in the southern Swiss Alps. Many other regions have also experienced major rock failures. In the Chugach Mountains, Alaska, an approximately $50 \times 10^6$ m$^3$ large rock and ice avalanche was released from Mount Steller in 2005. Some $10–20 \times 10^6$ m$^3$ of rock and ice released from Dzhimaraikh-Khokh (Caucasus) entrained large parts of the Kolka glacier in 2002, resulting in a devastating $>100 \times 10^6$ m$^3$ ice-rock avalanche (Figure 2).

Notably, climate change affects permafrost in rock slopes on different spatial and temporal scales. Knowledge of the temperature distribution and dynamics at depth, and related 3-D effects, is, in fact, important in order to improve understanding of how climate change affects slope stability. Noetzli et al. (2007) modeled temperature and distribution of permafrost in idealized 3-D topography and demonstrated that

contemporary permafrost temperatures at depth are significantly influenced by the climate of the past millennia, including the last Ice Age. In the perspective of such timescales of heat diffusion, the twentieth-century warming may only have reached a depth of some tens of meters on steep slopes at high elevations. Due to the large time lag of heat diffusion, permafrost at greater depth may be present where surface temperatures no longer favor its occurrence. As a consequence, potential effects on slope stability by recent warming may currently have penetrated to depths of tens of meters but will continue to reach increasingly greater depths with future warming.

Although 3-D thermal modeling of climate change effects on mountain permafrost is an important step forward, the processes through which air temperatures influence slope stability are not understood in sufficient detail. Davies, Hamza, and Harris (2001) demonstrated with laboratory tests that thawing permafrost is accompanied by a reduction of shear strength in ice-filled clefts. The resulting variations and the increase of hydrostatic pressure in previously ice-filled fractures might, therefore, result in reduced slope stability. Furthermore, slow growth of segregation ice over long periods of time during permafrost aggradation has been suggested to widen joints in their frozen state, and thus contribute to a reduction in stability when permafrost thaws under conditions of warming (Harris et al. 2009).

Permafrost degradation in steep bedrock is thought to be effective through heat conduction and by advection of heat through water percolating in fractures. Degradation by conduction is enhanced in convex topography (i.e., ridges, spurs, and peaks) due to warming from several sides. Several of the aforementioned large rock slope failures occurred from such ridge and spur situations. However, this understanding based on theoretical considerations and modeling assumes idealized homogeneous rock conditions without discontinuity systems. In nature, rock joints are likely to have a major influence on the rate and extension of permafrost degradation and slope stability. Recent measurements in rock slopes of the Matterhorn (Switzerland), for instance, revealed the importance of meltwater penetration into cleft systems as a driver of rock deformation.

### Changing sediment reservoirs and sediment supply

In addition to future changes in temperature and rainfall intensity, changes in sediment supply and land use are important determinants for mass-movement frequency and magnitude. Recent observations at several sites in the Swiss Alps indicate that sediment supply can, in fact, change significantly as a result of permafrost degradation of rock and scree slopes or mass movements related to other processes (Huggel, Clague, and Korup 2012).

While the average flow speed of rock glaciers in the Valais Alps (Switzerland) was usually below 1 m year$^{-1}$, ground and remote sensing based monitoring has revealed acceleration of rock glaciers’ surface flow-speed up to 4 m year$^{-1}$, and occasionally up to 15 m year$^{-1}$, in recent years (Figure 3) (Stoffel, Tiranti, and Huggel 2014). This phenomenon has been reported over wide regions of the Alps, with morphological features similar to those observed with landslides, such as transversal cracks, surface subsidence in the upper part, and rapid advance of the frontal part. Further field studies thereby indicate that rock glacier surface speed is increasing with increasing mean annual air temperature and, as such, warming exerts indirect control on debris-flow magnitude and frequency.
Reconstruction of the trajectory of the 2002 Kolka ice-rock avalanche in the Caucasus (Russia) overlain on a QuickBird false color infrared image acquired on September 25, 2002, five days after the avalanche. A massive slope failure in glacier ice and bedrock in the Northeast face of Dzhimarai-Khokh at about 4300 masl impacted Kolka glacier. A large portion of Kolka glacier was then destabilized to form a high-speed avalanche that traveled at maximum speeds of >300 km h⁻¹ down the Genaldon valley. The avalanche was dammed at the entrance of a gorge and formed a massive dam of about 130 × 10⁶ m³ ice and rock debris. Liquid parts of the avalanche traveled further downstream for about 15 km, devastated the valley, and caused about 120 fatalities.

(Fstoffel, Tiranti, and Huggel 2014). Permafrost thawing and increasing flow velocities of rock glaciers have been demonstrated to deliver more sediment into debris-flow channels under current conditions than in the past. The volume of the largest debris flows has, therefore, risen by one order of magnitude since the 1920s and is likely to increase further with ongoing climate change.

Whereas present-day debris flows typically deposit material on cones rather than eroding significant amounts of sediment, recent debris-flow events have been observed in the Swiss Alps that have developed sufficient erosive power to remobilize large amounts of sediment on Holocene fans. A model case is the August 2005 Rotlaui debris flow in Guttannen, which was the largest event in Switzerland for the past 20 years with a total debris-flow volume of 500 000 m³, about 300 000 m³ of which was entrained on the cone (Figure 4). The Rotlaui debris flow was triggered from extensive sediment uncovered by the recession of the local glacier in the past decades. As observed with previous debris flows, glacier retreat since the Little Ice Age and associated uncovering of large amounts of sediment was an important factor for particularly large debris flows in the Alps.

Future mass movements: implications for hazards and need for further research

The effects of changing mean and extreme temperature and precipitation are likely to be widespread and to influence both the occurrence (in terms of temporal frequency) and the magnitude of future mass movements in mountain regions around the globe. Despite uncertainties, slopes currently underlain by degrading permafrost will probably become less stable at progressively higher altitudes with ongoing climate change (Harris et al. 2009). It can also be speculated that the probability of rock instability and the incidence of large (>10⁶ m³) rockfalls will increase in a warming
Figure 4 View of the catchment of the 2005 Rotlaui debris flow at Guttannen, central Swiss Alps. A: zone of initiation consisting of an import body of partly frozen glacial sediment. B1: initial zone of debris-flow erosion in glacial sediment. B2: debris-flow transport zone with repeated channel erosion. B3: deep erosion on the Holocene fan, amounting to about 300,000 m³ additional sediment. B4: deposition of debris-flow material on the lower part of the fan, with run-ups on the opposite valley flank. C: destruction of the Grimsel highway and obstruction of the Aare River by debris-flow material (Base image from Google Earth, October 2009).

Glacier downwasting will result in the formation of further ice-marginal lakes and subsequent problems of glacier lake outburst floods (Worni et al. 2014). On steep slopes, warming firn and ice temperatures may result in new sites of ice falls and ice avalanches (Harris et al. 2009). Provided that sediment supply is not a limiting factor, debris flows have the potential to become larger in the future than they were in the past, but not necessarily more frequent and clearly conditioned by local site conditions (Stoffel, Tiranti, and Huggel 2014). The generation of cascading processes at high elevations might increase and result in chain reactions that are often difficult to predict (e.g., the impact of ice-rock avalanches into glacier lakes in the Cordillera Blanca, Peru, and other regions, with subsequent downstream flooding) (Worni et al. 2014).

Recent developments at high-elevation sites have shown clearly that the sensitivity of mountain and hillslope systems to climate change is likely to be acute, and that events beyond historical experience will continue to occur as climate change continues. Despite the lack of preserved analogs, and although paleoevidence for the link between mass movements and climate may be fraught with many questions of interpretation, the inclusion of paleorecords has the capacity to integrate signals over a wide area and to employ a broad range of supporting proxy information. In this perspective, observable evidence from the far and near past points to an increase in mass-movement activity and a major mobilization of sediment under warming and/or wetter conditions (Stoffel, Tiranti, and Huggel 2014).

Recent mass-movement processes originating from high-elevation sites have been observed at sites with no or little historical precedence (e.g., Rotlaui debris flow, Switzerland, Figure 4) and have threatened or destroyed critical transport and energy infrastructure. The risk of damaging events is often particularly high in developing countries, where both population and agriculture pressure on land resources lead to the exploitation of unstable slopes.

An improved understanding of the intrinsic complexity of mass-movement processes at
high-elevation sites, cascades of processes and their relationships with, and dependency on, climate variability and change is crucially important in planning appropriate and prospective measures to reduce the negative impacts of future events. This entry has attempted to shed light on recent developments and state-of-the-art knowledge on the possible effects of climate change on the occurrence and intensity of potential future mass movements. The contribution has also outlined the broad spectrum of recent research and the large suite of case study results available in the research field, but has also illustrated clearly that, despite all the progress made in climate–mass movement studies, many questions still need to be addressed in greater detail to overcome considerable gaps in knowledge that continue to exist in this challenging field of research.

Measurement theory

Nicholas R. Chrisman
RMIT University, Australia

Many geographic questions expect a measurement as the answer. This result can be a simple figure, such as the height of some peak, the distance flown by an aircraft, or the area of given parcel. In other cases, the measurement is the result of more complex analysis, such as a city’s rank in a contest for most liveable city, estimated carbon sequestration over the forests of a region, or the total area of tea plantations in a given district. In each of these cases, the measurement element appears unambiguous, but there are many choices involved, and theoretical issues to address. Often what appear to be simple questions should have been clarified with some details about the process and result of measurement required.

Much of the trouble comes from tacit expectations tied up in a long history of making measurement seem obvious and unambiguous. The “classical” school of measurement has its origins in Aristotle’s metaphysics and continues through to the physical sciences at the end of the nineteenth century. In the classical view, measurement discovers the numerical ratio between a standard object and the one measured. Clifford, a mathematician in the nineteenth century, used a definition of measurement very little altered from that of Euclid: “every quantity is measured by the ratio which it bears to some fixed quantity, called the unit” (Clifford 1870). The property was seen as inherent in the object and the relationship took on all the mathematical properties of numbers without question (Michell 1993). Take the attribute “length.” Every entity in space can be measured by comparing its length to some other length. If we adopt a “standard” measuring rod (originally derived from the foot of the king or something equally available), the ratio between the length of the rod and the objects measured embodies a number implicit in the relationship. Reciprocally, the realm of numbers is seen as deriving from these basic relationships of ratios.

The classical approach can be discerned in many geographic applications, particularly when attributes are considered to be inherent to an object, and the measurement of attribute values is considered to be unproblematic. Measurement of agricultural productivity, volume of grain per unit area, ties back to centuries of practical experience. The current attribute reference systems are only slightly evolved from the city standard carved into some stone in the marketplace. Spatial reference systems, particularly local vertical datums, also depend on these kinds of measurement scales. Pick some starting point as zero, measure with a standard unit using traditional leveling. It is a technology in current use by municipalities around the world. While it looks simple, there is more to consider.

Through a series of theoretical developments in mathematics, this classical paradigm was overthrown by a “representational” school in the first half of the twentieth century (Michell 1993). The representationalists impose a firm separation between the empirical world and numbers, first expressed by Bertrand Russell (Russell 1897, 1903). In the place of ratios and rational numbers as the core of mathematics, set theory permitted a more generic range of relationships:
Measurement of magnitudes is, in its most general sense, any method by which a unique and reciprocal correspondence is established between all or some of the magnitudes of a kind and all or some of the numbers, integral, rational, or real, as the case may be… In this general sense, measurement demands some one-one relation between the numbers and magnitudes in question – a relation which may be direct or indirect, important or trivial, according to circumstances.

(Russell 1903, 176)

Representationalism is unified by the understanding that measurement assigns numbers to objects according to external rules. These rules are developed by humans, not inherent in nature. Thus, the measurement result depends on conventions and the observer, rather than being intrinsic to the object measured. Within this sweeping change in the theory of measurement, the original branch of representationalists, called “operationists” (and including a preponderance of physicists), focused on the influence of the measurement operation (Campbell 1920; Bridgeman 1927). They noted that even the standard meter rod in Sèvres varied in length due to changes in temperature and pressure. Thus, the number obtained depended on the whole circumstance of the operation, not just immutable and inherent properties. In this respect, they expanded the approach to measurement, but their opening did not include everyone. These operationists, having their origins in physics, espoused a restrictive theory centered on the role of addition in building the basic “extensive” building blocks and physical laws that defined “intensive” (indirect or derived) measurements mostly as ratios of the extensive measures. Extensive measurement applies to the seven base units of the Système Internationale d’Unités (SI); the operationists expected virtually everything else to be defined as ratios of these units. Exclusive focus on extensive measurement left almost no room for the social sciences to develop a measurement theory. The physicists could not consider phenomena like perceived loudness of sounds as a measurement, since it did not involve extensive properties like addition. They could allow the observer into their scheme, but not in such a perceptual framework.

Before tracing the subsequent theoretical developments, it is important to note that operationism, though not directly recognized by citations to the classics in physics, is alive and well in the geographic information sciences. Geodesy is acutely aware of the various influences on measurement and works to reduce error through more and more elaborate mathematics. Remote sensing adopts a more statistical viewpoint but still tries to limit the influences of the measurement operation.

Returning to the historical narrative, the issue of human perception (of sound or anything else) brought forth the next developments. Stanley S. Stevens, a psychologist at Harvard University, wrote a paper in Science in 1946 on the subject of measurement (Stevens 1946). This paper played a formative role in a larger movement towards a quantitative methodology in the social sciences. It responded to an impasse that characterized the work of a committee established by the British Association for the Advancement of Science. This committee had been chartered in 1932 to consider the possibility of “quantitative estimates of sensory events.” In eight years of deliberations, the unity of sciences was far from apparent, and the physicists could find no way to accommodate the psychophysical efforts into their scheme for measurement (Ferguson et al. 1940; Luce et al. 1990, 109–111). Stevens’ proposed solution recognized that not all measurements lived up to the expectations of the physical scientists, particularly that addition might not be the primary axiom at the base of all measurements. He based his scheme
on the group of transformations under which a measurement would retain its meaning (an automorphism group). Stevens described four “scales” of measurement (Table 1) a scheme now familiar to almost any social scientist. Stevens’ use of the word “scale” fails to make a distinction between a particular number axis (such as length measured in meters) and the generic grouping in which it falls. In geography and cartography the word “level” is more commonly applied for the groupings of scales (Chrisman 1998b).

Stevens remained inside the representationalist philosophy but articulated a “nominalist” approach (Michell 1993), defining measurement as the “assignment of numbers to objects according to rules” (Stevens 1946, 677). Stevens’ reliance on automorphism derived directly from the mathematical approach of Russell and Whitehead. Stevens prescribed a simple sieve of tests to decide in which group a measurement belongs. First he asserted: “We know that the values of all scales can be multiplied by a constant, which changes the size of the unit” (Stevens 1946, 680). This sweeping statement aligns his ratio level with the classical viewpoint, and creates some difficulties, which are considered below. His purpose is to introduce less rigorous levels by relaxing the restrictions one by one. If a constant can be added, while retaining the meaning of the measurement, it is “proof positive” (Stevens 1946, 680) that it is no longer a ratio scale. If it can be transformed in nonlinear manner, it is not even interval. If it can be transformed “at will” (meaning non-monotonically), “the nominal scale is the sole remaining possibility” (Stevens 1946, 680). Although these levels are now usually presented in order of increasing rigor, they were presented from the familiar extensive ratio towards the less restrictive in the original.

Stevens also tried to expunge the distinction that physicists had drawn between “fundamental” (extensive) and “derived” measurement. In Stevens’ automorphic viewpoint, the number system was more central, not the method by which it was generated.

A key element of Table 1 is the connection between the levels and “permissible statistics.” Many textbooks on statistics for social sciences (beginning with Siegel’s (1956) classic on

nonparametric methods) adopted this connection between a variable and appropriate techniques. The four levels of measurement spread rapidly from psychology to sociology (Blalock 1960) and other social sciences. The Stevens framework provided a simple means to organize the different kinds of data available and to structure textbooks and courses for decades to come.

In the earliest explorations of quantitative methods in geography, Siegel's book was the one that sparked the interest in levels of measurement (Morrist, personal communication). Siegel framed a set of nonparametric tests by level of measurement—a direct implementation of Stevens' concepts. The levels of measurement then become a cornerstone for the presentation of quantitative methods in geography: Haggett (1965, 212) references Siegel, not Stevens; Cole and King (1968, 54–55) presented the four levels without any reference whatsoever. In some curious way, the four levels became a kind of charter for the quantitative movement in geography, dispensing it from any further need to examine the literature on theories of measurement.

While in geography the diffusion was slow and noncontroversial, the levels of measurement generated some sharp controversy in psychology and sociology that continues to this day. This section cannot investigate all of the developments, but it will demonstrate that the four levels have been effectively challenged and that the linkage between level and procedures has also been questioned. These debates and extensions will be related to the particular problems of geographic information in the following section.

Redefining the levels

The four levels have been presented as a complete set but there are other possible levels not handled by this system. Stevens (1959) himself proposed another level at the same rank as interval for logarithmically scaled measures. Unlike the linear interval whose zero can be relocated at will, these measures can be rescaled by changing the exponent (the zero remains fixed). This “logarithmic-interval” scale is not cited in any of the geographic literature, though it is used for earthquake intensities (such as the Richter and Mercali scales) and similar measurements. Some measurement scales such as densities, which are dependent on more than one ratio-scaled measurement, could be rescaled by an exponent as easily as by the choice of an arbitrary unit; thus, they are log-interval not ratio (Krantz et al. 1971, 487). The use of persons per area (squared distance units) is just a convention; population density could just as easily be measured by average distance to the next person (in distance units), though these two scales are not related by a simple linear transformation.

Following Stevens' invariance logic to its conclusion, ratio is not the highest level of measurement. A ratio scale has one fixed point (zero) while the choice of the value of “one” (the unit of measurement) is essentially arbitrary. A higher level of measurement can be obtained if the value of one is fixed as well. Then the whole scale is predetermined or “absolute” (Ellis 1966; Narens 1985) and no transformations can be made that preserve the meaning of the measurement. One example of an absolute scale is probability, where the axioms fix the meaning of zero and one simultaneously. Bayes' law of conditional probability works because the scale is fixed between zero and one. Probability is just one example of a measurement incorrectly classified by a four-level scheme. The measurement literature provided workable definitions of log-interval scales and absolute scales thirty or forty years ago, but these developments did not penetrate into cartography or geography.
While Stevens’ levels deal with an unbounded number line, there are many measures that are bounded within a range and repeat. For instance, angles seem to fit into the ratio level, in the sense that there is a zero and an arbitrary unit (degrees, grads or radians). However, angles have a singularity at $360^\circ$. The direction $359^\circ$ is as far from $0^\circ$ as $1^\circ$ is. Any general measurement scheme needs to recognize the existence of repeating or cyclical elements.

Even at the bottom of the hierarchy, the nominal scale deserves re-examination. It is all too easy to criticize geographical analysis for using a model of sharp sets (Curry 1995). The standard rendition of the nominal level emphasizes pure “equivalence” of all members in a nominal category. However, in practice, categories can be much more complicated. Members of a category often have some degree of membership. Either they represent “prototypes” (pure types) or less clear cases, or there is some probability of membership, or some distance metric. All these forms of graded membership produce “categories” that cannot be treated as if all members were strictly equal.

To summarize, the list of four levels presented by Stevens is just not adequate even inside its own automorphic approach. Table 2 presents an expanded list of levels of measurement with the information required to specify a scale. The ten levels cited are by no means complete, in part because geographic information is not just a matter of simple scales of attributes taken without consideration of the spatial component.

### Multidimensional measurement

Measurement scales become much more difficult to define in a multidimensional situation. In the one-dimensional world of Stevens, an open-ended ratio scale seems to provide the most information content; the real number line contains the most promise for mathematical relationships. When representing a two-dimensional space, the classic Cartesian solution uses two orthogonal number lines. However, a radial coordinate system contains exactly the same information with one distance (open-ended) and one angle (closed range) (Figure 1). These two representations are equivalent, even though the units of measurement do not seem equivalent.

The conversion from two ratio scales to one ratio scale plus an angle is not unique to geometric constructions. For example, radiant energy at various wavelengths coalesce into a particular color that can be represented in a cone-like object (Munsell's space or equivalent). The color cone is thus a “fact of nature, not a mathematical trick” (Suppes et al. 1989, 226). Multidimensional measurements create interactions not imagined in the simple linear world of Stevens.

Similarly, in GIS processing, the single phenomenon of “slope” is broken into two numbers for gradient and aspect (Burrough 1986). There are multiple methods in use (percent of rise/run versus angular measures) that are related through nonlinear trigonometric functions. These examples of “conjoint measurement” do not fit the linear scheme of Stevens. There is a substantial literature in psychology and sociology developing these kinds of measures (Krantz et al. 1971; Suppes et al. 1989; Luce et al. 1990). While this literature recognizes the contributions of Stevens, after decades of careful axiomatic development, everything does not reduce to fit into such simple levels. The system of automorphic groups may not be adequate to describe important characteristics of measurements.

**Linkage to procedures**

Almost as soon as Stevens’ original paper appeared, and before it became codified in statistical textbooks, there was a flurry of criticism in the sociology and psychology literature. The debate centered on the assertions about permissible procedures. For example, Lord (1953) wrote a mordant satire built upon a fictional analysis of the numbers on football jerseys. Savage, an established statistician, wrote a critical review of Siegel’s book, challenging the linkage between measurement scale and the choice of statistical test (Savage 1957). Such a reaction might be expected if the radical new paradigm was temporarily resisted by an “old guard,” but the controversy has continued without losing its heat. A self-styled “anti-measurement” group has continued the attack in a drawn-out series of articles (Gaito 1960, 1980, 1986; Borgatta and Bohrnstedt 1980), while others defend with equal intensity (Townsend and Ashby 1984; Maxwell and Delaney 1985). A more complete review (Khurshid and Sahai 1993) reveals more complexity than a simple dichotomy. The attackers correctly protest that some “permissible” procedures, such as Spearman’s rank correlation, involve addition and multiplication.
of ordinal scores, and use formulae that are equivalent to the nonpermissible procedures. Yet, the formalists (Luce et al. 1990) produce elaborate proofs of the central contention of Stevens that there are classes of invariance with consequences for validity of procedures. More recent work (Kampen and Swyngedouw 2000) has proposed five distinct forms of ordinal measures making the choice of method less direct.

Perhaps it does not particularly matter to geographers exactly how the sociologists and psychologists disagree. One lesson should be clear: the measurement level by itself does not guarantee a meaningful result following a particular procedure (Chrisman 1998b). For example, we can add the populations of counties within a state to derive the total state population, but we should not add city populations with county populations without understanding exactly how these objects nest within each other in that particular jurisdiction (in Virginia, the cities are county equivalents, in other states they are usually contained within the county figure, with a few exceptions). However, a figure such as median family income, though it falls in the ratio level, should not be added to another median family income. The result is not a median family income. Cartographers must also be aware of the date of the census material as well. Though the figures are in the same measurement scale, the addition of 1890 and 1990 populations does not produce a figure with an identifiable date. In other words, even for a simple operation like addition we need to know more than the scale of the population figures: we need to know about the spatial component and the temporal component.

Home-grown measurement theory for geography

To develop beyond the Stevens taxonomy, geographers need to re-examine some assumptions that have become a part of the discipline’s culture. The largest difficulties with Stevens’ scheme come not from the specific levels of measurement but with the overall model of the process. Stevens presumes a rather simple situation: the object to be measured is unambiguous. Most social sciences in the early quantitative period simply assigned numbers to “cases.” In some fields it might seem obvious what is a case, but there can be substantial questions even for those who study individual persons whether to measure households, neighborhoods, or other aggregates (Ragin and Becker 1992). The version proposed in geography was called the “Geographical Matrix” (Berry 1964), simply a matrix with “places” on one axis and attributes on the other. Places are problematic; geographic measurement requires many decisions involving time, space, and attribute.

One way to begin is to re-examine one kind of common cartographic data: counts aggregated over some region in space. Counts are discrete, since there is no half person to count, but a count captures more mathematical structure than the other discrete levels (nominal and ordinal). Since the zero is a fixed value, counts may seem ratios but, being tied to the discrete unit counted, it cannot be rescaled by some arbitrary factor. Counts have different properties from the absolute scale, as well. Counts do not have an upper bound in the same way as a probability or a proportion. Ellis (1966, 157) points out the difference between ratio scales and counting with the example that it is acceptable to present a unit of measurement by saying “Let this object be 1 minch long,” but it is not possible to say “Let this group contain one apple,” since it either has one apple or some other number when you start. The process of counting depends upon the recognition of objects, a procedure taken for granted in the Stevens tradition, but at the heart of the geographic data problem. A count only makes sense when you specify which spatial object was used to contain the counting process.
MEASUREMENT THEORY

The assumptions behind the assertion that a city “has” a population requires numerous assumptions. A population figure represents the estimate obtained by a particular agency applying a specific spatial definition of the city and a specific definition of people’s movements at a particular time. The agency selects its definitions for cities and for residents in response to a complex process of legal mandates, professional expertise and resource limitations. There are many possible population measurements that could be obtained, involving slightly different treatment of space, time, and attributes. The meaning of this number must remain contingent on understanding the whole set of circumstances that permit the measurement. A model of geographic measurement must handle much more than the number scales treated by Stevens.

A more fruitful model sees measurement not in terms of properties but in terms of relationships. Geographic information involves many distinct kinds of measurement and, as the example of census counts demonstrated, each kind invokes some combination of time, space and attribute rules. Wright (1955) attempted to enumerate all the possibilities – a huge task. Viewed from the perspective of measurement, these old issues take on a new clarity.

The simple taxonomy presented by Sinton (1978) provides a starting point to understand the relationships involved in measurement. In Sinton’s scheme, in order to measure one component, one of the others had to be fixed and one served as control. In this context, “control” does not refer to a geodetic reference system, or an experimental design. Control refers to a mechanism of restraint on the variation of a system to permit measurement of one component of a phenomenon while other components only vary within the limits of the control. In essence, the control is the choice of which components define the “objects” so that the last component is free to be measured. At the most basic, Sinton’s scheme distinguishes vector from raster because the first controls by attribute, while the later controls by space. This rough division provides a starting point but it does not explain the variations within these two approaches. A system of “measurement frameworks” articulates a home-grown theory of measurement for geographic information (Chrisman 1998a, 2001).

Attribute as control

When the attribute serves as the control, the spatial location can be measured. While this is the common basis for a vector representation, there are large differences between an isolated category and a connected system of categories. Table 3 summarizes some distinctions.

### Table 3  Attribute control frameworks.

<table>

</tr>
</tbody>
</table>
The simplest object control framework involves isolated objects, distinguished by a single category. Each distinct instance of the attribute identifies an “object,” an entity distinguished by its particular value of the attribute. Each object is described as a geometric whole, since it will forcibly occur in isolation. In the pure form of this framework, the only relationship is between the object and a position; there are no relationships between objects. These rules apply most directly to points and areas. Linear objects rarely remain isolated but connect with varying topologies, creating the need for the network framework (not isolated).

Isolines are formed by controlling for a specific value on a surface. Since isolines follow the contours and do not intersect, they have no topological relationships beyond the ordering of nested contours. Thus, the isoline is isolated from other isolines, requiring no structure for contiguity.

In the creation of GIS software, it was important to recognize that there were relationships between the objects in a database. When a coverage is formed with multiple categories, there will be topological relationships. Similar structure can be created by linear networks. The basic topology is required whether the categories form strict equivalence classes or some form of probabilistic or prototype categories. The distinction between the isolated objects and connected coverages is not a matter of database design but a recognition of the underlying measurement structure of the source material. Connected objects should not be treated as isolated objects. The decision to recognize a certain category as a part of an exhaustive coverage depends on the nature of the surroundings, not just on the category itself. For example, a given land use class is not simply defined by its own internal characteristics but also relative to its neighbors. This distinction creates some of the tension between an object-oriented technology that treats isolated entities and the topological approach that forces the world into exhaustive coverages. Though lumped into vector, these divisions are at least as deep as the divisions between raster and vector.

In terms of measurement, the attributes of all the attribute-controlled variants must be discrete. The spatial component can vary as needed to reflect the location of the edges of the discrete objects. One can dispute this approach on a variety of grounds, but the choices are bundled together. High resolution freedom in the spatial component comes from a choice to simplify the attributes into categories.

Spatial control

Rather than limiting the variation in the attributes to a certain set of objects, control can also be imposed by specifying a set of locations, often in the form of a regular spatial tessellation (Table 4).

Control by a set of points has different rules compared to control by areas. While both would be encoded in a raster representation, they must be understood differently. With a point-based control there are not too many rules. Center point provides a regular sampling of a landscape. Digital elevation matrices tend to expound a point-based sample in the documentation, though the actual operational procedures invoke models to arrive at this figure. Systematic unaligned is recognized in textbooks but rarely performed.

Control by area is more common for remote sensing and other applications of grid sampling. In each cell there is some rule that has been applied to all the possible values. Some sensors add up all the reflectance in a certain band width, others take the highest or lowest value (such as the minimum clearance elevation shown on aeronautical charts). A system that optimizes the choice within each cell by taking the most likely value may remove all traces of linear features and the minority elements. Unless these rules are known to the analyst, the information can be sorely misconstrued. GIS operations depend more on knowing how to combine these measurements than they do on the level of measurement.

Extending Sinton’s taxonomy

Control by object and control by space seem to be the only options, but they do not accommodate comfortably all the cases found in existing geographic information. The well-known choropleth map is an example of a composite framework, a sequential combination of the two forms of control. The base map is created using a categorical coverage for the set of collection units, then these objects serve as a secondary form of spatial control to tabulate the variable in question. Due to these two stages, the spatial measurements of the boundaries have little bearing on the precision of the eventual attribute measurement.

In the development of thematic mapping, the choropleth map dominated. The census viewpoint of tables of attributes for the same set of places was the origin of quantitative geography, expressed in Berry’s matrix. A whole set of techniques developed around standardizing these attributes to remove the unevenness of the varying sized spatial control. The “modifiable areal unit problem” (Openshaw 1984; Arbia 1989) and the early development of spatial autocorrelation (Cliff and Ord 1973) both addressed the peculiar situation of spatial control by uneven objects. Rather than generalizing from this special case to the rest of cartographic measurement, it makes more sense to see choropleth frameworks as composites of more primitive operations.

Triangular irregular networks (TIN) pose an additional problem. The TIN is composed of discrete triangles, but these do not arise from imposing a cookie cutter kind of control onto a surface. While the points may come from an isolated bunch of measurements (or one of the other cartographic choices for terrain representation), the TIN represents a set of relationships that cover space. The ideal TIN is constructed so that the triangles represent zones of uniform gradient and aspect, within the resolution available. Edges of triangles should conform to the topology of the surface, including ridges, courses and other breaks in slope (Peucker and Chrisman 1975; Mark 1979). These features of a surface are not based on an isolated value but on
the relationships of convergence and divergence, relationships of neighboring values. Thus, a TIN represents a novel class of measurement frameworks where relationships form the control, not the values of the attribute or the location alone.

A further example of a relationship control system involves attributes that attach to pairs of geographic entities. For example, international trade can be analyzed as flows of goods and money between pairs of countries. This kind of geographic information does not attach to any geometric object; it attaches to a pairing of objects – a relationship. This relationship creates the control for the measurement. This particular kind of geographic information is quite complex to portray using established thematic techniques. Edward Ullman (1954) built his economic geography around these flows and it became a long-standing data structure for regional analysis (input–output) and interregional trade (treated as its own specialization).

This initial collection of measurement frameworks provides a more durable foundation for processing geographic data. Compared to the levels of measurement that simply provided a hierarchy of linear relationships, this taxonomy mobilizes the interplay between geometry and attribute. It can also accommodate measurements in the temporal domain. As Langran (1992) has carefully documented, Sinton’s scheme of holding one element fixed, while it might be required for a two-dimensional display, is not a requirement in a database solution. Still, it seems a consistent constraint that only one component can be measured with full flexibility and resolution.

This system of measurement frameworks is grounded in the understanding that you cannot attain ultimate resolution in time, space, and attribute simultaneously. Measurement requires a choice of which component is more critical. From this scheme a taxonomy of geographic transformations (sketched in Chrisman 1998a) can be developed around the role of geographic neighborhoods and the rules of attribute combinations.

Measuring spatial dependence

Yongwan Chun
Daniel A. Griffith
University of Texas at Dallas, USA

Spatial dependence is one of the most prominent phenomena in the spatial sciences. It represents the spatial relationships of values in attributes that are measured at geographic locations. It refers to whether or not values in a single variable are correlated with other values in that same variable when they are inspected along with their spatial locations. This correlation is often positive in nature, so that observations at spatially close locations tend to have similar values. This correlation in georeferenced space is referred to as spatial autocorrelation because it involves only one variable, which distinguishes it from the conventional correlation between two variables. The presence of spatial dependence violates the independence assumption on which conventional statistical theories heavily rely. Hence, inferential statistics can become unreliable when spatial dependence is not appropriately handled. Measuring spatial dependence is an essential process to diagnose if conventional statistical approaches would produce proper results for a given dataset, and/or if spatial statistical methods that incorporate spatial dependence need to be employed.

Measuring spatial dependence requires several essential components. First, it needs an operational framework with which spatial locations are transformed to represent spatial proximity or spatial closeness among observations. This measurement involves spatial neighbors that covary with observations. A geographical topology structure, as well as geographical distances, frequently furnishes a basis for articulating this geographic neighborhood. Second, indices are used to numerically measure spatial dependence, and subsequently to perform an inferential statistical test. Numerical indices have been developed with extensive statistical concepts and theories, and can be considered as the core of measuring spatial dependence. Most of these indices are intended for quantitative attribute values (i.e., an interval or ratio measurement scale), but others are used for qualitative values. Also, indices are available to measure global spatial autocorrelation across an entire study area and local spatial autocorrelation for local subareas. Third, graphical tools are available to visually portray spatial dependence.

Spatial neighborhoods

Measuring spatial dependence requires identifying a set of values that has a spatial relationship among the values. The values in such a set are considered to be spatial neighbors. Spatial neighbors for a single observation within a set of \( n \) observations can be evaluated in terms of the other \((n - 1)\) observations. Identification utilizes spatial proximity or spatial closeness, with an assumption that spatially close observations are likely to be more strongly related to each other than to distant observations, an expectation often referred to as Tobler's first law of geography. Although distance is a natural way to represent spatial proximity, general geographical topology (i.e., spatial connectivity or adjacency) commonly is used, especially for areal features.
Figure 1 Representations of spatial neighbors based on the adjacency of 2010 census tracts in Dallas County, TX.

Figure 1a illustrates spatial neighbors for the 529 census tracts in Dallas County, TX, from the 2010 US Census, based on spatial connectivity. The dotted red lines connecting the centroids of these census tracts identify spatial neighbors that share a common boundary. The dotted red lines appear only for a small number (namely, 1380) of pairs among the \( \frac{n(n-1)}{2} \) (i.e., \( 529 \times 528/2 = 139656 \)) possible pairs. This neighborhood articulation can be represented numerically with \( n \) binary 0–1 indicator variables, where 1 denotes spatial neighboring pairs and 0 denotes spatial non-neighboring pairs. These numerical values are commonly organized in an \( n \times n \) matrix; here \( n = 529 \). Figure 1b shows the numerically coded spatial neighboring structure among the census tracts in a matrix, \( C \). Each \( c_{ij} \) element of matrix \( C \) denotes whether census tract \( j \) is \( (c_{ij} = 1) \) or is not \( (c_{ij} = 0) \) a spatial neighbor of census tract \( i \). Matrix \( C \) is called a spatial neighbor matrix and, for this specific case, a spatial connectivity matrix because it represents the physical contiguity among the areal units. Note that the diagonal elements of this connectivity matrix are zero. This means that areal units are not considered to have themselves as spatial neighbors.

Spatial neighborhoods can be configured in different ways. Spatial connectivity can be defined by two popular options: rook and queen. For rook connectivity, spatial neighbors are defined with areal units sharing nonzero length boundaries. That is, areal units connected only by a point (e.g., a zero length boundary) are not considered to be spatial neighbors. For queen connectivity, areal units connected by a point as well as a nonzero length boundary are considered to be spatial neighbors. These two options are similar to the movement options of rook and queen chess pieces. These two options produce a
substantially different spatial connectivity matrix for the regular square tessellations, such as a chess board or a remotely sensed image, but not necessarily for irregular tessellations, such as census tract boundaries where polygons usually do not meet only at a single point. Another set of approaches uses geographic distances to define spatial neighbors. When two areal units are within a preset distance threshold, they can be considered to be spatial neighbors; that is, \( c_{ij} = 1 \) when \( d_{ij} \leq d \), and \( c_{ij} = 0 \) otherwise, where \( d_{ij} \) denotes distance between areas \( i \) and \( j \), and \( d \) denotes a preset threshold distance. Types of transformation other than this binary transformation are possible. Inverse distance, especially, is widely used to represent spatial proximity. A general functional form of inverse distance is \( d_{ij}^{-\gamma} \), where \( \gamma \) is often set to 1 (i.e., \( c_{ij} = 1/d_{ij} \)). As \( \gamma \) increases, this specification approaches the structural form of the binary matrix. One characteristic of this distance-based matrix is that its off-diagonal elements have nonzero values and only diagonal elements have zeroes, while a spatial connectivity matrix contains a large number of zero elements.

Spatial neighborhoods are introduced as weights in indices to measure spatial autocorrelation. A matrix of these weights is called a spatial weights matrix. A binary spatial connectivity matrix, \( C \), can function as a spatial weights matrix. That is, each weight is 0 or 1 (Figure 1b). Furthermore, this binary spatial connectivity matrix can be transformed to a row-standardized matrix, \( W \). For example, if the \( i \)-th areal unit has two spatial neighbors, the two nonzero cell values (i.e., 1) in the \( i \)-th row of matrix \( C \) are replaced with \( 1/2 \) (i.e., 1 divided by the number of spatial neighbors). Hence, the sum of values in each row of matrix \( W \) is 1, and the total sum of its weights is \( n \). A distance-based matrix is also commonly used to construct matrix \( W \). Using matrix \( C \) results in comparing an attribute value at a given location with the sum of its neighboring attribute values. Using matrix \( W \) results in a comparison with the average of its neighboring attribute values.

### Indices measuring spatial dependence

Spatial autocorrelation measures can be categorized as global and local. A global measure furnishes an index of spatial autocorrelation across an entire study area, usually with a single value. It further involves a statistical test to confirm whether or not observed spatial autocorrelation is statistically significant. The most widely used spatial autocorrelation indices include Moran’s \( I \) and Geary’s \( c \). In contrast, a local measure investigates spatial autocorrelation associated with a specific areal unit. Measures and statistical tests are conducted for each areal unit. Their collective pattern of statistical tests can be used to examine local variations of spatial autocorrelation in a study area. The most well-known local measures include the local Moran’s \( I \), and the Getis–Ord \( G_i \) and \( G^*_i \); the local Geary’s \( c \) is also available.

These global and local indices are devised for quantitative values (i.e., interval and ratio measurement scale data). A join count statistic can be used to measure global spatial autocorrelation for qualitative values (i.e., specifically nominal measurement scale data).

### Global spatial autocorrelation measures

As a covariation measure, Moran’s \( I \) is directly related to the Pearson product moment correlation coefficient and has a similar functional form. A description of this functional form similarity can be found in spatial statistics textbooks (Chun and Griffith 2013, 10). Given
a variable \( Y \), the Moran’s \( I \) is calculated using equation 1:

\[
I = \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} (y_i - \bar{y})(y_j - \bar{y})}{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \sum_{i=1}^{n} (y_i - \bar{y})^2}
\]

(1)

where \( y_i \) denotes an observed value at areal unit \( i \), \( \bar{y} \) denotes the mean of variable \( Y \), and \( w_{ij} \) denotes a spatial weight for the pair of areal units \( i \) and \( j \). When binary connectivity is used as spatial weight, \( w_{ij} \) can be replaced with \( c_{ij} \) from matrix \( C \). Equation 1 returns a single number that represents the nature and degree of spatial autocorrelation.

As an analog to the Pearson product moment correlation coefficient, Moran’s \( I \) can be interpreted similarly while recognizing that it has different properties. First, the range of Moran’s \( I \) is no longer \([-1,1]\). For irregular tessellations, the maximum value of Moran’s \( I \) is slightly larger than 1, and the minimum also tends to be larger than \(-1\). Second, the Moran’s \( I \) value denoting no spatial autocorrelation is \(-1/(n-1)\), not zero. The theoretical range of Moran’s \( I \) values for the 2010 census tracts in Dallas County using matrix \( C \) is \([-0.7151, 1.1843]\); these extremes respectively are functions of eigenvalues associated with matrix \( C \) (Griffith 2003, 37). A Moran’s \( I \) value larger than \(-1/(n-1)\) represents positive spatial autocorrelation. That is, observations tend to have values similar to those of their spatial neighbors. In contrast, Moran’s \( I \) less than \(-1/(n-1)\) represents negative spatial autocorrelation, which indicates that observations tend to have dissimilar values with their spatial neighbors. A Moran’s \( I \) value closer to the maximum (e.g., 1) indicates strong positive spatial autocorrelation and, similarly, a Moran’s \( I \) value close to the minimum indicates strong negative spatial autocorrelation. However, a formal statistical test needs to be performed to confirm whether or not a calculated Moran’s \( I \) value is statistically different from zero spatial autocorrelation.

The statistical test for Moran’s \( I \) can be constructed under the assumption of a normal approximation. The expected value of Moran’s \( I \) is \( \text{E}[I] = -1/(n-1) \) and the variance can be calculated as \( \text{Var}[I] = \text{E}[I^2] - \text{E}[I]^2 \), where \( \text{E}[\cdot] \) denotes the calculus of expectation operator. Detailed derivations of the mean and variance can be found in Cliff and Ord (1981). Although the expression of its variance is complicated, Griffith (2010) shows that the variance is well approximated with the following simple equation for \( n \geq 25 \):

\[
\text{Var}[I] \approx \frac{2}{\sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}}
\]

(2)

The number 2 appears in the numerator because both \( c_{ij} \) and \( c_{ji} \) are involved in the calculation of Moran’s \( I \). Given the mean and variance, the z-score of Moran’s \( I \) value,

\[
Z[I] = \frac{O[I] - \text{E}[I]}{\sqrt{\text{Var}[I]}}
\]

(3)

where \( O[I] \) denotes the observed Moran’s \( I \), can be used as a test statistic. Here, the null hypothesis is that the observed Moran’s \( I \) is equal to its expected value, implying that observed values do not have spatial autocorrelation. A rejection of the null hypothesis yields the statistical inference that the observed values are spatially autocorrelated.

Geary’s \( c \) is also a widely used spatial autocorrelation index. It can be written as shown in equation 4.

\[
c = \frac{(n-1)}{2 \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij}} \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} (y_i - y_j)^2}{\sum_{i=1}^{n} (y_i - \bar{y})^2}
\]

(4)

The numerator of Geary’s \( c \) is a paired comparisons calculation that measures differences between the values of spatial neighbors. That
is, \((y_i - y_j)^2\) gets larger when spatial neighbors have dissimilar values. In the extreme case that observations have the same value as their spatial neighbors, Geary’s \(c\) becomes zero (in practice, where data are not uniform across a system, the index can only approach zero). As spatial neighbors have increasingly dissimilar values, \(c\) gets larger. The range of Geary’s \(c\) is roughly \([0, 2+\) with 0 representing extreme positive spatial autocorrelation, \(2+\) representing extreme negative spatial autocorrelation, and 1 representing zero spatial autocorrelation. Its theoretical range for the 2010 census tracts in Dallas County using matrix \(C\) is \([0, 3.1578]\); again, these extremes respectively are functions of eigenvalues associated with matrix \(C\). Geary’s \(c\) is inversely related to Moran’s \(I\). Chun and Griffith (2013, 12) show how these two indices are functionally related.

A statistical test for Geary’s \(c\) can be performed under the assumption of a normal approximation. Cliff and Ord (1981) show how the expected value and variance of Geary’s \(c\) are derived. The expected value of Geary’s \(c\) is \(E[c] = 1\), and its variance can be expressed with a relatively complicated expression. Meanwhile, Griffith (2003, 9) shows that the approximate variance of Geary’s \(c\) for \(n \geq 25\) is as given in equation 5.

\[
\text{Var}[c] \approx \frac{2}{\sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}} + 2 \left( \frac{\sum_{i=1}^{n} \left(\sum_{j=1}^{n} c_{ij}\right)^2}{\sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}^2} \right)^2 \tag{5}
\]

Using the expected value and variance, a Geary’s \(c\) z-score can be calculated in a manner similar to equation 3 and a statistical decision can be made about whether or not the null hypothesis, which states no spatial autocorrelation exists, should be rejected.

Figure 2 portrays 2010 population densities for census tracts in Dallas County. The map exhibits positive spatial autocorrelation with clusters of census tracts in dark red and other clusters of census tracts in light red. This can be statistically confirmed with Moran’s \(I\) and Geary’s \(c\). These population densities are transformed using a Box–Cox power transformation with \(\lambda = 0.33\) to better mimic a bell-shaped frequency distribution. The observed Moran’s \(I\) value is 0.4180 based on the binary matrix \(C\) and a rook definition of connectivity, which implies positive spatial autocorrelation. The corresponding expected value and standard deviation (i.e., the square root of the variance) are \(-0.0019\) and 0.0267, respectively. The z-score of Moran’s \(I\) (\(= 15.7128\)) and its \(p\)-value (\(= 0.0000\)) imply rejection of the null hypothesis, and accordingly indicates the presence of positive spatial autocorrelation. The observed Geary’s \(c\) statistic (0.6147) also implies positive spatial autocorrelation in the population densities. Its expected value and standard deviations are 1 and 0.0364, respectively. Its z-score is 10.5866, with an
accompanying $p$-value of nearly 0.0000, which implies rejection of the null hypothesis.

Join count statistics are intended to measure spatial autocorrelation for the nominal measurement scale. A binary definition with 1 denoting “black” (B) and 0 denoting “white” (W) provides a simple example of a nominal variable. A join is a classification of a $c_{ij} = c_{ji} = 1$ in matrix C as one of three types (i.e., BB, BW, or WW); join counts tally the number of joins for each type. These numbers of joins are compared with the expected numbers of joins based on a binomial probability model under the null hypothesis that no spatial autocorrelation is present. For example, a BB join count larger than its expected count under the null hypothesis may imply that B observations are co-located closely in space.

The functional form of the BB join count is

$$\frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij} y_i y_j$$

(6)

where $y_i = 1$ if the $i$-th unit is black, and $y_i = 0$ if the $i$-th unit is white. The BW join count can be computed with

$$\frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij} (y_i - y_j)^2$$

(7)

The number 2 in the denominator of these two expressions appears in order to avoid counting each join twice (i.e., $c_{ij}$ and $c_{ji}$). The WW join count can be calculated with the expression $J - (BB + BW)$, where $J$ denotes the total number of joins and

$$BB + BW + WW = J = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}$$

(8)

Cliff and Ord (1981, 38) furnish the expected values and variances for each join type:

$$E[BB] = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij} p_B^2$$

(9)

where $p_B$ denotes the probability of a 1, which may be defined empirically as $p_B = n_B/n$ for $n_B$ black units;

$$E[BW] = \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij} p_B (1 - p_B)$$

(10)

and

$$E[WW] = \frac{1}{2} \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij} (1 - p_B)^2$$

(11)

The variance of the BB can be calculated as $\text{Var}[BB] = E[BB^2] - E[BB]^2$, and the variances of the other two join types can be similarly derived. The equations for the variances can be found in Cliff and Ord (1981, 38). A statistical test can be performed under the assumption that the join count statistic is asymptotically normally distributed using these expected values and variances.

Chun and Griffith (2013, 13–14) discuss the relationship between the join count statistics and Moran’s $I$. The general formula relating equation 1 to BB, BW, and WW, using the empirical probability $p_B = n_B/n$, is given in equation 12.

$$I = \frac{p_B}{1 - p_B} + \frac{1 - 2p_B}{p_B(1 - p_B) \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}} \times 2BB - \frac{1}{(1 - p_B) \sum_{i=1}^{n} \sum_{j=1}^{n} c_{ij}} \times 2BW$$

(12)

$WW$ is accounted for implicitly by default, because $BB + BW + WW = J$. This equation highlights the role both similar and dissimilar joins play when measuring spatial autocorrelation.

Local spatial autocorrelation measures

Local indices of spatial association (LISA) are widely used measures for local spatial autocorrelation (Anselin 1995). Especially, the local Moran’s $I$ is frequently utilized to explore local
patterns of spatial dependence, and may be defined as shown in equation 13

\[ I_i = \frac{y_i - \bar{y}}{s_Y^2} \sum_{j=1}^{n} w_{ij} (y_j - \bar{y}) \]  

(13)

where

\[ s_Y^2 = \sum_{k=1}^{n} (y_k - \bar{y})^2 / n \]  

(14)

A local Moran’s \( I_i \) represents the level of spatial autocorrelation associated with areal unit \( i \). A positive local Moran’s \( I_i \) implies that the \( i \)-th areal unit has a similar value to its spatial neighbors, and a negative \( I_i \) implies that it has a dissimilar value to its spatial neighbors. Hence, a map portraying the whole set of \( n \) local Moran’s \( I_i \) values can reveal geographic clusters. Specifically, positive local Moran’s \( I_i \) values indicate clusters of similar values. However, this statistic itself does not distinguish a cluster of high values from a cluster of low values.

A test for significance can be conducted with its expected value and variance under the assumption of a normal approximation. Using a randomization hypothesis, the expected value of local Moran’s \( I_i \) is:

\[ E[I_i] = -\sum_{j=1}^{n} w_{ij} / (n - 1) \]  

(15)

Anselin (1995, 99) reports the corresponding variance. Equation 2 modified for local Moran’s \( I_i \) does not provide a good approximation of its variance because local statistics involve a small sample sizes (i.e., a small number of spatial neighbors). The z-score calculated with the mean and the variance, similar to equation 3, is a test statistic that can be referenced to the \( t \) distribution because of its small sample size context.

A local Moran’s \( I_i \) is directly associated with its parent global Moran’s \( I \). Specifically, the sum of local Moran’s \( I_i \)s is proportional to the global Moran’s \( I \). That is:

\[ I = \frac{1}{k} \sum_{i}^{n} I_i \]  

(16)

where

\[ k = \frac{1}{n} \left( \sum_{i=1}^{n} \sum_{j=1}^{n} w_{ij} \right) \sum_{i=1}^{n} (y_i - \bar{y})^2 \]  

(17)

In the special case that \( y_i \) is a z-transformed variable and \( w_{ij} \) are row-standardized, \( k \) becomes \( n \), and, consequently:

\[ I = \frac{\sum_{i}^{n} I_i}{n} \]  

(18)

This direct association allows us to investigate the contribution of each areal unit to the global spatial autocorrelation measure, and also to identify influential areal units.

Figure 3 shows an example of a local spatial autocorrelation map using z-scores of the local Moran’s \( I_i \)s. Significant positive local spatial autocorrelation is mapped in light red (at the

![Figure 3 Local Moran’s \( I_i \) for 2010 population density in Dallas County, TX.](image)
10% level) and dark red (at the 5% level). In conjunction with Figure 2, the positive local spatial autocorrelation around the boundaries of the county are clusters of census tracts with low population density. Positive local spatial autocorrelation in the north central part of the map shows clusters of high population density. Negative spatial autocorrelation is represented in light blue (at the 10% level) and dark blue (at the 5% level). The associated p values are calculated without considering multiple testing. Further discussion about multiple testing can be found in Chun and Griffith (2013, Chapter 6).

The Getis–Ord local statistics, $G_i$ and $G^*_i$, furnish another local spatial autocorrelation measure (Getis and Ord 1992; Ord and Getis 1995). These statistics were developed based on a distance rather than a spatial topology definition of spatial neighborhood structure. All areal units within a preset distance $d$ are deemed to be spatial neighbors. Distance $d$ can be considered a threshold for defining spatial neighbors. $G^*_i$ can be defined as shown in equation 19:

$$ G^*_i = \frac{\sum_{j=1}^{n} w_{ij}(d)y_j - \bar{y}\sum_{j=1}^{n} w_{ij}(d)}{s_y \sqrt{\left(n\sum_{j=1}^{n} w_{ij}(d) - \left[\sum_{j=1}^{n} w_{ij}(d)\right]^2\right) / (n-1)}} $$

(19)

where $s_y$ denotes the standard deviation of variable $Y$. The difference between $G_i$ and $G^*_i$ is whether or not a focal observation is included with its spatial neighbors. The $G_i$ statistic does not include this focal observation in its calculation. That is, $w_{ii} = 0$. In contrast, $w_{ii} = 1$ for the $G^*_i$ statistic. Because one less observation (i.e., the focal observation) is considered in $G_i$, its formula can be written by replacing $n$ and $n - 1$ in the denominator with $n - 1$ and $n - 2$, respectively. This distinction leads to a slightly different emphasis by these two statistics. The $G_i$ statistic focuses on spatial association between the $i$-th areal unit and its neighbors within a concentric zone of radius $d$. The $G^*_i$ statistic is intended to identify spatial clusters, because the $i$-th areal unit is considered conceptually to be a cluster member. Positive $G_i$ and $G^*_i$ values indicate clusters of high values that can be easily interpreted as hotspots. In contrast, negative $G_i$ and $G^*_i$ values indicate clusters of low values that can be interpreted as cold spots.

The $G_i$ and $G^*_i$ statistics follow the standard normal distribution when the underlying distribution of the variable $Y$ has a normal distribution. Hence, a calculated statistic itself furnishes a test statistic that can be referenced to the standard normal distribution. One weakness of these statistics is that the variable $Y$ must have non-negative values. Also, these statistics are sensitive to the distance value $d$. Hence $d$ should be carefully selected.

Figure 4 shows $G^*_i$ statistics for the 2010 population density in Dallas County. In this example, Euclidian distances between centroids of the census tracts are considered with $d = 5$. 

Figure 4  Local $G^*_i$ statistics for 2010 population density in Dallas County, TX ($d = 5$ miles).
miles (8 kilometers) defining spatial neighbors. The census tracts in red have significant positive $G_i^*$ values either at the 5% level (dark red) or at the 10% level (light red), indicating clusters of census tracts with high population density. In contrast, the census tracts in blue have significant negative $G_i^*$ values at the 5% level (dark blue) or the 10% level (light blue), indicating clusters of census tracts with low population density. Compared with the local Moran’s $I_i$ map in Figure 3, Figure 4 shows fewer significant values among census tracts around the edge of the county. A small number of spatial neighbors for these edge census tracts may have an impact on this outcome. Also, clusters of low values (i.e., cold spots) are identified.

Graphic portrayals of spatial dependence

Spatial dependence can be represented in forms other than spatial autocorrelation indices, which furnish summary numerical values. Especially, graphical methods provide a way to visually represent and qualitatively measure spatial autocorrelation. These methods are closely associated with exploratory spatial data analysis and usually do not involve a formal test of statistical significance. They include the Moran scatterplot, semivariogram, covariogram, and correlogram.

The Moran scatterplot (Anselin 1995) visually portrays the relationship between the value of the $i$-th areal unit and the summed spatially weighted values of its spatial neighbors. This graphic is a scatterplot between values at each location and their spatially lagged values. It plots the differences between each observation and the mean of the variable $Y$ (i.e., $z_i = (y_i - \bar{y})/s_y$) on the horizontal axis, and $\sum_{j=1}^{n} w_{ij} z_j$ on the vertical axis. As such, equation (1) is rewritten as

$$\frac{n}{\sum_{j=1}^{n} w_{ij}} \sum_{i=1}^{n} z_i \left( \sum_{j=1}^{n} w_{ij} z_j \right)$$

clarifying why the scatterplot is for $z_i$ versus $\sum_{j=1}^{n} w_{ij} z_j$. Figure 5 is a Moran scatterplot of 2010 population density in Dallas County using $z$-scores.

Each point in a Moran scatterplot is directly associated with a local Moran’s $I_i$ for the corresponding areal units. When four quadrants are considered based on the dotted lines (i.e., zero values on the horizontal and vertical axes), the points in the first quadrant represent areal units whose values are larger than the mean and whose spatial lagged values are also larger than the mean. That is, these areas have high values surrounded by high values, and are denoted by HH. In contrast, the points in the third quadrant denote areal units whose values are less than the mean and whose spatial lagged values also are less than the mean – that is, low values surrounded by low values – and are denoted by LL. Similarly, the second quadrant identifies low values surrounded by high values (LH), and the fourth...
quadrant identifies high values surrounded by low values (HL). Accordingly, while the first and third quadrants indicate positive local spatial autocorrelation, the second and fourth quadrants indicate negative local spatial autocorrelation. This direct association is revealed by the reduced form of equation 13:

\[ I_i = z_i \sum_{j=1}^{n} w_{ij}z_j \]  

(21)

where standard deviation of z-scores is 1. Hence, a Moran scatterplot can be used as a diagnostic tool to identify influential cases on the global spatial autocorrelation index (i.e., the global Moran's I). In Figure 5, more influential cases are differentiated with a different symbol, and generally are further away from the mean points, here (0,0). Also, the slope of the regression line without the intercept term is fundamentally equivalent to the global Moran's I that is calculated with the variable Y. With \( z_i \) for the horizontal axis and

\[ \sum_{j=1}^{n} w_{ij}z_j \]  

(22)

for the vertical axis, the formula for the slope

\[ \frac{\sum_{i=1}^{n} \left( z_i \cdot \sum_{j=1}^{n} w_{ij}z_j \right)}{\sum_{i=1}^{n} z_i^2} \]  

(23)

is the second term in equation 1. When row-standardized weights are used, the sum of weights is \( n \). Hence, the slope formula becomes exactly the same as the formula for Moran's I.

A semivariogram furnishes a graphical measure of spatial autocorrelation. It is often used to measure spatial autocorrelation among values of point features. It portrays the magnitude of the variance (the sill), the change of the variance with distance, and the distance interval in which spatial dependence appears (the range). It portrays how observations at a specific distance are dissimilar to each other, using a smooth nonlinear trend curve that is defined by a mathematical equation. Figure 6 presents a semivariogram using an exponential function (blue line) to describe the trend line; polygons are replaced with their geometric centroids to obtain point data. The blue line shows that semivariance is zero when distance, \( d \), is zero. It implies that observations zero distance apart (\( d = 0 \)) have zero dissimilarity; in other words, individual observations have zero semivariance and are perfectly correlated. As distance gets larger, the level of dissimilarity increases until a certain distance (the range). That is, as distance between observations increases, the level of correlation decreases (or the level of dissimilarity increases). Once \( d \) is larger than the range, observations become independent and have maximum dissimilarity described by the variance of the variable. An additional feature of a semivariogram is a nugget effect. Although the change in dissimilarity is continuous, it is not necessary zero at \( d = 0 \). Rather, a minimal change in distance may correspond with a sudden change in dissimilarity. This sudden increase in dissimilarity near \( d = 0 \) is captured with a nugget effect, which may indicate, for example, measurement error or specification error.

Estimation of a semivariogram requires exploring the dissimilarity of observed values together with the distance separating them. However, observation pairs do not provide a sufficient number of samples at every possible distance \( d \) (which is on a continuous scale). Therefore, a dissimilar pattern is discerned for bins that are defined with a range of distance intervals, such as is done when constructing a standard empirical frequency distribution. That is, a sample semivariogram, \( \hat{\gamma}(d) \), is estimated based upon:

\[ \hat{\gamma}(d) = \frac{1}{2 \cdot |N(d)|} \sum_{i \in N(d)} (y_i - y_j)^2 \]  

(24)
where \(|N(d)|\) denotes the number of pairs of observations contained in a certain distance interval. The points in Figure 6 that are plotted as coordinates for the center of each bin and its corresponding semivariogram value constitute an empirical variogram. Next, the best trend line is selected from among different semivariogram model specifications based upon parameter estimates and goodness-of-fit criteria. One common model is the exponential function defined by:

\[
\gamma(d) = \gamma_0 + \gamma_1 \left(1 - e^{-d/r}\right)
\]  

(25)

where \(\gamma_0\) is the nugget, \(\gamma_0 + \gamma_1\) is the sill, and \(r\) is the range parameter (i.e., spatial autocorrelation asymptotically converges on zero as \(d\) goes to infinity). The Bessel function furnishes another popular semivariogram model and is defined by:

\[
\gamma(d) = \gamma_0 + \gamma_1 \left(1 - \frac{d}{r} K_1 \left(\frac{d}{r}\right)\right)
\]  

(26)

where \(K_1\) is the modified Bessel function of the first order and second kind. A chosen semivariogram model with estimated parameters can be utilized further in spatial interpolation with kriging.

The summation term in the right-hand side of equation 24 can be expanded as equation 27:

\[
(y_i - y_j)^2 = [(y_i - \bar{y}) - (y_j - \bar{y})]^2 \\
\quad \quad = [(y_i - \bar{y})^2 + (y_j - \bar{y})^2] - 2(y_i - \bar{y})(y_j - \bar{y})
\]  

(27)

Accordingly, the semivariogram is a variance term minus an autocovariance term, which produces its concave downward increasing function shape. A plotting of the autocovariance versus distance creates a covariogram. In contrast with the semivariogram, this plot measures how observations covary with other observations that are separated from them by distance \(d\). This plot is also considered a portrayal of spatial autocorrelation. This covariation has a maximum value at \(d = 0\) because this case measures covariation of values with themselves. The maximum covariation at \(d = 0\) is equal to the variance at each location, \(\sigma^2\); that is, \(C(0) = \sigma^2\). As distance increases, covariation decreases. Similar to a semivariogram, a covariogram trend line can be described by a function of distance. A sample covariogram can be estimated as in equation 28:

\[
\sigma^2 = \int_0^d \gamma(d) \, dc \\
\sigma^2 = \int_0^d \left[\gamma_0 + \gamma_1 \left(1 - e^{-d/r}\right)\right] \, dc \\
\sigma^2 = \gamma_0 d + \gamma_1 \left(d - \frac{d^2}{2r} e^{-d/r}\right)
\]  

(28)

Figure 7  An illustration of (a) a semivariogram and (b) a covariogram.
Figure 8 Correlograms for 2010 population density in Dallas County, TX: (a) correlation based; (b) Geary’s $c$ based.

\[
\hat{C}(d) = \frac{1}{|N(d)|} \sum_{N(d)} (y_i - \bar{y})(y_j - \bar{y}) \quad (28)
\]

Figure 7 illustrates the inverse relationship between a semivariogram and a covariogram. Under the specific condition of intrinsic stationarity (Cressie 1993, 67), a covariogram is directly related to a semivariogram: $\gamma(d) = \sigma^2 - C(d)$. However, estimators from samples do not preserve this property.

A correlogram, similar to a covariogram, represents how observations covary using correlation instead of covariation. The correlation can be defined as $C(d)/C(0)$. Hence, correlation has its maximum value of 1 at $d = 0$ and decreases as distance separating observations increases. Covariograms and correlograms often can be utilized to visually represent spatial autocorrelation among areal units in terms of spatial lags (the horizontal axis). A spatial lag $k$ means that two areal units are $k$ steps apart when an immediate neighbor is considered to be one spatial lag. Figure 8a illustrates a correlation-based correlogram for 2010 population density in Dallas County. The observations at one spatial lag are highly correlated (>0.6), with the degree of correlation decreasing as the number of spatial lags increases. That is, observations separated by a large number of lags are weakly correlated. Figure 8b displays a correlogram based on Geary’s $c$. It has an increasing pattern similar to a semivariogram because Geary’s $c$ also measures dissimilarity between the value of an areal unit and those of its spatial neighbors.

Concluding remarks

Measuring spatial dependence requires underlying principles and theories, including a framework defining spatial proximity, numerical indices, statistical inference, and/or graphic representations. These principles and theories describe conditions for appropriately measuring spatial dependence. Such conditions include the geometric type of geographic features, measurement scales for attributes, and constraints of space. First, while measuring spatial
dependence is widely applied to either point or polygon features, line features have not been a common geometric type for dealing with spatial dependence. A lack of line features with attached attributes might contribute to the paucity of such analyses. Furthermore, a framework defining spatial proximity among linear features has not been extensively investigated. Papers related to this topic include Chun (2008) for logical linear features and Yamada and Thill (2007) for physical linear features.

Second, spatial autocorrelation indices often utilize a normal approximation that may not be appropriate for some variables. For example, counts hardly follow a normal distribution, and rates in the range of (0,1) are not likely to follow a normal distribution. Griffith (2010) provides insights about spatial autocorrelation measures for non-normal distributions. Sen and Soot (1977) furnish a spatial autocorrelation index for ordinal measurement scale variables. Third, spatial dependence is generally considered a 2-D continuous geographic space phenomenon, but other types of geographic space merit attention, too. Network space furnishes a popular example of a constrained space. For example, the spatial proximity of two car accidents on a street network can be better represented with network distance along the street network rather than Euclidian distance. Okabe and Sugihara (2012) provide details. Also, spatial dependence in 3-D space may need further development as the availability of 3-D data rapidly increases.

Measuring spatial dependence also requires tools for numerical processing. A number of implementations already are available. First, geographic information system (GIS) software packages include spatial dependence measuring functions. Second, specialized spatial statistical packages also include these functionalities. Finally, conventional statistical packages increasingly include more spatial statistical/econometrics capabilities.

Medical tourism

Valorie A. Crooks
Simon Fraser University, Canada

The term “medical tourism” is used to describe the intentional movement of patients from one country to another in order to seek medical care privately. As this care is intentional, emergency medical care accessed while abroad does not constitute medical tourism. Furthermore, as the care is privately sought (primarily through out-of-pocket payment, although sometimes through private insurance), formal cross-border care arrangements enabling patients to access in another country medical care that is paid for by their home health-care system are distinct from medical tourism. Medical tourism is a highly spatial practice that involves the movement between countries on a highly global scale of patients and the friends and family members who accompany them abroad, health workers and administrators, investors and their capital, and many other individuals.

Medical tourism is a global health services industry involving hospitals and clinics in destination countries that range in development and health indicators, and the procedures offered to international patients are highly varied (e.g., experimental stem cell procedures, fertility procedures, hip replacements, dental surgeries, cosmetic surgeries). Patients from countries around the world are motivated to go abroad as medical tourists for a number of reasons. They may be trying to avoid the high cost of care in their home health-care systems or to access procedures that are illegal in their home countries, among other factors.

It is thought that medical tourism can benefit destination countries by bringing in revenue and new investment opportunities, broadening the range of medical procedures available locally, and retaining health workers who may otherwise migrate elsewhere. At the same time, it is also thought that medical tourism can exacerbate health inequities in destination countries by draining resources from public health-care systems, lessening local citizens’ equitable access to care, and transforming aspects of health worker education (e.g., an increased focus on English language training). There are also concerns that patients can be exposed to a number of health and safety risks both at home and abroad through the practice of medical tourism and that the lack of neutral or third-party information about facilities and procedures threatens the process of informed consent. Meanwhile, advocates of the practice suggest that medical tourism enhances patients’ care options, thereby enabling greater choice and an opportunity for empowerment while lessening “system bottlenecks” in patients’ home countries through providing international alternatives.

Mediterranean-type ecosystems

George P. Malanson
University of Iowa, USA

Mediterranean-type ecosystems exist in the five regions with what is called a Mediterranean-type climate (defined by mild, wet winters and warm, dry summers) (Figure 1). From an ecological perspective, net primary productivity, the base of ecosystem functioning and structure, depends on energy and water being available simultaneously. Thus, Mediterranean-type climates are special conditions for plant growth because the summer growing period, when energy is available, is one of increasing aridity, and Mediterranean-type ecosystems, biomes, have plants that have evolved a range of adaptations to this combination. The Mediterranean-type climate also creates conditions that make fire a regular phenomenon (enough fuel that becomes dry during warm summers) to which the ecosystem has adapted.

The primary adaptations of Mediterranean-type ecosystem plants to the Mediterranean-type climate are means to conserve water while maintaining photosynthesis through the dry summer, relying on soil water from the previous rainy season. The primary adaptation is evergreen sclerophyllous leaves: small leaves with waxy surfaces and stomata that can close when soil water is low. All of these characteristics increase water-use efficiency (the ratio of carbon dioxide uptake to water loss by evapotranspiration) while slowing net primary productivity. The leaves are evergreen because there is no need to expend energy on reproducing them if they can become dormant as necessary. In contrast, some vegetation on drier sites can be drought-deciduous, lacking the structures for water-use efficiency; species grow during the spring but then become dormant by early summer.

The limited annual growth leads to the dominance of woody shrub (many-branched from the base, around 2 m height) life-forms in most Mediterranean-type ecosystems. This physiognomy allows canopy development with low costs for respiration. Other forms include evergreen sclerophyllous trees, such as Eucalyptus species in Australia and a smaller shrub form in drier Mediterranean-type ecosystems.

The shrub form and the sclerophyllous leaves together mean that the Mediterranean-type ecosystem vegetation is extremely flammable in warm dry summers. The shrub forms carry fire because the branches are closely packed with a high surface to volume ratio, and because they maintain upright dead branches, created by age and drought, for years. The sclerophyllous leaves are high in volatile oil content. Other forms, such as eucalypt trees, and even non-sclerophyllous plants, such as Californian coastal sage scrub, also have this high volatile oil content in their leaves.

Mediterranean-type ecosystems have common and uncommon adaptations to fire. Shrubs can commonly resprout from their underground parts, and many Mediterranean-type ecosystem species are well adapted in this regard, storing carbohydrate in root crowns to promote post-fire resprouting. Some shrub species have become obligate-seeders, however, having lost the primitive trait of resprouting but producing more seeds that can remain dormant until a fire triggers germination. This contrast in reproductive strategies (and species exist on a
gradient between the extremes) is seen as an adaptation to differing fire intervals and intensities. Short intervals lead to less intense fire and favor resprouting, while long intervals allow the build-up of fuels and, thus, higher intensity fires that suppress resprouting and open space for reproduction from seed.

Mediterranean-type ecosystems vary among the Mediterranean-type climate regions where they are found. Near the Mediterranean Sea, Mediterranean-type ecosystems are dominated by 2–3 m evergreen sclerophyllous vegetation, such as maquis, with *Quercus ilex* the most common species, but in France a lower shrub form, garigue, also exists with *Quercus coccifera* the most common species. These shrublands can grade into pine (e.g., *Pinus halepensis*). Land use over millennia has affected the distribution of these vegetation types. Shrubs also dominate in the Western Hemisphere. In California and Chile, chaparral and matorral, respectively, are similar to maquis. Californian coastal sage scrub is a variant in the former, often found on lower or south-facing slopes. These forms give way to pines and oaks as precipitation increases. These Mediterranean-type ecosystems are an example of convergent evolution, where different plant lineages have developed similar physiognomies to adapt to the climate.

In South Africa and Australia, the differences in evolutionary history become apparent. The Mediterranean-type ecosystems of Australia, dominated by Eucalyptus, support a taller sclerophyllous woodland, mallee (whether the tall Eucalyptus forests of southwestern Australia are a part of this type of ecosystem may be questioned, but they are in a summer-dry climate), although shrublands do exist. The Mediterranean-type ecosystems of South Africa show the greatest floristic diversity, with fynbos being the heart of the Cape Floral Region. Based on a variety of Proteaceae and Ericaceae, the fynbos is known for its unusually high diversity of species in a small area.
Mediterranean-type ecosystems face several of the challenges of global change. They are adapted to a particular type of climate with relatively narrow geographic distributions in their five regions. The challenge of spatially tracking changing climates, if they continue to exist, is compounded by changing fire regimes. This secondary problem may be greater than the effects of changed temperature and precipitation. Changing land use is also an issue. Except in western Europe, where farm abandonment has recently increased the area of Mediterranean-type ecosystems, habitat destruction for agriculture and other uses has reduced Mediterranean-type ecosystem area to fragments. Whether climate change and fire will affect this land-use trend is, as yet, unknown. Lastly, invasive species are a challenge. The unique floras of Australia and South Africa are affecting each other.

Megacity

Christopher J. Sutton
Western Illinois University, USA

The number of people living in cities has grown from nearly 750 million in 1950 to nearly 4 billion in 2015. The largest of all urban places are megacities — expansive, continuous urban population centers with at least 10 million people. Through their sheer size, megacities play a central role in the economies of their country and tend to be hubs of global urban connectivity.

Because megacities are defined by extent of urban buildup and not by administrative boundaries, the reported population of a megacity can vary widely. Since the mid-1950s, Tokyo generally has been considered the world’s largest megacity, with a 2014 population of 38 million. The World Bank considers the cities located on the Pearl River Delta in southern China — which includes the megacities of Guangzhou and Shenzhen — to be a single, expansive megacity. With a 2010 population in excess of 42 million, the Pearl River Delta surpasses Tokyo.

In 1950, only New York and Tokyo had populations larger than 10 million inhabitants. The number of megacities had risen to 10 by 1990, 23 by 2010, and the number is expected to increase to 41 by 2030. Of these 41, as many as a dozen are agglomerations with populations exceeding 20 million, and Tokyo, Japan, Delhi, India, and Shanghai, China, each have populations exceeding 30 million.

China and India are expected to account for much of the growth in the world’s population (see Population growth) during the first half of the twenty-first century as the number of persons residing in cities in the two countries is expected to grow by nearly 700 million. The number of megacities in the world’s most developed countries is projected to remain unchanged at seven until the middle of the twenty-first century. New York and Los Angeles will continue to be the only two megacities in the United States. The number of megacities in less developed regions is projected to increase from 22 in to 34.

By 2030, one-third of the world’s megacities will be in China and India. Much of the remaining growth of megacities will occur in Africa and, to a lesser extent, in Latin America, where Bogotá, Colombia, and Lima, Peru, are projected to achieve megacity status by 2030. The world’s largest slums — in excess of one million inhabitants — are found in the megacities of developing countries, particularly those in South Asia and sub-Saharan Africa. Managing growth in megacities, particularly within slum areas, will be a challenge for many countries.

Mental health geographies

Cheryl McGeachan
University of Glasgow, UK

Geographies of mental ill-health comprise a number of elements including the spatial variations in incidences of mental ill-health, the different environmental components employed in the creation of therapeutic regimes for those experiencing mental ill-health, and the range of locations occupied by the variety of institutions and facilities designed to diagnose and treat individuals experiencing mental health problems (Philo 2005). The concerns of “mental health geography” have intersected with the interests of a number of other subfields such as “health,” “medical,” and “social” geography. While some geographers remain content to deploy the models and terms of “mental illness,” others prefer to remain skeptical about conventional medical-psychiatric models and seek alternative ways of understanding the wide range of experiences felt by people with mental health problems. In doing so, a number of theoretical frames have been adopted, including insights from “anti-psychiatry” and “post-psychiatry,” utilizing a wide range of conceptual vocabularies from phenomenology, critical social theory, psychoanalysis, psychotherapy, and political economy. In part to connect with the ongoing attempts to reclaim “madness” as a politicized identity such as in the recent case of the “voice-hearing” movement (see Callard 2014), a number of geographers have elected to speak of “madness” rather than “mental illness.” Adoption of this term is also partly to acknowledge that “madness” has historically been the predominant mode of understanding different forms of mental difference (see Philo 2005).

In their substantial review, Wolch and Philo (2000) chart three “waves” of inquiry in mental health geography. The first “wave,” the authors suggest, was grounded in spatial science and often employed quantitative methods to investigate the distribution of “deviant” populations including those experiencing diagnosable mental illnesses. The second “wave,” in contrast and in line with the changing frameworks of the discipline, utilized more qualitative methods and remained rooted in social theory, centering more firmly on the social construction of difference. Trajectories towards a third “wave” are suggested by the authors as harnessing a range of theories and methods to uncover a more nuanced understanding of “place-specific happenings” alongside more structurally determined “space-compressing” processes (Wolch and Philo 2000, 149). This, the authors note, requires an ability to conduct research across scales and to pay acute attention to the uses and potential misuses of research findings, especially in relation to policy agendas. Following the pathways of the “waves” suggested above, this entry seeks to give a flavor of the subfield of mental health geographies. It begins with an introduction to so-called psychiatric geographies, continues through to the changing locational associations of mental health, specifically centering on the important shifts from asylum to post-asylum geographies, and finally returns to the experiences of mental ill-health and the new ways in which geographers are currently delving into the complex worlds these individuals inhabit.
MENTAL HEALTH GEOGRAPHIES

Psychiatric geographies

Throughout the early 1960s, and inspired by the pioneering work of sociologists R.E. Faris and H.W. Dunham (1939) on “mental disorders” in the city and their influential map of schizophrenia in Chicago, a number of geographers began to reconstruct what can be termed the “psychiatric geography” of the city (see Wolch and Philo 2000, 139). The resulting studies used a number of statistical methods to detect cross-correlations with spatially referenced data on other variables such as population densities and housing conditions to establish possible causal influences. From this work an interesting array of findings about inner-city concentrations of particular medicalized groupings (especially of schizophrenia) and their socioeconomic correlates was produced. They tended, in general, to confirm the earlier findings of Faris and Dunham with respect to schizophrenia that demonstrated a clear distance-decay in the prevalence of schizophrenia with increasing distances away from the city center. The quantitative rigor of such studies – which may be termed “spatial epidemiologies” (Wolch and Philo 2000, 139) – offers an elaborate way of describing spatial patterns and cross-correlations. For example, the work of Alun Joseph and Brent Hall (1985) into the concentration of social service facilities, including psychiatric group homes, applied a location quotient analysis to such services in Metropolitan Toronto. The authors argue that the localization data collected could be used in the formulation of placement policies to achieve a more equitable distribution of services; however, such studies do not necessarily succeed in explaining in any great detail the causal mechanisms involved in generating such patterns. Other geographers have attempted to develop their understanding of a city’s psychiatric geographies. Using methodologies that require researchers to enter more closely into the worlds of the range of individuals involved in the different processes of mental health practice allows a picture to emerge that accounts for more “contextual” factors.

Changing locational associations of mental health

An area of concern in the geographical literature focuses on the tensions and contradictions in attitudes and beliefs towards mental ill-health that can be revealed through an historical analysis of the spaces of care for mentally-ill individuals. Often referred to as “asylum geographies” (Wolch and Philo 2000, 138), which broadly refers to studies concerned with investigating the geographies of mental health services, attention has been given to the origins of mental health care facilities in the “lunatic asylums” that appeared across western countries. A number of geographers have used various archival sources to reconstruct the location adopted by asylums, “madhouses,” and hospitals run by a number of (state controlled) bodies and institutions. A key body of work in this respect is Chris Philo’s (see 2005) detailed investigation into “the spaces reserved for insanity.” Much of Philo’s work traces the changing geography of places and spaces associated with madness in Britain through the eighteenth and nineteenth centuries, paying particular attention to the discourses and practices that have created a succession of overlain and often disputed “landscapes of lunacy.” Questions raised in this type of work address the extent to which such locations – the specific spaces, places and environments – were shaped by medical, moral, or economic discourses, or by a deeper sense of wishing to remove certain “troubling” and “frightening” populations from “sight and
The different spatial dimensions of the regimes that operated in these institutions have also been examined. Studies have investigated what is known as “Jarvis's Law” (see Philo 2005, 587) of distance-decay in the numbers of asylum admissions decreasing with increasing distance from the asylum gates, while others have explored the tensions between surveillance and “moral architectures” present in the plans of many of the asylums.

Continuities have been traced between the asylum geographies of the eighteenth and nineteenth centuries through to the contemporary reinvention of carceral solutions to potentially dangerous mentally ill populations. From the eighteenth century onwards the asylum is presented in many western countries as a “carceral space,” with the wider literature presenting the asylum to be a “fortress” or “refuge,” protecting people with mental illness from aspects of harm and risk to which they are vulnerable in the wider community (see Curtis 2010, 185–214). These representations solidify psychiatric institutions’ characterization as “spaces of power,” and geographers have reflected, through figures such as Michel Foucault and his work on Bentham’s Panopticon, on the impacts this has for interpreting institutional settings as reflections on the power relations present in society more generally.

Asylum to post-asylum geographies

A key area of geographical concern has been the closure of older asylum spaces under the post-1960s drive to deinstitutionalization and community care in many western countries. This shift in mental health care ideology from institutional to deinstitutionalization solutions has had far-ranging spatial implications and has given rise to a new wave of geographical research on the different spaces and places of post-asylum care. Moving from large-scale “closed spaces” often located in set-apart areas and concentrating a substantial number of patients, carers, and other health professionals, to a maze of small-scale facilities such as drop-in centers, sheltered homes, general practitioner support, and others, has led to a changing pattern of dispersal across different communities. This significant transition, sometimes couched as one from asylum to post-asylum geographies (Curtis 2010; Wolch and Philo 2000) has, in effect, reintroduced into the spaces and places of everyday life people who had previously been spatially removed from community life.

Geographers have examined a wide assortment of care spaces in the community such as out-patient clinics, counseling services, and home spaces. While some have expressed concerns about the sufficiency of such spaces in terms of numbers and quality of service, others have questioned whether the new mechanisms, dispersed throughout diverse communities, amount to a tighter web of “psychiatric influence” (see Wolch and Philo 2000, 141–143). Two key texts in this respect, Michael Dear and Martin Taylor’s (1982) Not on Our Street and Michael Dear and Jennifer Wolch’s (1987) Landscapes of Despair, offer key statements on these issues. Dear and Taylor’s (1982) work sought to establish the nature, magnitude, and geography of community opposition in Toronto to proposed mental health facilities. In doing so they emphasized the challenges of many communities, notably middle-class suburbs, adopting a NIMBYist (“not-in-my-backyard”) attitude towards mental health facilities and their users. In contrast, Dear and Wolch’s (1987) study more broadly applies theoretical perspectives such as structural analysis and human agency to understand the downstream effects of asylum closure. They survey new
spaces of poverty, drug abuse, homelessness, and even reinstitutionalization through the penal and care systems that deinstitutionalized patients are inhabiting.

Further studies have illuminated the fractious politics involved in determining where facilities operate (often clustering in specific parts of the city, creating areas that are inundated with mental health clients), discussing the hierarchies of power and influence that are at play in these key locational decisions. Attention has also turned to the often abandoned asylum sites themselves. Research has shown the deeply symbolic value still placed on these sites by patients, workers, and communities long after the closure of the facility itself. Studies have demonstrated some of the aftermaths of the closure of certain long-stay facilities and, through detailed qualitative work, highlighted the significance of old hospital buildings and their surrounding sites (Moon, Kearns, and Joseph 2015). Connections can be drawn here with work conducted on the design and implementation of contemporary psychiatric care settings. For example, through their research into the perceptions of a newly built psychiatric unit in London, Curtis and colleagues (2009 in Curtis 2010) argue that important questions are raised in these newly restructured landscapes of care as “clinical space” is now extended into the community. In many ways, the authors argue, the psychiatric hospital has become a “permeable institution” which differs markedly from aspects of older asylum facilities. Attention has also turned to the afterlives of these asylum sites and their new economic, social, and cultural functions in contemporary society. Moon and colleagues (2015), for example, in surveying former public psychiatric hospitals in New Zealand, argue for the transcendent role of stigma in closure processes and subsequent building reuse.

Experiential worlds

A number of studies have also examined how post-asylum geographies have been experienced and encountered “from below.” This work has sought to consider the extent to which communities have proved to be “caring” places and has questioned the ongoing stigmatization of people with mental health problems as too different and therefore segregated in varying ways (see Wolch and Philo 2000). However, a range of studies have alternatively sought to uncover a selection of multifaceted caring practices surrounding people with mental health problems. Work on the “self-help,” “advocacy,” and “arts for mental health” networks materializing amongst people with mental health problems has focused on the friendships and relationships that are fostered in such informal spaces, such as cafes, parks, and street corners. This research focuses upon the “mad” geographies of everyday lives and has considered the role of the material spaces of the world and the different ways these are carefully negotiated by individuals experiencing mental health difficulties, as well as the virtual spaces and the rise of online communities (Parr 2008). In increasingly “insecure” times, research in mental health geography is crosscutting into the heart of broader geographical inquiry, tightly bound into issues such as environmental change and global health. Sustained engagements with the international population mental health agenda, such as the range of reports and statements from the World Health Organization, demonstrates a concern to investigate mental health at a global level and to view it as a crucial component of human health integrating once again with the work in “health geography.” For example, Sarah Curtis (2010, 215–238) discusses the complex question of how mental health might be improved at the population level, placing particular attention on strategies to provide and
promote good mental health in the population as a whole, as well as focusing upon treatment of individuals experiencing psychological distress.

Given the complex worlds that people experiencing mental illnesses present, it is increasingly evident that there is a need to consider the pain and suffering but also the hope that can be felt throughout both their “delusional” phases and everyday spaces of public interaction. Novel theoretical understandings of mental ill-health are being explored that are creating innovative cross-disciplinary studies. For example, recent scholarship is drawing on psychoanalytic and psychotherapeutic theory to inspire different routes of connection between space, psychoanalysis, and mental health geographies (McGeachan 2014). This continued desire to understand the created worlds and lived experiences of individuals experiencing mental ill-health at a range of scales, wrapped up within a continually restructuring landscape of care, demonstrates a continued and growing enthusiasm for exploring mental health geographies in creative ways.

Mergers and acquisitions

Milford B. Green  
*Western University of Canada*

The core rationale for mergers and acquisitions is to increase shareholder wealth. Pursuit of this goal generates one of the most important activities that exist in the capital markets: mergers and acquisitions (M&As). They influence not only the firms involved but also the regions and cities of operation and the locales of the acquired firms. The terms “mergers” and “acquisitions” are used here in a generic sense. M&As describes nearly any business combination involving new partnerships. Legally, mergers require one company to sacrifice its corporate life. An acquisition, which is the purchase of another company, does not require the cancellation of a charter of incorporation. The term “merger” refers to both mergers and acquisitions. Spatial consequences of the two are indistinguishable and the legal differences need not be of concern here. Transfers of assets, corporate headquarters, control functions, and personnel can affect the losing region or city. Such consequences have spurred researchers to examine in detail the economic and social effects of mergers. The discussion here draws from Green (1990).

Some mergers are large by any standard and size bestows effects. The $202.8-billion takeover of Mannesmann AG by Vodafone AirTouch in 1999 is the largest merger on record. Such a huge sum is unusual, but mergers with values greater than $20 billion are now common. Many corporations are very active in the pursuit of mergers, with some having more than 150 acquisitions in the last 25 years.

There are two types of merger, cross-border and domestic, with domestic being the most common. Domestic mergers happen within a country’s boundaries. This does not preclude firms that have an international presence, but the firm buying and the firm being targeted are headquartered within the same country. The size of the United States’ merger market coupled with the periodic concern by the American public regarding merger consequences makes US mergers the most studied. United States merger studies provide the template for most studies of non-US M&As. In this tradition, the discussion here concentrates on the US experience.

Geographic merger research of the last decade exhibits a more quantitative nature than older studies. The results substantiate previous findings, of merger activity declining with increased distance, of increased likelihood as the size of the urban centers involved increases, and of lower success rates across longer distances. These geographical relations are tied to asymmetries of information. Information is situated on a continuum from explicit (information that is codified and available to a wide audience) to tacit (information associated with personal contacts). The quantity and quality of tacit information typically decreases with distance. More and better-quality information lowers risks associated with M&As. Generally, the more remote the target, and the smaller the city, the less is known, raising risk and possibly lowering returns (Chakrabarti and Mitchell 2013; Basu and Chevrier 2011).

Recently, some domestic megamergers have occurred because of the interventions of investment bankers or merger brokers.
promoting mergers for the fees. Such brokers search for potential merger targets for a firm on their own initiative, presenting the candidates to a potential acquirer. These brokers are spatially concentrated in New York, Chicago, and Boston (Davidson 1985), increasing the likelihood of acquisitions by firms headquartered in those cities. These third-party agents contribute to the geographic findings mentioned above.

Research interest in M&As grows and falls with levels of merger activity. The bulk of M&A research is either of a “how to” nature, or studies mergers as an aspatial economic phenomenon. Financial economists concentrate on efficiency gains that theoretically arise from mergers, while analysts in the industrial organization tradition argue that mergers do not generate significant gains. No consensus exists, which is not surprising given the complexity of the topic and the uniqueness of each merger. Neither body of scholarship shows much concern for the effects mergers may produce in social, political, spatial, or economic arenas. Until very recently, they have seldom considered how changes in merger patterns relate to space or how space influences target firm selection. The geography of mergers can affect the organization of the economy, however, altering regional and urban structures and impacting firm concentration, production consolidation and employment impacts.

Mergers and acquisitions in the United States and elsewhere:
A brief chronology

The following short history of mergers in the United States illustrates the roots of the most widely cited theories of merger origination and of how mergers affect industrial structure. The impact of government regulation and changes in funding alternatives on merger occurrences are also illustrated.

Interest in domestic merger behavior began in the late nineteenth century as the US public became concerned about the rise of monopoly trusts such as Standard Oil and US Steel. This was the first of at least six merger waves. Research generally concedes that mergers occur in waves, although the timing and amplitude of the waves vary by country. It is not well understood why such waves occur: Research into long-term activity is severely restricted by lack of time series data.

The first, the horizontal monopoly wave, was fueled by the drive to create large but short-lived trusts (1895–1904). This wave placed an indelible imprint on the structure of the US economy, leaving in its wake small numbers of very large corporations in basic industries. Antitrust legislation in 1890 was the first significant federal legislation to control mergers, targeting monopoly creation. Subsequent enforcement marked the end of this horizontal merger wave.

Second came the oligopoly wave (1919–1929). This resulted in a sharp rise in the share of manufacturing and mining held by the largest 200 corporations (FTC 1969). Again, this activity prompted US federal legislation to rein in such merger activity, prohibiting mergers that seriously lessened competition. Serious enforcement of this legislation did not occur until after the stock market crash of 1929, in response to public outrage.

The third wave – the conglomerate wave – peaked in the late 1960s. Conglomerates are characterized by weak, or no, linkages between the firms held in a conglomerate. Many conglomerate mergers during this wave were predicated on the false belief that management skills required by a new acquisition are transferable from the unrelated buying
firm. Subsequently, many conglomerates were dismantled due to poor financial performance.

Hostile takeovers, junk bonds, and larger leveraged buyouts characterized the fourth wave of mergers (1984–1989). The bust-up merger became common: selling off an acquired firm’s component pieces, resulting in a divestiture boom. The savings and loan crisis in the United States in the late 1980s helped bring this wave to an end.

The first megamergers (except for the purchase of the R.J. Reynolds Tobacco Company in 1989 for $31 billion) characterized wave five (1993–2000) – defined as mergers above $1 billion. Extremely large corporations were formed in pursuit of advantages that came from a bigger size, with negotiated deals the preferred form of acquisition. Visions of a “new economy,” in which economic boom–bust cycles were thought to be a relic of the past, triggered a speculative market in mergers. The economic environment at the end of the twentieth century was one of apparent prosperity, fueled by the creation of dot-com companies (the Millennium bubble). Lack of proper regulation, malfeasance, and overemphasis on short-term performance caused this bubble to burst.

The sixth wave (2002–2008) (Figure 1) was populated with mergers valued at more than $20 billion in value. Globalization and governments’ attempts to create national champions along with cheap financing were contributing factors. The global financial crisis of 2008 brought wave six to a halt.

Figure 1 shows domestic mergers for six major economies. These approximately mirror US trends, except for China where government policy has a greater impact on merger behavior. The dominance of domestic mergers in China reflects the fragmented nature of Chinese industry. Reorganization of and encouragement of growth by state enterprises played a strong role. In addition, high-technology firms were pushed to scale up, with a friendlier regulatory environment encouraging more mergers.

Explaining mergers and acquisitions

Although mergers vary by type, many theories try to explain the general nature of merger activity. Geography is generally not a primary consideration, although it likely influences the outcome. When undertaking a merger search, management will consider elements from both the internal and external environments of the firm. Internal factors include the general character of the firm, its size in assets or employment, its ability to generate expansion or operating capital internally, the current state of its production technology, allocation of resources among various products manufactured, and the adaptability and expandability of its organizational structure. Externally generated considerations include: competition in various product lines, present and potential size of market demand, production processes and technologies employed by competing firms, conditions in the labor and capital markets, government legislation related to the business environment, import tariffs and tax code changes.

Higher levels of merger activity are correlated with favorable economic conditions, such as high stock market prices, rapid new firm formation, and adequate funding sources. An amenable regulatory environment is often present, one of deregulation or lax enforcement. The process by which a firm decides to undertake a merger is complex. The firm lives in an uncertain environment that calls its continued survival into question. Its need for resources connects the firm to the outside world. To ensure access to resources a firm must itself adapt, or force others to do so. Merger is one
method of adaptation. The merger process is not a routine event in the life of the firm, and requires many nonroutine decisions.

The reasons for any particular merger reflect the reasons as described by theory but also idiosyncratic motives. The more regularly cited theories emphasize markets for corporate control, tax considerations, synergistic gains, and inefficient financial markets, market structure valuation gaps, or executive hubris. “Managerial motivations” are an additional consideration. These are outlined briefly here; a more detailed review can be found elsewhere (Cook 1988).

Explanations emphasizing the market for corporate control are premised on the argument that mergers replace inefficient management teams with more efficient ones. Takeovers are used by external groups that believe the firm could be made more efficient through an exchange of management. This is based on the supposition that the market’s valuation of the firm’s worth is an adequate measure of managerial efficiency: that is, that less efficient firms will be undervalued. The group successfully gaining control of the firm accrues the difference between the old value and the new value imputed by the market due to increased efficiency. This theory has some empirical support.

The free cash flow model applies when a firm has limited growth potential, and existing cash flow is more than necessary to undertake projects (Jensen 1987). Managers may undertake such acquisitions to reduce excess cash, or the acquirer may use the cash, along with dismantling some parts of the firm, to pay for the merger. Having no free cash on hand and being in debt makes a firm a less attractive target, as a potential acquirer cannot use cash obtained from the acquired firm to help pay for the merger.

For tax savings to be a motive, the merger must generate savings significant enough to offset the costs of the transaction. Warshawsky (1987) identified three principal sources of tax savings: a carryover of net losses, an increase in leverage, and a change in the tax basis in asset depreciation. The problem with identifying taxation as a primary motive for acquisition is that such savings may be obtainable through other means. Tax considerations are probably, at best, secondary considerations.

Synergy is among the most cited reasons for a merger. Synergy results when the profitability of a combined unit is greater than the profit that would have been realized had the merged units remained independent. Efficiency gains are realized at both plant and firm level. Empirical demonstrations of such gains are rare. Valuation gaps created by coordination gains are commonly called synergistic enhancements. Although the logic underlying the potential synergistic-type benefits accruing from mergers is secure, empirical evidence shows that expected performance gains are often not realized.
Mergers and Acquisitions

Mergers may also occur as a result of differences in management expectations or differing discount rates between the firms. Market structure valuation gaps revolve around the gains realized through reduced competition in an industry.

In managerial motives, managers enact a strategy of sales or growth maximization that induces merger activity. This type of behavior is fueled by reward systems related more to the size of the firm than its profitability. With management compensation schemes tied to absolute volume measures, a conflict of interest between inside managers and outside stockholders is definitely possible. Evidence shows that the empire-building or growth motive has played a leading role in the drive toward conglomerate mergers in the United States. Related to this is executive hubris and greed, whereby senior management overestimates its ability to manage an acquisition.

Eschewing any principal cause of merger behavior, Steiner (1975) derived a multiple-cause hypothesis. The model theorizes that certain merger motivating forces are always present. These motives are multiple, complex, and controversial. Once one of the motives is triggered, the merger process begins. History supports this view. To summarize, the motives and impacts of mergers are still not well understood. No general theory has been able to effectively explain all facets of merger activity.

Classes of merger activity

Four broad classes of mergers can be identified using the industrial relationship between the buyer and seller: horizontal, vertical, conglomerate, and reciprocal. These classes describe the fit of the acquired company to the current business carried on by the acquiring firm. This type of classification is particularly relevant to the geography of mergers because it helps define the spatial scope of the markets affected. Horizontal mergers involve expansion into similar or related product lines. Vertical mergers result in a logical and orderly arrangement of facilities in the successive stages of a continuous production process. Conglomerate mergers are more difficult to describe specifically. A merger of this type results in a heterogeneous mixture of parts. Reciprocal mergers require purchases by suppliers from a new acquisition. A brief exposition of each class is given here.

A horizontal merger leads to the elimination of a competitor, to an increase in the market share of the acquiring firm, and to an increase in concentration within the industry. There are two subclasses, which are sometimes considered conglomerate but are more properly horizontal. Market extension mergers involve the same products, but within a different geographical area. Product extension mergers involve buying a company that produces a similar but not identical product. Expanding control of a business activity in the same product line is an attempt to increase the firm’s dominance in its relationships with other firms, thereby reducing uncertainty. This strategy may be employed to expand geographically into unsaturated markets or to lessen local competition. Thus, it is horizontal mergers that are most commonly subjected to careful examination by regulatory bodies. The increased concentration generated by this process could, for instance, lead to inefficient pricing in the marketplace if firms coordinated their prices. Many studies of the impact of mergers on employment study mergers of this type.

The vertical merger expands a firm’s control into allied product lines. The acquiring company wants to increase its control over more sources of supply and distribution. A firm can expand vertically either forward or backward, integrating components into its existing business. By integrating forward, the firm attempts to ensure a
continuous demand for its product. For example, a paper producer might acquire stationery firms or publishing firms to guarantee a market for paper. Backward integration helps guarantee raw material, ensuring continuous supply and eliminating vagaries associated with dependence on independent suppliers. For example, a clothing manufacturer might acquire various textile mills to guarantee continuous input for its product.

Conglomerate mergers are diversification forays into unrelated areas, to reduce business risks. Often, conglomerate mergers occur when diversified firms are engaged in the production of goods in different industries with stable technologies. Other conglomerate mergers occur when diversified firms seek to make an efficient distribution network the linchpin of their strategy. The question arises, can conglomerate acquisitions foster a more efficient use of scarce resources? It is undoubtedly true that the potential economies available for horizontal or vertical acquisitions are unlikely to be produced by pure conglomerate acquisitions. However, scholars do identify sources of potential conglomeration economies.

A fourth class, the reciprocal merger, constitutes predatory behavior: an acquirer forces suppliers to purchase from its new acquisition. Such coercion might force competitors to the new acquisition out of business. These mergers are illegal under US antitrust laws due to their potential to reduce competition.

Mergers that entail a search for economies in producing services may also occur. These economies may arise from efficient use of certain inputs into the production of services, such as marketing and accounting systems. Productivity improvement may also result when assets are removed from the inefficient control of conservative managers by a company with dynamic, profit-oriented management. Capital economies may be derived from conglomerate mergers, as capital is transferred or allocated between many alternative components of the company with the objective of maximizing the rate of return while reducing uncertainty. The acquisition of management control makes mergers more attractive than portfolio management for risk reduction.

Cross-border mergers

The second type of geographically defined merger is cross-border mergers, a form of foreign direct investment (FDI). Cross-border mergers accounted for about one-half of all FDI in 2012 (UNCTAD 2013). Because these mergers cross international boundaries, the explanatory literature has identified additional possible rationales. The effects of distance, urban size, and information asymmetry, as discussed for domestic mergers, continue to be relevant.

Globalization is clearly a driving force of cross-border mergers. The pursuit of global firm scale and global markets compel transnational firms to strengthen their position. A cross-border acquisition is generally quicker and more cost-effective than pursuing a greenfield investment. International economic conditions may result in an undervaluation of target firms, making them attractive. The elimination of a local competitor also can be an additional benefit. Two major cross-border merger waves have occurred since 1990. The first wave peaked in 2000, with a value of about $900 billion; the second peaked in 2008 with a value of more than $1 trillion.

Geographical and societal implications

Each acquisition has consequences. Whether spatial or aspatial, they impact local and regional economies. The geographical component of mergers consists of two parts: spatial growth and locational adjustment. The former inevitably
means that new elements are added to a firm’s spatial structure. This spatial dimension complicates aspatial economic explanations, as it introduces an element of monopoly – control by a firm over the area surrounding it. This makes the impact of distance crucial, something that is inconsistent with the ideas of perfect competition and equilibrium integral to classical economic theory.

Most of the literature examining post-merger effects deals with the financial outcomes of the merger. Which shareholders benefitted and which didn’t? Was the merger a good decision? Much less common is a concern with how the change in ownership affects the level of economic concentration in a nation, or how a change to extra-regional control of a firm affects a region. The economic concentration concept deals most commonly with the possible negative effects.

Mergers can lead to a reduction in competition and to inefficient allocation of resources in the economy (FTC 1969). Although this has been a concern, evidence suggests that mergers have maintained current levels of corporate concentration rather than significantly increasing them. Measures of concentration in a particular industry may not be rising, but concentration may still be increasing because large firms now have representation in many industries. An allied concern is the political effect of economic concentration. The belief in the United States is that regions and municipalities should exercise control over their territory. Concentration of corporate power can threaten that autonomy. There is no question that large firms can affect local politics. Whether such involvement is good or bad is open to question. The geographic literature on headquarters relocations is relevant here: the geographic concentration of corporate headquarters is lessening even while corporate power is increasing.

Whether the overall outcome of any particular merger is negative or positive depends on its unique circumstances. Negative effects of absentee ownership or external control include declining employment; decreased power of local elites, creating a leadership void; a greater likelihood of plant closure; reduced expenditure on public institutions; increased infrastructure costs; lost tax revenue; and the risk that the acquired firm becomes a cash cow. Positive effects may include improved civic welfare (because of the participation of better-educated corporate managers); the provision of increased opportunities for local executive talent; and improvement in the tax base. In a rural industrialization setting, increased incomes, reduced income inequality, increased corporate philanthropy, and increased access to debt finance may occur.

Much of the concern with the geographic effects of mergers has been at the local community level and is merger-specific. There has not been any emphasis on a more general overview of mergers. Until recently, geographic merger studies have focused primarily on the United States. While following the templates of earlier studies, the newer literature now deals with Western Europe.

Little attention is given to macro-level-based analyses of the geography of mergers or of industrial class interrelations. Playing an important role in the growth of leading corporations, mergers provide a means by which small and medium-sized companies may create a stronger base for expansion and development. Mergers are formulated and completed in a complex economic system whose components are linked not only by transportation and communication systems but also by corporate structure and business relationships.

Most merger research is an examination of the relationship between mergers, market structure, and efficiency. Inadequate attention has been paid
MERGERS AND ACQUISITIONS

to the social implications of large corporations, and even less attention has been paid to that of mergers. Borrowing from Siegfried (1980), the social outcomes from market structure changes induced by mergers include the distribution of income and wealth and local community welfare. Mergers are a major component of changes in such outcomes because they may dramatically alter market structure.

Metadata

Barbara S. Poore
US Geological Survey

Metadata, or data about data, describe the quality, content, and origins of a geospatial dataset. In the early 1990s, geographic information systems (GIS) technologies were becoming widely used. However, digital data about objects and their locations on the Earth were scarce and expensive to produce. Reusing geospatial data and exchanging data with other organizations became public priorities. Managing legacy data or using data produced by others can be problematic because geospatial data structures are complex and GIS technologies are inherently transformational. Each transformation results in a changed dataset and subsequent users must be made aware of the origins of the data and the processes that were used to produce them. Metadata that provided this information were seen as a way to increase data sharing. It is important to note that, even though metadata are created by the producer of geographic information, their main audience is meant to be the data user.

The metadata standard

The Internet and the World Wide Web, which also emerged in the 1990s, made widespread distributed sharing of geospatial information feasible and amplified the need for machine-readable metadata that could be exposed to users. In 1994, the Federal Geographic Data Committee (FGDC) (www.fgdc.gov), a committee of US federal agencies formed to promote data sharing among organizations, adopted the content standard for geospatial metadata (CSDGM) (FGDC 1998).

Metadata had roots in cartography. Although a visual medium, the map was always closely associated with written text organized into distinct linguistic codes of identification and explanation. Most maps contain a map collar that lists the map scale, projection, publisher, and other information. Metadata is the digital equivalent of the map collar.

The FGDC offered three rationales for widespread adoption of the CSDGM:

- metadata could help organizations manage their investments in data;
- metadata would promote data sharing among organizations by providing information to online data websites and clearinghouses;
- metadata could help users understand datasets produced by others (FGDC 1998).

Metadata were essential to the establishment of the national spatial data infrastructure (NSDI), part of the national information infrastructure, a Clinton-era technology initiative. The NSDI was described as the “technology, policies, standards, human resources, and related activities necessary to acquire, process, distribute, use, maintain, and preserve spatial data through all levels of government, the private and nonprofit sectors and academia (www.fgdc.org).” The NSDI had four components, an online clearinghouse or catalog of datasets available from different organizations, metadata describing these datasets, a series of standards for different types of geospatial data, and framework data – a cooperatively produced
and maintained national set of basic data such as elevation, transportation, and hydrography that could be used as a background for more specialized analyses. Federal agencies were required, by Executive Order to document their geospatial datasets using the metadata standard beginning in 1995 (FGDC 2000).

The NSDI clearinghouse was based on the model of a library catalog. Different organizations stored metadata records on their own servers. The main clearinghouse site had a gateway interface allowing users to search for datasets. The gateway server would query the distributed clearinghouse servers using the Z39.50 protocol – a search and retrieval standard promoted by the library community – and metadata records would be returned to the user (Figure 1).

The structure of metadata

The CSDGM is essentially a metalanguage – that is, a language about a language. It is structured as a nested hierarchy of object-elements, in conformance to the library model which depends on structured text. The main sections of the standard are shown in Table 1 and Figure 2.

In addition, there are several supporting sections whose contents are reused in various places throughout the standard. These are citation, time period, and contact (Figure 2). The categories that make up the standard were largely drawn from previous efforts in the geospatial community to standardize terms with which to describe spatial data quality for data transfer and interoperability.

Each section of the standard contains one or more compound elements that, in turn, contain one or more subsidiary data elements (Figure 3). In addition, the standard defines each element, the values that are permitted, and production rules for how the elements are to be organized. Some elements are mandatory, some are mandatory if applicable, and some are optional. The production rules are derived from the standard generalized markup language (SGML), an international standard sponsored by the library community. The syntax and semantics of the CSDGM are expressed formally in Backus-Naur form, a method for specifying context-free grammars in computer science.

The CSDGM does not specify any metadata presentation method. Because the metadata content and production rules are written using a formal syntax, it is possible to write computer programs that allow for many different types of presentations. The hierarchical structure of the metadata, derived from SGML, lent itself to the emerging use of the extensible markup language (XML), a subset of SGML that became the standard metalanguage for defining markup languages on the World Wide Web. XML is self-describing, thus a document encoded in XML could be read by all web browsers. In a typical CSDGM implementation, each data element of the standard is enclosed within markup tags that a parser can read, interpret, and display. The tags would allow clearinghouse users to search for particular fields in the metadata, for example, keyword or spatial domain.

Adoption of metadata

Despite the mandate for federal agencies to document their datasets, adoption of the CSDGM was slow. The authors of the standard attempted to document every aspect of a generic geospatial dataset. As a consequence, the standard was long and complex, containing 334 different elements, of which 119 were compound elements that did not themselves contain values but expressed the relationships among elements. The length and complexity made it difficult to implement, especially for small organizations. There were attempts to adopt simpler forms of metadata. The Alexandria digital library (http://gcmd.nasa.gov/records/Alex-Dig_Gaz-00.html), for example, a distributed library of georeferenced collections established at the University of California at Santa Barbara in 1994 narrowed the CSDGM to 35 fields. Some organizations that serve geospatial data have adopted the Dublin Core metadata standard, an initiative of the library community to provide simple and generic resource descriptions (http://dublincore.org/metadata-basics/). The Dublin Core has only 15 elements, which may provide enough information to locate datasets in repositories, but not enough to fully evaluate their fitness use.

Paradoxically, many organizations also found they needed additional metadata fields for specialized data, for example, to fully document data from remote sensing instruments. There was confusion about the proper level at which to document data. Should one metadata record suffice...
to describe an entire collection of similar datasets such as a topographic data series? Should each individual dataset be documented? Or if objects in the dataset were frequently updated, should there be metadata at the level of the individual feature? The FGDC modified the CSDGM in 1998 to allow user defined profiles and extensions. This edition of the standard also somewhat simplified production rules (FGDC 1998).

The FGDC did not directly supply tools for implementing metadata. Some tools to automate a metadata workflow were supplied by interested volunteers. For example, Peter Schweitzer of the US Geological Survey wrote *mp*, a parser that allowed computers to read and display metadata in various formats, and also a document-type-definition (DTD) defining the markup elements for expressing the standard in XML (http://geology.usgs.gov/tools/metadata/tools/doc/mp.html). Due to a lack of mandate to document data beyond federal agencies, few commercial vendors initially supported FGDC-compliant metadata in their GIS software, making it difficult to collect metadata at the time of data creation.

**Metadata in the twenty-first century**

There are two trajectories for metadata in the twenty-first century. As the metadata standard was adopted it underwent changes, and technological developments questioned the complexity and user friendliness of the standard – but not necessarily the need for metadata. On the one hand, the CSDGM was internationalized and adopted by many large mapping organizations, becoming a baseline for other standards with a global reach, and encouraging the spread of spatial data infrastructures. Apart from the spatial data infrastructure movement, CSDGM was taken up by many communities of earth and environmental scientists, such as geologists, biologists, and oceanographers, to manage and provide access to scientific data that are not strictly geospatial but that may contain spatial footprints. These scientific communities frequently wrote profiles for the metadata standard that accommodated types of information specific to their disciplines. A profile for biological data is one example (http://www.fgdc.gov/standards/projects/FGDC-standards-projects/metadata/biometadata).

On the other hand, geographic information technologies and methods for sharing data online changed rapidly between the late 1990s and the present (Goodchild, Fu, and Rich 2007). These disruptive changes include the rise of open GIS standards and distributed GIS, the development of web mapping applications and services in the private and public sectors, the semantic web, and the rise of robust communities of volunteer mappers enabled by web technologies, mobile devices, and social media. Each of these changes depended on metadata, but also redefined metadata, posing challenges to the CSDGM.

**Internationalization of the standard**

The FGDC initially enlisted the ASTM (formerly the American Society for Testing and Materials), a formal US group that develops consensus standards for the engineering community, to publish the standard more widely. Meanwhile in the early 1990s, the European community, under the leadership of the French standards body the European Committee for Standardization (CEN) (www.cen.eu), developed a series of geospatial standards, including a standard for geospatial metadata. In 1994, this activity was absorbed into the newly formed Technical Committee 211 (ISO/TC-211) of the International Standards Organization (ISO) (http://www.isotc211.org). ISO is the world’s
largest developer and publisher of standards. It is comprised of networks of national standards organizations with one official voting member from each of 157 countries and participation from many other groups and individuals. ISO standards are developed by consensus through an open process, although unlike the CSDGM the standards are copyrighted and must be purchased. Since 1994, TC 211 has published more than 20 basic standards for digital geographic information. ISO 19115, Geographic information – Metadata (ISO 2014) was first published in 2003 and has been subsequently updated. Like the CDGSM, ISO 11915 is an abstract standard that does not deal with implementation. ISO 11915 adopted much from the CDGSM, but its current version has fewer mandatory and more optional elements, the ability to capture more specific information, for example about temporal accuracy, and support for the documentation of new geospatial technologies including geodatabases, web mapping applications, data portals, ontologies, and data models. The FGDC participates in the technical development process of ISO/TC 211 and worked with Canadian standards organizations to publish a North American Profile of ISO 19115. Agencies are currently in the process of implementing this profile.

Over the past twenty years, geospatial metadata standards have been critical to the development of a global spatial data infrastructure (GSDI) to facilitate data management and to post data to online clearinghouses and catalogs (http://gsdiassociation.org/). The first meeting of the GSDI Association was held in 1996 in Bonn, Germany. Its membership consists of organizations concerned with geographic information, including the European Umbrella Organization for Geographical Information (EUROGI), the FGDC, private corporations, and universities. The ISO metadata document is slowly being adopted by members of the GSDI; for example, the European Commission established a spatial data infrastructure for the European Community through its INSPIRE directive of 2007 (http://inspire.ec.europa.eu). The directive requires that member organizations document their geospatial data using the ISO metadata standard and post information to their data portal.

The Open Geospatial Consortium: portals and interoperability

In 1994, the Open Geospatial Consortium (OGC) (www.opengeospatial.org) formed a voluntary standards consortium with membership from commercial firms, governmental agencies, and academic organizations. This effort was an attempt to align the development of GIS software and standards with the concerns of mainstream information technology development, the World Wide Web, and the open source movement. OGC standards are developed through a consensus process and changes are subject to public peer review. OGC also participates in the development of international geospatial standards through ISO TC/211 and has endorsed ISO 19115, further spreading its influence throughout OGC’s constituent communities. The CSDGM and ISO 19115 are aimed at producers of geospatial data, providing them the means to share data through data catalogs based on the library model. As well as supporting both metadata standards, OGC also published standards for catalog services that specify how metadata should be organized in online catalogs (http://www.opengeospatial.org/standards/cat). Current online geospatial catalogs give access not only to geospatial data, as the NSDI clearinghouses did, but also to online services for displaying, editing, and analysis of geospatial data. These collections of data and services have come to be known as geoportals.
Geoportals are organized differently than the NSDI clearinghouse. In the clearinghouse, the metadata resided on distributed servers that could be searched simultaneously. In a geoportal, metadata about geospatial datasets and services are periodically harvested from distributed servers and placed in a searchable central catalog.

Following trends in the larger world of information technology, OGC emphasized interoperability or the ability of the end user to seamlessly integrate data of different types, produced by different distributed systems, independent of the technical details of how the data were produced or exchanged. There are many ways in which computers must communicate to achieve interoperability in the geospatial realm: network protocols, hardware and operating systems, spatial data files, database management systems, data models, and semantics. A failure of interoperability occurs if machines cannot talk to each other on any of these levels. Complete interoperability continues to be elusive; however, over the past 20 years OGC has produced consensus standards for many of these levels of interoperability, including standards that prescribe how metadata about geospatial data services can be passed among machines.

Disruptive ideas, disruptive technologies

The standards consensus process is time consuming and the culture of technology innovation does not always wait for standards. The year 2005 was a watershed for mapping on the Internet. In late 2004, Google acquired Keyhole, a company funded by the venture capital arm of the US Central Intelligence Agency. Keyhole technology allowed users to virtually “fly around” geographic areas over the Internet. In early 2005, Google launched Google Maps and, later that year, using the technology acquired from Keyhole, Google Earth. Also in 2005, Google provided developers with access to the application programming interface (API) of Google Maps. This meant that map and data services could be delivered over the Internet and used in webpages. That same year saw the crystallization of ideas about a second generation World Wide Web dubbed Web 2.0. Collective intelligence or the notion that the intelligence of “the crowd” was more powerful than any one person alone was advertised as the major feature of Web 2.0. Web 2.0 also signaled a switch from users’ passive consumption of information to active creation. The GeoWeb is a manifestation of Web 2.0. Civilian access to GPS signals, the availability of geospatial APIs, the increasing maturity of open-source geospatial software, and the rapid spread of geo-enabled mobile devices have made it easier for non-experts to access, use, and create geospatial data online. A culture of collaborative online mapping by users who are not GIS professionals has emerged. OpenStreetMap (OSM) (www.openstreetmap.org), an online map of the world collectively developed by millions of users, was also begun in 2005. These technical and conceptual shifts multiplied the uses for some forms of metadata while enabling great quantities of geospatial data to be placed on the Internet without formal content metadata.

Machine-based metadata

Standardized metadata describing protocols and services is essential to the operation of the Internet. Metadata is thus the primary means of negotiations between machines. In the current GeoWeb, programmers can request map images over the Internet in real time from APIs on a server. For these images to travel between machines, it is not required that they have content metadata conforming to the CSDGM, however, the requests themselves are a form of metadata — machine-based metadata. For
example, a program can be written to query the server to ascertain what capabilities the server has through a “GetCapabilities” request expressed in XML. The request specifies parameters describing the service type and name of the request among other things. The server responds to the requesting computer with metadata describing the service, permitting other actions.

The GeoWeb runs on machine-based metadata that has been standardized, often by OGC, but also through de facto standards, that is, standards that have emerged through accepted use rather than being negotiated from the top. Google’s keyhole markup language (KML), an XML notation for displaying map images for use in 2-D and 3-D browsers, was submitted to OGC and adopted in 2008, but it has limited support for content metadata of the ISO or CSDGM type. Google also presents sparse details of the source or quality of the map data it collects and displays to the users of its map applications.

User-centric critiques of metadata

Many current GIS software packages now store content metadata records along with the dataset, allowing users to read the metadata in ISO or FGDC formats. This may make metadata more accessible to end users of these professional systems but researchers have also argued that metadata needs to be even more user centric and include the effects of uncertainty on uses of the data, quality descriptions that can be understood by non-experts, and tools to allow users to determine the effects of data quality on results (Goodchild 2007). In the GeoWeb, databases are likely to contain elements mashed up from many different sources, arguing for more attention to metadata that tracks the changes to each feature. Since producer and user do not communicate directly, metadata must contain information about the semantics of a dataset, or what the objects mean (Comber, Fisher, and Wadsworth 2008). However, current metadata standards, even when they are used, do not accommodate data semantics. Schuurman and Leszczynski (2006) proposed additional metadata fields for the ISO and CSDGM that would be sensitive to semantics and contain qualitative ethnographic data descriptions to elicit the meanings of data objects.

Interactive metadata

Most of the user-generated geospatial data in the GeoWeb, often referred to as volunteered geographic information or VGI, do not contain standardized content metadata, limiting their usefulness in the eyes of many. OSM, as a prime example of VGI, has been studied from the standpoint of data quality. In the United Kingdom, OSM has been compared to Ordnance Survey datasets showing that, in more heavily edited areas, the quality is comparable to the reference dataset (Hakley 2010). Others have taken what little metadata is provided in the OSM database to infer data quality. A distinctive feature of the wiki software that underlies OSM is that all edits are maintained in the database, giving the user a detailed idea of the history of changes over time. Each node in the dataset carries its own metadata about when and by whom it was edited. These metadata also include location and various user-supplied tags that indicate the type of object, the source from which the node was derived, and the other nodes with which it is associated. Researchers have demonstrated that the quality of any object in the OSM database may be inferred from the contribution patterns, the reputation of the user-editor, and the number of nodes with many edits. Each of these methods for assessing data quality depends on the assumptions of collective intelligence. That is, that more eyes on each node will improve
its quality over time. This may be true, but it may also be an incorrect assumption due to the inherent biases of the user-editor base for VGI, which is heavily young and male, and also to some documented occurrences of sabotage.

There is also a vast realm of ancillary data describing OSM, explaining how to use it, and facilitating community discussion and debate. These data are quite diverse, consisting of computer programs, tiling schemes, Internet relay chat (IRC) chat rooms, YouTube video demonstrations, tweets, e-mail discussion groups, and the wiki pages. All of these are socially mediated, produced by the community, and accessible to any user. While this is not metadata in the accepted sense in the professional geospatial community, it is a body of data that could be analyzed by data mining techniques to produce a different kind of bottom-up metadata for VGI projects such as OSM. Potentially this is the next research frontier for metadata. An exploration of these ancillary metadata could inform research into how to better present data quality to the end user for more traditional forms of metadata.

Website: http://smge-mexico.blogspot.mx
Membership: 55 academies and 33 members
President: Álvaro Sánchez Crispín
Contact: asc@igg.unam.mx, zamojj@igg.unam.mx

Description and purpose

The founding president was Justo Gómez de la Cortina who was interested in sciences, arts, letters, and socioeconomic studies. The initial principal objectives were to construct a map of the republic, published in 1850, to set up national statistics to consolidate the country as an independent nation, and to analyze the principal problems of the country in order to present alternative solutions to authorities. These actions permitted the establishment of laws to determine the geographic names of cities and settlements. They also promoted conservation of forests and archeological monuments, physiographic exploration of the territory, natural resources and their potential, and demographic, ethnic, and linguistic studies of the population.

Journals or major publication series

Boletín de la Sociedad Mexicana de Geografía y Estadística

La Carta General de la República Mexicana (The General Map of the Republic of Mexico)

Current activities or projects

The principal current function of SMGE is the diffusion of culture across the separate academies and their affiliates in the states of the Mexican Republic. The Academy of Geography is one of the most active and is in charge of organizing national congresses of geography every two years and symposia on the teaching of geography in Mexico. These events are supported by fees of its members, registration of participants in the events, and assistance from local and state governments, and/or institutions of higher education where meetings are held.

Through the Academy of Geography SMGE has fostered academic excellence since 2000 with a yearly prize for the best bachelor’s thesis presented in oral examination as well as a yearly award for MA and PhD theses presented in oral examination. It also presents the Benito Juárez Geographic Medal of Merit to a distinguished member of the geographic community of Mexico.

Brief history

SMGE started its activities as the National Institute of Geography and Statistics between 1833 and 1839, and then as the Commission of Military Statistics between 1839 and 1849, until changing its name to SMGE at the end of 1850. It is recognized as the first institution to organize scientific investigations in Mexico.
and the first institutional body for the development and practice of geography in Mexico. Francisco Díaz Covarrubias, a distinguished member, was the founder of the first astronomical observatory in Mexico. SMGE represents the strategic value of science for the development of governmental projects. Its successful scientific history stems from its relation with powerful state agencies that were charged with creating bodies and institutions to professionalize their activities and generate scientific and intellectual results to support the earth and social sciences and the humanities. SMGE currently has close to 40 divisions. The SMGE Bulletin enables and supports diffusion and development not only of geography and statistics but also of astronomy, chemistry, natural sciences, medicine, archaeology, linguistics, literature, and history.

Microbial biogeography

China A. Hanson  
Queen Mary University of London, UK

Biogeography is the study of the distribution of biodiversity over space and time, including the presence, absence, and abundance of species. It offers insights into the ecological and evolutionary mechanisms that generate and maintain diversity, such as selection, dispersal, speciation, extinction, and species interactions. An understanding of species distributions and the mechanisms underlying them has implications for the management of the environment and its resources, for example, the ability to predict ecosystem responses if species ranges shift due to disturbance. Natural scientists have investigated the geographic distribution of plant and animal diversity for centuries. However, the biogeography of micro-organisms (here, defined as bacteria, archaea, and the smallest eukaryotes) has gained interest only in recent decades, driven in part by the development and application of molecular genetic methods that make it possible to sample and characterize microbial diversity independent of culturing. These methodologies also revolutionized our understanding of the sheer magnitude of microbial abundance and diversity on Earth, and an increasing number of microbiologists have turned to the field of biogeography as a useful theoretical context by which to interpret the factors controlling this immense diversity. Further, understanding the distribution of microbes is fundamentally of interest because microbial activity has many important ecosystem-level and societal consequences, including nutrient cycling, primary production, decomposition, parasitism, and disease.

The Baas Becking hypothesis

A central theme in microbial biogeography has been the so-called Baas Becking hypothesis, which states for micro-organisms, “everything is everywhere—the environment selects” (Baas Becking 1934). The claim “everything is everywhere” is based on assumptions that micro-organisms are so numerous, small, and resistant to changing conditions that they can effectively travel or disperse, rapidly and unhindered by passive means, to every point on Earth. In other words, their distributions are not limited by dispersal. The claim that “the environment selects” implies that different environmental conditions allow for selective growth of microbial taxa that are adapted to those conditions. Therefore the Baas Becking hypothesis predicts that, if distinctive microbial assemblages exist in different locations, this is due to the environment selecting adapted taxa from a globally available pool of diversity.

In recent decades, the Baas Becking hypothesis has generated much controversy, which likely helped spark a new generation of research expanding our understanding of microbial diversity. One reason the hypothesis became so debated is that the postulation that “everything is everywhere” suggests that microbes are not dispersal-limited, and therefore, unlike most plants and animals, there are no barriers to the mixing of microbial populations. Without such physical isolation, classic concepts of

biogeography, ecological organization, and even speciation would be fundamentally different for microbes as compared to larger organisms.

Some of the first modern studies to describe the large-scale biogeography of any microbe, and thus attempting to test the Baas Becking hypothesis, found evidence in favor of “everything is everywhere.” These studies detected (i) virtually all globally known species of a particular group of eukaryotic microbe (defined by phenotypic identification techniques to group to the genus or near-species levels) within a single location, and (ii) these same species across a range of widespread and varied habitats (reviewed in Finlay 2002; Fenchel and Finlay 2004). This suggested that such microbes were indeed globally distributed, corroborating the first part of the Baas Becking dictum.

A wave of subsequent biogeographic surveys sought to challenge these results, further testing the ideas of the Baas Becking hypothesis for many different types of microbes in a variety of habitats, including soils, sediments, hot springs, marine, and freshwaters (as reviewed by Foissner 2006; Martiny et al. 2006; Lindström and Langenheder 2011; Hanson et al. 2012). Most of this work took advantage of newly available molecular genetic methodologies, allowing a more sensitive detection and characterization of microbes in environmental samples without the need for culturing or reliance on phenotypic techniques. Culture-independent methods also meant that more samples could be processed at once, so that the distributions of diverse microbes could be characterized at large scales in a statistically robust manner. Collectively, microbial biogeographic studies to date have generated much data, establishing that microbial communities are highly variable in space and time. However, whether this is due solely to environmental selection (as implied by Bass Becking), or whether dispersal limitation also plays a role, remains an ongoing debate, and much research in the field is currently focused on understanding the relative importance of these processes in controlling microbial biogeographic variation.

The processes shaping microbial biogeography

While the Baas Becking hypothesis provided a stimulating initial proposal for the processes potentially driving microbial biogeographic distributions, namely dispersal and environmental selection, a more comprehensive framework for understanding microbial biogeographic mechanisms has recently been adopted (Martiny et al. 2006). This framework borrows from a traditional biogeography perspective, which divides these processes into the effects of current environmental factors and the legacies of historical processes, both of which have an influence on the distribution of animals and plants (Ricklefs 2007). The contemporary environment includes abiotic variables (e.g., temperature, pH, nutrient availability) as well as biotic factors such as the interactive effects of other organisms. This is the same concept as that implied by the “environment selects” portion of the Baas Becking statement. Historical events include anything from the very recent to the geological past that might have influenced present-day distributions and caused differences in composition between locations, such as past environmental conditions, speciation and extinction, and evolutionary or ecological drift (stochastic changes in the composition of genes or communities). To observe evidence of historical processes, however, there must be dispersal limitation of some microbial taxa in the community; otherwise the effects would be long since homogenized, and microbial composition would only depend
on the current environment. This dispersal limitation allows for the effects of events in the recent or distant past to have a current signature on the microbial taxa present in a location. Thus, such a framework provides a more comprehensive way to evaluate the same notions proposed by Baas Becking, essentially the relative importance of environmental selection and dispersal.

**Evidence for the importance of contemporary environmental factors**

To assess the importance of environmental selection on microbial composition, many microbial biogeography studies examine the correlation between community composition (the identity and relative abundance of taxa) and measured environmental variables over space and/or time. For example, numerous studies have linked spatial variation in microbial communities to variation in pH or salinity (e.g., Fierer and Jackson 2006). Other studies have demonstrated that broadly defined habitat types, which are a proxy measure for a range of associated environmental variables, harbor significantly different microbial communities (e.g., Nemergut et al. 2011). Additionally, seasonal or temporal variation in microbial communities is increasingly being recognized, and such trends tend to be significantly correlated with temporal variation in environmental variables (Fuhrman et al. 2006; Gilbert et al. 2012). Nearly every microbial biogeography study to date observes some such relationship between similarity in community composition and similarity in environmental characteristics of those samples (Hanson et al. 2012), providing support for the importance of variation in environmental conditions in explaining why microbes are not uniformly detected in time and space.

**Evidence for the importance of historical factors**

In contrast, biogeographic variation in microbial community composition may arise because not all taxa can disperse to or establish in all locations equally, revealing differences based on the history of events at a location. Assessing the importance of historical factors in shaping biogeographic patterns is not straightforward, however. Because the movement and establishment of microbes are difficult to observe directly, the degree of dispersal limitation for microbes is often interpreted from the observed correlation between microbial community composition and geographic distance, after removing the influence of contemporary environmental factors. Since environmental variation is often spatially structured, as in an environmental cline or gradient (e.g., salinity or elevation), controlling for this environmental variation, either experimentally or statistically, is crucial to testing for the influence of historical factors.

When studies use this approach, some find a correlation between microbial composition and geographic distance after removing the effect of the contemporary environment (e.g., Cho and Tiedje 2000; Whitaker, Grogan, and Taylor 2003; Martiny et al. 2011). For instance, Whitaker, Grogan, and Taylor (2003) found clear genetic differentiation between hyperthermophilic archaea from geothermal hot springs on different continents. Significant genetic divergence between localities is not just a demonstration that the genetic diversity of microbes varies in space but also evidence that the sampled microbial communities are not completely mixed by dispersal of individuals between them – that is, that the communities are isolated from each other due to dispersal limitation.

A handful of studies have provided evidence that historical factors, manifested by some dispersal limitation, can indeed be responsible for
creaing biogeographic patterns in microbes. At the same time, other studies find no evidence for dispersal limitation in micro-organisms (e.g., Finlay 2002; reviewed in Hanson et al. 2012). Thus, a current question in the field is to determine when and where dispersal limitation in micro-organisms is more likely. In addition, if there is dispersal limitation, it remains to be investigated what historical processes are responsible (e.g., drift, speciation, extinction, or past environments).

Caveats to the interpretation of microbial biogeographic patterns

A balance between both contemporary environmental factors and historical processes likely shapes natural microbial communities. However, unraveling the importance of environmental selection, dispersal, and historical factors from observations of biogeographic patterns is not straightforward. First, these processes are likely highly intertwined over multiple scales of time and space (Ricklefs 2007), and pinpointing the singular influence of any particular process within natural communities will be difficult. Additionally, little is known about the ecology of the majority of microbial taxa in nature, so it is quite likely that many important selective factors go unmeasured. If any selective habitat features go unmeasured, they can cause a false relationship between microbial composition and geographic distance, and lead to a potentially incorrect conclusion that the biogeographic pattern is shaped by historical factors.

It is important to consider that the ability to detect biogeographic patterns and the importance of particular underlying processes may depend on various methodological aspects of the study, including the target microbial group and methods used to define taxa, as well as the environment type and spatial and temporal scale examined (Hanson et al. 2012). Microbial taxa likely vary in traits that affect their dispersal and colonization abilities (e.g., spore formation and dormancy stages) or their response to the environment (specific growth requirements versus more generalist strategies), thereby influencing their distributions. Similarly, studies using less sensitive techniques to define taxa may group together collections of microbes that differ widely in traits, making distributions appear more widespread and weakening correlations with environmental factors. Additionally, the importance of dispersal may depend on habitat type, as microbial communities associated with nonfluid (e.g., soils) or “patchy” habitats are expected to be more limited by dispersal than those in highly connected or well-mixed systems, such as the open ocean. Similarly, the likelihood of dispersal is expected to decrease as the distance between locations increases, and thus the importance of historical factors may emerge only at larger spatial scales. Last, because many microbial communities are temporally or seasonally variable, spatial biogeography studies should ensure that the timing of sampling is comparable across samples.

Finally, there are many unique aspects of micro-organisms and their communities that make it challenging to study their biogeography. Microbial communities are exceptionally diverse, consisting of a large proportion of taxa that are so rare (Sogin et al. 2006) that they will not be detected. Thus, characterizing the full complement of all taxa in a sample, or proving the absence of a microbial taxon within highly diverse natural samples, is nearly impossible with currently available techniques. Therefore, we may never be able to prove or disprove whether “everything is everywhere.” It is equally difficult to determine whether observed microbes are actually active in a given sample, and therefore
recognizing their surroundings as a suitable habitat. Certainly, many microbes are capable of dormancy, and evidence suggests that many taxa detected in environmental samples are dormant (Lennon and Jones 2010). Thus, without being able to determine activity from dormancy, the true habitat range of some microbes may not be distinguishable from a ubiquitous distribution.

Conclusions

Evidence suggests that many microbes exhibit biogeographic patterns, and that these patterns are likely shaped by a combination of both environment and history, similar to animals and plants. While at least some microbes appear to be dispersal-limited, it is often secondary to the influence of the contemporary environment. Thus far, these conclusions are broadly similar to larger organisms, although the relative strength of the underlying processes and relevant environmental factors may vary. But, given the immense diversity of microbes and their ecological roles, the distributions of all microbes are probably not uniformly shaped by the same mechanisms in the same ways. Thus the future of microbial biogeography lies in identifying the conditions under which the relative importance of these underlying processes may vary.

The interest in microbial biogeography extends beyond drawing and interpreting a map of microbial diversity. It aids in shedding light on countless microbiology questions and applications, for example, how much and on what scales to sample microbial diversity; the nature of microbial diversification or speciation; the function of microbes in ecosystems or in association with other organisms; and how to design and manage microbial communities with industrial applications such as wastewater treatment or biofuels. At the same time, given the unique qualities of micro-organisms, their varied roles, and their astounding abundances, they likely have much to teach us generally about the organization of life on Earth.

**MICROBIAL BIOGEOGRAPHY**

Further reading

Microclimatology is a subfield of climatology that focuses near the ground where most living organisms exist and where most human activities occur. Microclimatologists are particularly interested in measuring and understanding exchanges of energy, mass, and momentum between the lower atmosphere and components of the Earth’s land surface, including the soil, vegetation, and surface water. As such, there are numerous applications for microclimatological information in fields such as ecology, agriculture, forestry, hydrology, zoology, air pollution studies, and urban planning.

The beginnings of microclimatology as a field are frequently attributed to pioneering work by Theodor Homen in the late nineteenth century. Homen investigated the differences in energy budgets among various types of soils. His careful observations demonstrated the wide variations in temperatures and humidities at different levels above the surface over the course of a day. Gregor Kraus, a German botanist and plant ecologist, is described by Rudolf Geiger as the “father of microclimatology” for his published text titled *Boden und Klima auf kleinstem Raum (Soil and climate at the smallest scale)* in 1911. This text provides a detailed account of the relationship between plants and microclimate conditions. In 1927, Rudolf Geiger published the first comprehensive book on microclimatology *Das Klima der Bodennahen Luftschicht* (1927) or the *Climate Near the Ground* (published in English in 1965).

The scale of microclimatology

Microclimate phenomena can be identified within certain temporal–spatial scales, although there is no exact consensus on the exact thresholds. Microclimates are often considered as ranging horizontally from $10^{-2}$ to $10^3$ m, so that they might encompass conditions under a rock, on a single plant, within an alley in an urban environment, on an agricultural field, or hillside. Scales slightly larger than this, ranging from $10^2$ to $10^4$ m in magnitude, are often referred to as “local scale.” The depth scale of microclimate phenomena is generally limited to phenomena that occur within the planetary boundary layer (PBL). The PBL is the layer of the troposphere that interacts closely with the Earth’s surface and where turbulence plays an important role in energy exchanges. On average it is about 1 km in thickness but its size is dynamic ranging from as low as 20 m at night up to 5 km during the day. Some limit the scope of microclimatology to phenomena in the surface layer, which is approximately the lowest one-tenth of the PBL ($<10^2$ m) and the zone where most biological activities occur or an even shallower layer called the roughness or canopy layer ($<10^1$ m). Similar to the latter depth scale, Miller (1965) defines the microclimate zone as extending to the top of the forest canopy to the rooting depth of plants. Finally, the timescales of relevance depend on the spatial scale examined, with processes $<24$ h...
within the PBL and as low as 1 s for processes at the lower end of the spatial scale (e.g., <10^-2 m), such as on a leaf.

Microclimatology is closely related to the field of micrometeorology, utilizing the same spatial scales and similar physical processes occurring near the Earth's surface. An important distinction, however, is that micrometeorologists are particularly interested on short-term fluctuations and averages of usually an hour or less while microclimatologists tend to focus more on longer-term statistical measures of meteorological variables, such as at diurnal and seasonal scales, as well as on long-term trends in those variables.

**Physical processes in microclimatology**

In considering physical processes that create different microclimates, the “active” surface is of fundamental consideration. The active surface is the boundary between two media such as air and land, and Oke (1987) notes that it is the principal zone of climatic activity for: energy absorption, exchanges, and transformations; precipitation interception; and where much of the drag on airflow occurs.

The energy balance across this mass-less plane can be defined as:

\[
Q_{net} = Q_h + Q_l + Q_g \quad (1)
\]

where \(Q_{net}\) is net radiation, \(Q_h\) is sensible heat, \(Q_l\) is latent heat, and \(Q_g\) is ground heat flux. Net radiation is the difference between incoming solar and longwave radiation and reflected solar and outgoing longwave radiation. Incoming shortwave radiation varies temporally due to Earth–sun relationships and sky conditions, and incoming longwave radiation varies with atmospheric humidity and cloud cover. Outgoing longwave radiation is controlled by surface temperature and emissivity (>90% for most terrestrial surfaces). Reflected solar is a function of changes in surface albedo, with values ranging from about 5% for a dark wet soil up to 95% for a surface with freshly fallen snow.

The partitioning of surplus or deficit \(Q_{net}\) at the surface plays an important role in microclimate conditions. It is dictated by surface conditions and the ability of the atmosphere to transfer heat. Surplus \(Q_{net}\) during daytime hours is typically removed via convection of \(Q_h\) and \(Q_l\) away from the surface and the transfer of \(Q_g\) into the ground. At night, deficits in \(Q_{net}\) lead to downward transfers of \(Q_h\) and \(Q_l\) to the surface and upwards fluxes of \(Q_g\). Convective exchanges will be increased with greater mechanical and convective turbulence. The exact partitioning between \(Q_h\) and \(Q_l\) depends on surface moisture availability with greater \(Q_l\) relative to \(Q_h\) over wetter surfaces. \(Q_g\) is transferred through conduction and its magnitude depends on the thermal conductivity, which is related to soil type, density, and water content. Of course, the relative importance of these different energy transfers depends on the scale of study. A microclimatologist studying small objects likes leaves or animals, for instance, would focus on radiative and conduction as the principal energy transfer mechanisms.

The water balance at the microscale for a volume can be considered as:

\[
P = E + \Delta r + \Delta s \quad (2)
\]

where \(P\) is water input (e.g., precipitation, irrigation, or dewfall), \(E\) (evapotranspiration), and \(\Delta r\) (net runoff) are outputs, and \(\Delta s\) (net change in soil moisture content) is water storage. Net runoff is often negative over steep slopes, indicating a loss of water from the volume. Variations in soil moisture play a particularly important role in the surface energy balance and partitioning of energy exchanges by altering surface albedo, soil
thermal properties, and the relative importance of latent versus sensible heat exchanges.

Aside from water, mass balances of carbon, nitrogen, and oxygen may also be considered at the microscale with important implications for ecosystem processes. The magnitude and rate of biogeochemical cycling may be altered on microscales by local environmental conditions. Factors such as soil temperature and moisture, for instance, may affect respiration rates from roots and microbial organisms, and therefore carbon cycling. Similarly, locally produced carbon dioxide (CO₂) emissions within urban microclimates have altered the carbon cycle, creating urban CO₂ domes.

Finally, momentum exchange within the microclimate zone affects the amount of turbulence and the transport of mass (e.g., water vapor, aerosols, air pollutants) and energy. The wind field near the ground is strongly influenced by the frictional drag from the underlying surface. Wind speeds decrease sharply close to the ground due to the increased friction, giving rise to a logarithmic profile with height. Variations in surface roughness and atmospheric stability may alter the wind speed profile. Under neutral atmospheric stability, rougher surfaces such as a city center tend to increase the depth of the PBL and produce wind speed profiles that have lower vertical gradients. Eddies may be created by mechanical turbulence near the surface due to surface roughness and vertical wind shear. At greater heights above the ground (>2 m), the relative role of convective turbulence in momentum transfers increase and is controlled by atmospheric stability.

Factors that create microclimates

A variety of natural and anthropogenic conditions can alter the water and energy budgets within a given area to create diverse microclimates within the broader macroclimate environment. Topography is a particularly important factor and can alter microclimates by influencing inputs of solar radiation and the creation or modification of airflow. Differences in the slope and azimuth angles can affect solar radiation intensity and therefore create differences in radiant heating across the landscape. In the Northern Hemisphere mid-latitudes, for instance, south facing slopes may receive considerably more solar radiation than north facing ones. These energy differences can be particularly important in influencing the distribution of plants and animals or dictating favorable locations for agricultural activities.

Topography can also alter many elements of the local water budget. Steep slopes, for instance, favor increased runoff while other topographic configurations may encourage local ponding and wetter conditions. The interception of precipitation at the microscale is controlled by interactions between local winds and topography. More exposed locations may receive less precipitation during windy periods with small rain droplets as they are deflected downwind to more protected locations. Also, under windy conditions, the interception of precipitation will vary based on the angle of incidence of the falling rain droplets. Slopes that are oriented towards and more normal to the wind-induced trajectory of the droplets will receive more accumulation. Finally, topography can influence snow mass balances via differential heating and wind redistribution of snow to more sheltered sites.

Local winds can be created by topographic variations. These winds are best developed under weak synoptic forcing, such as during periods with anticyclonic circulation. During the day, the air above the slopes and floor of the valley will be heated, creating a circulation with upslope (anabatic) flow along the valley.
sides. At night, cold air flows downslope under
gravity and may create cold pockets in low lying
portions of the landscape. Temperatures increase
upslope until the top of the pool of cold air is
reached in a zone called the thermal belt. Above
this point, adiabatic cooling with height occurs.
The thermal belt provides a favorable location
for crops such as vineyards that are sensitive to
low temperatures.

The presence of a vegetation canopy can alter
the energy budget as well as modify air flow. The
particular influence on mass, momentum, and
energy transfers, however, depends greatly on
the stand architecture and variations in foliage
density. Some plant communities like grasses and
cereals show little difference in foliage density
with height while others may have the foliage
concentrated near the top (e.g., many trees, sun-
flowers, maize), the base, or at many layers (e.g.,
rainforest). Most commonly, the presence of a
vegetation canopy alters wind speeds by displac-
ing the active surface above the ground, so that
wind speeds go to zero at some location within
the canopy. This height is referred to as the zero
plain displacement and is often located at about
two-thirds of the height of the canopy. Weak air
motion, then, generally occurs at levels below the
active surface. Of course, there are many scenar-
ios where conditions may vary from this gener-
ality. For instance, forests without a well-defined
understory may channel winds beneath the
canopy to foster greater wind speeds than those at
higher levels and gaps and openings in vegetation
can lead to complex local wind patterns.

Radiative exchanges are also considerably
affected by the presence of vegetation. Solar
radiation penetrating to the floor is reduced
as it is absorbed and reflected by the foliage.
The magnitude of reduction is related to the
characteristics of the foliage, such as density and
height, the particular species, and solar angle.
Approximately, 80–95% of the insolation may
be attenuated in a mature stand of trees. Further,
the amount of light penetration may change
seasonally with leaf development and loss in
deciduous forests. Longwave exchanges beneath
the canopy consist of downward emissions of
longwave radiation from the atmosphere and
vegetation, and outgoing transfers from the
canopy floor. As the canopy becomes denser, net
losses of longwave radiation from the ground are
reduced because of the smaller sky view factor.
Thus, reduced solar heating during the day and
radiative cooling at night, tend to moderate the
climate under plant canopies. Plant canopies can
alter the water budget by intercepting a portion
of precipitation. The amount of interception, for
instance, ranges from 10 to 25% for deciduous
forests and from 15 to 40% for coniferous forests.
As intercepted moisture is evaporated from the
canopy, it does not recharge soil moisture or
provide runoff into streams.

Finally, human activity has transformed the
landscape by replacing natural surfaces with
homes buildings, sidewalks and roads. These
new surfaces considerably alter surface energy
and water budgets, creating new “urban” micro-
climates. Urbanized areas tend to have low
permeability surfaces where precipitation is
quickly lost. Evaporation is reduced because
of less vegetation and moisture storage. Urban
locations are often warmer than neighboring rural
areas, especially at night, due to alterations of the
energy budget. Some of the warmer conditions
are attributed to anthropogenic sources of heat
released from manufacturing, transportation,
and the heating of homes and offices. Also, the
reduced sky view factors associated with buildings
minimizes losses of longwave radiation. The
reduced water storage means more surplus energy
is partitioned into sensible heat (i.e., raising
temperatures) than into latent heat (i.e., phase
changes). Lastly, urban environments tend to have
greater heat storage, which is released in the late
afternoon and evening, elevating temperatures. The presence of buildings and other structures may alter wind speeds within the urban canopy. Generally, the increased roughness will reduce wind speeds relative to those in a rural environment. However, strong winds can be generated in response to channeling of air flow or due to the urban heat island effect which can create pressure gradients drawing air towards the city center.

Microclimatological instrumentation

Microclimatologists frequently use in situ instrumentation to measure surface meteorological conditions and fluxes of energy, mass, and momentum. The focus here will be on the instruments used for the most commonly measured variables of air temperature, humidity, wind speed, and short and longwave radiation. For each meteorological variable, there are often multiple instruments with different response times and degrees of precision. The most suitable instrument depends on the intended application and use.

Air temperature can be measured with mechanical (liquid-in-glass) or electronic (thermocouples and thermistors) thermometers. Air temperature sensors should be shielded from direct solar radiation in a ventilated shelter. Ground surface temperatures or objects such as leaves can be measured with an infrared thermometer. Hygrometers use multiple approaches to obtain a value for atmospheric moisture (e.g., air temperature/psychrometric or variations in the electrical, chemical, or radiative properties as water vapor changes in concentration). Psychrometric and electrical hygrometers are commonly employed for routine measurements of humidity. Hygrometers such as the infrared gas analyzer, which consider the absorption spectra of water vapor, are particularly useful when very accurate observations must be made in short time increments. Similarly, multiple approaches (e.g., mechanical, pressure, thermoelectric, acoustical) are used to obtain wind speed measurements. The cup anemometer (mechanical) is the most commonly used for average horizontal wind speeds. For studies of phenomena like turbulence occurring on short timescales, pressure devices and acoustic anemometers are often employed. Radiative fluxes are measured with many different devices, including pyrradiometers (net radiation), pyranometers (solar radiation), pyrheliometers (direct beam solar radiation), and pyrgeometers (longwave radiation). Reflected shortwave radiation for computation of albedo can be obtained by placing the pyranometer so that it faces the ground. Additionally, a shade ring or “occuling ring” can be used to measure diffuse solar radiation by obscuring the sensing surface from direct beam radiation.

These instruments are often mounted on a tripod or tower to obtain a profile for computing vertical gradients of meteorological variables. Flux-gradient methods utilize these profiles to quantify energy and mass transfers. An alternative approach, called eddy fluctuation or eddy covariance, attempts to directly measure the properties of turbulent eddies as they pass the sensors to obtain energy and mass transfers. Eddy fluctuation approaches provide high quality estimates but require very sensitive instrumentation.

Ongoing developments in microclimatology

Since the latter half of the twentieth century, there have been major advances in the field of microclimatology, including theoretical developments, improvements in in situ micrometeorological instrumentation and remote sensing techniques, and the development of computer
modeling and geospatial techniques. Sophisticated computer models, for instance, are now used to simulate the surface energy balance and fluid flow within the boundary layer. Indeed, urban canopy models have been developed that can account for 3-D shapes of building and are capable of computing the energy balance of different components of the built environment such as roofs, walls, and roads. Similarly, fluid dynamic models are now being used to understand dispersion and transport of pollutants and to understand flow around complex shapes. Remotely sensed data are increasingly employed in microclimatic studies. Light detection and ranging (LiDAR), for instance, has been used to develop 3-D digital terrain models of urban environments and for identifying vegetation architecture within a plant canopy. Also, a combination of remotely sensed data from global positioning systems (GPS) and geospatial techniques (e.g., development of detailed digital elevation models) are used in precision agriculture to identify microclimate differences within a crop and to determine optimal inputs of water and nutrients for portions of the crop within these different microclimate zones. In sum, microclimatologists continue to make important theoretical and applied contributions to an array of fields using the latest ground-based and remotely sensed datasets, and geospatial analysis tools.

Questions in microsimulation

Microsimulation is concerned with questions dealing with the demographic and socio-economic development of populations. Who will be born, get education, employment, and family over the years to come? What happens with income, wealth, and health? Who will die, when and where? Who moves from and to specific places? What about education, labor supply and income distribution, family formation, sick leave, geographic population distribution, settlement structure, and segregation? What is the impact on all these processes of assumptions regarding other parts of the system, such as changed taxes, transfers, immigration policy, medical services quality, fertility attitudes, and nutrition habits?

Such “what if” questions are studied extensively with the help of microsimulation. A recent article in the International Journal of Microsimulation (Jinjing and O’Donoghue 2013) defined a dynamic microsimulation model simply as “a model that simulates the behavior of micro-units over time.” With the help of such models, “what if” questions are often answered by comparing outcome of experimental simulations with and without the proposed policy, behavior or structural change implemented in the model. Or, the simulation produces an alternative, contra-factual development for a historic period to be compared with observed history for the same period.

How to perform a microsimulation

The basic structure of a time-driven dynamic cross-sectional microsimulation model, the most common variant, is quite simple and straightforward, as illustrated by the diagram and pseudocode shown in Figure 1.

The simulation moves an observed or synthetically created start population of individuals with attributes forward in time, year by year, person by person, and event by event while updating their existence and attributes, often via defined events such as death, giving birth, receiving an education, moving, partnering, and having a family, or getting a job and income. In the example, each “card” (representing a record in a computer database) carries information for one person for each year, $T$ and $T+1$, and so on. When an existence status event occurs (death, giving birth, immigrating, and emigrating), the card deck is reshuffled to mirror the new set of persons in the domestic population. Events not changing the basic features of a person’s existence might influence attributes of persons any year they exist in the model (e.g., education increases the attribute education level). The example person Per Andersson survives, becomes one year older, keeps his sex and birth country, does not improve his education but moves from Umeå to Lund to get a new job with substantially higher income while simultaneously divorcing from Lisa Andersson, and so his family status changes from “partner” into “single.” In addition, the link attribute to his specific partner Lisa Andersson is
For each year \( t \) and for each person \( p \) and for each event \( h \):

1. Calculate a probability for event \( h \) for this specific person in her specific context this year.
2. Fix an artificial lottery. If a drawn random number is less than the calculate probability, then the event will occur next year for this specific person.
3. Update corresponding attributes of the person, update families and context.

Calculate yearly aggregate results.

That’s it.

**Alternatives beyond microsimulation**

Microsimulation is about what could have happened or what might happen in the future to a large set of individuals, as is much of the other research and fictional accounts of individuals and the societies of which they are part. Comparing the life biography of a fiction writer’s main character with the series of events occurring to the agents in a microsimulation reveals distinguishing features. The talented fiction writer’s detailed story, told about the main character, is unbeaten in its internal logic of reason, action, and agency, and is often of a larger immediate interest to the reader compared to the story told by the relatively stripped-down sequence of life events produced by a simulation. Therefore, the bulk of biographies, fiction stories, and movies probably have had a much greater impact as decision support as have all microsimulation and other quantitative impact analysis studies together.

But the fiction writer’s substantive and communicative advantage comes with a price. The people surrounding the main character cannot be as thoroughly described as the protagonist. They pop in when convenient for the storyline of the main character and then disappear – without background history or a future life. They do not need to have a coherent life history of their own. Therefore, the invented life path of the main character is fiction in two ways. Not only is the person’s life trajectory invented by the author (no matter how internally consistent and plausible) but it also relies on interaction, at certain points in time and space, with other persons that eventually could not be there in the right moment with the right set of attributes because of constraints and events in their own life paths. These interactions are easy to manipulate in fiction, but harder in life outside the book covers.

In a microsimulation model, on the contrary, each person is a main character. Each and every
one develops their own life in parallel and interacts occasionally with the others. Their existence is not constrained to what is required for other person’s actions. But within that equal frame, their individual choices and actions are different because they are constrained by their own properties, preferences, and abilities – inherited or attained – and by resources and people in their vicinity and further away.

So, in a certain place, at a certain point in time, a person about to mate might not find a suitable and agreeable potential partner (and he or she does not have the fiction writer’s ability to invent one) and, therefore, has to postpone mating and family formation. The same goes for employment. If there is no vacancy in the person’s profession in the local labor market or if competition from other applicants is too fierce given the person’s experience and ability, then such a job is not available for the person at that time and place and a series of secondary adaptions might become necessary: commute to a more distant workplace, move to a living place closer to that workplace, abandon work for a while, go for a new education and profession instead, and so on. Similar constraints and differentiation apply to choice of education, living place, and housing.

On the scale between the fiction story and microsimulation, can be found (i) investigations based on life stories told to an interviewer, (ii) results from larger surveys based on answers to telephone or postal questions, and (iii) results of statistical analysis performed on the same kind of data (survey, census, and administrative registers) as used for starting a microsimulation. Contrary to fiction, interviews give observed information and they tell something about what actually happened to the selected individuals and, therefore, also what could have happened – but with less content than the fiction story. But it is hard to know how special or specific the stories are and whether they are somehow representative for the distribution of stories in the population at large. That problem is basically removed in a well implemented large survey, at the expense of even more detail and rationales compared to what is given in a few deep interviews. A description of the survey however, does not tell much about how different characteristics and actions in life and space link to earlier and later events, within and between individuals and places. That instead is the task for statistical analysis, which draws on a broad set of tools, including a substantial set of spatial regression methods. And, that is also the end of the line for the ambition in most contemporary quantitative social science research, including that performed in many kinds of human geography. So, why move further into microsimulation?

Why microsimulation?

One answer to the question of “why microsimulation” is exemplified by the initial “what if” questions posed earlier in this entry. A discrete choice regression equation might tell about the probability that a female gets a certain education. Another equation gives the probability that she moves if she gets that education, conditioned on a set of additional characteristics such as family status. A third equation (or a mating algorithm) might relate her education to the probability of family formation. When time goes on in the model (as in life), all those and other events occur, partly simultaneously and partly in a sequence, constraining some future choices and enabling others. The major advantage of microsimulation over a single regression equation applied on observables, then, is that the single equation does not answer the “what if” questions about a person some years ahead, as then many of the other drivers in that equation have also changed.
This ability to handle myriad “what ifs” is precisely the work performed by a dynamic microsimulation. Estimated equations and postulated rules for all intertwined individual events are put to work together and the outcome further on becomes contingent on the entire web of earlier life events and characteristics, for the person in focus and for those other persons and vicinities he/she was and became linked to. There are few workable substitutes for this kind of system-wide consistent computation of the development of each person’s existence and attributes in the pure statistical toolbox, even including those approaches that attempt to get at sequencing and relationships among entities and attributes, such as propensity score matching, panel data regression, and structural equation modeling.

Roots of microsimulation

Microsimulation originated with an article by Gay Orcutt (1957) followed by the first model in 1961. He realized the obvious shortcomings of analyzing economic policy based on aggregate statistics, especially those due to the averaging out of all differences between individuals. He proposed that micro-units (decision-making units) should be modeled individually in order to maintain heterogeneity in their responses to policy and development of their attributes. Macro-level results, such as the level and distribution of income, are thereafter obtained by simple summation over the individuals. A large number of microsimulation models has thereafter been produced, successively enhancing the original Orcutt model. Example model along these lines are: DYNASIM, CORSIM, APPSIM, SB3, MOSART, DYNCAN, LIAM, SESIM, LIFE MOD, MIDAS, DYNAMOD, SAGE, LifePaths, FAMSIM, SVERIGE, SMILE, and DYNAMITE. This list of acronyms can be extended into at least some 60 large, dynamic microsimulation models all over the globe but mainly developed in larger and richer countries (Jinjing and O’Donoghue 2013).

Alternatives within microsimulation

A static model changes some conditions and calculates the effect without considering time and side effects. Core examples are the large set of models used to evaluate income distribution consequences of major policy changes, such as a changed tax or benefit schemes. They often contain a huge set of tax rules and answers questions such as “How much more or less will this person/family get as disposable income if the rule is changed?” The implicit assumption is that the effect is instant, that nothing else changes in the meantime, and that no other behavioral adaption occurs (e.g., that the person, due to the rule change, reconsiders labor market participation or profession, or adapts by moving to a place with other rules).

A dynamic model, like the one exemplified above, instead explicitly considers time and duration, and by this focus on dynamics can accommodate side effects that stem from induced adaption or other behavioral responses such as those above. In a dynamic model, equilibrium might be approached but never reached (as outside the model in the real world).

A dynamic model might move just a single cohort (or one individual) forward in time or, instead, it moves each individual in an entire cross-section forward. Obviously, the cohort version cannot and the cross-section version can contain interaction between dynamically changing and adapting individuals.

The effects of events in a dynamic, cross-sectional model can be captured instantly or with a delay or slack corresponding to the time
period used. In an event-driven model, events immediately trigger other events (but they do not necessarily respond immediately) whereas a time-driven model gives each event just one chance to hit each time period (year). For low frequency events such as dying, moving, or getting education, the yearly time-driven event resolution is enough and not (much) influenced by who else dies and so on that year. However, for resource allocation or market-like events, such as mating in the partner market, or finding a job in the labor market, or finding a dwelling in the housing market, conditions change for other persons in the same market much more rapidly with each successful change. In these instances, an event-driven procedure is more appropriate than others (static or time-driven procedure).

Another source of alternatives within microsimulation is the nature of its starting data. The models’ start populations often consist of a random sample of the population obtained from a large survey or a census. In most cases, the number of sample individuals (or households) to simulate is less than 100,000. Several models are based on using a synthetic sample created by merging the information in a survey with detailed one, two or three-dimensional tables of the population as made available from the county’s census or administrative registers. A few models, such as the Swedish SVERIGE models and the Danish SMILE model, have access to individual, longitudinal databases covering each individual in the domestic population.

A demanding task is to accurately model the outcome for large choice sets, such as the choice of education/profession or the choice of destination when moving geographically. Such choices are often modeled with the help of multilogit-based equations or spatial interaction models pruned to produce large errors in the detailed outcome. Imitating the behavior of empirical “twins” with identical values on a core set of attributes (age, sex, place of origin, etc.) might sometimes stand out as a simple alternative. In the short term, such “alignment” to data can produce superior results at the expense of analytical/theoretical explanation, as too much of observed intrinsic, unexplained behavior will be preserved eternally (i.e., a systematic long-term shift in the impact of distance decay and population size on destination attraction will be lost).

Alternatives to microsimulation

Agent-based simulation, like microsimulation, maintains sets of individually interacting agents. It was developed some decades after the start of microsimulation. A dynamic microsimulation model furthers an observed population of individuals with all their changing attributes into the future, period by period. An agent-based model instead invents the starting context of agents with a few properties each (like age, race, location, ability, social network, etc.) but explores in detail the impact of goals, rules and agent interaction on emergence of structures not present in the initially created population. Both types of model applications might contain representations of a few (thousands) or many (millions) agent instances. There is a certain convergence between the two approaches. Agent-based models increasingly utilize microdata and some microsimulation models tend to contain more and more social interaction and ask questions related to emergence of order. Of note, long before the agent-based models appeared, substantial parts of their conceptual and theoretical underpinnings were formulated by the Swedish geographer Torsten Hägerstrand in his “time geography” (Hägerstrand 1970). The Swedish HÖMSKE and SVERIGE models were developed as much based on his time geography as on dynamic microsimulation (Clarke
and Holm 1987; Boman and Holm 1996; Holm and Sanders 2007).

**Spatial microsimulation**

Because of the relatively small samples available for most dynamic microsimulation model projects, very few micromodels produce and maintain fine geographic resolution. One reason for the small samples used is that it is enough for exploring nationwide income and wealth developments and distribution – a common focus of traditional dynamic microsimulation models. Increasingly, however, other objectives, including simultaneously demanding results with high spatial and demographic and socioeconomic resolution, have emerged on the wish list for impact studies. These demands argue for spatial microsimulation requiring very large samples, up to including each person in the target population. Related is the fast-emerging possibility to exploit relational, network-based information, be it the network of relatives from administrative registers or the new huge “big data” sources of personal contacts, purchases, and micromovements often derived from new technologies such as location-aware mobile phones. For example, the network of relatives based on mother and father pointers are useless in a sample because a 10% random sample does not contain the mothers of 90% of the children. Instead, the ideal situation is when an individual longitudinal database is available containing all individuals and all their attributes, including relations as required by the intended simulation. That situation is sometimes at hand in the Nordic countries based on annually updated official individual register data, at least for simpler models.

For most models, however, even in the data rich Nordic context, register data has to be supplemented by imputing survey data (e.g., registers do not contain attitude data) and by constructing synthetic individual data from aggregate cross-tables based on microdata that is not available. For the rest of the world this is the baseline situation. Whether or not annual longitudinal individual registers for the entire population exist, they are in any case usually not available for research and analysis on an individual record level.

The paucity of data is the main reason for creating synthetic populations. Such datasets can be constructed to mirror the population one by one and give a spatial resolution corresponding to the geographic division in used tables. A typical situation is that a large national survey is available and is then combined with, and constrained by, one, two, or three-dimensional cross-tables revealing aggregate information from the public registers. Several efforts to develop iterative algorithms to create useful synthetic populations exist using reweighting techniques, combinatorial optimization, iterative proportional fitting, record cloning, value imputation, and alignment (Rossiter et al. 2009).

The goal of creating synthetic populations is to find a set of individuals with attributes that, when again aggregated into the given tables, exactly reproduce all of them. When all tables derive from the same underlying population that goal should be possible to meet. The problem is that the tables together do not contain all the information in the missing target population. Therefore, several different distributions of attributes over the individuals, that is, different populations, might satisfy the constraints given by all tables and the question becomes “How different are those populations?” The result might be good enough for some analysis and simulation but the created synthetic population lacks some of the higher order interactions present in the unavailable target population and that might
therefore distort the simulation results. Neverthe-
less, since the current reluctance to give ana-
lysts access to existing large scale micro-level data
will likely persist, this development of “reverse
engineering” methods for recreating microdata
will remain necessary for furthering spatial
microsimulation into new realms of socially and
economically important impact analysis.

Future conditions for microsimulation

One obstacle for the development of microsim-
ulation is that their construction in most cases
requires extensive programming from the ground
up. Most current applied dynamic microsimula-
tion models so far, such as the MOSART model
in Norway, the Australian APPSIM model and
the Swedish SESIM model, are hard coded for a
specific national dataset and application range, as
were the original Dynasim and Corsim models
(Caldwell and Morrison 2000). Generic software
packages have not been available despite calls
from practitioners for greater cooperation in the
construction of such expensive models (Lymer,
Brown, and Harding 2007).

This lack of generic modeling approaches is
about to change. Promising efforts have emerged,
such as the ModGen toolset from Statistics Canada
and the LIAM2 development package from the
federal planning bureau in The Netherlands.
There is also heartening growth in the availability
of simulation tools based on the open-source
statistical language R contained in the UrbanSim
open source project (Waddell and Ulfarsson
2004). For modest numbers of agents, the growth
in agent-based frameworks, such as NetLogo or
RePast, helps considerably in the construction
of models with an explicit spatial representation.
Such tools are particularly useful for prototyp-
ing and for the construction of moderate size
models but probably packages will come which
also enable the construction of large, specialized
microsimulation models without requiring almost
any programming in the traditional sense.

This greater availability of more powerful yet
relatively easy-to-implement programming envi-
ronments would greatly enhance the possibilities
for new generations of scientists in academia
and in agencies to apply spatial, micro-based
dynamic modeling to urgent problems regarding
people and their environment instead of entirely
relying on regression analysis with its obvious
shortcomings in representing complex dynamic
interactions.

The International Journal of Microsimulation (http://www.microsimulation.org/ijm/) is the main source for recent developments in microsimulation. The ModGen toolset from Statistics Canada, mainly aimed at longitudinal, cohort models and the LIAM2 development package from the federal planning Bureau in The Netherlands aimed at building cross-sectional models are readily downloadable toolsets for microsimulation development. The NetLogo agent based framework helps particularly in the construction of models with agent interaction and an explicit spatial representation.
Microwave remote sensing

Fulong Chen
Chinese Academy of Sciences

Electromagnetic radiation is a form of energy released by electromagnetic processes (visualized as a self-propagating transverse oscillating wave of electric and magnetic fields at the speed of light) that plays an essential role in remote sensing using radio waves, microwaves, infrared radiation, visible light, ultraviolet radiation, x-rays, and gamma rays; frequency increases from radio waves to gamma rays while the wavelength decreases. Microwave remote sensing, using radiation with a wavelength from approximately one millimeter to one meter, enables observations in all weather conditions with penetration capability (e.g., of vegetation and subsurface) in proportion to the wavelength. Since the rise in interest in its use in the 1960s, microwave remote sensing has had promising applications in studies concerned with the ocean, land, meteorology, ice, disaster, and even archaeology.

Microwave remote sensing can be separated into two technological approaches, active and passive, according to sensors used. Active microwave sensors have an onboard power supply used to transmit a periodic energy pulse toward observed features and measure the echo signatures; this type of sensor is represented by microwave scatterometers (e.g., QuikSCAT Seawinds scatterometer), altimeters (e.g., Jason), and imaging radars (e.g., Radarsat 1/2 and TerraSAR/TanDEM-X). Passive microwave sensors, on the other hand, do not send pulses of energy; instead, they receive and measure emissivity from the Earth and the atmosphere. This type of sensor is represented by microwave radiometers (e.g., NOAA AMSU and Envisat MWR). Microwave sensors currently in use can be summarized as follows.

- Radiometer: microwave radiometers are used to measure a part of the microwave radiated by thermal radiation from the ground surface and/or the atmosphere. Brightness temperature measured by a radiometer conforms to Rayleigh–Jean’s law. An object radiates an unique spectral radiant flux depending on the temperature and emissivity of the object, thus this radiation is called the thermal radiation.
- Scatterometer: microwave scatterometers are used to measure the backscattering reflected from the surface observed (e.g., 2-D velocity vectors of the sea wind). Microwave scatterometers can be either pulse type or continuous wave (CW) type. The pulse type uses a wide band and there are restrictions in obtaining a license to operate it and to avoid obstructions. The CW type has the advantage that the bandwidth can be reduced to 1/100 times that of the pulse type, reducing the costs of the operation considerably.
- Altimeter: microwave altimeters are used to measure the distance between the sensor platform and the surface observed. Based on the precise measurement of the satellite orbit and the geoid, microwave altimeters are widely used for applications involving ocean dynamics of the sea current, geoid surveys, and sea ice surveys.
- Imaging radar: according to the working function of sensors, imaging radars are classified into real aperture radar (RAR)
MICROWAVE REMOTE SENSING

and synthetic aperture radar (SAR). RAR transmits a narrow angle pulse wave beam in a direction at right angles to the flight direction (also called the azimuth direction) and receives the backscattering from the observed targets to form a radar image. To distinguish among different targets, measurements of angle and distance to a target are made by recording the arrival times of the received signals. Improving the azimuth resolution is the main technical limitation of RAR. Compared to RAR, SAR synthetically increases the antenna’s size to derive an effective large antenna to increase the azimuth resolution via the similar pulse compression technique adopted for the range direction.

Microwave remote sensing has developed rapidly and vigorously owing to the advantages it has over the more conventional optical remote sensing technologies.

- It can be operated in all-weather conditions and both day and night. Statistical analysis demonstrates that 40–60% of the Earth, particularly over the oceans and in tropical regions, suffers from intense cloud cover. Both optical and thermal infrared remote sensing in those areas suffer from data acquisition constraints. In contrast, microwave remote sensing is capable of penetrating clouds to observe the surface by using a longer wavelength; furthermore, illumination from sunlight is not needed, confirming its 24-hour observation capability.
- It has the capacity to penetrate vegetation and even soils and other ground surface materials. Based on its physical principal, the microwave signal is backscattered by a target in a geometrical manner comparable with the wavelength and, therefore, longer wavelengths exhibit greater penetration capabilities. This rule is basically applicable for vegetation categories; taking the forest as an example, the P-band can totally penetrate while the L-band can penetrate only partly. C- and X-band electromagnetic radiations, on the other hand, can only register canopy backscattering. The capability to penetrate into the soil is complicated by a number of factors. Among them the most relevant are moisture content and soil porosity. Generally, increasing moisture content and reduced porosity obstruct soil penetration. Thus, microwave electromagnetic radiation penetrates dry sand to a depth of tens of meters (particularly when a long wavelength signature is applied) but is only capable of surface backscattering and/or shallow penetration (e.g., a few centimeters) when the soil is wet.
- Variable sensing mechanisms can be used. Microwave remote sensing uses variable electromagnetic spectrums to acquire information linked to the geometric and dielectric property of targets. It can often be a complementary tool to observations using optical and thermal infrared remote sensing techniques

A number of characteristics of microwave remote sensing favor its application in a variety of fields.

- Superposition. When two or more wave sources are encountered in space, they obey the rule of independent propagation; that is, each wave maintains its original features (wavelength, frequency, propagation direction, etc.) for the propagation. Nevertheless, at the same time, the vector formation of electric and magnetic fields also follows the principle of vector superposition, resulting
in the vector combination of the actual displacement at the encountered point of waves. Accordingly, any complex waveform can be generated by combining multiple simple waves; that is, a complex periodic function can be resolved by the Fourier transform using a series of simple sine and cosine waves.

- Interferometry. Two or more waves with uniform frequencies and constant phase differences propagate themselves in the same direction; interferometry measures wave amplitude enhancement or decline when two waves are overlaid in space. For instance, the side-looking radar is an intrinsic coherence system. The occurrence of speckle noise is caused by the coherent superposition of randomly scattered echoes within a resolution cell, resulting in the reduction of effective spatial resolution as well as the difficulty of subsequent imaging processing and feature discrimination.

- Polarization. Electromagnetic waves are synchronized oscillations of electric and magnetic fields that propagate at the speed of light. The oscillations of the two fields are perpendicular to each other and perpendicular to the direction of energy and wave propagation, thus resulting in a transverse wave. The oscillation of these fields may be in a single direction (linear polarization) or the field may rotate at the optical frequency (circular or elliptical polarization). Linear polarization is commonly used in radar remote sensing and can be divided into horizontal (H, the electric lines of force lie in a vertical direction) and vertical (V, the electric lines of force lie in a horizontal direction) polarizations. Vertically and horizontally mounted transmitting and/or receiving antennas are designed to transmit and receive vertically and horizontally polarized waves, respectively. Copolarization (i.e., HH and VV) corresponds to the case of uniform polarization waves transmitted and received; alternatively, cross-polarization (i.e., HV and VH) corresponds to oppositely polarized waves being transmitted and received. Generally, polarization modes of electromagnetic waves demonstrate different scattering characteristics, providing a wealth of information for feature detection and recognition.

Thanks to the advantages described above, microwave remote sensing has proved to be of critical value in various applications in the ocean, on land, in the atmosphere, and in ice, as well as during disasters and even in archaeology.

Ocean

Nowadays, environmental and geophysical monitoring of oceans is of growing urgency. Observations from passive microwave radiometers provide global measurements on sea surface temperature, wind speed, water vapor, liquid water in clouds, precipitation rates, sea ice, and sea surface salinity and have led to significant advances in meteorological, oceanographic, and ecosystem research as well as improvements in forecasting climate, weather, and fisheries trends (Gentemann et al. 2010). For example, ocean salinity data are useful for shellfish-bed health monitoring and in detecting coastal water masses, which can be indicative of fish distribution. The accurate geophysical retrieval of microwave remote sensing data in oceanography depends on the selection of optimum electromagnetic wavelength, the development of calibrated brightness for temperature variations, and retrieval algorithms. The microwave radiometer is capable of providing a synoptic remote sensing measurement of salinity. Studies conducted imply the need for the choice of
MICROWAVE REMOTE SENSING

Optimizing wavelength. Calibrating brightness temperature gradients is essential to create highly robust quantitative ocean geophysical retrieval. Successful calibration procedures have integrated geolocation analysis, attitude adjustment, along-scan correction, absolute calibration, hot load correction, and antenna emissivity. Geophysical retrieval of radiometer measurements is determined by a radiative transfer model through regression algorithms to calculate the model-fitting coefficients. A large collection of ocean–atmosphere measurements is firstly assembled; then one half of the measurements is used to derive the regression coefficients while the other half is used to test and validate the algorithm.

Active microwave satellite observations of the ocean surface, particularly from scatterometers, radar altimeters, and SARs, provide information linked to the spatial wind variability over large areas. Wind resources based on microwave scatterometers, for example, ASCAT on board the Metop-A satellite of the European Organization for the Exploitation of Meteorological Satellites and the SeaWinds instrument on board the QuikSCAT satellite of the National Aeronautics and Space Administration (NASA), have been intensively used. Radar altimeters, for example, Cryosat-2, have the potential to monitor mesoscale structures and oceanic circulation. First generation (e.g., ERS-1/2, Radarsat-1, and Envisat ASAR) and second generation (e.g., TerraSAR/TanDEM-X, Cosmo-SkyMed, and Radarsat-2) SAR missions have been used for wind resource estimations. Estimation accuracy can be enhanced through the synergistic use of the integration of measurements via the various spaceborne microwave approaches mentioned above.

Owing to the high spatial resolution, SAR remote sensing has been frequently used in oceanography. One potential is the detection of ocean sand ridge signatures. An ocean sand ridge is a submarine feature of the continental shelf shallow sea formed by sand deposits and tidal currents. Under conditions of low wind and strong tidal current, sand ridges and sea mounts can be imaged by SAR using the sea surface imprints of shallow water bathymetric features. Detection and tracking of ocean oil slicks, resulting from spills from ships, oil platforms, and natural seeps from the ocean bottom, have drawn significant attention from communities dedicated to improving pollution control and mitigation and ecosystem sustainability. Oil slicks in SAR images appear as a dark tone, determined by the dominant mirror reflection. Based on this backscattering anomaly, SAR images play an important role for oil slick monitoring and removal in near real-time.

Land

As the primary living space for humans on Earth, the terrestrial land supports agriculture and other anthropogenic uses. Microwave remote sensing, a complementary synoptic tool when compared to solely optical techniques, plays an important role for the monitoring, evaluation, modeling, and prediction of physical dynamics of the terrestrial Earth.

- Agriculture. Soil moisture is a crucial factor influencing agricultural production. Poor soil moisture is associated with dry spells and drought, leading to crop losses; on the other hand, extremely wet soils reflect poor drainage, which hastens anaerobic microbial processes that reduce soil fertility (Champagne, McNairn, and Berg 2011). Current soil moisture assessment methods primarily rely on in situ meteorological records or borehole measurements. Overcoming the spatial coverage limitation of such point-based observations, microwave remote
sensing has great potential for quantitative estimation of land surface soil moisture, particularly the synergistic use of brightness of temperatures and backscattering coefficients measured by passive and active sensors. Moreover, thanks to the development of SAR, polarimetric SAR (PolSAR), and polarimetric interferometric SAR (PolInSAR), microwave remote sensing is also becoming useful for agricultural land-use classification, crop growth monitoring, and statistical yield estimation.

- **Built environments.** Urbanization is a prominent economic and social issue in the world, particularly for developing countries. Nowadays, more than half of the world’s population lives in cities and 1.4 billion more people are expected to move into cities by 2030. Definitely, urban is the core residential area for mankind. Although they occupy only a small percentage of terrestrial land cover, urban areas significantly alter climate, biogeochemistry, and hydrology at local and regional to global scales, because of their hotspot characteristics linked to production, consumption, and waste generation. Previous studies have shown that global urban mapping can be derived from spaceborne SAR data, such as the newly launched Sentinel-1 with global coverage, because urban regions are indicated as strong backscattering areas and can be easily discriminated from other surface features.

Indeed, urban locations and their surroundings belong to a whole environmental system. For sustainable development, essential elements in the entire environment, for example, land-use and land-cover change, forest, and other natural resources, need to be regularly monitored to derive objective assessments, forecasts, and management. Owing to the development of PolSAR and PolInSAR technologies, SAR remote sensing has found widespread application for land-use classification, particularly in the tropics. Investigations have demonstrated that deforestation and subsequent changes in biomass not only influence the hydrology at the local-regional scale, but also contribute to the long-term carbon balance driving global change. SAR remote sensing for biomass assessments has been widely used to demonstrate the potential for the use of long wavelengths, such as the P-band SAR that was selected as one of the future mission priorities of the Biomass satellite of the European Space Agency (ESA). Furthermore, owing to the high spatial resolution, SAR remote sensing is also preferred for interdisciplinary investigations of hydrology and mineral exploitation.

**Atmosphere**

Near-surface water vapor and precipitation are central hydrometeorological variables whose measurements pose significant challenges for conventional point-scale approaches, such as rain gauges and climate stations. For instance, traditional rain gauge measurements lack spatial representativeness and are susceptible to uncertainties introduced by wind- and exposure-induced errors. Although radar observations on weather overcome the spatial coverage limitations, the reliability of results needs further improvement. In contrast to the two technologies mentioned above, the terrestrial microwave network is becoming a new tool utilizing the interaction of microwave radiation with the atmosphere. The propagation of microwave radiation through the atmosphere is affected by many variables, such as pressure, absolute humidity, temperature, suspended water droplets, and precipitation. Studies have shown that it is feasible to extract liquid precipitation and humidity from microwave
attenuation and phase delay (the atmospheric disturbance estimation of spaceborne multitemporal SAR interferometry, MT-InSAR (Hooper et al. 2012). For the assessment and mitigation of extreme weather events, for example, hail and hurricane, microwave remote sensing also plays an important role. Studies found that there is a strong relationship between the occurrence of hail and microwave temperatures. Furthermore, SAR can yield high-resolution and low-level wind information below the cloud that is rarely detected by other sensors. These characteristics provide theoretical justifications for the use of microwave remote sensing for monitoring and assessment of extreme weather events.

Ice

Spatial distribution and temporal evolution of ice and snow in the cryosphere has tremendous influence on Earth system studies considering its close relationship with analysis of ocean currents, water balance, and atmospheric circulation as well as global climate change. Changes in ice and snowfall exert impacts on the environmental, agricultural, and economic sustainability of human societies. Generally, the ice and snow in the cryosphere of Earth can be categorized according to the landscape occurrence, including snow/ice cap and glacier, permafrost, and floating ice in oceans, lakes, and rivers.

• Snow/ice cap and glacier. It is clear that radar altimeters can easily detect mass changes of snow/ice by differentiation of the geodetic measurements of their heights. These point measurements tend to be of high accuracy (decimeter) but have relatively poor spatial coverage. Glacier flow velocity is a quantitative indicator for the study of glacier dynamics and mass balance in spatiotemporal domains, providing precursory warning of glacier-melting-induced flooding, debris flow, and global warming. SAR remote sensing could be a powerful tool for monitoring the evolution of glaciers using the methods of offset-tracking and differential SAR interferometry (DInSAR). For fast-flowing mountain glaciers, SAR-intensity-based offset-tracking may be the most appropriate technique to measure motion. DInSAR technologies could be applied for mild–medium flowing glaciers owing to their sensitivity to motions only if the interferometric coherence is maintained.

• Permafrost. Research on permafrost in polar, cold mountains and plateaus is still a relatively young but rapidly evolving field of science. The impacts of climate change as well as the response to human activities on permafrost are increasing. Changes in permafrost conditions can greatly influence land surface hydrology, ecosystems, carbon cycle, and landscape as well as engineering and construction. For example, permafrost degradation and expansion in the arid and cold Qinghai–Tibet Plateau would generate significant impacts on the Asian monsoon system, ecosystems, and engineering and constructions (Chen et al. 2013). Monitoring temporal changes in active layer thickness is crucial to understanding and interpreting permafrost degradation. Conventional approaches use available boreholes to measure the depth of zero annual oscillations and the corresponding temperature profiles of the active layer and permafrost beneath. Nonetheless, those point-based measurements have spatial coverage constraints and high-cost limitations. Considering the inversion capability for surface settlements, DInSAR technologies can be employed for estimating the long-term average active
layer by measuring the thaw-season surface subsidence. Previous studies have demonstrated DInSAR’s potential for permafrost monitoring over large areas at high spatial resolution (Short et al. 2011).

- Floating ice. Measuring the seasonal transitions of floating ice, particularly sea ice, is important in order to better understand climate variability for numerical weather prediction and designing global climate models. Monitoring of sea ice phenology is feasible using scatterometer image reconstruction, brightness temperature measurements obtained from advanced microwave radiometers, and spaceborne SAR images. Compared with microwave scatterometer and radiometer images, SAR images are more effective in retrieving distributions and detailing the temporal evolution of sea ice owing to their high spatial resolution. Salinity, temperature, and density of the ice affect the dielectric constant and the penetration depth of the radar wave into the ice, determining the backscattering of return radar echoes. Generally, the radar intensity of new and first-year sea ice is dominated by surface scattering (shown as dark tones in SAR imagery), whereas for older ice, volume scattering is the dominant response (reflected as medium tones in SAR imagery).

Disaster

The application of microwave remote sensing for disaster mitigation, forecasting, and evaluation is primarily based on its all-weather and interferometry advantages. Previous studies have shown that passive radiometers and active scatterometers together with imaging radar can monitor storms by retrieving key parameters of wind, that is, storm eye, force, and direction (Gentemann et al. 2010; Hasager et al. 2015).

SAR constitutes a valuable source of information for flood mapping because of its ability to capture the different scattering behaviors between flooded and nonflooded areas. When the spatial resolution is improved (1 m and even 0.5 m), such as that possible with the use of the second generation of TerraSAR/TanDEM–X, Cosmo-SkyMed, Radarsat-2, and ALOS-2, a fully automated processing chain for near real-time flood detection is feasible. Earthquakes (seismic events) and landslides are two typical geohazards with signatures of crust and surface movements. Quantification of co-seismic deformation is useful for seismic source characterization, evaluation of accumulated or released stress, and detecting indications of future earthquakes. DInSAR is capable of delineating surface deformation in the line-of-sight (LOS) direction of SAR data acquisition with accuracy at the subcentimeter level. Its application for seismic geohazards focuses on source characterization using parameters of position, orientation, and slip distribution along the seismogenic structure. For forecasting and mitigation of landslide hazards, the MT-InSAR and ground-based SAR interferometry (GB-InSAR) are preferred. Usually, spaceborne MT-InSAR methods only measure the superficial displacement of extremely slow (ES, velocity <16 mm year\(^{-1}\)) and very slow (VS, 16 mm year\(^{-1}\) ≤ velocity < 1.6 m year\(^{-1}\)) slopes due to constraints of wavelength as well as temporal baseline (Chen, Lin, and Hu 2014).

In contrast, GB-InSAR is a powerful terrestrial technique, widely used in engineering and in geological applications, to detect the fast displacement; thanks to the higher frequency of measurements as well as the optimal observing geometry, GB-InSAR allows the assessment of surface movement of faster landslides, even for cases that may not be visible from optical spaceborne platforms.
Archaeology

Taking into account the need for high spatial resolution, SAR is gaining interest and appeal among archaeologists, particularly with regard to the detection of archaeological remains and the preventative monitoring of heritage sites.

- Archaeological detection. Compared with optical imagery, penetration is one of the merits of SAR systems. This capability is useful for detecting vegetation-covered relics in rainforests and buried remains (settlements and ancient water systems) in deserts using backscattering. Penetration depends on the wavelength (the longer the wavelength the deeper the penetration), surface properties (roughness, soil porosity, and moisture content), and imaging geometry. The coupling mechanism of surface roughness, incidence angle, and the scattering and propagation mechanism of SAR signals interacting with archaeological targets beneath the surface could be studied in detail in order to establish SAR image interpretation rules for archaeology. Generally, the occurrence of archaeological targets is detected by backscattering anomalies in SAR images, providing clues for the identification of relics through changes in multitemporal SAR images. Furthermore, constructed by humans, archaeological sites tend to be regular in shape and scale, as well as having a distinct, vertical archaeological layer, which results in soil moisture or vegetation anomalies on the surface and even in the surrounding landscape. The strong response to polarimetric signals can be used for target identification by means of polarimetric image fusion, scattering element analysis, and polarimetric target decomposition in order to compensate for the weak information from topology, vertical distribution, and soil moisture content in archaeological sites.

- Preventative monitoring. Deformation is an indicator of vulnerability of ancient remains to natural hazards and anthropogenic activities. DInSAR approaches provide motion measurements for preventive diagnosis, particularly the MT-InSAR techniques, which can detect subtle deformation (with measurement accuracy up to several millimeters). Taking advantage of large spatial coverage, MT-InSAR using spaceborne SAR data could be employed for mass movement monitoring around heritage sites. With regard to the structural stability diagnosis, differential tomography SAR (D-TomoSAR) (Fornaro, Reale, and Serafino 2009) and GB-InSAR are recommended. D-TomoSAR integrates MT-InSAR and tomography into one framework to distinguish scattering at different heights and monitor their geometric displacement. It overcomes the unfavorable layover impact of MT-InSAR (no signature on layover regions) and is capable of detecting motions along the monument in the vertical plane, facilitating the monitoring of fractional motion anomalies on monuments. The GB-InSAR instrument carries a portable coherent radar that is able to acquire both the amplitude and the phase of the received signals echoing from observed targets. The derived wave phase reflects the motion of the targets during the observation period. Parameter specifications of signal (e.g., bandwidth, function distance, and incidence angle) make the GB-InSAR system suitable for fine deformation monitoring and preventive diagnosis of heritage sites. In summary, DInSAR techniques
have the potential to support the sustainable development of heritage sites through the detection of driving forces of instability that can lead to monument damage and collapse.

Migrant division of labor

Jane Wills
Queen Mary, University of London, UK

The concept of the migrant division of labor (MDL) builds on existing understandings of the ways in which the labor market is segmented in relation to gender and ethnicity, by adding a focus on immigration status and/or citizenship. While it is well known that job opportunities are unevenly distributed in relation to gender and ethnicity, increased labor mobility has created additional segmentation processes on the basis of immigration status. The MDL refers to the way in which workers are segmented due to their status as migrants or foreign-born workers without full rights of citizenship in the country in which they are working. Such rights are variable but cover access to the labor market including rules about hours of work, access to welfare benefits for those in and out of employment, and the rules covering asylum applications. These rights play a key role in determining an individual’s incentives to work as well as their desirability in the eyes of employers.

In the context of oversupply, employers are able to differentiate potential workers on the basis of a combination of characteristics that might include skills, education, and immigration status alongside often stereotypical assumptions about nationality, ethnicity, and gender. As such, and in the context of increased penalties for employing those without the legal right to work in the country, those with unambiguous legal residence and rights to work are likely to be prioritized over those with less certain legal status.

The concept of the MDL was first developed through a number of geographical research projects conducted in London (UK) in the early years of the twenty-first century when strong labor supply from the extended European Union (most notably Poland) started to reshape labor markets that had previously been reliant on non-EU migrants with less secure status (including those arriving through the asylum system, international students, and irregular migrants). In this context, immigration status served to reinforce the re-racialization of the hiring queue, prioritizing white European workers over black African workers even if the latter group had been in the country for a much longer period of time (and similar trends have been identified in relation to the position of African American men in low-waged labor markets in the USA (Model 2002)). A growing body of research has highlighted the extent to which foreign-born workers are increasingly differentiated in relation to their immigration status in employers’ hiring queues, with different outcomes across time and space (May et al. 2007; McDowell, Batnitzky, and Dyer 2009; Pratt 2004; Wills et al. 2010).

Migrant labor refers to work undertaken away from one’s usual place of residence, often requiring residence in another locale where the worker may not intend, or be permitted, to settle permanently. As a result, migrant workers often have a connection to employment or work in one place, and an ongoing set of connections to an economy, household, family, or community located in one or more locales elsewhere. This migration can be either inter- or intranational, but implicit within the term is the notion that individuals are crossing political, administrative, or institutional borders of some kind in order to engage in work. The incorporation of migrant labor into local labor markets is a trend that grew significantly during the twentieth century, and that continues to expand in the twenty-first.

On its own, however, this brief definition belies the diversity and complexity that characterize contemporary migrant labor. This is in part because the term “migrant” is often used to describe groups of individuals who may hold vastly different rights of residency and work, employment contracts, access to social protections, or settlement aspirations. In legal terms, migrant status can also be produced through diverse forms of territorial regulation – at times a patchwork of immigration, residency, and workplace rights laws. The ways in which these laws “touch down” on individual workers can vary immensely: a refugee claimant who finds employment while awaiting a decision on their claim, a young person working part-time while studying abroad on an international student visa, the unpaid domestic labors undertaken by the trailing spouse of another migrant, and an elite professional employed under a skilled foreign worker scheme may all be considered, in different ways, “migrant labor.” Discursively, the term “migrant” frequently carries distinct racial, ethnic, gender, and class connotations, and is often used to refer to lower-waged and lower-status workers instead of more elite labels such as “expatriates” which tend to be reserved for more affluent, professional migrants. Thus, whether defined through law, policy, daily practice, or public discourse, migrant labor is always a composite social construction produced through multiple – and at times conflicting – social practices and institutional arrangements. Moreover, the delineation of migrant labor is a process that is always spatially embedded in that the laws, institutions, and practices that regulate and construct it vary from place to place, and it is often shaped through complex linkages to “elsewhere.”

In contrast to earlier eras of labor migration which, particularly in Europe and North America, were marked more heavily by opportunities for permanent settlement, labor migration in the twenty-first century has in many cases become increasingly characterized by a variety of intersecting conditions of temporariness relating to employment security, residency rights, and social protections. This is in part the result of a number of broad political economic shifts over the past several decades that have facilitated the incorporation of migrant labor into contemporary economies. The first has been the establishment of a diverse array of new territorial arrangements governing flows of migrant labor,
MIGRANT LABOR

including temporary foreign worker programs, live-in caregiver programs, special economic zones, or political-economic-territorial institutions such as the European Union which have been intended to facilitate the movement of temporary migrant workers across borders. At the same time, associated shifts in the nature of contemporary work and employment have also fostered the use of migrant labor, such as the growing flexibilization and contractualization of work, in which jobs have become increasingly short-term, casualized, or part-time; subcontracted employment arrangements have become commonplace; and/or wages have either been eroded or remained stagnant. Growing wage erosion and employment insecurity have served in some cases to make certain jobs less appealing to “local” workers, while declining unionization in certain sectors has increasingly enabled employers to look to unorganized migrant workers as a source of lower-cost labor. The decline of employer-sponsored apprenticeship and training programs for “local” workers arising from labor market deregulation, meanwhile, has frequently provided the basis on which employers seek out migrant workers with the appropriate skill sets.

Despite the arguably global character of these shifts, the incorporation of migrant labor into local labor markets has been profoundly uneven. Sectorally, the demand for migrant labor tends to be particularly strong in immobile sectors of the economy where offshoring production to countries with lower labor costs has not been possible. These include services and goods which must be produced or consumed “in place”: hospitality and retail services, domestic work, care work, construction activities, financial services, and mining and agriculture are some of the most prominent sectors in which migrants – both high- and low-waged – tend to be disproportionately represented. Occupationally, migrant labor in most countries tends to be heavily concentrated in lower-waged, casualized, or contingent jobs. Particularly in locales where women have entered the waged workforce en masse, these shifts have had deeply gendered impacts on migrant labor flows as the rise of service sector economies and the commodification of previously unpaid and culturally devalued forms of labor in the space of the household, such as care and domestic work, have become key labor markets for migrant women. Geographers and others have thus pointed to the feminization of flows of migrant labor in the last several decades as an interlinked set of relationships accompanying these transformations in work and employment. Finally, at the national scale, workers from some labor-sending countries tend to be particularly concentrated within the ranks of migrant workers; as Lee and Pratt (2012) point out, currently over 8 million Philippine nationals are working abroad in over 190 countries, the majority (approximately 85%) of whom are on temporary labor contracts. The labor markets of some destination countries, such as the United Arab Emirates, meanwhile, have become so structurally dependent on temporary migrant labor in recent decades that these workers now constitute between 80% and 90% of the country’s total population. With respect to migration taking place within national borders, an unprecedented growth of new intranational flows of migrant labor has taken place in recent decades, particularly within countries across South Asia, Africa, and East Asia. Often involving the movement of individuals from rural to urban locales, processes of time-space compression have allowed for the greater movement of people across space within nation-states. In some cases, scholars point out, this has been accompanied by new processes of economic enclosure and dispossession in migrants’ sites of origin, which in turn have eroded local livelihoods and resulted in workers becoming more mobile in
search of jobs. Outside of immigration law and policy, thus, an array of other sovereign legal and institutional relationships can regulate the flows of migrant labor within nation-states, many of which are shaping the contours of urban citizenship for migrants working in cities today.

Perhaps no single national policy has had a greater impact on regulating internal migrants in the contemporary moment than the Chinese *hukou*, or housing registration system. The most recent incarnation of China’s *hukou* regime, established in the mid-twentieth century, designates every citizen as either a “rural” or an “urban” resident. While the constellation of policies known as *hukou* has had a great deal of power to limit the mobility of rural and urban populations, China’s ascendance as a central node in a vast array of global production chains has been underpinned by the incorporation of rural Chinese migrants into urban and peri-urban factories in recent decades. Despite this, rural migrants are not permitted to settle permanently in the city because of their *hukou* designation, thus producing what has been called a “floating population” of an estimated 150 million migrants who live and work away from their *hukou* locations. *Hukou* policies have also played a key role in the systematic marginalization of internal migrants because, without an urban designation, rural migrants in the city are denied access to an array of social welfare services such as unemployment insurance, and subsidized housing, food, and education (Chan 2010; Fan 2004). As Kam Wing Chan (2010) argues, this has effectively enabled local governments to treat internal migrants like foreign migrants. While enduring national regimes like the *hukou*, new international immigration policies, and transformational shifts taking place in the global economy are all extremely important in understanding the growing reliance of many labor markets on migrant labor, they do not explain why individuals migrate, who migrates and who doesn’t, how migrants end up in particular jobs in particular sectors, or how migrants’ identities both shape and are shaped by day-to-day work and employment. Geographical scholarship throughout the 1970s and into the early twenty-first century has sought to complicate macroscale analyses of migrant labor that viewed migrants’ movements primarily as the result of capitalism’s need for a reserve army of labor, and to question rational choice models which assumed that wage differentials between countries “pulled” migrants across borders. This work challenged economistic tropes of the individual migrant, detached from the agency emanating from kinship or community ties or from emotional or other noncapitalist desires motivating migration and mobility. Feminist geographers, in particular, demonstrated the limitations of these various frameworks by uncovering a wider and more complex spectrum of workers’ reasons for migrating; by highlighting how migrant men and women’s experiences of migration, work, and employment could be vastly different; and by foregrounding how unequal and often patriarchal household relationships can determine who migrates and who stays behind. These interventions mirrored the ways in which geographical research from the 1980s to the early 2000s was marked to some degree by a shift of focus from migrant labor as a structural concept to a growing concern for labor migrants – for workers’ own experiences, the microscaled politics and connections between their workplaces and their households, and their strategies of navigating conditions that might be deemed outside their control.

In this same vein, overly economistic accounts of the motivations, agency, and experiences of intranational migrants have received much needed correctives through research seeking to understand the cultural politics of migration.
Gidwani and Sivaramakrishnan (2003), for example, offer a nuanced account of how Indian intranational migrants’ counterhegemonic expressions of consumption—such as changing dress habits—have served in limited but meaningful ways to challenge entrenched social hierarchies of caste and class. Meanwhile, in her interviews with migrants returning to the South African settlement of Cancele for the Christmas holidays, Ngwane (2003) explores the household as a space that is performed, displayed, and talked into being through migrants’ aspirations of upward social mobility. Through these activities, categories such as “family,” “tradition,” and “home” become unstable sites under discursive construction and contestation through the movement of people back and forth between the city and the countryside. This frame serves to, in Ngwane’s words, “collapse some basic binaries that ... scholars had taken for granted between, for example, ‘family and factory,’ women and migrant labor, and town and countryside” (2003, 688). This research highlights the ways in which migrants’ imaginings and performances of alternative modernities—ones with the potential to perforate both dominant local power relations as well as the modernization scripts that can imbue Eurocentric migration research—demonstrate the inseparable and mutable character of social positions such as citizenship, race, gender, or ethnicity; how they can be produced and transformed through work and migrants’ movements across borders; and how their mobilization affects both migrants’ experiences of employment and their prospects for fair and decent work. Developed alongside the emergence of the body as a crucial scale of analysis in geography, this literature has also challenged the Marxian notions of “embodiment” that imbued geographical scholarship on migrant labor, which predominantly conceptualized it through the physical work of a universalized, waged (male) laborer. Gendered, racialized, and otherwise “embodied” forms of migrant work—for example, jobs requiring “service with a smile,” love and caring, tough manual labor, or sexual services—are geographical in very intimate ways, as they require the mobilization and valorization of particular bodily attributes, dispositions, biological characteristics, or other purportedly immanent qualities of migrant women and men.

Since the beginning of the twenty-first century, a wealth of new empirical and theoretical territory has been covered in geography on the
topic of migrant labor. Five strands of inquiry and debate are highlighted in what follows, not because they offer an exhaustive view of new work on the topic, but because together they show the diversity and depth of recent scholarship. The first has been an ever-deepening set of engagements with migrant households. In their case study of Singapore, Yeoh, Huang, and Willis (2000) demonstrate how the very production of the global city rests on the naturalization of ideas about the Asian family and women’s work within the household, pointing out that the city’s economy is sustained in part through the unpaid work of both the wives of Singaporean men working abroad and the trailing spouses of migrants in Singapore itself. This literature illustrates the silences in this scholarship on the theoretical place of the household in the global city, and challenges the broader ways that migrant labor has been overwhelmingly constructed as waged labor in both migration and urban theory. Research on migrant households has also been a source of innovative developments in ethnographic, collaborative, and multisited research methodologies. In this vein, Mattingly (2001) has shown how the commodification of certain households that employ migrant workers has involved the mobilization of unpaid household work by extended family members to sustain migrants’ own social reproductive needs. This work illustrates the multinodal webs of social reproductive labor required to sustain the commodification of a single household, and highlights the racialized and gendered power differentials between working women that operate within these networks. Ethnographic studies have also been integral in further challenging notions about the migrant household as a cohesive unit or a site with a cohering or equitable set of interests, and in demonstrating the important role that factors such as migrants’ age, gender, or emotional family attachments play in determining how much of their earnings migrants tend to remit back home. Collaborative and performative research, meanwhile, has starkly illuminated the profound and long-lasting social cleavages that can result from the separation of transnational care workers from their families back home (Pratt 2012).

The beginning of the twenty-first century has also been marked by a reinvigorated engagement with the role of the state in the sociospatial regulation of migrant labor. This is in part due to a number of major crisis events that galvanized efforts in geography to delve more deeply into questions about the production of citizenship and new border-making practices aimed at migrants. First, the profound new policy directives involving the securitization of space following the September 11 attacks have had major impacts on the regulation of migrant labor in many countries; in the United States and elsewhere, new disciplinary and surveillant activities by states, adopted under the aegis of homeland security have since become imbricated with agendas of identifying and rooting out “unauthorized” migrants. Second, the 2008 global financial crisis illuminated the multiple vectors of risk and vulnerability that transect migrant workers’ livelihoods; many migrants were not only overrepresented in the sectors hardest hit by the crisis – construction, hospitality, manufacturing, and finance – but they also tended to be employed in jobs in these sectors that were the most casualized and insecure, and were thus most vulnerable to retrenchment. The financial crisis spurred geographers to point to the ways that employing migrant labor has become a significant strategy of offsetting the novel risks imposed by globally interlinked and financialized economies in the twenty-first century. At the same time, research has also foregrounded innovative forms of labor organizing and cross-border solidarities that
Migrant workers and their allies are developing in the face of the growing destabilization and criminalization of migrant work and employment. The recent successes of upcaled worker solidarity movements such as the International Domestic Workers’ Network, the urban-scaled, multioccupational politics of the London Living Wage campaign or the large, yet entirely informal, strikes waged by unorganized construction migrants in Arab Gulf countries show that migrants, migrants’ rights groups, and others have adopted a variety of strategies to confront these challenges. These forms of organizing, moreover, mobilize a diversity of scaled relationships that cross a variety of political, occupational, and sectoral borders and boundaries.

There have also been a number of recent efforts to explore how the discourses, institutions, and day-to-day practices associated with the territorial regulation of migrant labor are integral to the contemporary construction of nationhood, state sovereignty, and citizenship. While poststructuralist feminist scholarship has illuminated how the very term “migrant” both refracts and reproduces the notion of a national state and a “citizen” subject (Yeoh and Huang 1999), there are more recent Agambenian engagements with new ways that migrant workers are deemed “exceptional” subjects who face both the de facto and de jure withholding of welfare, civil, and labor rights. In these readings, it is not simply that migrant workers exist outside the institutions of the state; rather, ascribing exceptionality to migrant labor is fundamental to the ways in which territorial sovereignty is maintained. The importance of producing migrant workers as exceptional subjects is particularly visible, though not unique, in Gulf Cooperation Council states such as Qatar, where all migrant workers are excluded from state welfare entitlements and must also pay a yearly fee to a national citizen sponsor, who in turn grants them the right to work temporarily in the country. This particular form of migrant labor rentierism is a key financial contract that the state has made with national citizens, and it is fundamental to the ways in which the legitimacy of the non-democratic state is reproduced. These financial and regulatory architectures of exceptionality in which migrants are embedded are thus integral to the entitlements and obligations encoding national citizenship. Other research on the role of the state in regulating workers has made key strides in illuminating the gendered social norms that encode particular scaled representations in migration geography. Work by Silvey (2004) and Fan (2004), for example, has been integral in gendering the nation-state by showing how labor-sending and destination country governments reproduce traditional patriarchal gender norms in excluding migrant women employed in the “private” space of the home from the application of host country labor laws.

Third, in a shift from migrant labor research that has been overwhelmingly focused on work in lower-skilled, low-status, or precarious forms of migrant work, there has been a growing focus in recent years on examining elite forms of power and privilege within migrant labor markets. Ley (2010), for example, has traced the multisited migrations among wealthy East Asian migrants to Europe, North America, New Zealand, and Australia in the 1990s, pointing to the ability of this group of migrants to transcend the interests of both host and destination states to retain them. Additionally, there has also been a growing focus on mapping how white privilege and constructions of whiteness operate within migrant labor markets. Notable among these efforts have also been postcolonial, anticolonial, and critical race analyses of migrant labor. Andrucki (2013), for example, traces the colonial institutional structures that continue to maintain racial privilege among
white South Africans who migrate. Other work has illuminated how the entangled hierarchies of whiteness and nationality encode the relative status of migrant sex workers in the United Arab Emirates (Mahdavi 2013), while scholarship on migrant nurses in the United Kingdom has complicated homogenizing narratives about “Third World” migrant women’s incorporation into “First World” households by showing migrant care work takes place in an array of sites and encompasses a diverse range of skill sets, working conditions, and occupations (Kofman and Raghuram 2006).

A fourth theme revolves around debates about the costs and benefits of circular migration, in which migrants oscillate between their home and host destination(s) periodically. This form of migration – which can include, for example, repeat migration through temporary foreign worker schemes which at once facilitate the movement of workers over borders while explicitly precluding permanent settlement – has been described as a “triple-win” scenario by some who argue that it allows host countries to address labor shortages, generates remittances for migrants’ home economy, and reduces “brain drain” in labor-sending countries as migrants are expected to ultimately return home to settle permanently, bringing with them new skills which will enable them to find better work back home. Critics, however, have voiced significant concerns with immigration policies seeking to encourage circular migration. They argue that such directives feed into xenophobic antiforeigner political discourses and absolve host states from providing social services to migrants who need them. Yet others suggest that policies seeking to foster circular migration help legitimate the myth of labor shortages in many host countries, and provide a justification for the creation of a two-tier labor market in which migrant workers are denied permanent settlement. Recent empirical case studies, moreover, have found that the promise of upward economic mobility through circular migration is not being realized for the vast majority of workers (e.g., Takenoshita 2011).

A fifth and final theme inflecting recent scholarship has been a growing engagement with migrant labor intermediaries. Recent research has illuminated how a diversity of actors, including multinational temporary employment agencies, private remittance-transfer companies, labor-sending country consular staff, and informal moneylenders can play crucial roles in shaping and sustaining migrant labor networks. This work has broadened depictions of the kinship and friend migration chains or “hometown ties” often viewed as underpinning migration networks. It has also illuminated the relationships in the production of economic precariousness among migrants; for example, migration debt can circumscribe poorer migrants’ lives more fully because they frequently pay more to migrate and are more vulnerable to high-interest, predatory forms of moneylending than more affluent migrants. Migrant labor intermediaries can also play a key role in the production of migrant identities in that recruitment agents, consular officials, and others tasked with the management of migrant labor markets often actively participate in constructing racialized and gendered norms around the construction of desirable workers. As a result, they often wield considerable power in employing constructions of what constitutes “good” workers to filter out “unsuitable” candidates. These perspectives provide an important counterpoint to the state-centric literature on the regulation of migrant labor, as well as research that has focused primarily on migrants’ own experiences. In particular, they raise important questions about the territorial, juridical, and practical limits of any single state to protect migrants when narrowly delineated
MIGRANT LABOR

protective frameworks focused on workplace rights fail to account for the grey transnational networks of power that extend well beyond the worksite. Together, these strands of geographical scholarship on migrant labor illustrate the immensely diverse experiences, conditions of work, regulatory frameworks, and migratory channels that can be associated with migrant labor, work, and employment. They also help to form a broader recognition of what may be considered key sites and spaces of labor migration – from home and host country households, to wire-transfer shops, to church basements, to corporate boardrooms – that shape and sustain migrant workers’ lives, livelihoods, and migration trajectories.

Migrant settlement

Wardlow Friesen
University of Auckland, New Zealand

There are many types of migration, ranging from relatively “permanent” to more short-term, circulatory, and transnational movements that appear to be becoming increasingly important. In discussions of settlement, the focus has almost always remained on longer-term international migrant settlement issues, although it is no longer possible to characterize these inevitably as outcomes of permanent migration, since transnational and other forces are at work. Much of the attention in migrant settlement research has been on “settlement countries” with proactive immigration policies, namely Australia, Canada, New Zealand, and the United States, but many of the same issues are relevant in other countries worldwide.

Arrival, settlement, and integration

The conditions of arrival for international migrants in a new country of settlement are dependent on the immigration and settlement policies of that country. A fundamental issue is the legal status of the movement, since this can have considerable influence on employment and education opportunities, family reunion, and sociocultural integration. In many cases long-term residence may be the outcome of undocumented arrival, and it is likely that these migrants will have little government support for settlement and will be cautious about seeking support from other agencies. Even in countries with proactive immigration policies, there may be minimal support for most migrants, often with the exception of refugees coming via the United Nations High Commissioner for Refugees (UNHCR) quota system.

Longer-term settlement policies vary considerably between countries, and these partly depend on policies on the integration of migrants as well as on the resources available for new migrants. Integration policies and their outcomes, in their many manifestations, ranging from assimilation to multiculturalism, have been the focus of more migration research and discourse than any other topic. Assimilation, implying the complete economic, social, and cultural absorption of a migrant minority into the mainstream host society, is considered an extreme and usually undesirable form of integration, although the term is still commonly used. This process has often been idealized in the metaphor of the American “melting pot,” which represents the objective of American migrant settlement policy since the nineteenth century, and elements of this approach remain part of explicit or implicit policy in many places.

Multiculturalism, in both its descriptive and its prescriptive senses, can be constructed as the antithesis of assimilation. Descriptively, multiculturalism is the presence of a diverse range of ethnic cultures, languages, religions, and so on in a city or country, usually as a result of relatively large-scale immigration from a range of countries. Probably the best-known prescriptive use of multiculturalism at a policy level was that of the Canadian government from the 1970s onward, which involved the active promotion and celebration of multiple
MIGRANT SETTLEMENT

ethnicities within Canadian society and polity. According to Mitchell (2004), multiculturalism serves not only the interests of pluralism and social liberalism, but also the neoliberal project of globalization because of the manner in which it valorizes and commodifies difference. More recently, conservative governments in Canada, as well as in Australia, have abandoned multiculturalism as a formal policy, arguing that a certain number of “shared values” are critical to nationhood and successful migrant settlement.

In geography, generalized models of integration have tended to reject assimilation as a model while at the same time advocating socioeconomic integration with only limited cultural integration so as to maintain the cultures of migrants. Many geographical studies have been undertaken to determine the degree to which migrants have become integrated into host societies, both socioeconomically and culturally. Attempts to determine levels of socioeconomic integration range from measuring the evolving characteristics of individuals or groups of migrants through to the spatiality of migrant settlement, while studies of cultural integration are more focused on cultural maintenance and expression.

Commonly used measures of socioeconomic integration include indicators of income, education, labor market, and health outcomes. Studies of these factors proliferated during geography’s “quantitative era,” and they continue to remain the focus of much qualitative and quantitative analysis. Cultural integration is perhaps more difficult to measure than socioeconomic integration and is often more the domain of sociologists and anthropologists, but it is also regularly studied by geographers. Migration- and population-focused journals such as Population, Space and Place, Journal of Ethnic and Migration Studies, and International Migration regularly publish articles on migrant integration worldwide, and geographers comprise a significant proportion of the authors of these articles.

Earlier studies of migrant integration, often based on the premises of the Chicago School in the United States, were focused on less wealthy migrants whose choices in relation to housing, education, and health care were limited by their socioeconomic position. In these situations settlement is often understood within the context of a relatively slow process of economic integration and social mobility. However, as a result of the increasingly selective immigration systems in settlement countries, a much higher proportion of immigrants are well educated and highly skilled, so there is a much greater degree of choice in terms of residential location and resultant housing and education decisions. For wealthier migrants, settlement is no longer concentrated in poorer central areas of cities, but is more likely to be suburban, as in the “ethnoburb” (Li 1998) model. To some extent, success in these areas has even created negative reactions from host societies, for example stereotypes about the “monster housing” of Asian migrants (Mitchell 2004, 112–113) and the perceived competitive study habits of Asian students.

A common debate about migrant integration revolves around the question as to whether “second-generation migrants” (who are not actually migrants but are often ethnic minorities) have achieved a higher level of integration than their first-generation parents. In the United States, evidence suggests that second-generation groups tend to have achieved higher educational levels and jobs than their parents, though this is more likely to be the case for those of European and Asian descent than for Hispanic populations. Portes (2003) concludes that, on average, the children of migrants have higher aspirations than the children of American-born parents, but there is great variation between groups, with Mexican Americans, the largest second-generation group,
falling well below the average in terms of second-generation aspirations and achievement.

Debates about integration have often been constructed from the perspective of acceptance into the host society, but at least as important is the discourse about migrant experience in relation to racism and discrimination within the host society. The study of race spans many disciplines. Within geography, there is a long tradition of the analysis of spatial segregation, but also of other aspects of the construction of race and racism. Cultural racism is perhaps the most significant form of racism in terms of host–migrant interaction in countries of migrant settlement. Rather than focusing on biological difference, there is a concern for cultural difference, and especially the impact that increasing cultural diversity might have on a dominant, sometimes “national,” culture and society. This may be expressed against individuals through specific acts of discrimination, through media and public stereotyping of cultural groups, or in some cases through institutional racism practiced by governments or other institutions discriminating in terms of employment or other services.

Academic attention to discrimination based on cultural difference and religious affiliation has increased significantly since the events of September 11, 2001, especially in relation to Muslim migrant populations. Within the United States, Muslims have often been targeted by conservative groups as representing a new or restigmatized other. In some countries, such as France and the Netherlands, Muslim migrant populations (and some other groups) have been perceived as acting outside a national ideal of secularism, especially within the education system, for example with the French state banning headscarves and other clothing representative of religious affiliation in schools.

### Migrant identities

As well as acknowledging that there has been a diversification of mobility types and durations, scholars also recognize that migrant identities, whether self-adopted or imposed, are fluid, multilayered, and contingent, and that significant perspectives on these ambiguities include cultural hybridity, transnationalism, and diaspora. Geographers have also been interested in identity politics and in the development of a “politics of difference.”

Broadly used, “hybridity” refers to the transgression and displacement of boundaries related to binaries such as other/same and them/us. When used in relation to race/ethnicity, the transgressed binary may be the “Western us” and stereotyped conceptions of non-Western people. Thus cultural hybridity is an important concept when considering the identities of migrant populations in which there may be a reconfiguration of characteristics and categories based on racial, cultural, linguistic, religious, historical, nationality, and other factors. In many cases this has involved the “return” of postcolonial subjects to the country of their former colonizers, with obvious examples including migration to France, Netherlands, Italy, the United Kingdom, and the United States. An example of this is the development of a hybrid “black British” identity among both migrants of African and African Caribbean heritage settled in the United Kingdom, and their descendants. “Black British” has been taken on as a term of pride, asserting difference but also the right to be British. In this and other cases the assertion of hybridity has been used to claim rights to citizenship in its broadest conception.

Since the 1990s, transnationalism has become one of the predominant paradigms within migration studies, and, although migrant linkages back to home countries and to third countries have
MIGRANT SETTLEMENT

a long history, it appears that the forces of globalization have accelerated transnational phenomena in recent decades. From one perspective, transnationalism may be seen as disrupting “migrant settlement” in that it suggests that many migrants are never settled but are rather in a (potential) state of constant mobility. However, an alternative perspective is that “transnational” is most helpfully used to focus on phenomena that involve continued cross-border mobility, including transnational spaces or channels of mobility, rather than to categorize individuals or groups (Collins 2012). These phenomena impact on (potential) migrants whether they participate in frequent and short-term movements or are largely “moored” in a single locality. In identity terms, these transnational phenomena influence the way in which migrants view their “place,” with the reality that many have dual or multiple citizenships in a legal and/or social sense.

Migrant identities are also manifest in terms of diaspora. The dominant usage of “diaspora” until the late twentieth century was as a term for victimized groups, especially Jewish, driven from their homeland. More recently, studies of diaspora have used the term more broadly, and, while a focus on dispersion has been maintained, a more positive perspective is common in relation to homeland orientation and boundary maintenance between members of a diaspora and others, especially the dominant society (King 2012). The larger diasporas such as Chinese, Indian, and Filipino are increasingly intergenerational and are spread worldwide, but a great diversity of smaller diasporas have developed under conditions of accelerated global mobility resulting from changes in transportation, communication, and global linkages generally. In some cases diasporic forces have resulted in resettlement and return migration, such as in the Indian case, where the Indian government has become proactive in seeking the return of skilled expatriate Indians, especially in the information technology industry.

“Identity politics” is a term often used by geographers and others to refer to the political rights and activities of an oppressed minority, whether that oppression is based on gender, ethnicity, sexual orientation, or other characteristic. In terms of migrant settlement, it relates to the political mobilization of ethnic groups who have been historically oppressed under colonial conditions or within hegemonic “host” societies. An alternative and much contested term is the “politics of difference.” Assimilationists may use the term to justify complete assimilation or, alternatively, total separation, whereas rights-based groups use the term to refer to political movements and forces which recognize the right of minority ethnic groups to social recognition and acceptance based on their shared histories and cultures. The latter perspective may be applied to a critique of governments and other institutions in relation to their policies toward racism and the support of diversity of various kinds. For example, Dunn, Hanna, and Thompson (2001) show how most local governments in Australia practice “assimilatory multiculturalism” rather than “radical multiculturalism” in that they support celebratory ethnic festivals and information provision to foster tolerance for ethnic minorities, but rarely confront racism directly.

Urban spatialities of migrant settlement

In most countries with large-scale immigration, migrants tend to settle disproportionately, at least initially, in larger cities, which are often described as gateway cities. The gateway metaphor suggests that in the longer term migrants will move on to other parts of the country and, while this is sometimes the case, often this does not happen
and migrant groups and their descendants remain concentrated in gateway cities. Ley (2010) has undertaken a detailed study of the way in which Vancouver serves as a gateway to Canada for wealthy Asian migrants, especially from Hong Kong and Taiwan. Other classic examples of gateway cities in settlement countries include Los Angeles, New York, Miami, Toronto, Sydney, and Auckland. Another term that has been applied to cities with large and diverse migrant populations is “cosmopolis.” This may be seen as an ideal for urban futures, in which cities globally embrace diversity, democracy, social justice, and livability, cities which Sandercock (2003) celebrates as “mongrel cities.”

One of the main areas of focus for geographers is the spatiality of migrant settlement within urban areas. The Chicago School proposed one of the original models of migrant settlement which highlighted processes of neighborhood “invasion and succession” as part of broader patterns of urban growth. According to this model, migrants initially settled in rundown central areas of large American cities, but as (and if) they became more established and well-off they tended to “filter” to suburban areas. Migrant groups that did not manage to progress socioeconomically often ended up in what became known as “ghettos,” a term adopted from the European context of Jewish enclaves.

The term “ghetto” is the most pejorative of those used to describe ethnic concentration and describes an area where disadvantaged migrant groups are located, as a result of socioeconomic disadvantage and/or discrimination, and this location is usually involuntary. The use of this term has been hotly debated by geographers (e.g., see Peach 2010), and they have often turned to quantitative measures of segregation to determine what might qualify as a ghetto.

Migrant and minority group segregation has been measured quantitatively by geographers in various ways. The most widely used has been the index of dissimilarity (ID), which measures the distribution of a minority population within an urban subarea in relation to the distribution throughout the city. The ID measures the percentage (sometimes proportion) of a minority group that would have to move to create an even distribution, so an ID of 0 denotes no segregation while 100 denotes total segregation. One weakness of this is that the ID is highly influenced by the size of the minority population within the broader urban population, with smaller groups receiving a higher ID because of random allocation as well as actual segregation. Many other measures have also been used, but according to Johnston, Poulsen, and Forrest (2007) there are just two broad dimensions to be measured: separateness (combining unevenness, isolation, and clustering) and location (combining centralization and concentration). They use these as a basis for a typology consisting of six types of area based on ethnic minority and host society shares of the local population in a census tract (or equivalent). This typology has been applied to cities within six countries (United States, England and Wales, Canada, Australia, and New Zealand) with conclusions including: (i) variable degrees of segregation can be attributed to common processes including discrimination, disadvantage, and self-segregation; (ii) there are significant across-country differences, including African Americans being more segregated than any other group in the United States, and South Asian groups in England and Wales being more segregated than Asian groups in other countries; and (iii) Northern Hemisphere countries are more segregated than Southern Hemisphere countries, which is partly explained by the recency of movements of relatively wealthy migrants to Australia and New Zealand.
MIGRANT SETTLEMENT

There are also a number of more qualitative descriptors applied to migrant clustering. The term “ghetto” has already been mentioned. The broader term “ethnic enclave” may describe areas of disadvantage but can also be applied to areas where an ethnic group (or groups) has had more locational choice based on the presence of coethnics, economic opportunities, and cultural or religious facilities catering to particular ethnicities, but there may also be an element of reduced choice in relation to the cost of living, especially housing. The term “ethnic precinct” is used in similar ways to “ethnic enclave,” although in academic writing it is often used in relation to the economic opportunities which migrant clustering offers for “ethnic entrepreneurialism.” Further, it is sometimes used to assess the political aspects of clustering, both in terms of the (potential) political power that ethnic groups may wield in areas in which they are concentrated, and in terms of the strategic imperatives of political parties.

Another group of descriptors of ethnic concentration is based on specific (or aggregated) ethnicities. The most common is “Chinatown,” which is used to describe usually inner city concentrations of Chinese population and/or business operations (Anderson 1991). This term is used worldwide, with well-known Chinatowns in San Francisco, London, Sydney, Singapore, Johannesburg, New York, and Vancouver, but they are also present in many smaller towns and cities in the Caribbean, Pacific Ocean, and elsewhere. In some cases (e.g., Vancouver), many Chinese have moved to other, more suburban locations but retail and restaurant functions have remained, which are often increasingly dependent on tourism. Similar terms have been used to describe the concentrations of other migrant groups, and these include Little India, Koreatown (or Little Seoul), Little Manila, Japantown, Little Saigon, Little Italy, Greektown, Little Havana, and Little Jamaica, as well as many others. Similar to Chinatowns, these named enclaves have generally originated as areas of significant migrant settlement but have increasingly become areas used in urban place branding. An important aspect of these ethnic concentrations and migrant settlement generally has been the development and evolution of “ethnic cuisines” serving new migrant populations but also reflecting the desire of host populations to “eat the other.”

While the Chicago School postulated that most migrant settlement was in central cities, and most Chinatowns as well, more recently immigration has often been predicated on migrants being admitted on the basis of high levels of education, skills, and investment assets, and one result of this is that migrant residential patterns have changed. Wei Li (1998) coined the term “ethnoburb” to describe the San Gabriel Valley near Los Angeles, where Chinese are the dominant minority population but live alongside other ethnic minorities as well as the white majority population. This illustrates the fact that many relatively wealthy new migrant Chinese have chosen to live in suburban areas, and, while this still represents significant clustering, it also represents choice and advantage rather than the disadvantage implied by earlier models. Ethnoburbs have also been identified in other cities, including London, Vancouver, Sydney, and Auckland, and can be seen as a phenomenon found widely in migrant settlement countries.

Although first proposed by the anthropologist Arjun Appadurai, the concept of “ethnoscape” has been adopted by some geographers to conceptualize the presence of migrants within urban areas. As one of a number of “scapes” resulting from global changes and linkages, an ethnoscape was envisaged as “the landscape of persons who constitute the shifting world in which we live:
tourists, immigrants, refugees, exiles, guest-workers and other moving groups and persons” (Appadurai 1990, 297). Although this definition seems to focus on tangible aspects of mobile persons and the landscapes that they create (neighborhoods, temples, shops, markets, festivals), ethnoscape has also been used to consider the less tangible or the intangible aspects of migrant presence (transnational “nations within states,” political projects, virtual linkages). It thus allows the conceptualization of outcomes of migrant settlement beyond the spatially contingent, to include possibilities of heterolocality, transnationality, and other types of linkages and processes.

Conclusion

The study of migrant settlement has engaged geographers for many years, and the models and paradigms used for this study continue to evolve. The analysis and naming of processes of integration have been a central focus of attention, and, while there has been overall movement from assimilative to pluralistic models, this has not been unidirectional. Constant themes of geographic research on migrant settlement have been migrant integration into institutions of the host society, and the barriers of racism. Studies of migrant identity have multiplied, just as the ways of conceptualizing these have diversified. Emergent paradigms of hybridity, transnationalism, diaspora, and identity politics have now entered the geographical mainstream. Geographers have always been prominent in the study of the spatialities of migrant settlement. Within urban areas spatial clustering of migrants and ethnic minorities have been quantitatively and qualitatively modeled through the use of concepts such as ethnic enclaves, ethnic precincts, ethnoburbs, ethnoscapes, and qualitative descriptors such as Chinatown. While these approaches are shared with other disciplines, in many cases, geographers have played a leading role in their development.

The recent “mobilities turn” and increased attention to transnationalism have reminded us that there are many types of migration besides “permanent” long-term settlement, including a variety of short-term, medium-term, and transnational movements, and these often have implications for longer-term settlement (King 2012). Movements for international education, which have escalated in recent decades, have often been facilitated by the location of diasporic populations and service infrastructures. In some countries without proactive settlement immigration policies (e.g., some countries in Europe), the movement of contract workers has sometimes resulted in longer-term settlement as a result of intermarriage, long-term overstaying and amnesties, and other factors. Settlement countries have increased the range of short- and medium-term migration opportunities related to employment and education, and in some cases these have been supplemented by “transition to residence” schemes. These changes and others generated by accelerating mobility and transnational forces will provide new challenges for geographers studying migrant settlement in the immediate and longer-term future.

Forced migration may be viewed as a particular type of population movement across or within nation-state borders marked by clandestine processes and irregular status, and tied to highly specific motivations to move where free will is said to be limited. Despite differences in various forms of forced migration – political refugees, environmental refugees, and trafficked persons in particular – they are united by the absence of choice in people’s decisions to leave and, oftentimes, where to move. Forced migration therefore raises several important issues for geographers about mobility, identity, violence, exclusion, and racism.

Important questions following from these issues concern the causes of forced migration, the multifarious ways in which forced migration relates to conflict, violence, racism, how territories receive (or not) forced migrants, and what exactly constitutes force in a person’s experience of mobility. Forced migration is often connected with renewed territorial vulnerabilities associated with conflict, natural disasters and climate change, and transnational crime over the past two decades. Four key groups of forced migrants have gained particular traction in discussions of this phenomenon in the contemporary era: political refugees, environmental refugees, trafficked persons, and those who move because of gendered discrimination. Insights developed in studies of transnationalism, postcolonial theoretical approaches, the meaning of home and methodological issues also present potentially novel insights into the experience and understanding of forced migrants as complex subjects of mobility.

Forced migration in retrospect

The most severe and large-scale episode of forced migration in history was arguably the African slave trade, which removed somewhere between 12 and 30 million Africans from their homelands to regions of North America, South America, and the Middle East. Geographers concerned with this movement have principally addressed two themes: the contemporary manifestation of racism against African Americans, and the reconfiguration of identity and community among slaves and their descendants. Other than this topic, geographers have been concerned more broadly to elucidate geography’s links to empire-building processes in the eighteenth and nineteenth centuries (Livingstone 1992).

The incidence of forced migration has increased starkly since the 1990s. In the pre- and post-World War II period until the early 1990s migrations associated with force were a peripheral concern in geographical discussions of population movements. The Armenian exile from Turkey (1915–1917) and the Jewish exile from Europe during the 1940s inextricably linked early episodes of forced migration with specific racial cleansing projects, most irrevocably genocide within war-torn Europe. The theme of racial cleansing and escape from political persecution were themes that united refugee movements in other regions, particularly in Asia where extensive refugee movements
accompanied Cold War political tensions in Southeast Asia, principally Vietnam. Geographers’ interest in forced migrations associated with the World Wars and the postcolonial conflicts in Asia has generally been limited to refugee settlement and integration in the countries to which they have fled, as well as the diasporic imaginings associated with their relationship to the homeland.

Both of these foci have interested geographers because of their potential to illuminate subjects of broader interest to the discipline, including racialization of and segregation in the city, and national identity and tourism. If geographers’ interest with urban assimilation and multicultural conviviality are not specifically reflective of a concern for refugee and asylum seeker mobilities per se, geographical scholarship on diaspora does take the experience of forced migration as a significant analytic frame in the study of these pre-1990s experiences of forced migration. Tim Coles and Dallen Timothy’s (2004) edited volume on tourism, diaspora, and space is provocative in its focus on diaspora tourism as a lens to explore refugee negotiations with “the homeland” as an imagined space marked by the violent history of their removal from it. Beyond this, little has been surmised about these movements through the geographer’s analytic gaze.

The Rwandan genocide of 1994 led to renewed attention to the subject of forced migration generally and in geography, and heralded the onset of the current era of forced population movements associated with civil war, ethnic cleansing, and racially motivated violence centered on disputed ethno-territorial claims. In the 1990s there were 34 territorial disputes within nation-states, of which most are ongoing at the time of writing, including protracted crises in Somalia and Ethiopia. Indeed, the break-up of the former Yugoslavia and the establishment of the new nation-state of East Timor are the only of these conflicts that have been resolved more or less successfully. They have nonetheless heralded further negotiations around memory and justice in the form of truth and reconciliation commissions (former Yugoslavia) and reconstruction (East Timor). These post-1990 forced migrations have attracted far more attention from geographers than the earlier movements briefly reviewed above.

Migrants who are forced today

Forced population movements tied to political violence, and often associated with ethnic or racial cleansing, have historically been seen as the most numerically significant and urgent expressions of forced migration. This emphasis is reflected in published work in geography which focuses on political refugee and asylum seeker (im)mobilities. Apart from refugee and asylum seeker populations two other key groups of forced migrants have nonetheless gained some traction in recent discussions of forced population movements as they are manifest in the contemporary period. These are environmental refugees and trafficked persons. The issue of gender in forced migration, especially as it relates to female forced migrants has also gained some purchase in recent discussions.

Political refugees and asylum seekers

The fact that most published work in geography on forced migration takes political refugees and asylum seekers as key subjects is no surprise since those writing on these issues are often based in major asylum seeker destination countries, including the United States, Canada, the United Kingdom, and Australia (Crawley 2010; Hyndman 2010; Mountz 2010). Migrants who
are forced by politically volatile situations in their countries of citizenship move because of threats to their life and liberty. These movements are both internal (in the case of internally displaced persons, or IDPs) and international (in the case of refugees and asylum seekers). Asylum seekers are a small, but politically contentious cohort of refugees. The sensitivities their movements generate are in large part explained by the fact that they make claims on destination states for protection (asylum) based on well-grounded fears of persecution should they return to their country of citizenship.

Geographical scholarship in this area has been particularly concerned to elucidate the ways these claims are productive of particular discourses and infrastructures of accommodation or refusal within destination states. Bordering processes concerned with the deflection of asylum claimants are spatialized in ways that aim to contain asylum seekers either onshore (principally through detention centers) or offshore (principally through offshore processing and detention centers). This manipulation of territory involves re-drawing the boundaries of a nation-state in jurisdictional terms (for example, by inscribing new functions to remote territories, such as Australia’s Christmas Island where a processing center for asylum claimants was established in 2006) or “renting” the territory of contiguous but independent nation-states to accommodate refugee claimants (for example, by building detention centers and offshore processing centers in neighboring countries in return for the conferral of development aid or other material benefits to these third states). Australia is exemplary in its execution of such political-territorial rezoning, and as recently as late 2013 added yet another element to these tactics by introducing the controversial “no boats” policy. In this policy the Australian government turns boats containing asylum seekers back to their Indonesian point of launch. This policy is achieved through active bilateral cooperation between the Indonesian and Australian governments, under which the Indonesian coast guard will intercept returning boats and detain asylum seekers in one of nine purpose built detention centers in Indonesia until their claims are heard by the UNHCR. What is most striking about these processes of containment, classification, and removal, however, is the way in which they themselves can present a further episode in the forced migration and human rights abuses of those seeking protection. Suicides, hunger strikes, and other dramatic embodied expressions of desperation and depression only highlight what human rights activists have been continuously documenting since these geographies of containment institutionalized through the infrastructure of detention became routinely invoked a decade ago.

Asylum seeker mobilities also raise important questions about the journey itself. Tracing asylum seeker trajectories and routes allows us to explore the geographies of transit, as well as arrival and reception in the destination. Michael Collyer (2007) has studied African asylum seekers in transit in North Africa, arguing that transit points themselves are inscribed with new meanings, communities, and landscapes as those who seek onward journeys become “stuck” at these staging points, often for years. The same trajectories of (im)mobility are evident in the Asian region, particularly as Indonesia and Malaysia navigate the intractable problem of large arrivals of refugees with the inability to secure onward passage. There is some evidence in both contexts of the widespread abuse and exploitation of these vulnerable migrants. Malaysian authorities, including police and immigration officers, were exposed transporting Rohingya refugees from Myanmar across the Malaysian–Thai border where they were sold into slavery on Thai fishing
vessels. In an obfuscation of vulnerabilities, these refugees also became trafficked persons. With the establishment of nine refugee detention centers in Indonesia, widespread detainment and abuses of unaccompanied refugee children have been documented recently. They invoke multiple geographies of violence, bare life, and spaces of exception.

Environmental refugees

Graeme Hugo’s (1996) seminal article on environmental refugees initiated what is now a substantial body of geographical scholarship concerning the vexed relationship between human mobility and environmental crises. In that original article Hugo argued for a distinction between migrants who are truly compelled to move (as in political refugees) and what he termed “environmental migrants” whose migration is associated with environmental problems, but lacks this same “overt force.” This definitional fixity is nonetheless unsatisfactory given the complexity of natural and human-induced disasters associated with climate change and the contextual variability of disasters. The degree of force that propels these environmental migrants to seek new homes can vary greatly and begs geographers to attend to the nuanced landscapes in which disasters and their relation to migration are to be best understood. Thus, geographers pursuing this line of inquiry have tended to focus on predicting the effects of climate change on migration by examining the impacts of environmental problems on migration (Reuveny 2007). Reuveny’s own efforts at predictability modeling have foregrounded the extent of environmental problems and migration capabilities as key factors determining the propensity of populations to move. Not surprisingly, in the developing world the propensity to move is the greatest because of poor capabilities to respond and the absence of systems that enable resilience in affected populations.

Myers, Slack, and Singelmann (2008) extended the possibilities for thinking spatially about environmentally induced population movements to wrest it from the “third worldism” that appears to slip rather unproblematically into much of the current discussion. They suggest that place-based social vulnerability to environmental crises as well as post-disaster mitigation are certainly regionally variable, but that this variability is directly related to the extent of social vulnerability of the population. Examining Hurricane Katrina in the United States as one example, they found that socioeconomically disadvantaged groups were more likely to suffer severe damage to their homes and property and therefore their propensity to outmigrate far outweighed that of other socioeconomic groups.

Trafficked persons

Trafficked persons are defined by the United Nations under the Trafficking Protocol of 2000 as those who are deployed in exploitative laboring situations (apart from those trafficked for organ removal) by the use of force, deception, or fraud in the recruitment process, and where there are often networks of connected actors (traffickers) working in concert to transport, harbor, and deploy a person into this exploitative laboring arrangement. In this sense some trafficked persons may in fact move willingly and voluntarily with their recruiter/trafficker, believing they are to be provided with legitimate job opportunities in the destination. This marks these subjects as significantly different from other forced migrants whose propulsion outwards is based on fear and discrimination in the home country, rather than a desire for economic betterment. Although some victims of trafficking are abducted or kidnapped (and so forced at the point of origin), by far the vast majority are willing migrants.
Unlike with political and environmental refugees, published work on human trafficking in geography is almost entirely absent from the discipline. Nina Laurie et al.’s (2011) work with Nepalese women and girls trafficked across the border into India for prostitution is an important exception to this general malaise. Their work foregrounds the way issues of citizenship, gender and moral geographies intersect in the figure of the sex trafficked Nepalese girl/woman. When these victims return to Nepal they are often met with societal and familial discrimination, institutionalized via exclusion from Nepalese citizenship, which is always granted to a woman by a male relative. These moral geographies of exclusion from the sociopolitical body are extreme responses to sexual transgressions, but other research has demonstrated the ways return from trafficking is productive of “moral geographies” of marginalization (i.e., where morality is spatialized in ways that produce exclusions from the social and political body), especially for women and girls sex trafficked abroad (Yea 2014).

Gender in forced migration

In these studies of trafficking, gender intersects with forced migration through moral lenses in the context of return and with gendered and class-based discrimination in producing vulnerabilities in the migration process. The Filipina entertainers in Yea’s ethnography in Korea, and the sex trafficked women and girls in Laurie et al.’s study are positioned not only through force in their migration trajectories, but they must negotiate their post-trafficking lives in ways that are yoked to their prior trafficking experiences. Nonetheless, the interstices between gender and forced migration remain a peripheral research topic in geography. This intersection offers many possibilities for feminist and migration geographers. Thus, for example, while the issue of female genital mutilation has been the subject of extensive discussion in the context of sexual health and in international law, migration driven by fear of female circumcision is a subject entirely absent in geography.

Reflecting on the groups of forced migrants, there are at least two areas of convergence in the experience of forced migration, particularly as it affects refugees/asylum seekers and trafficked persons. The first of these relates to the efforts of receiving/destination states to classify these populations into those with legitimate claims for protection and those whose experiences are deemed unworthy of redress under human rights norms. There is, in other words, an emerging hierarchy of legitimacy among forced migrants, which oscillates around the thorny question of who counts as a “victim” worthy of protection under state norms and international obligations. Geographers who have documented these sorting and labeling processes have found them anything but neutral, with gendered, ageist, and racial stereotypes predisposing authorities to particular interpretations of the worthiness of any claim being made. Crawley’s (2010) study of unaccompanied asylum seeker children in the United Kingdom, for example, exposes the ways these children’s applications for asylum are prejudiced by their exertion of “too much agency”; behavior seen as inappropriate for children, especially traumatized refugee children.

The second theme that unites the experiences of asylum seekers/refugees and trafficked persons is their relationship to third parties involved in the business of people moving. This is a fascinating area of inquiry for geographers given the intersecting issues of clandestine and illicit movement, the role of social networks, and the ways intermediaries – whether people smugglers or human traffickers – can act to compound the precariousness of vulnerable and forced migrants. What is often overlooked in the imposition of such rigid binaries between
MIGRATION: FORCED

traffickers/smugglers and those they move is that many of these individuals are driven not by criminal intent, but by concern for the welfare of the persons they move; assistance is often a muted subject when traffickers and smugglers are positioned as criminals profiting from the vulnerability of others. A fascinating book length account, *The People Smuggler* by Robin de Creispigny, of the first people smugglers convicted under Australia’s antismuggling law, draws out just such complexities. Iraqi national Ail Al Jenabi was variously a refugee, an asylum seeker, and finally an unwitting people smuggler before his arrest in Thailand and extradition to Australia to stand trial. The extraordinary account of his life emphasizes what is lost in much research in geography on both refugees and, more particularly, trafficked persons; namely, detailed accounts of their lives.

The question of force and the proclivity to intervene

One of the key undercurrents of much academic treatise on forced migration concerns the debate about what exactly constitutes force in a person’s migration trajectory. Are there, for example, degrees of force in people’s decisions to move, or should force be defined in a binary opposition to freely motivated movements? And if so, what should define “free movement” as opposed to compulsion? Geographers have been involved in debating these questions, with Russell King (2002, 89) arguing more than a decade ago in relation to Europe that previously dominant binaries in migration studies – internal versus international, forced versus voluntary, temporary versus permanent, legal versus illegal – blur as both “the motivations and modalities of migration become much more diverse.” In relation to the forced–free dichotomy both King and others have recognized the need for changing discursive conventions when speaking about the relationship between migration and force.

To date related disciplines – particularly anthropology – have embraced this task to a greater extent than have geographers, because of the methodological complements that ethnography yields to understanding the nuanced complexities in people’s experiences of mobility. Conceptual developments in cognate disciplines provide some clarity to discussions of the relationship between decisions made voluntarily or through force. Anthropologist Larissa Sandy (2009), for example, developed the particularly useful concept of “constrained choice” in her treatise on the decisions of Cambodian women to enter prostitution. According to this approach, women’s decisions result from a combination of deliberate and careful weighing up of the options available to them, including an appreciation of the fact that while most of these women are not forced to enter prostitution because of physical threats to their life or liberty, they consider themselves to have “no real alternative” open to them. This more complicated and nuanced understanding of agency and choice in forced migration is useful for geographers to further explore since it unbinds the idea of force from the violence of physical compulsion and enables the extension of discussions of force to compulsion felt by the subjects of these precarious movements in circumstances of heightened gendered and economic insecurity and vulnerability.

The other key issue that has dominated academic engagements with forced migration in the past decade concerns the question of interventions. Like development, forced migration is principally a field of humanitarian intervention characterized in large part by the application of high modernist rationality to technocratic solutions. The journals *Disasters* and *Forced Migration Review* both express this emphasis on
interventions and on-the-ground documentation of refugee situations, best practice, and the logistics of delivering effective relief and longer term development aid to forcibly displaced populations within their own borders and internationally.

The emphasis on interventions itself generates a further subdisciplinary focus on identification and mapping of refugees. Crawley’s (2010) research with unaccompanied asylum seeker children reveals how, despite the aura of transparency surrounding the bureaucratic procedures for sorting legitimate from illegitimate claimants, preconceptions of appropriate subjects and experiences of violence predetermine the outcome of claims. Jennifer Hyndman (2010) makes a similar point in relation to her examination of the differential treatment of two child soldiers, one of whom received international acclaim through the re-telling of his experience, and the other who was remanded in the notorious Guantanamo Bay Prison. In the reception of forced migrants, geopolitical imagination influences the way that law, protection, and rights are applied.

New directions for geographers studying forced migration

Many of the scholarly directions mapped by geographers to provide novel insights into the experiences of other migrants should arguably also inform discussions of forced and vulnerable migrants. There are four particularly significant directions, namely: the possibilities offered by transnationals; the value of postcolonialism as a theoretical lens; the meaning of home; and methodological impasses.

Geographers view transnationalism as a practice of connecting across borders that applies principally to the experiences of successful – and usually legal – migrants. Although geographers now clearly appreciate the importance of the dynamics of transnational practices as they differ – or perhaps overlap – between middling, elite, and lowly positioned migrants, illicit population movements have received little attention in these discussions. Al-Ali, Black, and Koser’s (2001) work is a notable exception, with a focus on transnational practices of refugee populations as the move to Europe. They identify “limits to transnationalism” within geography, which are visible through the absence of scholarly attention on refugees and asylum seekers. They focus on the empirical cases of Bosnian refugees in the United Kingdom and the Netherlands, and Eritrean refugees in the United Kingdom and Germany in identifying the role of history and social and political factors in explaining highly variable modes of transnational life. Several UK-based geographers have explored the relationship between political activism and transnationalism among Islamic state refugees. Whether political refugees engage in the politics of the homeland from the “safe space” of the United Kingdom is a question that opens up new insights into the modes and content of transnational relations. The focus on transnationalism within the experience of forced migration could be further developed to include emotional geographies of shame, stigma, failed migration, family reunification, and the anxieties generated by the simple technological impossibility of maintaining communication with family across borders.

Following the above point, the meaning of home has proved a significant concern in advancing the geographies of transnationalism. Geographies of home are, however, not just the remit of long settled migrants, but also figure in the mobility experiences of refugees who remain in limbo in refugee camps or as noncitizens in neighboring territories. These populations in limbo are sustained by the single hope of
return to the homeland. Home thus operates as a powerful territorial imaginary among both political and environmental refugees. For trafficked persons though, as both Laurie et al. (2011) and Yea’s (2014) work suggest, home may be a site filled with anxiety marked by further vulnerabilities. Events in the home may present new spatialities of shame, stigma, and marginalization, including return to the home country, without necessarily involving return to the home community. Nor should such concerns be restricted to trafficked women, with men trafficked for forced labor, for example, also subject to the scrutinizing gaze of home communities. The Bangladeshi men in Yea’s (2014) study of migrant workmen in Singapore reveals that labor trafficking and the anxieties of return home are equally felt for male victims as they are for women. The interest of geographers in return migration more generally could thus be unfettered from its location in the experiences of voluntary and “free” migrants and usefully expanded to include the complex and multiple homeward trajectories and imaginings of forced migrants.

The sociospatial practice of “othering” marks a representational stumbling block in enabling the emergence of more progressive popular and statist views of forced migration that cries out for further elaboration. For both the Australian and United Kingdom contexts geographers have documented the ways asylum seeker incorporation into society is hindered by the syndrome of NIMBY-ism (or Not In My Backyard) (Hubbard 2005). While these spatialities at the societal level reinforce institutionalized modes of exclusion operating within the state, their location within discourses of the racially and politically marked other are areas not examined in particular detail by geographers to date. Geographers are well positioned to advance such a project because of attention to the spatialities of marginalization that have been documented in relation to other excluded and stigmatized groups in society, such as Roma and prostitutes. To these existing popular and statist discourses asylum seeker mobilities present additional axes of exclusion that hinge on fear of political extremist and Islamic fundamentalism in particular, as well as economic concerns about refugees taking jobs and posing additional burdens on welfare budgets already stretched in the current era of austerity.

Forced migration presents many research challenges for geographers, especially those interested in the experiences and theoretical significance of groups such as trafficked persons or refugee camp occupants, for example, or subjects, such as the meaning of home, life in transit, and transnational relations. We may begin to understand these research predilections in the context of concerns about methodology and ethics. Methodologically, studying the “everyday” lives of forced migrants, including their transnational (dis)connections, their embodied experiences of living in transit, or their trajectories of return home, require novel and creative approaches. Yea’s (2014) study of trafficked Filipina entertainers in Korea, for example, required a sustained ethnographic engagement that involved living with many of these women in Korea over the course of one and a half years. This, she felt was necessary to disrupt the stereotypes associated with this form of forced migration that limited the insights gained in other studies on sex trafficking. Ethnography and participant observation are certainly valuable approaches to research that could produce novel insights into the experiences of forced migration; insights that may disrupt a violent, episodic framing in favor of a recognition that forced migrants also have every day, nuanced lives and aspirations. But such approaches are logistically hard and on occasion dangerous. Moreover, forced migrants – because of the clandestine nature of their movements – are often difficult to locate and/or unwilling to
share their experiences lest disclosure predispose them to further vulnerabilities in migration. Ethics problems also hamper research in this area, as it does with any vulnerable research participants. But ethical problems normally encountered by participants considered “at risk” by university ethics committees are further compounded in the case of forced migrants because of the ways their mobilities can challenge regimes of legality. These troubling methodological and ethical concerns need geographers who have studied the lives of forced migrants in-depth to reflect on these concerns in published academic forums. Pathways through this research impasse can only benefit this increasingly significant area of geographical inquiry and lived experience.

References

Internal migration refers to the movement of people within the boundaries of a nation-state. The term covers a multiplicity of different kinds of migration, including rural to urban migration, rural to rural migration, intraurban migration, displacement due to civil strife or environmental hazards, movement that is voluntary or forced, and movements that are permanent or circular. Studies of internal migration share many features of international migration research, including substantive themes, theoretical frameworks, and policy concerns, but have tended to fade into the background in migration work more generally. This is surprising, given the numerical importance of internal migration: while estimates suggest a worldwide figure of 214 million international migrants, this figure is far exceeded by numbers of internal migrants, currently estimated at 740 million, with 100 million internal migrants in China alone.

Internal migration has long been an important feature of human experience across various historical periods, but recent evidence suggests that it is on the rise, facilitated by better communication and transport links, and brought about as people move in response to the inequitable spatial distribution of resources, services, and opportunities, or to escape violence, natural disasters, or the increasing number of extreme weather events. Given that overall rates of fertility and mortality change quite slowly, internal migration may be the most volatile dimension of population change within a country, transforming settlement patterns and reinforcing or ameliorating geographically uneven development. As rapid increases of population in destination areas affect competition for food, housing, and other resources, and in many contexts exceed the provision of these, internal migration carries significant implications for human wellbeing, social justice, and equitable governance. At the same time, policies that facilitate internal migration are justified in terms of its development potential – as a strategy enabling low-income households to diversify incomes and mitigate livelihood risks.

The significance and extent of contemporary internal migration

The scale of contemporary internal migration underlines its importance as a fundamental process of social and demographic change. A recent estimate from the United Nations Development Program, based on national census data, states that around the world there were 740 million people living outside their region of birth in 2005, while further analysis using additional national datasets revised this figure upward to 763 million people (UNDP 2009). Ambiguities in the figures for internal migration reflect the fact that there is no single source of data capturing migration within countries, and variations in data collection methods make comparisons problematic. There are differences in the types of data collected (e.g., events or transitions), the intervals over which migration is measured (e.g., one year, five years, since birth, or latest move, regardless of the timing), and the distance over...
MIGRATION: INTERNAL

which internal migration, compared to other forms of local mobility, is defined.

In a recent study, demographers Bell and Charles-Edwards (2013) attempted to iron out some of these ambiguities in order to draw international comparisons of five-year and lifetime course internal migration. They concluded that the most mobile regions of the world are North America, Australia and New Zealand, and Europe, especially in terms of lifetime migration. This reflects an interplay between relatively inexpensive housing, flexible housing and financial markets, limited government regulation of housing markets, and long-term historical forces in so-called white settler societies. However, the researchers also note a decline in the intensity of internal migration in these regions in the 20 years between 1990 and 2010. This pattern runs counter to prevailing narratives of hypermobility and dislocation, but is seen as reflecting an aging population, increased rates of homeownership, and the increased number of dual-earner couples with a propensity to geographical fixity.

Compared to findings from North America, Australia, and New Zealand, Bell and Charles-Edwards (2013) report lower rates and intensities of internal migration in Asia, Africa, and Latin America, although China is noted as an important exception. Here, there has been a substantial increase in interprovincial mobility recorded over the 2000–2010 period. The emergence of China as an industrial giant has given rise to the largest migration the world has ever seen: more than 100 million people have been drawn to the expanding industrial zones of the east from the rural and less developed provinces of the interior. The visibility of internal migration within national statistics in countries such as Vietnam, which also reported an increase, reflects the existence of government policies restricting internal mobility (e.g., household registration systems). Elsewhere, it is likely that figures reported in quantitative studies of this kind severely underreport internal migration. Understandings of past and contemporary patterns of internal migration are best gleaned from case studies and smaller surveys, as nationally available census data is limited to interprovincial mobility. National data of this kind obscures the most common types of movement, including rural–urban migration and intraprovincial rural to rural migration, and movements of durations shorter than five years, none of which are easily captured by conventional population measures.

Historical contexts

While data of this kind suggest that internal migration is a relatively new phenomenon, this kind of mobility is a long-established facet of people’s lives throughout the world. However, histories of internal migration vary across different places, making generalizations awkward and unhelpful. Internal migration figured, for example, in response to events such as the enclosure of the commons and dispossession of the English peasantry, in movement from the countryside to burgeoning eighteenth- and nineteenth-century cities during the Industrial Revolution in Europe, and in the migration from the deindustrializing north of England to London and the southeast in the 1980s as neoliberalism took hold in the United Kingdom. In the United States, key internal migration streams have included the westward movement from the east coast of poor and working people in the mid-nineteenth century, the mass migration of African Americans from the rural South to Northern cities in the 1920s, and migration to California to escape drought and indebtedness during the Great Depression in the 1930s.
In regions such as Asia, Africa, and Latin America, internal migration has also followed particular historical phases, including, for example, migration for work on colonial plantations and trading posts, rural to urban migration following rapid industrialization and declining returns to agriculture from the 1980s onward in much of Asia and Africa, not to mention forms of displacement linked to infrastructure development, environmental protection, war, and conflict. For much of the Global South, internal migration is part of people’s lives, often forming part of a strategy in tandem with natural resource-based livelihoods, and in response to pronounced seasonality in monsoonal and semiarid regions. Examples include swidden cultivation systems, where soil fertility is managed through forest clearance, cultivation, and extended fallows coupled with the movement of settlements, and pastoralism in semiarid areas, where resources are managed by the movement of livestock. Migration in search of labor opportunities in other rural areas or in towns and cities is a feature of pronounced seasonality in sedentary farming in Asia and also in African farming systems, where household members depart to find temporary work to cover the slack season.

In many places, this is a pattern with a long history: in rural Vietnam during the colonial period as much as two-thirds of the peasantry were involved in circular movements between rural areas during the wet rice transplanting and harvesting seasons. The “rice floods” in the Mekong Delta are strongly linked to seasonal migration to cities and urban centers. Internal migration is also associated with various crop booms (e.g., oil palm in Sarawak, cocoa in Sulawesi, Indonesia, shrimp farming in Thailand, and coffee cultivation in Vietnam), which have encouraged rural to rural mobility from the colonial period to the present day. Furthermore, the intensification of internal migration since the 1980s reflects the simultaneous impacts of rapid industrialization and declining terms of trade for agricultural commodities, prompting rural to urban migration across a range of contexts (Rigg 2007). More recently, economic crises, structural adjustment, and the precarious nature of much urban employment have meant even more complex patterns of mobility, including rural–rural and peri-urban–urban connections, now predominate (Tacoli 2009).

Conceptualizing internal migration

Studies of internal migration have been influenced by the same theoretical frameworks that underscore migration theory generally. These include theories that focus on the drivers of migration and theories that focus on how migration is facilitated and reproduced. Aside from emphasizing the material dimensions of movement, theories have been developed to examine the role of power, subjectivity, and identity in internal migration, and the remaking of places through rural–urban interconnections. Theories focusing on the initiation of internal migration have fallen broadly into three camps. The first of these includes behavioral explanations that emphasize rational choice and voluntarism, in that the decision to migrate is seen as made by individuals in response to particular stimuli, such as wage differentials between place of origin and destination (Thadani and Todaro 1979). Critics have pointed to the ways this ignores the social dimensions of migrant decision-making, such as family and community context, and note that the wider political economic context of migration is elided.

By contrast, this latter dimension is given prominence in structural explanations, which emphasize wider forces shaping individual and aggregate migration patterns (e.g., the workings
MIGRATION: INTERNAL

of new international divisions of labor and labor market segmentation under capitalist and neoliberal systems; Sassen-Kooob, 1983). This approach enabled consideration of the gender, racial, and ethnic dimensions of labor migration to be included in analyses, emphasizing the ways in which migrant labor markets are segmented along racial and gendered lines. In Southeast Asia, since the early 1980s the growth of export-oriented industrialization has been closely linked to the migration of women from rural areas to work in urban and peri-urban factories (Mills 1999), while analyses of rural migrants in urban informal sector labor markets highlight the connections between particular jobs and ethnicity in Asian and African contexts.

The third approach has emerged from studies of the new economics of labor (Stark 1991) and was given renewed impetus in sustainable livelihoods approaches, which emphasize household livelihood strategies. Internal migration is part of a wider diversification of income sources across activities such as agriculture, petty enterprise and formal employment shaped by household labor availability, consumption needs, and production possibilities (alternative forms of income) insofar as these are conditioned by wider economic and sociopolitical shifts. Although this perspective has been useful for understanding the factors that prompt migration, it has the added benefit of directing attention to the role of migrant remittances in household livelihoods, and the links between agricultural and nonfarm work (Rigg 2007). As a result, this perspective on migration underpins much of the research and policy work on migration and development, and has been used as a framework by studies that demonstrate the positive ways in which internal migration mitigates environmental and economic risks, shocks, and stresses for low-income households (Tacoli 2009; UNDP 2009). Further nuance is added to this perspective by approaches that look closely at gender and intergenerational dynamics within households, in order to understand the ways in which internal migration is negotiated within the context of family power relations and thus has gender- and age-specific impacts on wellbeing (Resurreccion and Khanh 2006).

Theories that focus on the perpetuation and reproduction of migration explain how current flows can produce further internal migration, for example through the role of social networks that link the origin and destination of migrants. These approaches share much with those developed in relation to international migration, and include both formal and informal institutions. Of the latter, family and kinship are of critical importance in providing practical and material support for those who may follow migrants to other destination areas. Networks focusing on villages of origin are also of critical importance for similar reasons. Both of these kinds of network facilitate circular migration: the regular to and fro movement of people between city and countryside, which has been emblematic of much movement in African and Asian contexts.

Work on migration to forest frontier areas in upland Southeast Asia has noted the ways in which such networks link places of origin and destination, shaping the geographies of migrant settlement in forest areas as newly arriving migrants are able to stay with neighbors and work on their plots before establishing themselves. Informal networks of this kind can become increasingly formalized in efforts to channel and direct the ways in which migrant earnings are used. Elmhirst’s (2002) study of female rural migrants working in Jakarta factories showed how elite, city-based men from the same village of origin created a “village organisation” which took on the role of encouraging them to save, and send money home, with a view to improving life in the village. These networks work in a similar way to the kinds of
hometown associations described in the international migration literature and seen by the World Bank as potential agents for development.

Theories that examine the role of power, subjectivity, and identity in internal migration have drawn attention to the ways in which movement is motivated by matters beyond a simple economic calculus, and how individuals and spaces are transformed through processes of mobility. By focusing on the crafting of “modern” subjectivities, research has drawn attention to the aspirational dimensions, particularly of youth mobility from rural areas, where a desire to shake off a rural identity is manifest in migrants’ narratives. Migration for work or education is part of “becoming somebody” (Crivello 2011). Concepts such as modernity and cosmopolitanism are woven into analyses of how internal migration is integral to the ways people negotiate contrasting subject positions as “modern” or “traditional,” and how it contributes to the achievement of complex social goals linked to dominant cultural discourses about modernity and progress (Mills 1999). Other work that draws on similar bodies of theory explores the links between internal migration, identity, and place-making, as social and economic remittances connecting village and city produce rural villages as socially urban spaces and foster forms of rural cosmopolitanism (Gidwani and Sivaramakrishnan 2003).

Links with international migration

While many textbooks on migration would suggest that debates on internal and international migration have developed in parallel and with little cross-fertilization, migration scholars have suggested that this divide is artificial and unhelpful for three main reasons. First, shifting geopolitical boundaries blur the distinctions between internal and international migration. Europe’s Schengen Agreement has created a borderless zone for mobility within much of Europe, making international moves more akin to internal migration. The collapse of the Soviet Union and of Yugoslavia also turned internal migrants into international migrants or minorities in newly created states. The creation of nation-state boundaries in Africa following decolonization in the 1960s cut across areas where there was once free movement based on ethnic affiliations or nomadic circuits: in some cases these have continued, but in others they have been blocked (King and Skeldon 2010). Elsewhere, forms of graduated citizenship and differentiated entitlement accorded to ethnic minorities also have the effect of producing de facto borders within countries, as the examples of China and Vietnam attest.

Second, individual and aggregate migration trajectories reveal linkages between internal and international migration in important ways. King and Skeldon (2010) describe stepwise migration from internal to international, as rural migrants move first to the city in their country of origin before moving overseas: examples of this kind of flow include Turkey, Thailand, and Mexico. They argue that this kind of sequencing is shaped by the nature of global capital and geographies of labor demand. A second sequencing they identify is where international migration leads on to internal migration, as international migrants move on within destination countries. They cite studies of refugees in the United Kingdom, United States, and Sweden who move to larger cities in their host countries in search of better economic and educational opportunities. Third, King and Skeldon point to the gains to be had from linking theoretical approaches developed independently for internal and international migration. There is evidence that this kind of theoretical cross-pollination is already happening, as both kinds of migration research
are influenced by new developments in social theory, and as there is increasing recognition that the policy implications of migration (whether viewed as a negative or a positive phenomenon) are also shared.

Government policies on internal migration

While international migration is directly shaped by government policies on immigration and citizenship, there are only a few areas of internal migration that are directly controlled in this way. State-sponsored resettlement schemes of the kind found in Indonesia, Vietnam, and Laos involve the relocation of people to state-established resettlement sites from areas where they had been considered “out of place” (in remote or marginal places, in conservation areas, in the way of infrastructure developments). State-sponsored internal migration of this kind is driven by factors such as a desire to facilitate the delivery of services to remote and mobile upland populations and to remove upland swidden cultivators from fragile watershed environments by relocating them in lowland resettlement sites (Elmhirst 2012). In Indonesia, state-sponsored resettlement has also become entwined with corporate interests as transmigration settlements are being established around oil palm investments.

For the most part, however, internal migration is governed and shaped indirectly, through state policies relating to housing tenure and employment, and at a broader scale to planning, investment, and development strategies. Such policies have the effect of opening up and closing down opportunities for would-be internal migrants. In China, the household registration system (hukou) has been used to restrict migration and keep people in the countryside, as those seeking to change residence are required to obtain approval for hukou change from local authorities: possession of the appropriate hukou is a requirement for accessing services such as education and health care (Nguyen and Locke 2014). Critics have suggested that, while the system has not prevented rural–urban migration from taking place, it has created severe inequalities in the entitlements of migrants, leaving them precarious and vulnerable. Although reform of the system has recently been announced, there is skepticism about whether migrants will experience much change, given that reforms are limited to hukou in smaller cities and where there is a risk of corruption and rent-seeking behavior on the part of officials.

Rural–urban migration in Vietnam has been shaped by a similar system designed to restrict migration and, despite some relaxation of institutional controls, they continue to structure qualifications for residency and related social entitlements. While 80% of migrants in Vietnam have some form of temporary registration, fewer than 5% have permanent registration where they work, because they don’t meet the requirements (Nguyen and Locke 2014). Opportunities are also closed down by land-use zoning and restrictive tenure regulations that make it difficult for would-be rural migrants to settle in urban areas. Migrants without officially recognized tenure are easily displaced by processes of urban redevelopment, as has been the case in a number of cities across the world.

Indirect influences on internal migration have included development policies based around import substitution and industrialization, and urban-based investment in government services such as health and education, which created the conditions that encouraged migration to urban areas in search of economic and educational opportunities. In the 1980s and early 1990s structural adjustment and restrictions on government spending had the effect of creating uncertainties in urban incomes, prompting a
stabilization of rural–urban ties, and in some instances urban to rural migration. At an international level, the World Bank has set out a policy approach that is designed to encourage rural–urban migration, with urban agglomeration seen as crucial for fueling economic growth. Particular targets for this approach include registration systems such as those found in Vietnam and China, but other kinds of obstacles to urbanization (lack of transportation infrastructure, etc.) are also seen as important. This approach has drawn strong criticism for failing to consider the social and environmental impacts that follow from these kinds of urban mobility, where precariousness and poverty for some exist alongside privilege and prosperity for others.

Emerging areas of research on internal migration

Internal migration for development

There has been a resurgence of interest, led by scholars working from a sustainable livelihoods perspective, in the ways in which internal migration can foster positive development outcomes for low-income people (UNDP 2009). As part of an overall household livelihood strategy aimed at acquiring assets from a range of sources in order to insure against future shocks and stresses, internal migration is not necessarily a strategy of last resort (Tacoli 2009). This kind of approach highlights the potentially positive role of migration and migrant remittances in fostering development, through the transfer of economic and social remittances. Economic remittances may be used to pay for the education of children, the improvement of housing, and food and health care, thus enhancing wellbeing in areas of origin. Moreover, the migration experience may have fostered capacities for dealing with bureaucracies and figures of authority, thus enhancing household capabilities. There has been a mushrooming of empirical studies that seek to explore this dimension of internal migration and, taken together, emerging evidence suggests that optimism in relation to migration as a development panacea needs to be tempered by a recognition that the outcomes of migration depend heavily on the type of migration, the selectivity of migrants, and the destinations. Moreover, migrant remittances, as a form of bottom-up development assistance, are unlikely to solve deep structural development obstacles such as poor macro-economic policy, questions of social justice and uneven prospects for political participation, insecurity, corruption, and deficient infrastructure.

Internal migration and life course transitions

Scholars have been interested in exploring the link between internal migration and life course transitions of various kinds. Youth migration has provided a strong focus for recent research, reflecting the fact that a large proportion of internal migration is accounted for by the movement of young people, either for education or for employment. Geographies of student mobility have explored the internal migration of young people moving from home to university, focusing on the impact of student migration on the economic and social landscape of university towns in the United Kingdom and other parts of the world (Smith 2009). Some of this work has also explored the onward mobility of students after they graduate, and the link this has with the uneven development of labor markets and social mobility. In developing countries, the focus has been on youth transitions and migration for education or work. The World Bank has estimated that, across 29 developing
countries, young people were found to be 40% more likely than older people to move from rural to urban areas or to move across urban areas. The higher propensity of rural youth to resort to internal migration reflects a lack of employment opportunities in rural areas, but this is coupled with a generally negative perception among young people of agricultural labor, which is associated with low returns, drudgery, and low social status (Elmhirst 2002). Crivello’s (2011) study of internal migration for education in Peru shows how young people and their parents connect migration with the process of “becoming somebody in life” and view it as a strategy for achieving their educational aspirations. This is linked to dependencies between parents and children and, in particular, the roles that children play in mitigating family poverty (Crivello 2011). Rapid increases in internal migration and its potential impacts on wellbeing underpin recent work on marriage and social reproduction in areas with high levels of labor migration, particularly of women. Resurreccion and Khanh’s (2006) work in Hanoi is one of a number of studies that shows how parenting is affected by women’s rural–urban migration in Vietnam, particularly as gender norms limiting men’s domestic responsibilities prove intransient in the face of other kinds of social changes.

**Internal displacement, war, and conflict**

One aspect of internal migration that has received special attention in recent years concerns the displacement of people within a country’s borders, either as a direct or indirect consequence of war and conflict, or as a result of the structural violence of the state and other agents, who forcibly remove people to make way for development projects of various kinds. In relation to war and civil conflict, there are an estimated 33.3 million internally displaced persons (IDPs) worldwide, with the largest populations in Colombia, Iraq, and South Sudan. Conflicts in many other African countries, alongside Sri Lanka, Afghanistan, and Indonesia also have had large IDP populations, although recent increases reflect the escalation of conflicts in Syria and the Central African Republic. Unlike refugees, IDPs are the responsibility of their own government, since they have not crossed international borders, yet it is often this very government that has persecuted and displaced them. Despite the differences in legal status and of entitlement to aid from the international humanitarian community, the causes of displacement and the experience of being displaced are often similar for IDPs and refugees. Much like refugees, IDPs often feel like strangers in their place of refuge, where the local population may be from a different ethnic and/or religious group and/or may speak another language. Consequently, IDPs may not feel welcome, despite sharing the same citizenship as the host population. Identifying the processes that lead to conflict-driven internal displacement means recognizing multilayered causes, including the inequities of globalization and development, coupled with antipathies that have deep historical and cultural roots. Work has suggested that people only move when threats to their safety are perceived to exceed the risks of travel to a new and unfamiliar destination. Unless violence reaches certain levels, people are more likely to confine themselves to the safety of their homes, family networks, and surroundings they know and trust.

Other forms of displacement are associated with structural violence – that is, invisible forms of violence inherent in political and administrative actions that prevent poor people from making a living – and this too has formed a new avenue of research on internal migration. Development-induced displacement is one of the drivers of internal migration in
both urban and rural areas. The construction of spectacular high-rise apartments, shopping malls, and regional corporate headquarters has been a leitmotif of mega-urbanization in cities such as Jakarta, Bangkok, and Manila, and is accompanied by the displacement of the poor and politically marginalized. In addition, aggressive acts of “accumulation through dispossession” are evident in Vietnam – for example, in the establishment of the Thu Thiêm New Urban Zone, which led to the eviction of 14,000 low-income households, the razing of all built construction, and the filling in of marshes and streams to make way for new office space, luxury high-rise apartments, and new public spaces.

In a similar vein, recent research on migration and agrarian change in rural areas has drawn attention to large-scale land acquisitions by the state and the corporate sector for commercial or conservation purposes, which are associated with population displacement, the undermining of viable livelihoods, and subsequently the fostering of new patterns of internal migration. Processes of land acquisition for carbon sequestration, so-called green grabs, have become a feature of parts of Asia and Latin America, while the expansion of large-scale agrofuel plantations in parts of Africa and Southeast Asia are associated with the dispossession of local people, prompting new waves of internal migration as those displaced seek income alternatives elsewhere.

Internal migration, natural disasters, and climate change

Debates about the impact of climate change have focused attention on the linkages between the environment and migration, following alarmist reports that future environmental change will lead to mass displacement of populations from locations vulnerable to climate change effects. Although much of the research prompted by such pronouncements has focused on international migration, a growing body of research is emerging that draws attention to climate change and internal migration. Two key directions are evident in research. The first is work that looks at climate change as one of a series of drivers of migration, and that demonstrates the importance of internal migration as those displaced by climate-related environmental hazards follow already established migrant networks and relationships (Black et al. 2013).

A second thread explores the role of migration as an adaptive, resilience-building strategy, which enables individuals and households to accumulate assets and thus adapt to climate change more effectively. A key dimension of this work has been to encourage policies that support sustainable forms of local migration through better planning, economic diversification, and investment in smaller urban centers (Tacoli 2009). Critically, this work also recognizes the multiple linkages local migration has with various forms of environmental change (from slow-onset droughts to environmental shocks such as floods and typhoons), and thus points to the need for a nuanced, contextual approach that is not only restricted to examining internal migration but considers its connections with all other forms of mobility too.

International migration, movements of people who leave one country to settle in another where they establish social ties (Migreurop 2013, 13), has stimulated a voluminous and growing geographical literature that examines the volume and diversity of migration flows, their meanings for migrants and the societies where they settle, and representations of migration. Geographical accounts have been particularly important in explaining the increasing spatial variegation and complexity of contemporary international migration and its historical foundations in ongoing processes of colonization and imperialism. Contemporary migration trends include the illusionary binary of permanent and temporary migration, the feminization of migration, the rise of migration induced by environmental change, and the challenges that ethnoracial diversity among migrants poses for immigrant-receiving societies across the world. In addition to efforts to explain international migration, geographical perspectives have been important in examining how representations of international migration and international migrants are linked to state efforts to exert and maintain control over national borders.

International migration is racialized and gendered. The geographies of contemporary migration are rooted in the European colonization of territories in the Americas, Africa, and Asia. The forced migration of colonized peoples contributed to the racialized hierarchies that still underpin many state efforts to control migration. Recent research has examined how gender affects migration, comparing the international movements of men and women; investigating how women’s roles as caregivers affect their decisions to migrate, their choice of destinations, and subsequent links to family and friends; and assessing how migrant women are represented by the public and policymakers (Pratt 2012). The interest in gender has also drawn attention to the heteronormativity of contemporary international migration and migration regimes, highlighting the barriers to international movement for many people who identify as LGBTQ (lesbian, gay, bisexual, trans, or queer) and the emancipatory potential of international migration.

Historical foundations of contemporary migration

Most introductory human geography textbooks deal with migration, often with a map showing population migrations over time. Such a map often gives the impression that the world’s population is on the move — arrows highlight flows to and from different continents and a dizzying number of arrows underline the intricate flows between states within the same continent. But what is new about such movements and why do the short- and long-distance moves of people across borders and boundaries continue to interest so many geographers?
Migration is not new. The movement of *Homo erectus*, and later *Homo sapiens*, out of Africa set in motion processes of social and biological change that shape the human experience to this day. The evolution of our species is tied to acts of migration, making it impossible to summarize human migration succinctly. Nonetheless, there are clearly important antecedents to contemporary migration because past migrations influence current geographical understanding of contemporary international migration, particularly thinking about its causes and impacts.

Empires, from the Holy Roman empire up to the Ottoman empire and the many European empires of the seventeenth to twentieth centuries, necessitated international migration. Maintaining control of far-flung territories required moving troops and administrators, and in many instances European colonial powers also facilitated the movements of their own citizens to exploit resources and deal with population pressures and indigence at home. Colonialism is tightly woven with processes of industrialization and migration. The industrialization of agricultural production in Europe created surplus labor that migrated to the emerging industrial cities and towns of England, Belgium, and the Netherlands to work in factories processing raw materials extracted from colonial territories. Some rural to urban migrants moved on to colonial territories such as the United States, Canada, and Australia. Their jobs were often taken by migrants from Ireland and southern and central Europe who were fleeing desperate economic conditions and political repression. The economic processes and migrations that colonialism encouraged also led to the decimation of aboriginal populations in the Americas, Australia, and New Zealand as European migrants built settler societies. At the same time, millions of Africans were abducted or sold into slavery and transported to work in the mines and plantations of the Caribbean and North and South America.

Slavery and indentured work are important antecedents to modern labor migration, as they illustrate how capitalism exploited and reinforced uneven geographies of resources and power, set in motion the emergence of ethnoracially diverse societies, and relied on involuntary movement. Highly sought-after goods such as sugar, tobacco, coffee, cotton, and gold were produced through slavery for European markets, and the labor of slaves underpinned the economic and political power of colonial states such as Britain, France, Belgium, the Netherlands, Spain, and Portugal from the seventeenth to the nineteenth centuries. It is estimated that, by 1850, 12 million Africans had been taken as slaves to the Americas under conditions of unprecedented brutality. Slavery involved women and men, and, while abysmal working conditions dominated every slave’s life, women’s experiences were also shaped by sexual exploitation. Systems of indentured work essentially continued forced labor practices in the nineteenth and twentieth centuries as migrants from India, China, Japan, and other regions of Asia were recruited to work in mines, plantations, and infrastructure projects across colonial territories. Although indentured laborers were paid, their wages and working conditions were usually dangerous, dirty, and undesirable.

Historically, migration has been highly uneven in terms of participants, motivations, and consequences. In the colonial period, migrants became essential parts of a capitalist economic system characterized by significant international variation in wages and working conditions that continue to this day. Ethnic, cultural, and racial diversity are inherent in the landscapes that migration, colonialism, and capitalism exploit and reproduce. Although migration had been a force in Europe long before the colonial period, and many cities and towns were marked
by cultural, linguistic, and religious diversity, colonialism drew the peoples of Africa, Asia, the Caribbean, and the Americas into a global system of trade, exploitation, and movement. The other became a potent force in shaping social relations and politics in settler societies and in the metropolitan societies that governed them.

**Trends in contemporary migration**

Contemporary migration builds on the uneven geographies laid down in the colonial period. The particulars of migration are structured by specific economic, social, and political histories and, as a result, contemporary migration flows vary geographically. The dynamics and implications of migration in Europe are different from those in North America, and different again from those in East Asia or Africa. Mixed migration flows predominate, with people migrating for many different reasons ranging from a search for better professional opportunities abroad to flight from conflict and environmental degradation. It is impossible to capture fully the diversity of contemporary migration, but four important trends stand out: permanent versus temporary migrations; the feminization of migration; migration caused by environmental degradation; and the challenges of ethnoracial diversity.

Because of the financial, social, and emotional costs associated with migration over long distances, many individuals leave their countries of origin knowing that the move will be relatively permanent. Historically, this was especially true when the financial costs of migration were high relative to income, long ocean voyages had significant risks, and weeks if not months were required to cross great distances. As a consequence, images of migrants leaving country, home, and family behind, never to return, are conveyed through novels, plays, and movies, and are strongly rooted in the popular imagination. Nevertheless, the distinction between temporary and permanent migration has never been straightforward. Historical research indicates that, even in the nineteenth and early-twentieth centuries, migrants maintained ties to their homelands and many viewed migration as a temporary relocation that would provide the resources needed to support a family and acquire land in the homeland. It is almost impossible to quantify the number of people around the world who move permanently and temporarily, in part because of the fluidity of migrants’ decisions. Immigration laws and regulations that permit some migrants to change their status from temporary to permanent also complicate attempts to count the two groups of migrants. Traditional settler societies such as the United States and Canada, as well as many European countries, are now admitting temporary migrants in response to domestic labor shortages. In many countries, there is a growing connection between temporary and permanent immigration systems, especially for skilled labor. For instance, in response to the boom in high-tech industries in the United States in the late 1990s, Congress increased the annual number of temporary worker visas (H-1B) from 65,000 to 195,000 each year from 2001 through 2003. In addition, many temporary admission categories in the United States now waive the requirement that individuals demonstrate intent not to remain permanently. As a consequence, some temporary visa holders can apply for permanent residency without leaving the United States. In this regard, the system in the United States is illustrative of the ever more complicated relationship between “permanent” and “temporary” migration.

The upswing in the number of “temporary” migrants has also been facilitated, if not encouraged, by several states in the global
periphery and semiperiphery which see remittances from individuals working abroad as an increasingly important component of their economies. The efforts of the Philippines government to arrange and certify employment opportunities for its citizens are perhaps the best known. The Philippine Overseas Employment Administration (POEA) manages a “temporary” labor flow of approximately 1 million Filipinos who work in jobs that range from domestic service to engineering and nursing (Tyner 2009). The majority of deployments are for work in the Gulf States and East and Southeast Asia, although many Filipinos also work in Europe and North America. As temporary foreign workers in domestic service, construction, and manufacturing, Filipinos are literally building countries but enjoy few of the rights afforded the national population. The direct involvement of governments in facilitating the temporary migration of their citizens, as well as the alignment of education and work experience with those demanded by employers, are new aspects of international migration. In many ways, the growth of temporary migration on a worldwide basis reflects an emerging agreement between origin and destination countries that are responding to distinct economic and political challenges. In many wealthy countries where permanent migration has become a politically charged issue, temporary migrants are an effective response to labor shortages. As long as “temporary” migrants remain temporary, the concerns about social, cultural, and economic integration and intergenerational social mobility that characterize debates about permanent migration are sidestepped (Khoo, Hugo, and McDonald 2008).

Debates about permanent and temporary migrants frequently overlook the women and men who make international moves. Migration is a gendered process that more women are undertaking on their own rather than accompanying husbands and other family members. Research increasingly highlights the feminization of migration, with women making up almost half of all migrants worldwide (King 2012). Although women’s motivations for migration are as diverse as those of men, a sizable number migrate in response to gendered aspects of everyday life. In many wealthy countries, growing numbers of women have entered the labor force since the 1970s. The feminization of the labor force has created a demand for child and elder care, and help with cooking, cleaning, and the other reproductive tasks needed for household survival (Romero, Preston, and Giles 2014). At the same time, many states have reduced spending on care, expecting family members to provide services that were formerly available publicly. The gap between care needs and the caregiving capacities of family members is often filled by migrant women. Ever more female migrants are also working in physically taxing and poorly paid occupations outside the domestic sphere, such as nursing assistance, food preparation, and clothing manufacturing. The numbers of female migrants leaving countries such as Sri Lanka and Indonesia have increased, with many working in private households as well as formal workplaces. Many of these women are part of global care chains in which they provide the financial resources that allow female relatives to care for their children and aging parents. Simultaneously, their physical and emotional labor ensures the wellbeing of families in the Gulf States, Southeast Asia, Europe, and North America. With strong ties to social reproduction in their home countries and places of settlement, many migrant women are part of two families, two cultures, and two economies, juggling conflicting obligations and loyalties.

Concentrated in Asia and Africa, forced international migration is also gendered. In 2013, the United Nations High Commissioner for
Refugees (UNHCR) estimates, there were 51.2 million forced migrants in the world, the highest number since 1989. Of this total, approximately 17 million were refugees, of which 49% are women (UNHCR 2014). Women experience as much political and social persecution as men, although sometimes in a different manner. For instance, although both genders suffer discrimination and persecution on the basis of sexual orientation or transgender identity, women are particularly vulnerable to sexual violence and gender persecution.

Among the new arenas of migration research, growing attention is being paid to environmental or climate change migrants who move as a consequence of environmental degradation (Black et al. 2011). Predictions about the number of people who may be displaced vary widely—from thousands to millions—but it is clear that climate change is associated with temporary, often local, displacement due to environmental catastrophes such as cyclones and floods, as well as with international migration from places where livelihoods are no longer sustainable. Migration is a long-established coping strategy for dealing with social and economic instability in ecologically vulnerable locations. Although there is general agreement that environmental and climate change migrants should enjoy the human rights guaranteed under international and national laws, existing legal instruments are most effective in dealing with people made homeless by sudden-onset disasters such as earthquakes, flooding, and landslides rather than with those who move in response to the slow-onset disasters and cascading environmental degradation associated with climate change.

One of the great challenges posed by contemporary international migration concerns responses in countries of settlement to ever more culturally, linguistically, socially, and economically diverse migrants. Research is already demonstrating that ethnoracial and linguistic diversity characterizes many cities across the world. Although many states, such as Australia, Canada, Argentina, and England, have long migration histories, the past provides few models for how to achieve integration, equity, and social mobility in contexts of high ethnoracial diversity. The roots of diversity in colonialism, capitalism, and the processes of climate change that do not respect international borders are seldom acknowledged. Contemporary migrants are being met by regulatory environments that increasingly attempt to “manage” who will cross borders as a response to domestic social, economic, and security concerns. Rather than discussing nation-building and the needs of migrants, contemporary discourses about immigration and diversity in countries of reception emphasize domestic economics and politics.

Explaining migration

Many geographers have tried to account for the volume, composition, and impacts of international migration. The “Laws of Migration,” published in 1885, which summarizes and explains migration flows prevailing in Western Europe at the time (Ravenstein 1885), is a seminal analysis that still influences geographical thinking about international migration. Ravenstein (1885) emphasized that migration flows diminish over distance according to a distance–decay relationship, in which the volume of migrants declines with distance from the origin. Geographers have also seized on Ravenstein’s observation that people migrated mainly for economic reasons. In the late nineteenth century, the minority of migrants who moved long distances in Europe were attracted to centers of industry and commerce where the Industrial Revolution created employment.
Geographers paid far less attention to Ravenstein’s observation that women were more likely to migrate than were men. In late-nineteenth-century Europe, young women were often viewed as economic liabilities and sent away to work, so their families no longer had to feed, clothe, and sustain them. As domestic and factory workers, many young women sent money home, enhancing their families’ economic wellbeing, and some even accumulated dowry monies that allowed them to return home for marriage. Social historians have documented migrant women’s vulnerability to economic and sexual exploitation as domestic and factory workers, but they also noted that migration could benefit young women. The independence and autonomy that migrant women sometimes enjoyed in large cities allowed them to forge new identities and lives that were not always sanctioned by their distant families.

Ravenstein was also prescient in recognizing that the national context influenced the volume and composition of migration. He distinguished countries of absorption that attracted more migrants than they produced from countries of dispersion where the opposite situation prevailed. After analyzing migration flows in the United States, he also acknowledged that the economic and political circumstances in each nation-state influenced international migration. For example, the promise of free land for settlers in the United States encouraged migration over longer distances than in Europe.

Neoclassical economics, gravity models, and international migration

One stream of geographical research took up Ravenstein’s observation that international migration was motivated by economic considerations, especially wage inequalities across space. Accepting the underlying economic logic of international migration, geographers drew on the ideas of economists who argued that people would migrate from locations offering low wages to locations with higher wages. Geographers suggested that the attraction of high wages could be offset, in part or in whole, by travel costs and the lure of intervening places that could be reached at lower cost than the original destination. They proposed a gravity model in which the attraction of high wages would be traded off against travel costs that increase with distance from the migrant’s origin. The gravity model draws on an analogy with Newtonian physics that the attraction between two bodies is related to their sizes and inversely related to the distance between them. According to the simplest adaptations of the gravity model, international migration flows will increase as the populations of two locations increase and decline as the distance between them increases. The gravity model was adapted in three respects. Rather than relying solely on population size to predict the probability of migration, locations were described in terms of their social and economic characteristics. Specifically, unemployment rates, wages, and number of working age adults were some of the variables used to describe the attraction of destinations and the propensity to migrate from various origins. The cost and effort involved in overcoming distance were also evaluated in terms of travel time and travel costs. Competing destinations and origins have also been incorporated in gravity models that take account of migration flows among a number of locations, rather than individual pairs of locations.

Despite these efforts to improve the empirical validity of the gravity model, serious criticisms remain. Gravity model approaches to migration are criticized for treating migrants as independent and atomistic social actors, detached from family and friends. Gravity models are also criticized as static descriptions of past migration
MIGRATION: INTERNATIONAL

trends. They offer no means of forecasting how changes in transportation and communications technology, the ever-changing social and economic characteristics of origins and destinations, and migrants’ evolving social roles and identities will influence migration flows.

Concerns that economic factors other than wages and migrants’ social relations influence migration encouraged new theoretical conceptualizations. Stark and Bloom (1985) suggest that migration decisions are made communally in the best interests of the household to reduce the risk of fluctuations in household income. Household members are sent abroad to diversify income sources and thereby reduce the risk of unexpected and sudden declines in total household income.

Taking these premises on board, gravity models have been modified to include a wide range of economic indicators to describe the economic attraction of competing destinations. Researchers have also devoted considerable effort to estimating travel costs for different migrants. Additional factors such as the presence of coethnics who could provide information about migration and settlement and state regulations have also been incorporated into gravity models.

An important legacy of Stark and Bloom (1985) has been the shift from investigating the motives and characteristics of individual migrants to examining the household context of migration. A growing body of research has investigated how familial structure and household concerns affect who migrates, and when and where people migrate (Kofman and Raghuram 2006). Studies of transnational migrants who try to maintain social identities and social links in multiple countries have revealed diverse migration trajectories. Highly skilled men and women, such as Ghanaian nurses, migrate alone for professional training and opportunities and often pay remittances to their extended families left behind. Likewise, Filipinas also migrate to take up domestic work that allows them to send remittances. “Astronaut families,” in which one parent, usually the father, returns to the origin country to take advantage of economic opportunities and the other parent and children settle at the destination, are highly dynamic. In astronaut families, decisions about who migrates, destination, and the timing of migration are influenced by family considerations at each stage in the life course (Kobayashi and Preston 2007). Recently, growing numbers of international students have travelled abroad to study, some of whom intend to establish residence at their destinations, while others simply seek the cachet of a foreign education. Like the children of astronaut families, they return to their countries of origin to benefit from their foreign education and credentials. Between Canada and the United States, there is a regular flow of seasonal agricultural workers from Central and South America whose families depend on their remittances. Similar flows of migrant labor occur between southern European countries and Africa, albeit on a more irregular basis. Much of this research illustrates how case studies that pay attention to the households from which migrants originate and which they struggle to remake at their destinations can enhance theoretical understanding of contemporary migration. Moreover, attention to the households of migrants recalls Ravenstein’s astute observations about the social contexts in which women migrate.

Systems theory and dual labor markets

One response to Ravenstein’s ideas and their legacy has been to move away from individual migrants as the focus of geographical theorizing and empirical analysis. In a seminal analysis of migration in Africa, Mabogunje (1970) proposed a systems approach that viewed migration
as a self-perpetuating and regular pattern of exchanges between places. The relationships that link migrants and their households across places are the central components of the migration system, which is in constant flux as a consequence of feedback between origins and destinations that alter migration flows. By specifying the components of the migration system, Mabogunje draws attention to explanatory factors at multiple scales ranging from the individual migrant to the nation-state. With its recognition that migration alters origins and destinations and the relationships between them, the migration systems approach moves beyond static gravity models.

Other systems approaches to international migration, world-systems theory and dual labor market theory, emphasize how the interactions between social and political structures affect international migration (Arango 2000). World-systems theory posits a capitalist world economy in which international migration is one of the processes that establishes and maintains a privileged core that exploits the periphery as a source of raw materials and labor. Dual labor market theory extends this analysis by arguing that migrant workers play essential roles in capitalist societies: as a flexible source of labor that can be laid off and returned to its origins when rates of profit fall, and as a reserve army of labor that disciplines the working class.

**Network theories of migration**

Recent explanations of migration focus on the social networks that link current and past migrants with nonmigrants at their origins and destinations. Social networks are seen as a potential source of social capital, resources that can be accessed through social relationships (Arango 2000). For international migrants, social networks are the crucial link between individual migrants and broad social structures. They offer crucial information about the timing and routes of migration and essential support such as temporary housing and referrals to employers that facilitate settlement. While acknowledging that migration decisions always involve individual people, network explanations of migration also highlight how, over time, individual decisions and the social networks that influence them may alter origins, destinations, and the relations between them. In this way, network explanations of migration are dynamic, helping us understand how migration can become self-perpetuating.

Geographers have used network explanations of migration to evaluate how and in what circumstances remittances and return migration are durable strategies for development. Feminist geographers have shown that many women learn about migration pathways, obtain referrals to employers, and care for children and family members at a distance through their social networks (Kofman and Raghuram 2006; Pratt 2012). Others migrate as sponsored family members whose legal status at the destination often depends on maintaining the conjugal relationship.

Research about social networks has concentrated on migration to the wealthy states of Europe, North America, Australia, and New Zealand. We know far less about the social networks associated with the growing migration flows within much of Asia, Africa, Central and South America, and the Caribbean. Researchers have also focused on personal networks, although there is growing evidence that other types of networks, such as those rooted in hometown associations, alumni organizations, and professional associations, influence migration decisions and settlement experiences.

Recent attention to the social networks that structure migration flows reflects a growing interest in mobility and mobilities within human geography (King 2012). As a form of movement,
MIGRATION: INTERNATIONAL

International migration draws attention to who moves and who stays, and to the social conditions that give rise to movement. Research in this vein challenges the normative assumptions that people live sedentary lives, which still frame much thinking about international migration. Recognizing the significance of social networks that connect systemic processes of globalization to individual migration decisions, geographers are investigating how gender, race, class, and sexuality influence migration, as well as how migration alters these dimensions of social identity. This research draws attention to the social, economic, cultural, and political contexts of international migration, highlighting its increasing spatial variegation.

Role of the state

Research is responding to the contradictions inherent in state efforts to control who enters national territory while facilitating the rapid movements of goods, money, and information across national borders. This tension has proved fertile ground for geographers who have found that the competing imperatives of globalization and security contribute to punitive policies that render many migrants temporary or without status at their destinations (Migreurop 2013). Temporary migration policies that are intended to ensure the recruitment of a migrant workforce that grows with labor demand, and shrinks quickly when demand falls, have proven to be highly racialized and gendered.

The attempts of receiving states to coordinate and enforce border policies have heightened the vulnerability of growing numbers of migrants who are desperate to escape poverty and conflict. On the United States–Mexico border, human smuggling has increased as the American government hardened the border, while the creation of Frontex, the agency that patrols the external borders of the European Union, is associated with a growing number of migrant deaths as states try to keep potential migrants at arm’s length by externalizing border control (Migreurop 2013). Packed into every form of transportation from boats to shipping containers, desperate people are being apprehended far from their destinations. Across the Mediterranean, the European Union has signed agreements with North African states such as Morocco and Libya, paying them to detain people who might otherwise migrate to European member states. Having risked their lives, many migrants are held for long periods in isolated locations, living in a legal limbo where they have few rights, and yet they are unwilling or unable to return to their countries of origin.

The competing imperatives of globalization and national security are evident in the growing numbers of migrants without permanent residency. The experiences of caregivers recruited as domestic workers around the world provide a particularly compelling example. Caregivers usually arrive in destination countries with temporary status and few legal rights with respect to employment conditions. As a consequence, they are vulnerable to the capricious and arbitrary demands of their employers and the states where they live and work. Even in the rare circumstances that domestic workers qualify for permanent residence, their experience as domestic workers is devalued in the labor market and may contribute to the tendency of many employers to discount their professional qualifications and experience. For example, Pratt (2012) found that women trained as nurses and teachers in the Philippines who entered Canada as caregivers experienced substantial downward mobility as employers simply ignored their Canadian work experience. Their status as temporary migrants required to work for specific employers in private residences, where there are few
workplace protections, exposes domestic workers to exploitation; however, the gendered nature of their work also contributes to their deskilling.

With no right to secure presence, migrants without status are even more vulnerable than those admitted on temporary visas. Geographical studies have revealed in detail how the border has been internalized as it has hardened. Everyday life is reconfigured as migrants without status try to avoid any interaction with state authorities. Informal taxi services replace driving, children are withdrawn from school, and social networks mobilize to share information about enforcement activities (Stuesse and Coleman 2014). Migrants without status often seek jobs in the informal economy, although their efforts to connect with employers are being stymied in many cities. Some local authorities use loitering bylaws to ban day laborers from congregating on street corners where they wait to meet potential employers. Lacking official status, migrants are being challenged on their rights to be present in the city. These studies underscore the ways that borderlands have expanded as border security has increased. The border has been internalized; it is present throughout the territories of many states.

Another research stream compares how migration policies are formulated and implemented by different jurisdictions within a single state, seeking explanations for policy similarities and differences. States emerge from these analyses as contested, multiscalar, and often contradictory. In the United States, the delegation of immigration enforcement to local police services and secure community policies revealed political divisions between big cities that are home to growing immigrant populations and the suburban municipalities surrounding them (Walker and Leitner 2011). Voting patterns also affected the propensity of municipal governments to institute sanctuary policies rather than enforce federal immigration law. Municipal jurisdictions that had voted Republican favored local enforcement activities, while those with Democratic-voting histories offered municipal services to all residents regardless of immigration status and promoted “don’t ask, don’t tell” policies to discourage municipal employees from asking about immigration status. Similar trends are apparent in Canada where the large metropolitan areas that are immigrant gateways are more likely to implement sanctuary policies than small towns and rural areas where anti-immigrant sentiments are sometimes expressed openly (Leitner and Preston 2011). In Canada, devolution of responsibility for the selection of migrants and the provision of settlement services from the national to the provincial and territorial levels has encouraged provinces and territories to pursue diverse goals. Some facilitated the rapid recruitment of workers to meet employers’ immediate needs while others sought migrants who had specific language and cultural competencies. The contested nature of migration policy is readily apparent in the European Union where states often pursue contradictory migration policies despite their commitment to shared enforcement of the European Union’s external borders. For example, Italy and Spain have a history of amnesties for migrants without status whereas Germany, the Netherlands, and other states in northern Europe have resisted calls for regularization on the grounds that they fuel irregular migration.

A parallel stream of research has compared the migration of highly skilled and business migrants with that of less skilled and less desired migrants. In some states, highly skilled and business migrants enjoy swift access to permanent residence, along with rights to family reunification and full access to national labor markets, while in others they are treated as privileged temporary migrants. Although their economic advantages and privileged migration
status protect highly skilled and business migrants from many of the difficulties experienced by their less skilled and less desired counterparts, the transnational lifestyle still presents challenges. Many transnational migrants struggle to maintain social ties and social identities at their origins and destinations at the same time as they try to make themselves at home at their destinations. The homing desire is highly spatialized. Numerous case studies describe the efforts of all migrants, even the most privileged, to achieve a sense of belonging by creating new homes at their destinations (King 2012).

Representations of international migrants and international migration flows underpin many state interventions. Highly skilled workers are viewed as attractive global talent entitled to permanent residence and citizenship because they will enhance the wealth and economic productivity of the nation-state (Yeoh 2006). Migrants who are considered less skilled are considered suitable for filling short-term and immediate labor needs rather than making long-term economic contributions. Although their remittances are now viewed as indispensable and effective development tools, the migrants that are the sources of these remittances are not seen as worthy of permanent residence. Although a few will benefit from the proliferation of two-step migration procedures by which temporary workers earn the right to apply for permanent residency, the majority will be expected to return to their origins or to live precariously without status. States often demonize refugee claimants and migrants without status as threats to the nation-state. Whether these migrants are labeled as terrorists or as queue jumpers, the representations are used to justify repressive state measures such as detention and deportation.

Geographical views of international migration highlight its social, political, and spatial complexity. Geographers have sought to describe and explain international movements, portray the experiences of increasingly diverse migrants, and investigate how representations of assorted migration flows and migrants influence state efforts to control international migration. There is growing concern that the spatial variegation of contemporary migration will exacerbate long-established geographies of inequality. As a result, geographers are asking how international migration can be a tool for achieving social justice.

Migration: skilled international labor

Jonathan V. Beaverstock
University of Bristol, UK

Expatriation, international assignments, and global talent mobility

The success of the multinational producer service firm rests on three major interlocking facets: the quality of its key asset, a highly skilled workforce, in terms of their knowledge, expertise, experience, skills and professionalism, and, in some sectors, the status and recognition of their formal qualifications (e.g., legal, accounting); the firm’s reputation, usually built up over a relatively long time period from a business model that has the firm–client relationship at its core; and the ability of the firm to manage its knowledge and practice, reputation and client relationship model on a global scale. Consequently, given that the firm’s knowledge, expertise, skills, and reputational assets are “embodied” within its highly skilled labor force, the strategic deployment of such labor within firms’ international office networks and/or to clients has become a crucial process for global knowledge management, transfer, and exchange. Skilled international migration within the international internal labor markets of producer service firms has become a normalized process of “transnational” work (Beaverstock 2007).

Producer service multinational firms have a cadre of highly skilled professional and managerial labor working outside of their home country on international assignments or other forms of mobilities. Such forms of mobility have been referred to in a historical context as expatriates. Back in 1977, Edström and Galbraith published a seminal text on the transfer of managers within multinational corporations (MNCs). They suggested that managers transfer across borders within firms to fulfill three main strategic functions: (i) to fill vacancies abroad that cannot be filled by home country nationals, across the entire range of the firm from key leadership positions to filling middle-ranking vacancies; (ii) as a part of the firm’s formal management development program to train and develop the global managers of the future, involving both junior and middle-ranking persons; and (iii) as a strategy to disseminate knowledge and practice within the entire firm to build an overall corporate strategy, ethos, and culture. Since 1977, thousands of texts have been published on “expatriation” and international assignments that have used Edström and Galbraith (1977) as the yardstick. For example, Sparrow, Brewster, and Harris (2004) suggest that firms send staff on international assignments for six main reasons: for career development; to establish a cadre of international staff; to fill local vacancies; to transfer knowledge and expertise; to manage local assets; and to provide leadership to roll out corporate strategy and best practice. Skilled international migration within producer service firms encapsulates all of these strategic roles for international assignments, with the addition of direct secondments to clients as a process to supply and deliver bespoke services in co-location.

From the early 2000s, Beaverstock (2007) reported a subtle but important change in the strategy of international assignments (transfers, exchanges, and secondments) within global
accounting firms and wholesale banks – the shift away from designated expatriation or formal assignment programs to much more flexible modes of mobility and movement. Millar and Salt’s (2008) analysis of global mobility in the aerospace and extraction industries corroborated these observations, and they advocated a “portfolio of mobilities” within organizations, including a combination of long-term assignments (1–4 years), short-term assignments (3–12 months), rotations (in months), extended business travel (30–90 days), and business travel (up to 30 days).

From the late 2000s, the discourse on expatriation and international assignments has switched to viewing such mobility of labor as “global talent.” For example, PricewaterhouseCoopers’ report on Talent Mobility 2020 concluded that there will be “more business travel, more virtual tools, and especially more quick, short-term, and commuter assignments,” because “along with short-term and long-term assignments we have frequent travellers, commuters, intra-regional, and virtual secondments to customers and supplier sites, as well as various assignee and talent types, such as executive, skill set and project-based, developmental, and employee initiated” (PricewaterhouseCoopers 2010, 4, 16).

Official statistics on skilled international migration

All OECD (Organisation for Economic Co-operation and Development) members collect official data on international migration (persons leaving or entering a country for more than a year). The collection of international migration statistics for the “highly skilled” are often categorized as “professional and managerial” (as in the United States). From a UK perspective, there are two main types of official data sources on highly skilled international migration: international migration and work permit/working visa statistics. Each will be discussed in turn.

The UK Office for National Statistics (ONS) collects data on long-term international migration (LTIM) for “professional and managerial” occupations, which can be categorized as the “highly skilled.” These include intercompany transfers, and highly educated, technical, scientific, professional, and/or other intrinsically talented persons, for example musicians, entertainers, and sportspeople. From 1980 to 2010, four main trends can be reported from an analysis of ONS LTIM statistics for British and non-British professional and managerial migration.

First, since 1980 and almost year on year for the United Kingdom, there has been an absolute increase in the inflow (immigration) and outflow (emigration) of both British and non-British professional and managerial migrants. In 2010 the number of all professional and managerial immigrants entering the United Kingdom was +245% (+108 000) greater than in 1980, and was +78% (+48 000) for emigration (Table 1). An analysis of the net migration balance (the difference between inflow and outflow) recorded more professional and managerial migrants of all nationalities entering the United Kingdom than leaving in 2010 (+40 000), 2000 (+34 000), and 1990 (+16 000), with more non-British professional and managerial migrants entering the United Kingdom than leaving (+60 000 in 2010; +57 000 in 2000; +25 000 in 1990; +8000 in 1980). For each year reported in Table 1, there have always been more British professional and managerial migrants leaving than entering the United Kingdom. Second, in each of the four time periods, there were more male than female
professional and managerial migrants for both inflow and outflow in all citizenship categories (Table 1). But what is greatly significant about the 40-year period is the growth in the proportion of female migrants entering and leaving the United Kingdom, for both British and non-British citizens. In 2010 the proportion of all female professional and managerial migrants entering the United Kingdom was 42% and of those leaving the United Kingdom was 38%, compared to 27% and 26%, respectively, in 1980.

Third, for all time periods, almost three-quarters of all professional and managerial migrants entering and leaving the United Kingdom were in the 25–44 age range (Table 1). This is not unexpected given that these migrants are by definition “highly skilled” and may have entered the labor market late because of higher or further education, and being in a position to migrate (to a new job vacancy or to seek work) only when they have gained a track record of work experience and/or an established career. Finally, the Commonwealth (new and old) accounted for the highest proportion of non-British citizen professional and managerial migrants entering the United Kingdom for each of the four time periods, representing 46% of total non-British citizen immigration in 2010 (52 000), 45% in 2000 (49 000), 44% in 1990 (24 000), and 46% in 1980 (12 000) (Table 1). Between 1990 and 2010, the number of EU citizens entering the United Kingdom who had been in professional and managerial occupations prior to migration increased from 13 000 to 30 000 (+131%), followed by citizens from other foreign countries, which increased by +82% from 17 000 to 31 000 during the same time period. With respect to the outflow of non-British citizen professional and managerial migrants, with the exception of 1980, EU citizens account for the highest proportions of this occupation group leaving the United Kingdom: 45% in 2010 (24 000); 36% in 2000 (19 000); and 43% in 1990 (13 000).

The UK Border Agency regulates the entry of non-European Economic Area (non-EEA) highly skilled immigrants through a points-based system of first entry and extension work visas (see Salt 2009). The highly skilled immigrant is included in one of two qualifying relevant “tiers”: Tier 1 encompasses high-value migrants like entrepreneurs, exceptional talent, and investors (who do not have a job offer); Tier 2, covering skilled workers who have a job offer and sponsor, includes skilled workers in general, intracompany transfers (ICTs), ministers of religion, and sportspersons. In 2012 a total of 45 740 (excluding dependents) Tier 1 and Tier 2 migrants were allowed to enter the United Kingdom for work purposes, with 82% (37 600) in Tier 2 (Table 2). Tier 2 migrants are non-EEA citizens who enter the United Kingdom to work in organizations, like firms, the public sector, and nongovernmental organizations (NGOs), and the highest proportion of these workers are given permission to work in the United Kingdom as intracompany transferees – that is, they come from outside of the EEA to work in a subsidiary, branch office, or global headquarters of their employing UK or foreign-owned MNC. Between 2009 and 2012, the number of working visas issued to Tier 2 ICTs increased from 8970 to 21 800 (+143%), and they accounted for almost a 50% share of all Tier 1 and 2 visas issued in 2012. These ICTs are in all sectors of the economy.

Prior to 2009, the UK government’s Highly Skilled Migrant Programme (HSMP) issued work permits across all economic sectors, including ICTs. Out of a total of 77 660 work permits issued in 2008, the highest numbers were in computer services (21 690, of which 87% were ICTs); administration, business, and management (10 249, 48% ICTs); financial services

(7852, 51% ICTs); education and cultural activities (6274, 4% ICTs); and health and medical services (5883, 6% ICTs) (Salt 2009). Between 1995 and 2008, the number of work permits issued in the HSMP increased by +53 499, from 24 161 to 77 660 (+221%) (Table 3). In 2008, the highest share of ICTs as a proportion of work permits issued were present in these seven sectors: computer services (87% or 18 870 permits); telecommunications (82% or 2020 permits); extraction, manufacturing, and transport (each 59%, or 821, 1860, and 504 permits, respectively); utilities (53% or 500 permits); and financial services (51% or 4000 permits) (Table 3).

Corporate highly skilled international migration: the cases of global accounting and legal firms

Outside of official statistics on highly skilled international migration, case study research on organizations provides a rich source of data, often derived from a qualitative approach, to understand the organizational strategy for the global mobility of highly skilled staff within, and between, the internal labor markets of MNCs, and small and medium-sized enterprises (e.g., see extraction and aerospace: Millar and Salt 2008). The following case studies of highly skilled professional and managerial migration within large global accounting and legal firms illustrate the strategic importance of such global mobility in the firm’s armory to deliver knowledge across borders, to supply services to clients and cosuppliers, to develop the global ethos and human capital of the organization, and as a mechanism to switch labor resources to markets which require specific demand at certain times of the financial year.

Corporate international migration in global accounting firms

Since the late 1970s, the swift internationalization of the global accounting industry has led to it becoming one of the most prolific producer services sectors responsible for organizational highly skilled professional and managerial labor migration in the world economy (Beaverstock 2007). Despite the availability of smart information and communication technology in the workplace like videoconferencing and the availability of fast and frequent airline travel, global accounting firms continue to move high volumes of professional and managerial staff (partners, qualified accountants, technical staff, and trainees) on international assignments within their extensive international office networks, and outside of the firm in secondments to clients.

and cosuppliers. In 2014 the Big Four accounting firms, Deloitte, PricewaterhouseCoopers (PwC), Ernst & Young, and KPMG, employed over a half a million fee-earning staff (partners, seniors/principals, and qualified staff) in an average of just over 150 countries around the globe (Table 4). Given the client-facing nature of accounting as the archetypal producer service, a firm’s professional staff will liaise and supply services to clients and cosuppliers, mainly through close physical relationships. Given the significance of embodied knowledge in the accounting profession, the competitive advantage of the firm rests on the quality, reputation, and client relationship qualities of its professional staff. In all of the major global accounting firms, the success of the organization is aligned to a wholly owned physical presence in the market, often with multiple offices, delivering services in co-location with clients. At the crux of service delivery is the ability of professional staff to maintain a highly mobile relationship with clients and to supply high-quality services that are accredited and require legal closure.

For over 20 years or more all of the Big Four global accounting firms (and many below that ranking, like Grant Thornton, DBO, and Baker Tilly, for example) have formalized organizational highly skilled international migration within the firm, and between the firm and its clientele, in international transfers and in exchange and secondment programs. Such global mobilities have now become standardized within the firms’ international offices and organizational structures, involving many nationalities and international offices, superseding the primacy of firms’ headquarters as the major source of outwardly mobile staff (Beaverstock 2007). As of 2014, the Big Four firms have established global mobility programs: to provide structured pathways for career development, for example student trainee rotations and as part of formal management development systems; to fill organizational vacancies, often associated with partners required to go offshore to head divisions or departments, or for qualified staff to fill vacancies in tight labor market locations; to build the global culture and ethos of the organization by circulating staff of all nationalities between world regional offices; and as a mechanism to second professional staff to clients and cosuppliers (e.g., law firms). All of the Big Four have globally functioning mobility programs, which attract a few thousand new assignees per annum (Table 4). In 2014 Deloitte had almost 6000 professional staff on its International Assignments program, but for the firm (as for all the other firms), these are just the tip of their international assortment of staffing mobility. As Deloitte (2014, 17–18) states:

International experience at Deloitte means more than just a job in another part of the world. It includes everything from an international assignment in or transfer to another country, short- and long-term international business travel, and working on or managing international projects and teams. Last year [2013], ... nearly 6,000 mobility assignments helped Deloitte professionals develop cultural understanding, as well as language, networking, and managerial skills ... Professionals with global mobility experiences develop and enhance communications, coordination, and management skills, as well as global networks, to be able to better serve clients and effectively carry out global projects.
Ernst & Young (n.d.) offers an assortment of global mobility opportunities for professionals, which include:

- a Global Student Exchange Program, whereby part of an internship is spent abroad for several weeks in “an exciting international location … gaining new experiences … while obtaining global insight”;
- serving global clients abroad and working “alongside a team of EY people from all over the world, which provides you with exceptional cross-cultural experiences and learning opportunities”;
- short-term assignments, which “can offer you a taste of international work … when we have the need for additional resources in another country during busy season”;
- a Global Exchange Program, specifically for “high-performing seniors or managers” with partner potential who apply for a 18–24-month overseas posting in any function of the firm;
- a New Horizons Program, tailored for the “junior ranks to experience geographic mobility through short-term rotations”;
- a Corporate Responsibility Fellows Program, involving three-month assignments, directed at juniors who wish to travel to Central and South America to improve “the success of … high-impact … entrepreneurs in underserved communities”;
- strategic leadership and management opportunities for partners and senior managers, who are offered “a strategic opportunity to relocate to another practice or country to provide leadership or … management, … transfer your knowledge and share your experience”;
- international transfers: self-initiated mobility for professional staff who wish to apply for another position in the organization on a competitive basis, searching the firm’s worldwide vacancy list.

Corporate international migration in global legal firms

At the strategic hub of the global legal firm is the “embodied” expert knowledge of its partners and legally qualified lawyers, and their trusted and established relationship management of clients in home and international markets. As the leading global (mainly US and UK) law firms have internationalized their office footprint in the major world cities and international financial centers, a significant accompanying organizational strategy has been the international migration and mobility of partners, lawyers, and trainees between such office networks. As Beaverstock (2004, 166) notes, global mobility is, “a critical globalization strategy for knowledge management and transfer within professional service legal firms’ transnational office networks.” A recent research report by TheCityUK (2014) estimates that the largest UK law firms in London have about 45–65% of their lawyers working outside the country, compared to the leading US firms, which have about 25% of their lawyers working outside the United States.

At the nub of the organizational strategy for professional staff migration and mobility is the necessity for the global law firm to deal in multijurisdiction law in a single jurisdiction location when involved with global (or local) clients in cross-border and/or local cases or projects. Global law firms frequently use a combination of international staff, who provide expertise in an international jurisdiction (e.g., English) Common Law, and local qualified staff, who are registered to practice in the local jurisdiction, to manage their client work. For example, qualified English Common Law professionals are sent on an international assignment to New York,
Singapore, or Hong Kong to supply an English Common Law jurisdiction to clients in those locations that require such a service, working alongside locally qualified lawyers where appropriate. Global legal work is exceptionally multijurisdictional across the globe, irrespective of the location of the legal firm’s international office network. Also, it is important to recognize that partners especially are sent on international assignments to lead and/or manage a particular specialization of the firm in an international location, or to replace a partner returning to the United Kingdom who has been assigned to another international location.

Both the leading London- and New York-headquartered international firms, including members of the so-called magic circle, and beyond, continue to rotate early career staff (trainees and just-qualified lawyers) for training and to build their individual career paths and experiences, but also as an instrument for the individual to fully understand the global ethos and culture of the firm, outside of the main headquarters. A recent addition to trainee international secondments within the firm is the global mobility initiative of client secondments, where trainees are embedded in the client firm. Thus, many of the leading global firms have international secondment, international student exchange secondment, and client secondment programs, usually lasting 6–12 months for trainee lawyers. Often these are headlined in the recruitment literatures and websites for graduate trainees. For example, Slaughter and May (n.d.) have an international secondment program for trainees solicitors, providing “an excellent opportunity to experience working in a different environment and jurisdiction,” and in 2013 20% of Linklaters’ trainees went on international secondment within the firm, and 26% on client international secondment (Linklaters 2014).

The following quotation from CMS International (n.d.) summarizes very clearly the organizational rationale for global mobility, particularly client secondments during the training contract:

One of our key aims is to become a leading relationship firm. We have many ways of building relationships, but perhaps one of the most personally exciting … arises from our secondment programme. Client secondments really help us to forge the best relationships with our clients while giving you the chance to experience a new industry or profession … For us, international secondments help us work as one team, regardless of international borders – for you they can be hugely stimulating and rewarding life events … You may also find you have other opportunities to develop your career in other offices on a longer-term basis; again we will provide you with assistance, for example, with the logistics and expenses of relocation and with cultural and language training.

The leading global law firms rarely publish data tracing the international opportunities of their staff involved in assignment or secondment arrangements with international offices or other “best friend” firms or clients. Data from TheCityUK (2014), originally reported by the Law Society, estimates that in 2010 there were, “6000 solicitors on the Roll in England and Wales who are working abroad,” with almost a quarter based in Hong Kong (883, or 15%) and Singapore (524, or 9%). A word of caution, however: these solicitors on the Roll working abroad may be employed by a range of global and local law firms, but also in other allied sectors of the knowledge-based economy, for example in corporate finance (including wholesale banking), retail and private banking, shipping and maritime, accounting and consulting, and financial services.

Looking to the future, as producer service firms are at the vanguard of introducing innovation and
new corporate and knowledge management systems to establish, nurture, and fulfill client relationships, and are progressively being organized more across borders and in transnational project teams consisting of an array of cosuppliers (e.g., law firms, corporate financiers, real estate), the likelihood of more flexible modes (both physical and virtual) of highly intensive, “business travel” corporate mobilities are a greater possibility in lieu of traditional longer-term assignments.

Military geography

Rachel Woodward
Newcastle University, UK

Definitions of military geography

Military geography is the study of the ways in which militarism and military activities are geographically constituted and expressed. Central to this definition is the idea that military practices, both material and conceptual, not only have observable effects on space and on places, environments, and landscapes, but also that militarism and military activities themselves are brought into being through the inherent spatiality of social relations. Also significant to the definition is the idea that military geographies emerge both through the material practices of military institutions, organizations, and associated social groups, and through the conceptual and discursive processes of militarism. Militarism is the prioritization of military force in the resolution of conflict, and analysts talk also of militarization, a broad set of social, cultural, economic, and political processes by which military approaches to social problems and issues gain both elite and popular acceptance (Woodward 2004; 2005). Armed conflict itself, and all the indirect, non-conflict activities that armed forces undertake to prepare for the deployment of military power, are of equal interest to military geography.

Military geography, then, is a subfield of human geography, which takes as its central focus the spatialities of military practices. Because military geography engages with the outcome of primarily political practices, it is frequently understood as complementary to political geography, and shares with political geography many of that subdiscipline’s epistemological concerns with poststructuralist theoretical approaches and heterogeneous methodologies. It is notable, however, that many of the topics studied within military geography draw explicitly on broader economic, social, and landscape geography traditions and approaches to make sense of the spatialities of militarism and military activities. Also, and reflecting the wide-ranging impacts of military practices, materialities, and discourses, military geography looks across the social science disciplines (sociology, political science, international relations, feminist studies, and social psychology in particular), the humanities (particularly historical, cultural, archaeological, and landscape studies), and the environmental sciences, meaning that the subfield is defined less by disciplinary parameters and more by its multidisciplinary perspectives on a core set of issues relating to military forces and all this entails.

Military geography has existed as a term defining a field of study for as long as the discipline of geography itself has existed, with a formalization of its scope and approach emergent in the mid-nineteenth century as a consequence of the colonial and imperial ambitions of nation-states, particularly the United Kingdom and the United States. A definition established at that time and still in circulation within some academic groups defines military geography as the application of geographical tools and techniques to the solution of military problems (Galgano and Palka 2011). Although this – very applied – understanding of military geography still has some purchase, the majority of writers within contemporary
Anglophone geography would seek to distance themselves from the notion of military geographical scholarship as contributing to the military aims and objectives of states and armed forces and their efficiency, working instead with a more critical approach, which sees military issues as the outcome of social life and political contestation, rather than just accepting “military” as a functional and given category, and emphasizes militarism and militarization as simultaneously discursive, ideological, and material. With this critical turn, military geography has paralleled developments within military sociology and international relations, which are in their own ways working toward a more political, less functional, military scholarship.

Dimensions of military geography

The scope and dimensions of military geography have always been responsive to developments in military organization, strategy, and technology, and to shifts in the political relationships between military institutions and civil society. Military geography therefore has a dynamism reflecting this responsiveness, but fewer well-established traditions among its approaches. There are, however, four key dimensions to military geography through which most research has been focused: summarized as spatiality, place, environment, and landscape.

Spatiality

Spatiality, both as a capacity of social (and thus military) relations, and as an empirically observable feature or outcome of social activity, is the first key dimension in military geography. At its most basic and conceptually straightforward, and reflecting a long tradition of interest in battlefield strategy, military geography is interested in the operation of military activities across space – the “terrain and tactics” approach that seeks to understand how specific military campaigns or incidents have been shaped by environmental factors including local geomorphology, topography, climate, specific weather events, or biogeography, which in turn may or may not have proven significance for the outcome of that particular campaign or event. More nuanced and conceptually sophisticated approaches to the study of the practical deployment of military force have in recent years explored the battlespace in its entirety (so including the aerial and maritime as well as land-based dimensions), looking at how the geographical imaginations implicit in military planning and strategizing become played out across space and demand particular visualization and mapping practices (Williams 2011). The spatialities of interest to military geographers also include global, regional, national, and local power plays over territories, borders, and boundaries, and the ways in which military power and action shapes territorial blocks. Also significant here are changing modes of warfare, including developments in the technologies of armed conflict and deployment of lethal force, the ways in which these have transformed the nature of armed conflict in the twenty-first century, and the ways in which state and non-state actors can pursue armed violence. The pursuit of armed violence includes obvious kinetic activities, but also less visible practices around visualizing, mapping, and conceptualizing the battlespace in order to exert military control over space in ways other than direct physical presence or violent destruction of people and place. Increasingly, military geography’s interest in space is expressed less as empirically orientated descriptions of actual deployments of military power, and more as explorations of how space is conceptualized by military planners and strategies, and what
these theoretical understandings might in turn mean for the uses (and abuses) of military force in the present and future.

**Place**

Military geography has a range of interests in questions of place, a second key dimension to the topic. Reflecting a broader human geographical interest in the specificity of places as nodes within networks of social relations, work on place has tended to take specific types of military places as case studies for the exploration of wider social relations. So, for example, research on the economic geographies of the defense industry and defense economy has tied the growth of national and increasingly multinational defense industrial capacities to both the changing fortunes of (inter)national manufacturing industry and associated research and development functions, and to the use of the defense industrial base as a tool of both economic and military power projection. Defense economies are also evident in the economic relationships between military installations (i.e., bases and barracks) and their surrounding localities, and a key area of interest here has been the extent to which military bases do, or do not, support wider economic activities in the localities and regions in which they are based. Military bases also raise a host of issues concerning the social relations they shape and reproduce, and military geographers, along with sociologists and anthropologists, have sought to trace out the complexities and consequences of civil–military relationships in localities where a military base is present. The place-making practices of military power are also evident in the reproduction of urban and infrastructural forms and built environments around the globe as a consequence of the extension and consolidation of military power particularly (but not exclusively) by the US armed forces (Gillem 2007). Geographers have also focused on the ways places come to be imagined, and the specific ways in which military power, control, and objectives can be seen to provide particular readings of places at scales from the specific to the regional as part of mechanisms to legitimate a military presence (Farish 2010).

**Environment**

The effects of military activities on environments, and the ways in which discourses of environmentalism become articulated for specific purposes and ends, constitute a third key dimension of military geography. Military activities have profound environmental impacts, ranging from the modification of local ecologies and geomorphological features through to contamination and pollution. The environmental effects of military activities are associated primarily with instances of armed conflict; the physical destruction brought by the deployment of artillery, practices of aerial bombardment, or processes of infantry maneuver can be readily imagined, and accounting for environmental impacts in both the immediate aftermath of war, and over much longer-term time periods, remains a significant element of military geographical study. In addition, military geography has also been attentive to the more mundane and prosaic impacts of non-conflict military activities through, for example, the pollution effects of military basing or the environmental protections inadvertently brought to some environments by the blocking effects of military presence. The apparent paradox, that military sites can be simultaneously sites of military presence and of high environmental value, has prompted a wealth of studies that have looked to tease out both the validity of the claims made by military organizations about the benign effects of military practices, and the politics of such claims (Havlick
In parallel with the approaches of environmental historians, military geography seeks to explore also the role of representations of environments and their specificity in arguments about national identities and the pursuit of armed conflict in assertion or defense of those identities.

Landscape

The fourth key dimension of military geography is the focus on landscapes. Military landscapes can be conceptualized in a great variety of ways (Woodward 2014) but underpinning this range is a focus on the distinctive ways in which military and nonmilitary/civilian actors view, interpret, and represent landscapes, the political functions of these diverse interpretations, and the insights that a specifically landscape-focused approach can bring to understanding the operation of military power. Studies of military understandings of landscape include the specific ways in which ground is read for military purposes, at scales ranging from the efforts of small infantry patrols to assess territory for tactical purposes through to the mechanisms by which swathes of territory are interpreted for broader strategic purposes. As with assessments of military environmentalism, military landscape studies have been heavily influenced by concepts of representation, in turn reflecting dominant approaches in cultural geography since the 1990s. The focus on representation has generated a wealth of studies of, in particular, sites of memorialization, as geographers attempt to engage with the meanings and understandings of armed conflict conveyed through, for example, battlefield sites, sites of mourning and remembrance such as war memorials, and sites of wartime atrocity. Studies of military landscapes, again reflecting developments more widely in cultural geography, are increasingly attentive to ways of being in landscape, including awareness of and interest in the perceptual, haptic, sensory, embodied, and affectual effects of military landscapes. With the attention to the phenomenologies of encounter comes also an awareness of the politics of being in such place; military landscapes are not neutral spaces, and there are practical and methodological issues these sites raise for the geographer which shape the possibilities for their exploration.

Military geography in relation to human geography

In addition to its focus on the range of topics within these dimensions, military geography is also increasingly concerned with contributing to two significant developments within human geography. The first of these concerns the ways in which concepts of militarism and militarization are defined and used. Although definitions of these terms are given at the start of this entry, it would be misleading to suggest that they are fixed or that they have shared currency across and beyond geography. That these terminologies and associated conceptualizations are used in often markedly different ways by different writers is indicative, first, of the novelty within the social sciences of taking militarism and militarization seriously as objects of study. Reflecting human geography’s seeming disinterest in military issues in the postwar period, these terms and their conceptual uses have only relatively recently been subject to critical interrogation. Indeed, arguments have been made for their increasing obsolescence in a world where specifically military concerns and issues might be seen as part of, or on a continuum with, a broader range of issues pertaining to security and securitization. Conversely, the specificity of military organizations as agents of states, of military violence as planned and executed by state-legitimized actors who sit
in a relationship with civil society by virtue of that state sanction, and of military capabilities reflecting investments by the state, indicates that geography may need to engage with questions of military specificity – as well as related but distinct issues around security – for a while yet.

The second development in human geography has been the extension of specifically military-related studies across political (and to a lesser extent social) geography; the study of military geographies, in other words, is not the sole preserve of those self-identifying as military geographers. This extension of the study of military phenomena reflects the fact that in the first decade and more of the twenty-first century the US-led wars in Iraq and Afghanistan, the ongoing military violence in Israel and Palestine, and the long-running armed conflicts in central Africa, have made armed conflict inescapably real as a feature of daily life for geographers working in a variety of national contexts. Accordingly, political geography, and in particular critical geopolitics, has become much more alert to issues of militarism and militarization as part of the latter’s attempts to grapple with the spatialities of violence (Dalby 2010). This development in turn has prompted explorations of popular cultural engagements with the materialities and discourses through which armed violence is understood; the rich emergent literature on military-themed video gaming is a case in point.

In turn, geography has been significant for military studies more generally, particularly for critical military studies, which seek to question not only causes, consequences, and effects of armed conflict and military capabilities, but also the ways in which military processes and practices can be seen as the outcome of social life and political contestation, rather than just viewing “military” as a given functional category. In exploring the spatial constitution of military power, the multiple ways in which this works at a range of scales (including, significantly, the individual and embodied), and the intersections of different scalar effects, geographical approaches to military topics (whether branded as military geography, critical geopolitics, or something else entirely) have a significant contribution to make to a cross-disciplinary critique of the uses and abuses of military power. And while to date the engagements between those advocating serious study of military topics and those arguing for a focus on a geography centered on nonviolence and an ethics of peace have been limited, it is important to note that in its contemporary critical incarnation, military geography should not be assumed to be antipathetic to antimilitarism.

Future research directions for military geography

Of the many future directions and issues for military geographical study, three stand out for particular scrutiny. The first of these is methodological. Military phenomena continue to be studied, as they have long been, drawing the full range of methodologies and research techniques used across the social sciences (Williams et al. 2016). These include quantitative data collection and analysis, the usual variety of interactional methods including interviews of various types, focus groups, and ethnographic studies, textual analysis of documentation, visual methodologies, and field-based practices of walking and observation. Military research, however, raises questions about accessibility in ways that have quite pronounced effects on what can, and cannot, be studied, because of the nature of military institutions themselves. Although not always closed, secretive, or hostile to social scientific researchers, they frequently are. This hostility in turn has an effect on what
MILITARY GEOGRAPHY

can be studied and how. Methodological innovation as means of countering access problems is a hallmark of military geography – and much critical military research is not sponsored or endorsed by military gatekeepers. That said, the relative obscuring of military geographical studies within human geography is at least partially explained by the difficulties of doing military research, and this remains an issue for those concerned to explore the nature and effects of military power.

The second key area for future research lies with the political economies of military institutions and military power which arise from the movement toward the privatization of military functions and the consequences of the retraction of the state from the direct execution of military activities. The knock-on effects of neoliberal economic policies in many advanced capitalist nation-states since the 1980s have played out in distinct ways with regards to military issues. While geography is starting to become alert to the most visible of these effects, in, for example, the exponential increase in the number of private security contractors deployed by NATO governments and other agencies as part of force deployments, the less obvious, sometimes mundane, but equally profound effects, such as the transfer of personnel accommodation, facility management, specialist equipment training, and recruitment services to the private sector, are all in the process of prompting new spatialities of economic and social relations at scales from the individual to the global, and with effects from the battlespace to the home base.

A third area for future research is the contribution that military geography can make to understanding civil–military relations. There is considerable potential for a more spatially alert conceptualization of the relationships between military institutions and organizations and the civil societies in which they are located. Over the past decade, more critical approaches in military studies have looked to reconceptualize civil–military relations less as a managerial issue where the purpose of theoretical critique is the greater efficiency or management of armed forces as a tool of democratic states, and more as a discursive relationship where the categories of “military” and “civilian” are in constant states of imagination and rearticulation. The role of scale and of spatial relations in the process through which the categories consistently define themselves against each other is a pressing political as well as geographical question.

Mining and mineral resources

Gavin Bridge
Durham University, UK

Mining is one of two primary activities by which societies acquire raw materials, the other being cultivation. The extraction of mineral resources is part of a broader process of “resource metabolism” through which human beings create social, economic, and political order via the mobilization of materials. Understood narrowly, mining refers to a set of techniques associated with the removal of solid materials that, unlike fluids, will not move of their own accord: used in this way, mining describes the application of human labor and energy to separate and remove materials. However, mining is often used more broadly, describing the process by which all physical states of matter are taken from the Earth, whether as solids (coal, gravel, gold, peat), liquids (brine, oil, water), or gases (natural gas, helium). The association of mining with physical removal means it is also commonly used as a synonym for the depletion of exhaustible resources. In this context the application of the term to resources that are potentially renewable has a particular evaluative force: the mining of groundwater supplies or soil fertility, for example, describes a condition in which the rate of extraction exceeds the rate of recovery (see Natural resources and Resource extraction). Consequently the verb “to mine” has become a metaphor for the unsustainable use of resources.

To a physical scientist, a mineral is a naturally occurring substance with specific chemical and physical properties, composition, and atomic structure. To most geographers, however, mineral resources are concentrations of nonliving materials whose form, qualities, and quantity are valued positively by society. Modern societies are materially complex and the range of materials valued as mineral resources has grown over time. Material complexity has enabled improvements in the performance of products and the productivity of personal, corporate, and national economies: for example, a computer chip utilizes over 60 different elements (i.e., half the number of elements in the periodic table); and the nickel-rich “super-alloys” used in high performance aircraft turbine blades have over time incorporated a growing suite of additional elements – cobalt, molybdenum, niobium, hafnium, rhenium – in order to operate at progressively higher temperatures (Graedel et al. 2015).

The integral role of minerals within modern economic life means that mining and mineral resources occupy several core areas of policy concern. These include physical availability and the implications of resource depletion, the geopolitical consequences of resource distribution and patterns of resource consumption, the environmental effects of mining, and the challenges of mineral-based development (see Natural resources development). Geography has made significant contributions to understanding these issues. Over time, geographers have adopted a progressively more relational perspective on mineral resources: they have become focused less on “the mine” (as an industrial unit and point of extraction) and more on the interdependencies between mineral resource production and consumption and economic,
political, and environmental outcomes at a range of scales. Recent work, for example, highlights the accumulation of mineral resources in the built environment and entrained in consumer waste flows (see Waste and waste management), and the implications of international trade in fuels and metals for geographically uneven development.

Mineral resource classification

By convention, mineral resources are divided into 
*metals* (e.g., gold, iron, nickel), 
*fuel minerals* (e.g., coal, shale oil, uranium), 
*industrial minerals* (e.g., gypsum, phosphates, salt, sulfur), and 
*construction materials* (e.g., building stone, gravel, sand). However, because these categories reflect socially meaningful differences in how minerals are utilized, they may be differently combined or subdivided to distinguish, for example, *bulk minerals from specialty minerals*; *nonrenewable, recyclable* (metals), and *potentially renewable* mineral resources (such as beach sand, river gravels, sea salt); or to identify a subset related to particular policy concerns (e.g., *strategic minerals, critical minerals, conflict minerals*).

“Mineral resource” is therefore a social category applied to a range of materials, and, as a social category, it folds within it the unsettled nature of value, the possibilities of technological change, and the artfulness of industry. Whether or not the designation “resource” holds depends, among other things, on prevailing systems of valuation, the impacts of production technology on costs and prices, and the distribution of social power. Mineral resources, therefore, are always in a state of “becoming” (see Natural resources). This dynamic nature is reflected in formal classification systems – such as the McKelvey box (Figure 1) – that distinguish reserves from total resource base, and inferred reserves from those that have been demonstrated. These distinctions reflect the degree of geological certainty with which quantities and qualities of materials are known, and the economic feasibility of their extraction. As knowledge and/or economic conditions change, so do the size and location of mineral reserves. It is for this reason that the relationship between reserves and current rates of production – the so-called R/P ratio – is a poor indicator of future availability: the R/P ratio for most minerals has remained static or improved over time, despite prodigious rates of mineral resource consumption. A rise in the price of oil, from around $20 to over $100 per barrel, underpinned a 50% increase in the size of global oil reserves between 1990 and 2013 as formerly subeconomic reserves became commercially viable, and higher prices spurred new exploration. Similarly, the decision of the Chinese government to restrict the export of rare earth elements in 2010 drove up their price, increasing reserves by 25%. Although mineral resources are an inherently dynamic category, the everyday sense we have of materials such as oil, iron, and gold conceal the conditions of their possibility. However, unconventional resources – such as oil shale, tar sands, gas hydrates, or e-wastes – often reveal the work necessary to stabilize materials as mineral resources, as resource classification methods and the techno-economic assemblage through which value, costs, and markets are constructed are in the process of formation (Kama 2015).

For the most part, however, mineral resources take on the appearance of independent physical objects – stocks in nature’s warehouse – awaiting incorporation into economy. Mining moves mineral resources across a significant conceptual threshold dividing “nature” from “economy.” Once entrained within economy, mineral resources commence a trajectory from extraction, through material processing and product manufacturing, to final demand. This sense of mining as a physical and defining act of taking, in which

materials innocent of human needs are bent to human will, is reflected in the popular association of mineral resources with “virgin” raw materials, a psychosexual gendering of Earth and extraction that has been integral (rather than incidental) to the expansion of extractive enterprise over the past few centuries (see Merchant 1980; Kolodny 1975). However, the relation between mining as a technique and the lithosphere as its target is not a necessary one: the technologies and practices of mineral prospecting, selection, and removal can also be applied to secondary material recovery and recycling in which mineral resources are extracted from the “ores” of accumulated urban infrastructures and wastes (Wallsten et al. 2013). “Urban mining” encapsulates the application of extractive techniques to concentrations of construction, municipal, and electronic wastes deposited in the environment (e.g., in landfills) and, potentially too, to the stockpiles of “hibernating” materials incorporated into the built environment during earlier periods of growth but no longer being used (such as old mobile phones that have yet to be recycled, or abandoned utility and transportation infrastructures). For some metals, such as copper, the volume and value of total “anthropospheric” mineral resources – consisting of wastes and hibernating materials, as well as materials currently in use – is broadly similar to known geological resources. For many elements, the concentration in industrial waste streams is richer than for geological ores (Kapur and Graedel 2006). Recent work to quantify the scale of above-ground stocks of mineral resources
MINING AND MINERAL RESOURCES

accumulated in the metropolitan built environment, and to map the complex trade networks around scrap metal and other wastes/resources (Gregson and Crang 2015), subverts conventional geographical imaginaries that locate minerals underground in the “resource periphery.” Material flow, life cycle, and material footprint analyses, for example, generate new understandings of the geographies of mineral resource stocks and the “anthropogenic mineral cycle,” and are indicative of a growing interest in how prevailing patterns of mineral resource production and consumption sustain socioeconomic and political-ecological relations (Müller et al. 2006).

Mineral resources in the Anthropocene

The scale of mineral resource extraction has grown at an unprecedented rate over the past century. For many mined materials, over half of all production has occurred in the last 50 years or less and, for some, the volume of material moved by humans now rivals background natural flows. Mineral resource acquisition has attained such scale that it has become possible to consider it equivalent in scope and significance to a geological force: mining and quarrying, for example, move around 60 billion tons per year, while the amount of material moved by water erosion is estimated to be around 53 billion tons (Douglas and Lawson 2002). This pattern is not limited to bulk minerals: the amount of sulfur mobilized through fossil fuel combustion and metal smelting, for example, is as large as that attributable to volcanic activity. Recognition of these cumulative effects re-imagines mining and minerals processing as a planetary-scale process of material mobilization in which humans act as geological agents. Such thinking has been central to the rise of the Anthropocene as a way of framing contemporary nature-society relationships (see Anthropocene and planetary boundaries).

The primary drivers of the enormous growth in mineral resource production and consumption have been Industrialization and the expansion of economic demand. These have been assisted by technological changes in production that reduce the costs of extraction, pulling down prices and expanding consumption, and by a growth in world population. At the broadest scale, four significant inflection points can be identified within the trajectory of mineral resource consumption, associated with (i) nineteenth-century industrialization in Europe and North America and the advent of bulk shipping for mineral resources such as coal and copper ores; (ii) the new materials of the so-called Second Industrial Revolution in the late nineteenth and early twentieth century; (iii) a postwar expansion in economic demand centered on “core” economies but also associated with peripheral industrialization; and (iv) the period from 1990s onwards, linked to the deepening of neoliberal economic reforms and a shift in the center of gravity of the world economy decisively towards Asia. As outlined below, these four periods map loosely onto distinctive techno-material assemblages over the past 150 years, in the manner described by Kondratiev’s longwave economic cycles. The material and technical shifts associated with the first three also correspond broadly with the characterization of eotechnic, paleotechnic, and neotechnic phases of civilization outlined by Lewis Mumford (1934).

Preindustrial uses of mineral resources were relatively constrained – stone and metals, for tools and armaments, building materials, arts, ornamentation, and exchange – and limited by prevailing techniques of physical and chemical separation. The so-called seven metals of antiquity associated with the material foundations of the ancient world – copper, gold, iron, lead, mercury, silver, tin – were either those that could be taken from the environment in
elemental form, or those that had melting points within the range of charcoal furnaces. A number of other metals were isolated during the Middle Ages, but it was industrialization from the eighteenth century onwards that brought about a fundamental shift from biomass to mineral-based metabolism (Barca and Bridge 2015). Industrialization drove an expansion in metal and fuel use, in construction materials associated with urbanization, and in the application of mineral resources to improve agricultural production (lime, guano). The revolution in organic chemistry in the mid-nineteenth century based on coal also gave rise to a number of novel materials, including aniline chemical dyes (the so-called coal tar colors, of which mauve is among the most striking). Recognition of the possibility for chemical recombination and synthesis laid the foundations for materials science, whose creative possibilities would later be given even greater rein in the context of petrochemicals.

The second major shift in mineral resource metabolism is associated with the materials revolution that occurred at the start of the twentieth century associated primarily with electricity and a growing understanding of atomic structure. This produced a suite of “neo-technic” materials: steel alloys (including stainless steel, via alloying with nickel and chrome), light metals such as magnesium and titanium, and the availability of materials in quantities enabled by electricity, such as aluminum (following development of the Hall-Héroult process in the late 1880s) and the widespread application of electroplating techniques. In comparison with the minerals most closely associated with industrialization – coal, iron, and steel – these materials were lighter and more easily worked: by understanding their molecular structure, they could be tailored for novel and precise applications, as in the development of specialized stainless steels. This period also saw a process of partial substitution, in which formerly biomass-based materials were augmented by mineral-based substitutes: in textiles, rayon substituted for silk, nylon for cotton, and polyester for linen and wool; while in agriculture “fossil” fertilizers – particularly natural gas and mineral supplies of phosphate and potash – largely replaced organic fertilizers, such as manure, guano, and bone meal. This second great shift in the scale and diversity of mineral consumption was centered initially on the United States: between 1918 and 1952 the United States consumed more minerals than had the rest of the world in the entire period before 1914.

A third shift – characterized by environmental historians as the “Great Acceleration” – occurred in the postwar period. It saw not only an intensification of mineral demand, but also a quite dazzling process of diversification in materials, particularly around nonmetallic mineral resources linked to the petrochemical sector. Growing consumer demand, and the need of a hitherto militarily orientated petrochemical sector to find domestic applications for a wide range of chemicals and plastics, drove a process of substitution. Plastics, for example, partially replaced glass and metal in packaging, domestic design, and industrial applications. A fourth and more recent shift in the scale of mineral resource production can be identified around the turn of the new millennium. This is associated, in part, with the proliferation of information and environmental technologies. Production of materials such as platinum and cobalt, for example, widely used in electronics, has increased fourfold in last 15 years, while lithium production has doubled in the same period. However, the significance of the past couple of decades is not limited to new materials: coal and uranium production have also doubled, and iron ore has followed a similar trajectory, with output tripling since 2000. A significant driver of these shifts has been geographical shifts in industrialization.
MINING AND MINERAL RESOURCES

associated with rapid economic growth in Asia, facilitated by neoliberal trade legislation including the accession of China to the World Trade Organization (WTO) in 2001. The current rate of global mineral resource Consumption is unprecedented, and has risen faster than the rate of population growth: global resource consumption per capita is estimated to be around 10 tonnes per year, implying an annual draw of 70 billion tonnes but also concealing wide variation in mineral resource consumption: industrial countries dominate material flows on a per capita basis, although a number of developing economies (and China in particular) have seen rapid and substantial growth in their material use in the past couple of decades.

Concern at the continuing expansion of mineral resource flows – and recognition of their complex geographical expression – has encouraged a number of efforts to calculate the material “footprints” associated with resource consumption. Direct material consumption is relatively straightforward to calculate on a national basis from domestic production and trade figures. Such statistics indicate, for example, that the average European will use 460 tons of sand and gravel, 166 tons of oil, 39 tons of steel, 1 ton of copper, and lesser amounts of other metals and rare earth elements in a lifetime. However, the weight of consumed resources is an imperfect measure of environmental impact for four reasons. First, it excludes the “hidden flows” of wastes generated during extraction, materials processing, and use which, for metals in particular, can be many times that of the mineral resource. Second, although sand, stone, and gravel account for the greatest weight of material moved, the complex geochemistry of metal ores and the use of reagents for mineral processing mean that the pollution effects of metal mining can be much more severe than those associated with the extraction of construction materials. Third, a measure of materials apparently consumed within an economy over a given period does not account for the ways in which some of them may be subsequently recovered and reused. And fourth, exposure to low-volume/weight materials, such as PCBs (polychlorinated biphenyls), mercury, cadmium, and benzene, may be far more significant for environmental and human health than exposure to those that dominate mineral resource flows by weight or volume, particularly where their effects may be amplified by bioaccumulation.

Nonetheless, mineral resource “footprint” calculations can be valuable because they point to the growing geographical interdependence of mineral resource trade. As the volume and diversity of materials consumed have grown, so supply chains linking production and consumption have also become increasingly global. Over the past three decades trade in raw materials has increased 2.5-fold (Weidmann et al. 2015) and many minerals have experienced large shifts in the geographies of demand and supply. In bauxite production, for example, the mid-twentieth century’s giant producers – Jamaica, Suriname, and Russia – have been eclipsed by Australia, Brazil, and China; similarly in iron ore, China, Brazil, and Australia now account for three-quarters of global production, replacing the dominance of Russia, the United States, and France several decades ago. The geography of mineral resource consumption is closely tied to industrial use and urbanization and therefore maps onto patterns of economic growth: China, India, and Brazil, for example, have rapidly become very significant mineral resource consumers. Their growth has also spurred significant domestic mineral production: for example, China was the world’s largest producer for 14 major minerals in 1995 but, by 2012, its lead role had expanded to 44 minerals (British Geological Survey 2014). The production of a few mineral resources has become more geographically concentrated over
time: the global supply of fluorspar, graphite, tungsten, and rare earth elements, for example, has grown much more dependent on production in China. However, other supply chains have become significantly more diverse: the long dominance of South Africa in gold and Canada in nickel production, for example, has sharply reduced, associated in the case of nickel with the development of new sources of supply in the Philippines, Indonesia, Russia, and Australia.

Perspectives on mineral resources and policy

The economic, political, and environmental issues associated with their production and consumption ensure mineral resources are frequently an object of social concern. The analytical perspectives of resource economics and political science have long dominated the policy space surrounding mineral resources. Geographers, however, have made a number of significant interventions, characterized by (i) a critical interest in the scales and spaces through which mining and “mineral problems” should be understood; (ii) adoption of a relational perspective, centered on the interdependencies between mining and other livelihoods, between extraction and consumption, and between Natural resources development and political institutions; and (iii) a thorough-going critique of Malthusian assumptions about physical scarcity and resource limits. Two broad areas of geographical inquiry into minerals are briefly presented here: mineral resource availability (including questions of strategic and critical vulnerability); and the environmental and political-ecological consequences of resource mobilization.

The availability and criticality of mineral resources

Availability is the original “environmental problem” surrounding mineral resources. It relates not to the impact of mining on the environment, but to the environment’s capacity to furnish society’s expanding demand for raw materials. Mineral depletion and the prospect of future Scarcity are hoary human concerns with roots in antiquity (Glacken 1967) which break into popular consciousness from time to time, often triggered by abrupt (although frequently short-term) changes in price. Rapidly expanding use of coal in the mid-nineteenth century led economist William Stanley Jevons (1865) to conclude Britain faced an imminent “coal crisis” that would inevitably lead to national decline. The country’s coal production did peak early in the twentieth century, although as a consequence of shifts in demand and fuel substitution rather than physical constraints on supply. The US Conservation Movement, most closely associated with fears of a national “timber famine” in the early twentieth century and the establishment of the US Forest Service, also expressed concern at the breakneck pace of coal, gas, and other mineral development. Gifford Pinchot, the first US Chief Forester, expressed this alarm, observing that “the five indispensably essential materials in our civilization are wood, water, coal, iron and agricultural products … We have timber for less than thirty years at the present rate of cutting … We have anthracite coal for but fifty years, and bituminous coal for less than two hundred. Our supplies of iron ore, mineral oil and natural gas are being rapidly depleted, and many of the great fields are already exhausted” (Pinchot 1910, 123–124, cited in Tilton 2002).

Pinchot’s prognostications on the availability of reserves proved misguided, as national reserves of oil, gas, and other mineral resources grew rapidly in subsequent decades. In the mid–1950s, right at the heart of the country’s postwar boom in
domestic oil production, geologist Marion King Hubbert projected US oil production would peak in the 1970s and then permanently decline. Crude oil production in the United States peaked in 1972 at 10 million barrels per day, and subsequently shrank to around 5 million barrels by 2010. However, the rapid development of unconventional “tight” oil resources, combined with offshore oil production from the Gulf of Mexico, has seen domestic crude oil production rebound to around 9 million barrels per day. The rate of rebound is such that the International Energy Agency have forecast (2012) the United States will outstrip Saudi Arabia as the world’s largest oil producer by 2020; others caution that the resurgence of domestic oil production cannot be sustained at such a level.

Growing environmental consciousness in the 1960s fueled a public debate over mineral resource constraints and other “limits to growth.” The Massachusetts Institute of Technology-led Meadows Report to the Club of Rome, for example, used computer simulation modeling techniques to conclude that mineral resource availability was a significant constraint on future growth. However, falling prices for many mineral resources during the 1980s and 1990s appeared to indicate scarcity was in retreat. Sharp increases in price in the first decade of the new millennium subsequently put resource availability and the prospect of peak supply back on the political agenda. Two mineral resources – phosphorus and oil – have been particularly significant in this regard. Phosphorus is an essential plant nutrient for which there is no substitute and its application as a fertilizer underpins crop yields worldwide (see Soil fertility and management). Uncertainty over the size of phosphate reserves has driven concern that global production of phosphorus will peak somewhere between 2030 and 2070. However, the most pressing limit (for import-dependent regions such as the European Union (EU) and Australia) is likely to be geopolitical: Morocco and the occupied territory of Western Sahara account for 85% of global reserves and the bulk of phosphate exports. In response, research is seeking ways to better manage on-farm phosphorus utilization, improve the efficiency of application, and instigate phosphate governance at a global scale (Cordell and White 2014).

Similarly, proponents of “peak oil” forecast an impending permanent decline in the availability of conventional crude oil as geophysical limits begin to bite. However, growing production from unconventional sources – such as Canada’s tar sands, the heavy crudes of the Orinoco Delta, or so-called tight oil formations such as the Bakken in North Dakota, combined with the erosive effect of high oil prices on demand growth – have allowed total oil output to keep pace with demand. The continued growth of output has been underpinned by a significant qualitative shift in global oil reserves that can be characterized as the end of “easy oil.” Although the abundant, low-cost, conventional oil reserves of the Middle East continue to dominate supply, reserves replacement increasingly relies on higher cost reserves that are more complex to develop, and more energy and greenhouse gas intensive. A similar process is underway in metals, where the transition to lower grade ores over time means rising energy, greenhouse gas, and process water requirements. As with oil, these sustainability constraints act as soft boundaries rather than geophysical limits: in the case of greenhouse gas and water requirements, for example, they can readily be exceeded, although at environmental and social cost. This suggests, therefore, that mineral resource availability is not simply a net effect of the forces of depletion and scientific knowledge, as resource classification systems such as that shown in Figure 1 would suggest. Mineral resource availability is, to a very significant degree, a social and political choice.
about what level of environmental and social disruption will be tolerated, and on whom their environmental and social costs will fall.

As the example of phosphorus illustrates, mineral reserves and mineral consumption are geographically uneven and frequently poorly aligned. As a consequence, mineral resource availability is very often a geopolitical concern. The result is a national focus on the availability of militarily strategic or economically critical minerals that parallels a concern for “global” resource availability and planetary boundaries (see Energy security). A strategic or critical mineral describes one for which there is little if any domestic production but domestic consumption is militarily or economically significant. The combination of supply risk (likelihood of disruption associated with import dependence) and impact of a disruption to supply (a function of a mineral’s importance in use) defines a “criticality matrix” (Figure 2). The EU’s Raw Material Initiative, for example, was launched in 2008 in recognition of Europe’s high dependence on raw material imports for sectors such as construction, chemicals, automotive manufacturing, aerospace, and renewable energy. As part of a wide-ranging initiative that includes resource diplomacy, innovation, and efficiency, the EU has identified 14 “economically important raw materials which are subject to a higher risk of supply interruption.” These critical “EU14” include antimony, fluorspar, graphite, germanium, indium, rare earth elements, cobalt, niobium, and gallium. A high degree of import dependence is not, in itself, a measure of criticality: also important is vulnerability to supply interruption, associated with reliance on a geographically limited range of sources and/or the possibility for politically motivated restrictions (including cartelization). In the case of the EU14, for example, criticality reflects the concentration of production for these minerals in China, Russia, Brazil, and the Congo, as well as limited options for substitution and low levels of recycling.

The concept of strategic minerals implies relevance to military or national emergency planning, and emerged to prominence in the United States in the wake of the Korean War. A surge in raw material prices during the conflict rekindled long-standing concerns about the availability of mineral supplies, and led to the formation of the President’s Material Policy Commission in 1952 (the Paley Commission). Written in an historic context marked by the defeat of Fascism and an escalating Cold War with the Soviet Union, the Commission’s report – Resources for Freedom – examined whether the United States had “the material means to sustain its civilization.” The Commission defined the country’s “Material Problem” as “consumption … expanding at

**Figure 2** Criticality matrix, in which the degree of criticality increases from lower left to upper right (i.e., mineral A is more critical than mineral B). [http://www.nap.edu/openbook.php?record_id=12034](http://www.nap.edu/openbook.php?record_id=12034). National Research Council 2008. Reproduced by permission of National Academies Press.
compound rates ... pressing harder and harder against resources which, whatever else they may be doing, are not similarly expanding.” While observing that the United States had outgrown its domestic resource base to become a major importer of many mineral resources, it nonetheless rejected self-sufficiency as a response to the country’s changed materials position. It proposed a mix of free-market and government-led response, encouraging US companies to invest overseas in search of low-cost mineral supplies, while also invoking the government’s capacity to extend price guarantees and requisition plant and equipment in a time of war, and making permanent stockpiling provisions for strategic materials.

During the Cold War the United States designated over 60 “strategic and critical” minerals and metals, holding reserves of many in the National Defense Stockpile. Strategic vulnerabilities associated with a high degree of import dependence have resurfaced as a concern of US mineral policy from time to time: in the 1980s, for example, dependence on South Africa for supplies of chromium, manganese, and platinum-group metals (platinum, palladium, rhodium, ruthenium, osmium, and iridium) was considered a source of strategic vulnerability, as the struggle against apartheid in South Africa had the potential to disrupt exports of these minerals. More recently, concern about strategic and critical supply has focused on the availability of minerals integral to the advanced digital economy and the so-called rare earth elements (REE) in particular (despite their name, REEs are relatively abundant in total quantity but occur in low concentrations so that their extraction and processing are difficult and costly). REEs such as neodymium, dysprosium, and cerium have key applications in information technology (smart phones, computers, flat screens, and light-emitting diodes (LEDs)), the clean-tech sector (in magnets for electric motors, for example), and in many defense applications (for guidance, control, and weapons systems). REE production has doubled in the past 20 years and, notwithstanding that mineral reserves are relatively widespread, around 90% of production has come from China since the 1990s. In 2010 China announced a policy of reducing exports in order to protect domestic consumption, igniting policy concern among importing countries and particularly in the EU, United States, and Japan.

From environmental impacts to the political ecologies of resource mobilization

Mining and mineral resource development take up a small proportion (less than 1%) of the Earth’s surface: estimates for the United States, a country with an extensive mining history, indicate that mineral extraction occupies only 0.25% of the land area, compared to 3% for urban areas and 70% for agriculture. In the nineteenth century, geographer and proto-conservationist George Perkins Marsh (1965/1864) largely dismissed the impacts of mining, noting they “must always be too inconsiderable in extent to deserve notice in a geographical point of view.” However, a growing body of research challenges this perspective by (i) expanding its analytical scale, away from the mine as a single point of extraction, to consider the ecosystems and biogeochemical cycles within which mines are embedded; and (ii) considering the broader political ecologies to which mining, and international trade in mineral resources, gives rise.

The extraction, processing, and consumption of mineral resources generate a wide range of environmental impacts, many of which have been long-standing sources of concern for individuals and communities exposed to them. Agricola’s (1998/1556) meticulous observations of mining in sixteenth-century Saxony record
not only mining’s effects on forests, rivers, and wildlife, but also how these impacts can undermine the legitimacy of extraction and rally those challenging the primacy of mineral development over other land uses and livelihoods:

[T]he strongest argument of the detractors is that the fields are devastated by mining operations … Also they argue that the woods and the groves are cut down, for there is need of an endless amount of wood for timbers, machines and smelting of metals. And when the woods and groves are felled, then are exterminated the beasts and birds … Further when the ores are worked, the water which has been used poisons the brooks and streams, and either destroys the fish or drives them away … Thus, it is said, it is clear to all that there is greater detriment from mining than the value of the metals which mining produces.

Because mining’s impacts can be severe, societies have wrestled for hundreds of years with the conditions under which rights should be granted to miners for access to land, or for the release of wastes to air and water. Agricola’s commentary neatly expresses how mining’s environmental impacts exceed the process of excavation, narrowly understood, to include mining’s energy demands (on timber and charcoal to fuel furnaces, or water to power lifting gear); the utilization and release of chemical reagents; and the effects of material removal on waterways and aquatic life. A large body of research now outlines mining’s role as a source of soil, water, and air pollution at local and regional scales, with significant work on acid mine drainage, mercury mobilization, the failure of tailings dams, and the impacts of smelting operations and fossil fuel combustion on land cover and water quality. By focusing on the transport, behavior, and fate of physical and chemical pollutants in the environment, this work opens up a broader perspective on mining’s environmental impacts including, for example, the way materials are modified (dilution, recombination, bioaccumulation) by biogeochemical cycles. Paralleling this concern with pollution, research on biodiversity and ecosystem health has examined the suite of ways in which mining modifies ecological processes operating over broad geographical scales, including mining’s role in driving regional land-use/cover change (see Land-use/cover change and climate), habitat fragmentation, and associated effects on biodiversity. One effect has been a growing recognition of off-site impacts, particularly around water, biodiversity, and the ways in which mineral resource production articulates with livelihoods. In the area of policy, this has included a growing recognition that some landscapes should remain off limits to mining, and has led to a greater concern with the cumulative effects of mineral resource development.

The field of Political ecology has made significant contributions to illustrating the wider social and environmental implications of mineral resource development, highlighting alternative scales and temporalities through which the significance of mining can be understood. While much of this work remains focused on spaces and communities affected by resource extraction (Bebbington and Bury 2013), political ecology has also shown an interest in understanding the wider political and ecological relations to which flows of mineral resources give rise. Its critical move is (i) to see site-specific conflicts over mineral resource extraction as part of a more generalized extension of the commodity frontier (see Frontiers), associated with bourgeoning material demand and the adoption of economic policies favorable to external investment in mining; and (ii) to focus on interdependencies between these “resource struggles” and the high rates of economic growth enabled in some parts of the world by the consumption of mineral resources. This deep relational perspective reframes mining and mineral resource development as a matter of global social justice: a
MINING AND MINERAL RESOURCES

distributional conflict that centers on the capacity of some groups to acquire and use mineral resources while displacing the impacts of these processes onto others (Muradian, Walter, and Martinez-Alier 2012).

Research on the ecological distribution conflicts associated with trade in mineral resources draws conceptual support from neo-Marxian arguments about capitalism as a process of spatial differentiation and uneven development by which country and city – core and periphery – become distinguished from one another and co-produced (see Cores and peripheries and Dependency theory). A useful heuristic in this work has been the notion of “metabolic rift” (Foster, York, and Clark 2011). In its original formulation, this term recognized how nineteenth-century urbanization significantly disrupted the historical pattern of nutrient cycling. The growth of urban food demand removed nutrients from the countryside (via the export of food crops) and effectively piled them up in the city (in the form of wastes), simultaneously setting in motion a geographical search for new sources of soil fertility, and efforts to manage urban wastes. Metabolic rift has been applied to planetary resource flows describing, for example, anthropogenic influences on biogeochemical cycles consequent to industrialization, such as disruption of the global carbon cycle and the flooding of atmospheric carbon sinks (Clark and York 2005). The concept’s critical value for contemporary work on mining and mineral resources is its capacity for understanding how international trade in mineral resources is simultaneously a process of political-ecological differentiation at the world scale based on the appropriation of energy and matter. It enables mineral resources trade to be reinterpreted as a form of ecologically unequal exchange, through which materials with enormous productive potential (metals, fuels) are siphoned from parts of the world with limited industrial capacity. Appropriation and consumption of these materials enables the creation of economic value, thereby differentiating core from periphery and ensuring the core continues to accumulate the technical and political-economic capacity to acquire future resources (Hornborg 2015).

Critical perspectives such as these have meant geographical research has tended either to be skeptical of efforts to promote development through the extraction and export of mineral resources, or to argue that its ability to do so is contingent on a specific set of institutional, technological, and environmental conditions. Such critical caution in the face of policy assertions is a hallmark of contemporary geography’s engagement with mineral resources. The continuing promotion of mineral resource exports as a pathway to economic development (notwithstanding its strikingly poor record; see Resource curse), and the emergence of “sustainable mining” as an active policy agenda, suggest such caution is warranted. For most mineral resources, the idea of sustainable harvesting or sustainable yield does not apply, because the resource is unable to regenerate over timescales that are meaningful to humans. The economic case for sustainable mining rests on three arguments: (i) that mineral extraction and processing convert stocks of natural capital into replaceable human capital; (ii) that wealth creation is compatible with the antipoverty objectives of sustainable development; and (iii) that a diversity of mineral resources are key to a “green growth” agenda, centered on high-technology, resource efficiency, and renewable energy (see Ecological modernization). Each of these arguments merits scrutiny: the first rests on strong claims for the substitutability of natural and human capital; the second (and third) on assumptions about the relationship between growth and the distribution of wealth; and the third that green growth
actively substitutes for other growth forms (via policies that squeeze out high-carbon material flows, for example, or which steer investment from primary extraction to secondary recovery) rather than serving as a supplemental “niche market” expanding overall metabolism.

Mixed-method approaches

Timothy L. Hawthorne
University of Central Florida, USA

Many geographers increasingly recognize the value of mixed-method approaches in their research. Definitions of mixed-method research vary across and within fields, including in our own discipline of geography. Mixed-method research is defined here in a way similar to Creswell and Plano Clark (2011) as any form of research where the researcher intentionally combines multiple methods in order to harness the strengths of multiple approaches, while recognizing the limitations of using only one research method for data collection and analysis.

Geographers utilize mixed methods in their research for a variety of reasons. First, they recognize that added rigor may result from combining methods and analyzing datasets using both qualitative and quantitative methods. Such combinations often allow the researcher to explore and uncover deeper meanings and understandings in her/his research, which would not be possible using only one method or approach.

Qualitative methods on their own are often valued for the fact that they are subjective, inductive, and allow context, meaning, and individual lived experiences to emerge from a research study. In order for such themes to emerge, researchers often utilize methods that directly capture the experiences of individuals or groups of individuals. Such methods often include observation, ethnography, interviews, focus groups, phenomenology, case studies, and/or grounded theory. The data emerging from qualitative methods often allow the researcher to contextualize and understand geographic processes in a way that emphasizes the voices of an individual being researched, while demonstrating that all knowledge and individual experiences are socially constructed in a particular time and place.

Quantitative methods on their own are often valued for the fact that they are objective, deductive, and allow for theories and hypotheses to be proposed, tested, and analyzed. Statistical analyses are often at the core of such approaches where the goal is to understand relationships across variables in a way that can be quantified and analyzed with some statistical power. Quantitative methods are often lauded for their objectivity, their likelihood for replication across geographic settings, and their ability to generalize from a smaller sample to a larger population. Common quantitative methods may include descriptive surveys, statistical analyses, or case-control studies, to name a few. In many cases, geographic information systems (GIS) is often viewed as a predominantly quantitative method (though as discussed below, GIS can be viewed as a mixed method).

Mixed-method approaches are valued for their ability to combine the power of both qualitative and quantitative approaches to provide a more complex account of the issue, construct, process, or phenomena being researched. Often mixed-method researchers celebrate the intentionality of choosing multiple research methods to draw out the strengths of multiple approaches and to uncover the hidden silences inherent in any one method or approach. As many geographers move toward a more mixed-method
Mixed-method approaches are faced with a serious challenge in their research design: determining the appropriate way to integrate data gained from qualitative and quantitative methods. Creswell and Plano Clark (2011) demonstrate three viable integration options for mixed methods, including: merging data, connecting data, and embedding data. Merging integrates the qualitative data gained from interviews, group discussions, and images or videos with the numerical information captured from quantitative data. In many mixed-method studies, merging is achieved by reporting the different types of data separately to inform both sets of data. For example, a researcher studying health-care accessibility in an urban area might first report the quantitative data of travel distances computed in GIS between an individual’s home and her/his health-care provider. Then the researcher would introduce qualitative data in a series of themes or quotes to contextualize the travel distance and accessibility experience by demonstrating how difficult it was for an individual to access a health-care provider in an urban area.

A second integration strategy in mixed-method research, according to Creswell and Plano Clark (2011), involves connecting data. Connecting occurs when a researcher uses the analysis of one dataset or method to inform subsequent analytical methods. Extending the health-care accessibility research example discussed above, a researcher using a connecting strategy might choose to first examine the travel distances of participants in the study. The researcher might find that lower-income residents have to travel longer distances than higher-income residents to find an affordable health-care provider. Using these data and results through a connecting approach to integration, the researcher could then create a series of questions for use in an in-depth interview that asks participants to explain how they felt about their long commuting times and the experiences of their journey from home to the health-care provider. In this way the results of the quantitative GIS method to measure travel distance could be connected to the follow-on interview questions to understand the experiences of an individual’s journey to a health-care provider.

A third approach to data integration, according to Creswell and Plano (2011), involves embedding data. Embedding occurs when a primary research strategy and method are utilized and a secondary dataset is included to support the larger research design. For example, a health-care study might be designed to test whether or not a certain physical activity intervention can help with weight loss in obese individuals. An embedded qualitative method might be included in the intervention to quickly assess how an individual is doing with the physical activity intervention.

The recent, increased adoption of mixed-method research in the discipline of geography is a direct result of the field’s diversity and its greater internal debates about what counts as rigorous knowledge production. In an effort to avoid dualistic and divisive thinking, mixed-method researchers seek to move toward a more hybrid view of knowledge production where one method is not necessarily more valued than another method.

Though there are several examples of movements and debates about hybrid, mixed-method approaches in our field, one of the recent examples within geography is from the early 1990s GIS and society debates (see Sheppard 1995) and the field of critical GIS (see Schuurman 2000) which emerged
from these debates. Throughout the GIS and society debates of the early 1990s, some geographers called for a stronger recognition that knowledge was socially produced, and that technologies such as GIS were not value-free and objective, but rather simultaneously shaped by and shaping society. During the time of these debates, a pivotal disciplinary moment occurred in which many within the social theory and GIS camps proposed that multiple research methods were necessary to uncover the complexities of geographic processes and phenomena.

As Kwan (2004) argued in her centennial piece in *The Annals of the Association of American Geographers*, the GIS and society debates (and the subsequent cultural turn seen in emergent critical GIS studies) provided a unique moment for many in the discipline to discuss knowledge production. Using the GIS and society debates as one example, Kwan argued for a radical departure in thinking about knowledge production. She challenged Thomas Kuhn’s definition of scientific inquiry in which Kuhn argued that dominant paradigms must supplant other paradigms in scientific revolutions. Kwan contrasted Kuhn by arguing that a complete discarding of one paradigm for another would be unhelpful for geography as a whole and GIS specifically. She proposed the concept of hybridity for recognizing the strengths and weaknesses of two or more ways of thinking. At the time, Kwan stated that: “through these processes of polarization and boundary enforcement, alternatives are less likely to emerge, and geographers tend to be conveniently identified in terms of rigidified, incompatible, stereotypical, and binarized identities” (Kwan 2004, 757). Hybrid geographies as Kwan noted recognize the potential for unique findings and innovative ways of thinking at the intersections of seemingly incompatible knowledge bases and research methods.

Mixed-method approaches are a form of the hybrid geographies Kwan called for in 2004. A handful of recent hybrid, mixed-method studies that challenge dualistic thinking through the combination of qualitative and quantitative methods in order to capture the complexities of real-world processes and phenomena are introduced here. Knigge and Cope (2006) introduce grounded visualization as a mixed method and suggest that using only quantitative data fails to show important processes occurring in local neighborhoods as they research community gardens. In their work, qualitative interviews with participants, participant observation, and GIS analysis of land-use data are used together through a grounded theory approach in which “contextualized cartographic narratives in geographic discourse” are created (Knigge and Cope 2006, 2023) to reveal the everyday lived experiences and situated knowledge found in their research study site.

Another example of mixed-method research is evident in Pavlovskaya’s 2002 study of economic restructuring in Moscow. Pavlovskaya shows how GIS is used in a period of economic transition to understand the city’s economic structure. She notes that informal economies at the micro level (i.e., the household scale) are not considered in official statistics of the city. Through qualitative interviews with individual households, she uncovers the importance of these informal activities and complements official economic statistics of urban change. Such data suggest to policymakers that they may be missing an important component of the city’s survival.

Kwan (2007) uses 3-D geovisualization (focused on GIS, mapping, and individual interviews completed while riding through the city with research participants) to examine the emotions and feelings of Muslim women as they travel around a major US city after September 11, 2001.
11, 2001. In these 3-D visualizations, participant feelings and perceptions of safe and unsafe spaces in the city are revealed in a way that has not been done in conventional GIS research.

The mixed-method studies introduced above are just a small sample of a growing body of work within geography, but share a commonality that points to the value of mixed-method scholarship. Such studies openly recognize the situatedness of all knowledge and challenge so-called objective truths. By assuming that all knowledge is situated, mixed-method researchers move toward more context-specific analyses of people, places, and geographic processes.

In closing, it is important to recognize the intentionality of mixed-method scholars in designing studies with multiple methods and understand that all knowledge is socially constructed and situated within large debates about epistemology, ontology, and methodology. It is also prudent to stress that mixed-method scholars understand that qualitative and quantitative methods alone have value and provide different explanatory and descriptive powers in geographic research. The real power for mixed-method scholars, however, lies in combining the strengths of qualitative and quantitative methods to uncover hidden silences in the data and to provide a more complete understanding of the construct, process, or phenomena being studied in geographic research.

“Mobility gaps” issues are concerned with whether every individual has adequate access to mobility to be able to satisfy the needs of their everyday life. Daily mobility depends on a wide range of determinants which can restrict or force it.

Some of these factors seem obvious. Depending on income, the economic budget that an individual can devote to transport either limits or opens up the size of the perimeter and the set of choices within which he or she can carry out everyday activities. The more one can spend, the further one can go and the more opportunities one can access. Likewise, residential location – which is also related to income – influences daily travel options. Individuals who live close to shops, schools, or jobs that suit their needs increase their chances of reaching many destinations within a realistic time or money budget, whereas living far from urban resources reduces it. The characteristics of a neighborhood also facilitate or impede travel because different neighborhoods provide uneven transport services as alternatives to car ownership. Among obvious determinants, there is no doubt that physical capacities (including the effects of age) also affect freedom of movement.

But less evident social characteristics also matter. The position of individuals in society, based on their social and cultural capital, can explain a certain relationship with space and a pattern of exposure to other individuals. For example, migrants with low proficiency in the host-country language may lack the know-how required to travel (find information, read directions or maps, or understand the symbols that serve to locate oneself in space), and people suffering social domination may feel unwelcome in some neighborhoods. The upper classes may feel a greater legitimacy to navigate through unfamiliar spaces.

Other social determinants of daily mobility involve the gender perspective. It has been observed that women have a smaller spatial range and average commute than men (Hanson and Pratt 1988) although the gap is narrowing. The major reason for this lies in the social role of women, who are much more active than men in domestic work and therefore have less time available for other activities, including work. As these obligations put pressure on their personal schedules, the need to reconcile their domestic and professional lives means that it is easier for them to work close to home. Thus, the allocation of paid and unpaid work within a household imposes variable limits to the geographical range of the household members. This has long been at the expense of the occupation of women, as spatial entrapment can restrict the proper matching of qualification and job.

These observations show that mobility determinants are not solely the outcome of individual characteristics: social, economic, and spatial environments play a considerable role. How easy it is to travel and access opportunities, or even...
whether this is possible at all, also depends on the environment at large: how the transport system is organized and benefits people; how populations, employment, and services are distributed in space, which itself depends on how land use and the land market are regulated; how working hours make the existing services available to people; how social norms influence behaviors; and so on. Finally, the conditions likely to impact individual mobility are those that define accessibility (i.e., the potential for reaching opportunities), namely the availability of nearby opportunities and/or the ease of traveling to more distant ones (Handy and Niemeier 1997).

The social effects of barriers to mobility

Barriers to mobility can impair life chances. A long tradition of surveys has studied the consequences of travel constraints on access to fundamental needs such as employment, education, health, social services, and so on. Initially in the United States, and then in other countries, the issue of accessibility has stimulated a vast amount of work that examines these effects. For example, all things being equal, it is acknowledged that low-skilled workers face poorer job accessibility than other workers, that is, the job opportunities available within a given travel time and budget from home are more limited. This is both because low-skilled workers often live at greater distances from the main employment centers and have fewer resources (access to car and travel budget) to overcome these distances. On this basis, poor accessibility is seen as part of the explanation for the longer periods of unemployment experienced by low-skilled job seekers (Kain 1992). More broadly, the accessibility issue is today related to the risk of social exclusion, whereby people are prevented from participating in many aspects of social life (Lucas 2006).

Nowadays, access to travel is judged to be a major issue because the nature of contemporary urban societies calls increasingly for mobility in the conduct of everyday life. Job insecurity demands the ability to be mobile in order to change job location. Working time flexibility increases the need for autonomous means of transport, as mass transit is often inadequate during off-peak hours. Women’s employment requires transport services that allow children to move on their own. Urban sprawl necessitates the ability to travel long distances and use a car. The increasing structural need for mobility and the adverse effects of restricted mobility make equity in transport a strategic issue for policy agendas, and its measurement a matter of concern. However, the meaning of mobility indicators is not obvious and the increasing need for mobility is contested.

Mobility as a problematic indicator of inequity

Unlike accessibility, which describes a range of choices, mobility refers to choices that are actually made: the decisions between options, in which personal preferences play a role. Indeed, daily mobility occurs in a world of constraints but is not exclusively the result of constraints. A trip is rarely the automatic consequence of either pure constraints or the strict need to perform an activity that does not contain any degree of choice. To some extent, journeys help an individual to fulfil personal goals. Residential location or lifestyle, in particular, are frequently primary choices that affect travel decisions and the nature of mobility, and which are often made possible by daily mobility. Since daily mobility combines constraints and choices whose relative importance is hardly discernible, interpreting mobility is complex. How would we analyze travel behavior? How would we assess inequity?

Daily mobility is measured by synthetic indicators which make it difficult to read. Traditionally,
the number of trips a day tells us about an individual’s level of participation in social activities and number of relations in the community. However, what about individuals who return home three times a day because of a fragmented working day or those who multiply contacts without travel, using distance communication? The distance traveled usually tells us how free a person is to travel – access to money, time, and a convenient mode of transport or freedom from cultural barriers. But what about individuals who have no choice but to travel far or those who have the choice to give priority to neighborhood-based living? Are long trips the sign of great freedom of action and short moves the sign of restricted options? Or, conversely, are short trips the sign of individuals who have the resources to control their environment and long trips a mark of forced actions?

In the classical economic vision, all things being equal, people are assumed to prefer short distances and low expenditures. In such a scenario, nearer is better. However, for a long time, wealthier groups were the ones moving the greater distances, and short trips were distinguishing low-income groups and were seen as a sign of restricted options. Given that all things are never equal, Zahavi and Talvitie (1980) have argued against the classical vision proponents that, with time and money limits, people may chose to satisfy more important personal aims – such as residential aspirations – than save on their travel distances and costs. In the second half of the twentieth century, there was a massive movement of population from the inner cities to the outer suburbs, as individuals were able to own their own homes in low-density environments, with increasing daily travel distances as the price to pay for achieving that goal. For these individuals, nearer was not better. However, nowadays, great distance seems less and less to be synonymous with free choice. Because of rising house prices, many households are forced to live far from employment centers and to endure travel over long distances.

Thus, it is difficult to say whether the level of mobility is a sign of restricted options or a sign of freedom. The significance of daily mobility indicators is uncertain because they say little about the range of options that prevailed before the actual choice. Since mobility behaviors include an element of choice, assessing equity or inequity would assume that it is possible to distinguish between behaviors that are chosen on the basis of individual preferences and those that are determined by exogenous constraints and determinants. Otherwise, mobility indicators would be unequivocally interpreted as measures of inequity according to a hierarchy of travel behaviors. The notion of mobility gaps thus seems questionable, because we cannot say that there is such a thing as a consistent norm according to which it could be categorically stated that an individual has a deficient or forced mobility.

In past decades, the hierarchy of travel distances actually used to conform more or less to the hierarchy of socioeconomic status. But preferences and social norms have evolved, and this may explain why previous traditional hierarchies of travel behaviors no longer apply and often present reverse trends. On average, men and women show more and more similar travel behaviors. The inhabitants of big cities now travel lower distances than in smaller cities. More and more, blue-collar workers are commuting further than executives; and cycling or the use of public transport becomes the privilege of the former while driving is the mark of the latter – while it used to be the opposite in the past. This blurs the assessment of mobility according to a single hierarchical scale. But it might not totally condemn the prospect of assessing behaviors in relation to new social norms that signal what is socially desirable.
MOBILITY GAPS

Contradictory goals

Equity in daily mobility is an important issue but it is difficult to assess and to address. Policy-makers are increasingly concerned about this crucial question, but to frame policy is challenging. Facilitating the satisfaction of everyday life’s needs by enhancing individuals’ facility to move has long been the prevailing option. But it becomes apparent that encouraging private autonomy is controversial in light of sustainable development goals, and financing alternatives such as public transport is challenging. In addition, it is clear that facilitating travel raises the norm of expected mobility and doesn’t reduce gaps (Orfeuil 2011). One group’s higher capability to travel creates a context that worsens the consequences of the other group’s lower travel capabilities (Fol and Gallez 2014). That is why more and more critics are opposed to the mobility credo. Facilitating the satisfaction of everyday life’s needs by promoting spatial proximity to opportunities (instead of mobility) is another option that is less often pursued because it demands complex and active land-use and land market regulation.

Modeling uncertainty in digital elevation models

Ashton M. Shortridge

Matthew T. Rice  
*George Mason University, USA*

Digital elevation models (DEMs) provide representations of the Earth’s continuous surface elevation. While various data models and structures are possible, the raster model is the most common: a rectangular region of the landscape is depicted as a gridded array or square or rectangular cells, each of which stores a height value representing the elevation above sea level for its location. The Earth’s surface is of fundamental importance for a vast range of physical and human processes. Consequently, DEMs are used in an especially wide variety of applications, including suitability analysis, viewshed delineation, route optimization, image registration, environmental risk assessment, and as inputs to climate, hydrology, and soil models.

There are differences between any particular DEM and the real-world elevations it represents (Fisher and Tate 2006). These differences may be due to mismatches between the underlying ontology of the DEM and its reference terrain (ontological mismatch) or from errors introduced during measurement and processing (production error). Where these differences are unknown, either because they have not or cannot be measured precisely, uncertainty exists. This entry considers the sources of uncertainty in digital elevation models, their consequences for the application of DEMs, and approaches that have been taken or proposed to deal with uncertainty, particularly through statistical models.

### Error and uncertainty

This section begins with definitions for some critical terms – error, uncertainty, and fitness for use – before discussing sources of error in DEMs and exploring the nature of uncertainty in more detail. “Error” is the difference between the actual elevation and its representation in the DEM (Heuvelink 1998) gives a broader discussion of this definition). “Actual elevation” implies an independently collected ground truth measure to compare against a portion of the dataset, though this measure is itself subject to error. Typically, error is not known throughout the domain of the dataset but only at sampled locations. In contrast, “uncertainty” is the degree to which the fidelity of the DEM to the actual terrain is open to question. This is quite different from error. At sampled locations where the error is known, uncertainty is actually zero. It is at the other locations that uncertainty exists.

In general, DEM users are not interested in the dataset itself but rather in the real-world terrain that the dataset imperfectly represents. They need to know how imperfect this representation is, as it relates to their applications (Fisher and Tate 2006). A user deploying a DEM to identify what can be seen from an observation tower cares about how imperfection in that DEM may lead to imperfection in the calculated viewshed. Another user might wish to identify water runoff flow paths for the same area, and that user should
care about the consequences of imperfection in the DEM for the calculated flow paths. It may well be that uncertainty in the elevation values has different impacts on these different applications. “Fitness for use” is a paradigm in the quality standards community that poses the utilitarian question: is the fidelity of this dataset sufficient for my particular application? To satisfy fitness for use, uncertainty from DEM elevations must be propagated to the process output.

Earlier two quite distinct sources of DEM error were briefly described: that due to mismatch between the specifications of the DEM and of the reference data used as ground truth, and that due to production, either in measurement or processing. Both are considered in more detail here.

Ontological mismatch
As reflected in its very name, a DEM is fundamentally a model: a characterization of real-world terrain that necessarily involves simplification and abstraction from the conceptual model to its representation in a spatial database. A standard conceptual assumption is that each location has a single and theoretically measurable elevation. Real-world surface features with multiple elevations (e.g., cliffs and overhangs) are not supported by this model. Further, locations with ambiguous heights (e.g., unstable terrain like marshes or bogs, or with thick surface vegetation cover) may not be precisely measurable, or may have different heights at different points in time.

A key DEM computational modeling choice is the selection of an output raster spatial resolution. This resolution is connected directly to the spatial scale, or support, at which the terrain is represented. A coarse spatial resolution maintains a more general approximation to the actual landscape, with fewer fine-scale topographic features. Also important is the ontology of the reference data used to “ground truth” the DEM. These reference data have their own conceptual and computational model, the details of which may not match those of the DEM. As an example, consider the use of differential GPS gathered in the field as reference to calculate error in GDEM, a near-global product derived from ASTER stereopair imagery. GPS heights are measured at essentially point support, while GDEM is a 30-meter resolution raster, in which elevations within grids may be thought of as averages. Differences in measured elevations indicate mismatches in what is being characterized.

Production error
A range of production methods have been used for DEMs. In one general family of approaches, elevation measures for discrete locations are obtained from some primary source (e.g., manually surveyed locations, LiDAR point clouds) and then these measures are interpolated to regular grid points or cells to construct the DEM. In another general family, the primary sensor collects data in a gridded format initially (e.g., interferometric synthetic aperture radar (SAR), stereophotogrammetry) and through processing these data are converted to elevations, often, though not exclusively, at the spatial resolution of the primary sensor. Both the initial collection and the subsequent interpolation or assignment can, and do, contribute an error component to the elevation estimates. The nature of error in any particular DEM will have characteristics particular to the measurement technology and the production method used. The remainder of this section describes specific, characteristic errors for several common DEMs and links error properties to particular aspects of measurement or production.
Figure 1  Example DEM errors: (a) Contour artifacts in 1” NED near Bakersfield, CA. (b) Firth Effect in older 1” NED near Niles, MI. (c) Forest artifacts in 1” NED at Howard Prairie Lake, OR. (d) Aerial imagery for the Howard Prairie Lake site.

Paper contour map sheets (or the metal plates used to print them) were commonly used to develop twentieth-century DEM products. This approach required the digitization of contour lines and spot heights, followed by interpolation to grid. Artifacts from this process are evident in hillshaded DEMs, particularly in relatively level areas. Figure 1a shows contour artifacts in a gently sloping landscape. Positional accuracy of contours may be rather low in these level areas, and on surfaces covered by vegetation; elevation errors up to and beyond half the vertical contour interval should be expected in such areas. Different patterns of errors are evident in DEMs produced via stereophotogrammetric image processing, a process by which multiple
aerial or satellite images of the ground are taken from different perspectives, common points in both images are identified, and the difference in their relative positions due to the different angle of the camera is calculated to derive heights. Elevation errors in these DEMs may result from lack of precision in the identification of ground control points, changes in film media, reflectance from the sensor, instrument error, and operator errors. An example of this latter error is depicted in Figure 1b: on older semiautomated profiling stations, elevations were often underestimated by the operator when moving upslope and overestimated when moving downslope. The resulting systematic error is called the Firth Effect.

Interferometric SAR was deployed on the space shuttle in February, 2000 and processed to generate a near-global DEM. Surface heights obtained in this way were biased upwards in areas with substantial forest canopy cover, as reflectances came from the initial surface encountered. Figures 1c and 1d depict an example in the SRTM 1” product for an area around Howard Prairie Lake in south-central Oregon. The edge of the forest northeast of the lake is clearly visible in the DEM, with sharp-edged 10–15-meter high “cliffs.” This might be considered an ontological mismatch: the DEM has faithfully recorded the reflected surface height, while the DEM user could prefer bare surface elevations. Similar vegetation-related effects are observed with LiDAR elevation data, as returns of airborne laser pulses are likely to reflect from the top of vegetation, buildings, and bridges.

**Error measurement**

Error classifications have been useful for DEM producers. A common approach identifies three fundamental types of error: blunders, which are very large in magnitude; systematic errors, which have some regular pattern or association; and random errors, which are those remaining after accounting for the others (a good description is given in Fisher and Tate (2006)). These errors may be identified through internal or external validation. Internal validation uses properties of the dataset itself or production method to flag errors. External validation is the most common method for calculating error: it compares values in the DEM to a dataset of known higher quality. Defining error as the difference between one dataset and another requires a key modeling assumption: that one conceptual model (e.g., one based on a kinematic GPS survey) is superior to another (e.g., the one underlying the DEM). The preferred model may match our understanding of elevation more closely, or it may reflect better measurement or production methodologies. The reference dataset is assumed to be a

![Figure 2](image)

**Figure 2** A study area near Medora, IN: (a) SRTM 3” DEM. (b) MODIS vegetation cover percentage. (c) Error map of SRTM 3” using NED as reference.
proxy for ground truth, and the discrepancies between its elevations and collocated DEM elevations are defined as DEM error.

A standard summary error metric is root mean square error (RMSE), which is calculated from a set of $n$ reference elevations ($z_t$) and their corresponding DEM elevations ($z_i$):

$$RMSE = \sqrt{\frac{\sum_{j=1}^{n} (z_{ij} - z_{tj})^2}{n}}$$  (1)

RMSE is a measure of central tendency of error. It is a useful but incomplete error metric (Hunter and Goodchild 1997). While the RMSE of an elevation model may be relatively low, local errors may be much larger. Further, the sample of reference points typically comprises a small and possibly nonrepresentative fraction of the DEM and may be a poor estimate of overall error. Other global measures such as average error and 95% error are subject to similar issues.

Further, spatial variation in DEM error is important and not well described by simple global measures such as RMSE or mean error. Consider Figure 2a, depicting SRTM 3” data for a rugged region near Medora, IN, and Figure 2c, SRTM error, using NED as reference data as it is a higher accuracy source. For this example it is assumed that NED is correct and any differences between it and SRTM indicate errors in the latter. Positive errors indicate cells in which SRTM is higher than NED, while negative errors indicate cells in which NED is higher. Average SRTM error is 6.8 meters. The inner-quartile range is from 1.5 to 11.4 meters, and the RMSE is 9.1 meters. These metrics paint a very incomplete picture of the error, however. A river flows through the northern part of the region; most low and negative error in that area is located in its level, largely treeless floodplain. Large, positive errors are associated with the ridges to its south, while valleys between the ridges have much lower errors. Some regions along the ridgetops, especially in the far south of the region, have low error as well. It is visually apparent that error is not distributed in a spatially random fashion, but rather is spatially autocorrelated and associated with other landscape features such as slope magnitude and forest cover (Figure 2b).

Error modeling

In the example illustrated in Figure 2, error is known everywhere, and the SRTM for that region could be fixed by simply subtracting the observed error from each SRTM elevation value. In real applications, reference data for a region of interest are either incomplete or missing entirely, giving rise to uncertainty about the magnitude of error at most or all locations. Although exact errors may not be known for some locations, particular characteristics may be estimated from samples or inferred from properties of the DEM product. In this way an error model can be developed that captures key statistical properties of these characteristics into a stochastic model.

A measurement of some quantity $z$ at a particular location $u$ may be characterized as a random variable $Z(u)$. The probability distribution of $Z(u)$ is a model of the possible values that $z$ can take at location $u$. A random field is a set of random variables defined at locations $u$ over the spatial domain of interest. Any number of cumulative distribution functions (cdfs) can be defined for the random field; they are characterized by the joint cdfs of any subset of its random variables. In practice, it is not possible to estimate the cdf for each observation. Therefore, additional stationarity assumptions about the properties of the random field are required. A very strong one might be that all variables in the field are Gaussian, with a constant mean and
independent, constant variance. With this strong stationarity assumption, DEM errors at measured locations could be pooled and estimates of the mean and variance of the distribution could be made, and the cdfs would be fully specified with just two estimated parameters. On the other hand, most spatial phenomena, including elevation and its error, cannot be well described by this simple model with its strong assumptions. Second-order stationarity is a more flexible approach with weaker assumptions but requiring more effort to model. Relaxing the constant but independent assumption of the first model and instead assuming that joint cdfs are not a function of their absolute locations but solely of their separation vector (distance and direction) \( \mathbf{h} \), enables the pooling of point pairs separated by \( \mathbf{h} \) to develop the model. Spatial covariance is then a modeling requirement. The spatial covariance is:

\[
C(\mathbf{h}) = E\{Z(\mathbf{u})Z(\mathbf{u} + \mathbf{h})\} - E\{Z(\mathbf{u})\}E\{Z(\mathbf{u} + \mathbf{h})\} \tag{2}
\]

and an alternative statistic, widely used in geostatistics, is the variogram:

\[
2\gamma(\mathbf{h}) = \text{Var} \{ Z(\mathbf{u}) - Z(\mathbf{u} + \mathbf{h}) \} = E\{[Z(\mathbf{u}) - Z(\mathbf{u} + \mathbf{h})]^2 \} \tag{3}
\]

Both statistics can be estimated from data. Either measure can be plotted against \( \mathbf{h} \). An uncorrelated random field will have constant semivariance equal to the variance for all \( \mathbf{h} \). For spatially autocorrelated random fields like elevation and elevation error, covariance and variograms have characteristic shapes: the covariances will be high for short lags (highly correlated over short distances) and lower for long lags (decay in correlation at greater distances), while the semivariances will be low for short lags (low variance over short distances) and higher for long lags (increase in pairwise variance at greater distances).

Three example error models of increasing complexity are presented in Figure 3. The first model (Figure 3a), characterizes a spatially random Gaussian field. Errors are drawn from a Gaussian distribution with mean-zero and variance 100. A realization from this model is shown in Figure 3c, and its empirical variogram (the blue circles) closely match the model variogram. Variances at all distances are constant, indicating a lack of spatial structure in either the model or the realization drawn from it. The second model characterizes a spatially autocorrelated process. While errors are distributed normally, nearby values are expected to be similar to one another (low semivariance), as depicted by the model semivariogram, which rises at longer distances (Figure 3b). A realization from this model is mapped in Figure 3d, and shows characteristic spatial patterns with some degree of random noise.

The third example model incorporates additional environmental variables. It attempts to model error in the SRTM 3” product for a study area in southern Indiana portrayed in Figure 2, and is based on an accuracy assessment in Shortridge and Messina (2011). That research conducted an extensive analysis of North American SRTM data, and determined that SRTM slope, aspect, and vegetation canopy cover were significant predictors of SRTM error. The continental model is shown in equation 4.

\[
\text{Error} = -0.90 + 0.007 \times \text{DF328} + 1.39 \\
\times \text{Sl} - 0.015 \times \text{DF328} \\
\times \text{Sl} + 0.078 \times \text{FCC} \tag{4}
\]

where error is predicted SRTM error, DF328 is SRTM aspect measured in degrees from 328 (northwest, and perpendicular to the shuttle’s orbital path over North America), Sl is degrees...

of slope, measured on SRTM itself, and FCC is the forest canopy cover MODIS product, measured in percent. On national samples the model R-squared was 0.583. Residuals from the model had modest spatial autocorrelation (Figure 4a). These residuals were themselves modeled, resulting in a compound approach called regression kriging in which the expected value of error for a location depends on the output of the regression model in equation 3 and deviations from the trend are characterized by an additive spatially autocorrelated random field. Figure 4b depicts a realization from this model for the study area; compare to the actual error for this area, shown in Figure 2.

Uncertainty propagation

Uncertainty modeling is typically motivated by the pragmatic goal of the fitness for use paradigm: what is the impact of data uncertainty
MODELING UNCERTAINTY IN DIGITAL ELEVATION MODELS

Figure 4  (a) Variogram of residuals from the SRTM error regression model. (b) Realization from a regression kriging model for a 3” SRTM near Medora, IN.

on my application (Fisher and Tate 2006)? This is the domain of uncertainty propagation. DEMs are integrated with auxiliary information like a high quality dataset at a subset of locations, or a vegetation dataset, as was used in the model illustrated in Figure 4. For a subset of problems, uncertainty can be propagated analytically from the error model to the application (Oksanen and Sarkakoski 2005), but the trend has been to more general simulation-based approaches (Heuvelink, Burrough, and Stein 2007). As depicted in Figure 5, the Monte Carlo simulation approach deploys the error model to generate a set of DEM realizations in a procedure known as stochastic simulation. Each realization conforms to all information known about the actual spatial phenomenon. The realizations are then independently processed through a geospatial operation just as the original data would have been. The resulting distribution of application results may then be analyzed to determine the impact of data uncertainty for the specific application (Heuvelink 1998).

As an example, consider an application to identify significant surface depressions in a DEM. If a set of deep pits are artificially drilled in the NED DEM for the southern Indiana study site, perhaps they represent human activity on the landscape that was subsequently filled in by the time the SRTM shuttle mission was flown. Can a change detection analysis be conducted to identify the locations of these former pits by comparing SRTM to NED? A straightforward approach would be to subtract the NED raster from the SRTM raster. Locations with a large positive difference would indicate spots with a vanished pit. This difference map is presented in
Figure 6 Identifying former pits. (a) A basic SRTM–NED approach; dark red values indicate positive anomalies. (b) Propagated error approach; cells are shaded to indicate the number of SRTM realizations (of 99 generated) with lower elevations than that of NED.

Figure 6a. Pit candidates are apparent as regular dark red rectangles.

However, this approach does not account for error in the DEM. This error may be in excess of the depth of a pit, resulting in many errors of omission and commission. Indeed, on this map, the bulk of the study region is shaded red, indicating large positive differences. From the previous discussion of SRTM, it might be expected that many of these areas are forested. To account for this and other errors, stochastic simulation via the regression kriging model presented earlier was used to generate 99 error realizations (one is presented in Figure 4). Each was subtracted from the SRTM DEM to produce a realization of what the actual terrain might look like. Finally, for each cell, the NED elevation was ranked with all 99 terrain realization elevations. The output value in each cell in Figure 6b is the number of terrain realizations with an elevation lower than the NED elevation. It is visually apparent that many more pit locations are visually identifiable in this result. Much of the red “error of commission” cells in Figure 6a have been filtered out; the error model was able to reduce the influence of vegetation on the outcome of the spatial operation.

A substantial advantage of this approach is that it is completely general and can be used to identify propagation to any application. If an analyst wanted to calculate viewsheds for this region, the same terrain realizations could be used to identify the probable viewshed (Fisher 1991), accounting for error. There are disadvantages as well. Most obviously the approach is computationally expensive, both for the stochastic simulation of realizations and the additional geospatial processing on every realizations. Second, the choice of model is not straightforward. Even if restricted to a basic univariate geostatistical approach, the number of valid model forms is endless. Variogram model type, number of structures, anisotropic form, and model parameters comprise an infinite domain. More research into the development and implementation of error modeling and propagation systems is clearly needed. Nevertheless, the general Monte Carlo propagation approach demonstrated above, coupled with data-specific DEM uncertainty models, appears to be the most effective way of satisfying the fitness for use requirement.

Modeling uncertainty in categorical fields

Guofeng Cao
Texas Tech University, USA

Categorical spatial data, or equivalently, area-class data, represent distribution of categories or class labels in a geographic space. The class labels can be distinguished only by their attributes (nominal, e.g., land-use and land-cover classes), ranked orders indicating whether an observation has a higher or lower value than another (ordinal, e.g., health and sick), or truncation of continuous variables by specification of cutoff values (interval, e.g., 100–200). Spatially, the boundaries of class labels may be a type of bona fides or fiat depending on the nature and origins. The former exists mainly as the result of physical discontinuities (e.g., land-cover class data), and the latter exists due to human-related actions or decisions (e.g., a choropleth map of population density in California). In categorical spatial data, complex spatial patterns occur that are similar to those observed in continuous data and can be characterized with reference to many of the same general concepts, such as spatial autocorrelation and scale effects. For example, Figure 1 shows a land-use class map of the southern Santa Barbara, CA, area, a typical example of categorical spatial data, where the color green represents forested areas, brown represents woodlands, yellow represents grasslands and gray represents urban areas. In this map, the spatial patterns of different classes can clearly be seen; from the north to the south, the forested areas tend to be adjacent to class of woodlands, woodlands adjacent to grasslands, and grasslands adjacent to urban areas. A good understanding of such spatial patterns is critical for many analyses involving categorical spatial data, such as hypothesis testing of spatial data (e.g., land-use and land-cover change detection), spatial classification (e.g., classification of remote sensing imagery), and spatial uncertainty modeling.

As with other types of geographic information, categorical spatial data are approximate representations of complex real-world phenomena. Since it is impossible to create a perfect representation of the infinite complex real world, all types of spatial data are subject to uncertainty. Spatial uncertainty basically describes the disagreement between the spatial data and the corresponding true phenomena or processes they represent. The uncertainty of spatial data has been described as the Achilles heel of geographic information sciences (Goodchild 1998), and modeling and accounting for such uncertainty in spatial analysis has long been considered as one the most fundamental yet challenging problems in spatial science. Compared with other types of spatial data, the uncertainty issue is particularly prominent for categorical spatial data and rather challenging to model. Consider the derivation process of the example map in Figure 1. New sources of uncertainty can arise in every step of the derivation process and parts of the process are rather subjective. For example, the map in Figure 1 may be generated based on remote sensing images. In addition to the uncertainty in the remote sensing images, different map-makers may use different classification algorithms and label the same area different land-use classes due to the vague definition of land-use classes. From a representation perspective, categorical spatial
Figure 1  A land-use class map of the Santa Barbara, CA, area: a typical example of categorical spatial data.
data can be represented in discrete objects and categorical fields. In the former case, the basic properties of area class can be separated into feature attributes and geometry, and, accordingly, positional uncertainty can be modeled separately from the uncertainty of feature attributes. In the latter case, however, this separation of uncertainty is generally not possible, as geometry and feature attributes are more intimately intertwined. This discussion will primarily focus on the latter case of categorical fields.

Traditionally, one of the most commonly used approaches to assess the uncertainty of categorical spatial data is to compare the data with ground truth or reference data that are believed to have greater accuracy, and report the uncertainty, or agreement with reference data, in terms of a confusion matrix or its derivatives (e.g., kappa coefficient). By summarizing the overall false inclusion and false exclusion errors of the categorical spatial data compared to the reference, a confusion matrix provides a global accuracy measure that is assumed to be invariant across the geographic extent of the data. Consequently, locality (location-dependent) information and complex spatial effects (e.g., spatial correlation and scale effects) in area-class data uncertainty are ignored in confusion matrices.

Geostatistics provide a comprehensive framework for statistical modeling of spatial data while accounting for complex spatial effects and data heterogeneities (e.g., data support and reliability). The geostatistical approach has been widely used for characterizing spatial uncertainty and evaluating the impact of uncertain data in spatial analysis and spatially explicit modeling (Kyriakidis and Dungan 2001). The basic idea is to view maps as outcomes of spatial stochastic processes (or random fields); the characteristics of spatial processes are first inferred from the (sampled) maps and uncertainty distribution across the map may then be characterized through spatial variability measures of the spatial processes or an ensemble of stochastically simulated alternative maps. Figure 2 shows a flowchart of this typical process. The most fundamental component of this process is to stochastically model spatial data, while accounting for locality and spatial effects in a spatial context. Specifically, for uncertainty modeling in categorical fields, the essential task is equivalent to estimating the joint probability mass function of a set of georeferenced categorical variables or, more intuitively, the

Figure 2 Flowchart of a typical process for modeling uncertainty of categorical spatial data and assessing the impact of such uncertainty in physics-based models.
multipoint conditional (or posterior) probability of class occurrence at a target location (where the actual class is unknown) conditioned jointly on all known source data (class labels available at sample or source locations). Based on the specified joint probability or conditional probability, stochastic simulation (Figure 2), a broadly accepted tool for investigating a stochastic process, can be conducted to characterize the uncertainty distribution regarding the spatial occurrence of class labels, for example, a specific class tends to appear at certain locations on a map. The procedure of stochastic simulation generally involves generating an ensemble of alternative class labels that are consistent with the modeled conditional probability distribution from the (sampled) maps. By conducting spatial analysis or spatially explicitly models (e.g., climatic models or ecological models) on an ensemble of alternative realizations, the uncertainty propagation in the process can be monitored and evaluated.

To illustrate the statistical modeling of categorical spatial data, consider a spatial process $C(x)(x \in \mathbb{R}^d)$ on a categorical field, and $C(x_i)$ at an arbitrary location $x_i$ can take one out of $K$ mutually exclusive and collectively exhaustive class labels. Figure 3 displays an illustrative example for a spatially indexed variable with two categories, represented by blue and red. A target location $x^*$ (question-marked location in Figure 3) with unknown state $c(x^*)$ is surrounded by sample locations, $x_1, \ldots, x_N$ with states $c(x_1), \ldots, c(x_N)$, respectively. As discussed previously, for modeling the spatial process $C(x)$, it is necessary to estimate the conditional class occurrence probability for $x^*$ given sampled labels, that is, $P\{C(x^*)|c(x_1), \ldots, c(x_N)\}$. With the class occurrence probability, maximum a posteriori (MAP) could be applied to estimate the class label for the target location. It is a typical setting for geostatistical modeling, but the discrete nature of categorical spatial data (e.g., categorical attributes, sharp boundaries, and complex geometrical characteristics) limits the application of successful geostatistical methods that have been conventionally used for continuous variables including the celebrated kriging family of methods (Chilès and Delfiner 1999).

In geographic information system (GIS) literature, Goodchild, Sun, and Yang (1992) proposed one of the earliest algorithms for error modeling of categorical data via stochastic simulation. Further refinements and other developments regarding uncertainty mapping of categorical spatial data can be found in Zhang and Goodchild (2002). In the past decade, promising progress has been made and numerous methods have been proposed from different perspectives, particularly in the field of geostatistics and Bayesian statistics. According to the underpinning principles, these methods can be generally grouped into three categories: latent variables based

---

**Figure 3** An illustrative example of statistical modeling of categorical spatial data: a target location $x^*$ (question-marked location) with unknown state $c(x^*)$ is surrounded by a collection of sampled class labels.
approaches, multipoint geostatistics approaches, and probabilistic integration approaches. The multipoint geostatistics approaches were primarily developed and are mainly applied in the field of petroleum reservoir engineering, although recent efforts have been reported to apply multipoint geostatistics in addressing problems in geographical sciences, such as improving classification of remote sensing images. The remainder of this entry briefly introduces each group of methods with an emphasis on recent developments in latent variables based approaches and probabilistic integration approaches; it then discusses the future directions.

Latent variables based approaches

Categorical spatial data can be regarded as the result of discontinuities in underlying (latent/unobserved) continuous physical processes. This concept actually creates a convenient platform for statistical modeling of categorical spatial data by an explicit introduction of latent spatially correlated variables (latent random fields) to account for spatial effects. Figure 4 gives an illustration of the latent variables based approach. Latent variables based spatial models have been an active research area in the past decades; many methods have been proposed both analytically and computationally within this paradigm. The key to latent variables based approaches is to conduct inference on the introduced latent variables from the sampled categorical values, since the latent variables cannot be observed directly.

In geostatistics, truncated Gaussian simulation (TGS) has long been used for categorical spatial variables modeling. Assuming there is a single Gaussian-distributed latent variable and it can be truncated into different class labels by a specification of threshold values, categorical spatial variables can be simulated based on the specification of a Gaussian random field (GRF). TGS is attractive as it can take advantage of numerous available GRF simulation methods and is free of the order relation problem (see section “Indicator variants of kriging” for details). Characteristics of the latent GRFs (e.g., spatial covariance functions) could be inferred via stochastic simulation that is consistent with the categorical observations. TGS only generates simulations with ordered categories due to the simplicity of connections between categorical data and the single latent variable. Truncated plurigaussian simulation (TPS), an extension of TGS, was later proposed to address this issue by introducing more than one latent GRF.

The generalized linear mixed model (GLMM) is another commonly used venue for modeling spatially correlated non-Gaussian phenomena. As in TGS and TPS, latent GRFs are introduced to account for the spatial effects, and the connections between non-Gaussian variables and latent GRFs are usually modeled by a so-called link function (e.g., a logit function is often used for spatial binary data and a soft-max function for multinomial data in contrast to a specification of threshold values in TGS and TPS; Figure 5 shows an illustration of GLMMs).
Such spatial models, coined generalized geostatistical models or model-based geostatistics (Diggle, Tawn, and Moyeed 1998), have been successfully applied to model spatial binary and count data (Diggle, Tawn, and Moyeed 1998). In model-based geostatistics, Markov Chain Monte Carlo (MCMC) sampling is often employed to infer the distribution of the latent variables. This method, however, has been criticized for high computational demand and intrinsic convergence issues. To address these issues, approximation methods of Bayesian inference have been proposed. It is worthy noting here that ancillary information (e.g., observations of other related spatial variables) can be easily taken into account in the GLMM-based models. It has been shown that there is close connection between the latent variable based (Bayesian) approach and regularization theory. By exploiting this connection, a spatial multinomial logistic mixed model has been specifically proposed for categorical spatial data modeling (Cao 2011), and, accordingly, the proposed model could be represented as a multinomial logistic function of spatial covariances between target and source locations. This method was later extended to incorporate heterogeneous auxiliary information for spatial prediction of categorical variables (Cao, Yoo, and Wang 2014).

Multipoint geostatistics

Multipoint geostatistics (MPG) is a recently proposed approach to model the multipoint conditional probability by directly scanning carefully designed training images (Strebelle 2002). The training images are deemed representative of the expected spatial patterns in the study area and can be built by experts based on their prior knowledge regarding the phenomenon under study. The central idea of the MPG paradigm is to capture multipoint statistics or spatial patterns by scanning training images using a predefined template, and to generate pattern realizations using such multipoint statistics in stochastic simulation. Most recently, a pattern-based geostatistical approach was developed based on MPG by extending multipoint statistics to a pattern histogram. MPG-based methods avoid the assumption of
an underlying random field and alleviate the computational cost associated with large scanning templates (necessary to capture large-scale features) through a pattern search tree. On the one hand, the lack of specification of an underlying random field improves flexibility and efficiency; on the other hand, it impedes further inference in categorical fields, since the underlying model (training image) is hard to parameterize efficiently and may be difficult to acquire.

Spatial cumulants have been recently proposed as alternative multipoint statistics to measure multipoint (higher-order) spatial continuity in nonlinear and non-Gaussian random fields (Dimitrakopoulos, Mustapha, and Gloaguen 2010). Through higher-order cumulants of the underlying spatial distribution, multipoint statistics can be computed in a formal probabilistic way instead of via empirical feature matching in MPG. The computation flowchart of spatial cumulants is similar to MPG but cumulants can also be applied in continuous data. Studies have shown the great promise of spatial cumulants especially in non-Gaussian fields, but formal models of spatial cumulants and analytical methods based on cumulants have yet to be developed.

**Probabilistic integration approach**

In MPG, direct modeling of the multipoint conditional probability \( P\{ C(x^*)|c(x_1), \ldots, c(x_N) \} \) may become difficult as the number of samples increases. The basic idea of the probabilistic integration approach is to decompose the complex conditional multipoint class occurrence probability into a combination of two-point (or three-point) elementary spatial continuity measures. Specifically, two-point spatial continuity between \( x^* \) and each of its neighbors \( x_n \) can be evaluated through an spatial continuity measure \( \delta(c(x^*), c(x_n)) \). The objective of probabilistic integration methods is to best approximate the multipoint conditional probability \( P\{ C(x^*)|c(x_1), \ldots, c(x_N) \} \) with a combination of \( \delta(c(x^*), c(x_n)) \) while accounting for possible spatial dependence information. It could be represented as shown in equation 1.

\[
P\{ C(x^*) = k|c(x_1), \ldots, c(x_N) \} = f(\delta\{ C(x^*) = k, c(x_1) \}, \ldots, \delta\{ C(x^*) = k, c(x_N) \}) \tag{1}
\]

Figure 6 gives a graphical example based on Figure 3, where the class label for target location \( x^* \) depends only on its six nearest neighboring observed states. Each arrow indicates a pairwise spatial interaction, quantified by a spatial continuity measure \( \delta\{ C(x^*) = k|c(x_n) \}, n = 1, \ldots, 6 \).

A key concept in this probabilistic integration approach is the choice of the spatial...
CONTINUITY MEASURE (CHILÈS AND DELFINER 1999), \( \delta(x, x') \), WHICH USUALLY QUANTIFIES SIMILARITIES OF CATEGORIES AT TWO DIFFERENT LOCATIONS. INDICATOR (CROSS-)COVARIOMS ARE THE MOST COMMONLY USED SPATIAL CONTINUITY MEASURES IN INDICATOR VARIANTS OF KRIGING. MOST RECENTLY, SPATIAL TRANSITION PROBABILITIES (CARLE AND FOGG 1996; LI 2006) AS WELL AS BIVARIATE JOINT PROBABILITIES (ALLARD, D’OR, AND FROIDEVAUX 2011) HAVE BEEN PROPOSED AS ALTERNATIVE SPATIAL CONTINUITY MEASURES TO INDICATOR (CROSS-)COVARIOMS.

ONE OF THE SIMPLEST FUNCTIONS \( f \) IS THE WEIGHTED LINEAR COMBINATION OF THE SPATIAL CONTINUITY MEASURES (EQUATION 2):

\[
P\{ C(x^*) = k | c(x_1), \ldots, c(x_N) \} = \sum_{n=1}^{N} \lambda_n \delta\{ C(x^*) = k, c(x_n) \}
\]  

WHERE \( \lambda_n \) REPRESENT WEIGHS FOR \( \delta\{ C(x^*) = k, c(x_n) \} \) TO ACCOUNT FOR SPATIAL DEPENDENCY BETWEEN \( x_n \) AND ITS NEIGHBORS. INDICATOR VARIANTS OF KRIGING METHODS INCLUDING INDICATOR KRIGING (IK) AND INDICATOR COKRIGING (ICK) (CHILÈS AND DELFINER 1999), AND TRANSITION PROBABILITY BASED INDICATOR GEOSTATISTICS (CARLE AND FOGG 1996) CAN BE SEEN AS SPECIAL CASES OF THIS ADDITIVE FUSION MODEL.

ANOTHER SIMPLE FORM OF \( f \) IS THE MULTIPlicative FUSION, WHICH EXPRESSES THE MULTIPPOINT CONDITIONAL PROBABILITY IN A MULTIPlicative FORM OF SPATIAL CONTINUITY MEASURES IN CATEGORICAL FIELDS (EQUATION 3):

\[
P\{ C(x^*) = k | c(x_1), \ldots, c(x_N) \} = \prod_{n=1}^{N} \delta\{ C(x^*) = k, c(x_n) \}^{\varepsilon_n}
\]

WHERE EXPONENT \( \varepsilon_n \) REPRESENTS A WEIGHT FOR \( \delta\{ C(x^*) = k, c(x_n) \} \) TO ACCOUNT FOR SPATIAL DEPENDENCY BETWEEN \( x_n \) AND ITS NEIGHBORS.

THIS MULTIPlicative FORM IS USUALLY A RESULT OF BAYES’S FACTORIZATION RULE. THE RECENTLY PROPOSED MARKOV CHAIN RANDOM FIELD (MCRF) (LI 2007) AND BAYESIAN MAXIMUM ENTROPY (BME) BASED METHODS (ALLARD, D’OR, AND FROIDEVAUX 2011) CAN BE TAKEN AS SPECIAL CASES ALONG THIS MULTIPlicative FUSION MODEL.

### Indicator variants of kriging

AS EFFORTS ARE MADE TO ADAPT THE KRIGING FAMILY OF GEOSTATISTICAL METHODS FOR CATEGORICAL VARIABLES, IK IS PERHAPS THE MOST FREQUENTLY USED METHOD FOR ESTIMATING THE POSTERIOR (CONDITIONAL) PROBABILITY OF CLASS OCCURRENCE AT ANY TARGET LOCATION. AS FOR OTHER KRIGING VARIANTS, IK INVOLVES FITTING INDICATOR VARIOGRAMS AND THEN ESTIMATING THE PROBABILITY OF OCCURRENCE OF EACH CLASS INDEPENDENTLY VIA A KRIGING SYSTEM. IK CAN ALSO HAVE MANY VARIANTS DEPENDING ON ASSUMPTIONS OF THE LOCAL MEAN VALUES OR CLASS PROPORTIONS OF CLASS OCCURRENCES.

BASED ON IK, SEVERAL VARIANTS HAVE BEEN DEVELOPED TO IMPROVE THE PREDICTION ACCURACY OF PRIMARY CATEGORICAL VARIABLES. ICK, FOR EXAMPLE, IS A NATURAL EXTENSION OF IK FOR MULTIVARIATE CASES (CHILÈS AND DELFINER 1999), IN WHICH AUXILIARY VARIABLES ARE INCORPORATED INTO THE PREDICTIVE PROCESS VIA (CROSS-)COVARIANCE FUNCTIONS OF PRIMARY CATEGORICAL VARIABLES AND AUXILIARY VARIABLES. PRACTICAL APPLICATIONS OF ICK, HOWEVER, ARE CUMBERSOME OWING TO A NUMBER OF (CROSS-)COVARIANCE FUNCTIONS (OFTEN THROUGH THE LINEAR MODEL OF COREGIONALIZATION) HAVING TO BE JOINTLY FITTED. WHEN AUXILIARY VARIABLES ARE LINEARLY RELATED TO THE CLASS OCCURRENCE OF PRIMARY CATEGORICAL VARIABLES, THEY CAN BE INCORPORATED INTO AN IK SYSTEM AS DETERMINISTIC LINEAR FUNCTIONS (NONSTATIONARY MEAN). THIS IS REFERRED TO AS INDICATOR KRIGING WITH EXTERNAL DRIFT (IKED) (CHILÈS AND DELFINER 1999), WHOSE IMPLEMENTATION IN PRACTICE IS CHALLENGING, AS IT IS
often problematic to simultaneously estimate the parameters of external drift and the covariance function of the stochastic component. As a hybrid method of kriging and multiple regression models, regression-kriging (RK) has been developed to combine a regression of the dependent variables on auxiliary variables with kriging of the regression residuals. An indicator variation of RK, regression-kriging of indicators (RKI), has been proposed for categorical variable and this method has evolved into regression-kriging of memberships (RKfM) by substituting crisp indicator values with continuous membership values. Most of these IK-based methods, however, share the inherent problems that the original IK suffers from: the probabilities of occurrence are not guaranteed to be between 0 and 1 (e.g., IK, ICK, RKI), the sum of the predicted probabilities may not be equal to 1 (e.g., IK, ICK, RKI, and RKfM), and the outcome values of conditional cumulative distribution function may not be monotonic (order relation problem). A posterior correction of the resulting conditional probabilities is often necessary either through a Gaussian transformation or via a logistic regression model.

### Transition probability based geostatistics

The concept of transition probability is not new but, until recently, it has been regarded as a spatial continuity measure in categorical fields. Similar to the conventional definition of transition probability, spatial transitional probability $\pi_{k'k}(h)$ is defined as the transition probability from class label $k$ to $k'$ over a spatial lag $h$:

$$\pi_{k'k}(h) = P\{C(x + h) = c' \mid C(x) = c\}.$$

The transiogram is typically defined as a parametric diagram of transition probabilities as a function of a spatial lag $h$ (Li 2006). Similar to variogram or covariance models, sample transiograms can be collected by directly scanning sample data, and transiogram parameters can then be fitted from sample transiogram values. There is a relationship between the parameters of transiogram models and spatial distribution of class labels (class proportion, mean length, compactness, and class juxtaposition) (Carle and Fogg 1996; Li 2006; Cao 2011). This connection provides an interpretation of the behavior of transiogram models, and more importantly, offers a guideline for incorporating expert knowledge on the categories distribution in the construction of transiogram models.

Compared to indicator covariances and variogram models, transiograms are more interpretable in categorical fields and easier to integrate with ancillary information (Carle and Fogg 1996). Based on this concept, Carle and Fogg (1996) reformulated IK and ICK as systems of spatial transition probabilities according to their analytical connections with indicator covariograms. As with variograms in kriging systems, not every function of distances can serve as a valid transiogram for the reformulated system. It has been found that in most cases the exponential form and several of its variants are eligible for transiogram modeling (Cao 2011).

Based on the concept of spatial transition probabilities, the idea of a Markov chain has been applied for categorical data modeling in spatial settings. Most recently, MCRF has been proposed (Li 2007) by assuming that a single spatial Markov chain moves or jumps in a space and the state at any uninformed location is specified by a multipoint conditional probability conditioned on its its nearest neighbors and its last stay location. Under the conditional independence assumption, the multipoint conditional probability could be factorized into a multiplicative combination of (two-point) spatial transition probabilities.

From another statistical perspective, a BME approach has been used to address the statistical
modeling of categorical spatial data (Bogaert 2002). BME is based on a joint multidimensional multinomial assumption in the desired categorical random field, and estimates parameters (actually joint probability tables) by a nonsaturated log-linear model of main effects and interaction effects under certain marginal constraints (most often formulated in terms of bivariate joint probabilities). Most recently, a simplified variant of the BME approach (Allard, D’Or, and Froidevaux 2011), namely Markovian-type categorical prediction (MCP), was proposed to alleviate the heavy computational cost of categorical BME. For each target location, instead of modeling all possible interactions (in terms of joint probabilities), this simplified approach only considers pairwise spatial interactions between the target location and its neighboring known source data (in a perspective of multipoint conditional probabilities).

Despite the background differences between MCRF and MCP, both of these approaches were designed to decompose the difficult-to-get multipoint conditional probability into a combination of two-point probabilities, based on the assumption of conditional independence. The assumption of conditional independence has been widely used in the field of Bayesian statistics and, despite its simplicity, practice has shown that this assumption performs quite well. However, in the presence of actual data dependence when an independence assumption is difficult to corroborate, it tends to lead to nonrobust and inconsistent results (Journel 2002). A robust alternative is the assumption of permanence of ratios, which is based on the engineering paradigm that ratios (in this case, odds ratios of spatial transitional probabilities) are typically more stable than their components (Journel 2002). It has been applied to relax the assumption of conditional independence in categorical spatial data modeling (Cao 2011).

Future directions

In past decades, much has been learned about how to model spatial uncertainty in categorical fields and how to evaluate uncertainty propagation in spatial analysis and modeling. The majority of research tends to view categorical fields as static and focuses on the investigation of spatial effects in categorical fields. Geographic phenomena are essentially dynamic. With the advancement of spatial data acquisition and dissemination technology, temporal information of categorical spatial variables as well as other ancillary information (e.g., measurements of related spatial variables) is typically available. Incorporation of such information is expected to improve our understanding of the change dynamics in categorical fields. While much progress has been made in general spatiotemporal statistics, efficient and generally accepted theory for change detection and hypothesis testing in categorical fields that can effectively account for complex spatial effects (or geometry) are still largely lacking.

From a computational perspective, unlike simple models such as the Gaussian, models for categorical spatial data usually involve a large number of parameters, and inference of such models could become very computationally intimidating. In the past decade, computational science and technology has been dramatically advanced and provides a transformative paradigm for scientific research. Great progress has been made in the past few years to solve computationally intensive spatiotemporal problems by exploiting advanced high-performance computing capabilities, for example, the emerging CyberGIS framework (Wang 2010). It is still rare in the literature of uncertainty modeling to take advantage of this advancement.

Despite the progress that has been made for uncertainty modeling in categorical fields, a
large portion of the proposed methods is comparatively inaccessible, particular for domain communities outside of statistics and geographic information science (GIScience). This is probably due to the complexity of the involved mathematics and computing technologies, but it is, nevertheless, important to make the tools accessible to domain scientists. The rise of open source and the cyberinfrastructure paradigm in the scientific research community provide a promising opportunity to further increase the awareness of the uncertainty problem in categorical fields, and improve the adoption of existing methods and tools to address this problem.

Ecologists and biogeographers grapple with understanding the dynamics of systems that operate across an extended range of scales in time and space, from the almost instantaneous (e.g., physiological processes such as photosynthesis) to the millennial (e.g., range shifts in response to climate change). Despite the ever-expanding range of environmental proxies and data available to describe these dynamics, some scale-related issues are simply intractable for empirical approaches. In such settings modeling, and in particular simulation modeling, has become an important and widely used tool by biogeographers.

Models are simply representations of some phenomena (system or entity) of interest. This means that they are, necessarily, abstractions and are also, therefore, false. There have been many attempts to classify models on the basis of their implementation. A typical such classification would recognize mathematical, empirical, and simulation models as distinct approaches. Mathematical models represent systems using the formalisms of mathematics – the classical reaction–diffusion models of spread and invasion are archetypal examples. Such models are often abstract and their qualitative insights of more interest than their exact quantitative predictions. Mathematical models are typically top-down and seek to explain the behavior of broad classes of systems (e.g., free-living populations) rather than being site- or taxa-specific. Conversely, empirical models start with observations (data) and seek recurrent patterns in them – they are probably the most widely used of all models by biogeographers. Species distribution models, in which correlative relationships between environmental conditions and taxonomic distributions are established and then extrapolated across space and time, typify empirical models. The oft-repeated critique of such approaches is that they lack structure and causality, so have limited explanatory power beyond the specific conditions (scale, location, taxa, etc.) they were developed for. While this is a valid concern, modern model-building approaches, such as multiple model inference, are also explicitly concerned with hypothesis testing. The third broad class of models is simulation models. This class encompasses a broad range of approaches, all of which are concerned with the in silico representation of some system of interest; simulations typically contain elements of both mathematical and empirical models. A type of simulation that has received much attention among ecologists is individual-based models (IBMs) (Grimm and Railsback 2005), in which every entity of interest (e.g., trees in a forest, individual baboons in a troop) is represented and their behaviors and ultimate fate (e.g., growth, reproduction, mortality) tracked. In such bottom-up frameworks the broad-scale properties of the system arise from individual-level interactions – so, for example, shifts in composition across succession emerge as a result of interactions, such as facilitation and competition, between individual trees and their environment.

Another, perhaps more useful, way to think about classifying models is on the basis of their purpose. A simple, perhaps simplistic, dichotomy is
between modeling exercises focused on predicting the behaviors of the systems they represent and those focused on learning about them. Of course, these two goals are far from mutually exclusive. The purpose of a given modeling activity will determine where it lies in terms of fundamental tradeoffs, such as those between model simplicity and complexity, the level of mechanistic detail included, and the scale (grain versus extent) at which a model will operate. Simulation models span the full range from simple (but hopefully not simplistic) high-level generalized abstractions through to highly detailed mechanistically-grounded representations of specific locations, processes, and taxa. It is perhaps tempting to see the latter as more realistic and, hence, preferable – after all, detailed models contain more of the “real” world – but this realism comes at a cost in terms of interpretability and uncertainty in both model structure and parameterization. Modern approaches to model development, such as pattern-oriented modeling, aim to identify model structures that are sufficiently realistic to be useful but are not overburdened with unsupported detail. Unsupported detail acts both to increase model uncertainty (both in terms of parameterization and also in terms of representing poorly understood processes) and to inhibit the development of understanding of the system and processes of interest. In short, distinguishing between the processes that need to be included in a given model and those that can be omitted reduces to a tradeoff between realism and generality (as discussed in the classic paper by Levins (1966)). An important question given growing increases in computational power and data is (Held 2005 considers this tension): “Does it matter if we do not understand our simulation models?”

Such fundamental questions become even more difficult when we seek to explicitly represent humans and their behaviors in our models. As the role of humans in most ecological systems has grown in significance, there has been increasing recognition that models need to directly represent human activity and decision-making. It is not adequate to simply treat humans as boundary conditions or represent them as just another exogenous forcing factor, nor can the reciprocal nature of feedbacks between humans and the environment be ignored. Adequately representing human agency is particularly important, for example, when processes such as land-cover dynamics in peri-urban environments are being considered or, more generally, when socio-economic processes are stronger drivers of ecological change than biophysical ones. A framework that has proved particularly useful in such contexts is agent-based models (ABMs) (Heppenstall et al. 2012), which are closely related to the IBMs described earlier. Agents are goal-seeking entities whose behaviors are plastic and who interact in a reciprocal way with the environments they inhabit. The agents’ behavior is not necessarily rational, but may be designed to represent both the vagaries of the decisions that people make and the uncertainties involved in such decision-making.

There is growing interest in using coupled ecological and agent-based models to represent the dynamics of socioecological systems. Once any model is implemented it is important to evaluate its “usefulness.” While there is no doubt that the “quality” of a model’s outcomes need to be closely scrutinized, it is not necessarily obvious what quality means, with mimetic accuracy, heuristic usefulness, and/or the ability to provoke dialogue all among the qualities different evaluation frameworks emphasize. It is also important to distinguish between evaluations that focus on the implications of uncertainty in a model’s parameters (e.g., sensitivity analysis) while (usually) treating model structure as fixed versus those that seek to understand how a model’s structure (decisions about representation) affects
its outcomes (e.g., structural analysis). Arguably, structural uncertainty is at least as, if not more, important than parameter uncertainty but it rarely receives as much attention. Standard tools of model analysis, such as sensitivity evaluation and statistical measures of model predictive capacity, are useful but many other approaches have been developed for model evaluation and tools originally designed for statistical modeling are now being used for simulation models (Hartig et al. 2011). Ultimately, as with model design, what constitutes appropriate model evaluation depends on the context in which a model is being used—that is, its purpose.

In any context, understanding the role and usefulness of models and modeling hinges on carefully isolating the purpose of the exercise. There is no doubt that ever-growing computational power, coupled with the advent of “big data,” crowd-sourced information, and citizen science will enable models to explore issues that were previously technically limiting. On the other hand, to be truly useful models, of any sort, need to be more than highly detailed, but potentially inscrutable, representations of the system of interest. Finding the middle ground between the overly complex and the overly simple remains the fundamental challenge for all modelers.

Further reading

Geomorphological models are representations of the external reality of Earth surface processes and landforms. A primary distinction can be made between (i) conceptual models, (ii) scale models or analogs, and (iii) quantitative models (e.g., Huggett 1985).

Conceptual models are verbal or visual representations of a system or process, ranging from a sequence of relationship statements or a “story,” to flow diagrams and schematics, often in a graphical or cartoon form. Many historically (in)famous geomorphic models, and indeed paradigms, are of this kind, such as Davis’s (1899) “Geographical Cycle,” often represented as a sequence of landscape cartoons, or the general systems framework championed by Chorley (1962) and Strahler (1980), usually drawn as flow schemes resembling electronic circuitry diagrams. This type of modeling is referred to as an activity of conception in Haggett and Chorley’s (1967) taxonomy, representing a geomorphic system as an integrated whole synthetically (e.g., as a flow scheme), or as a black box model where the precise details of processes or constituent parts are not further defined.

Scale models and analogs aim to represent a geomorphic system on a (sometimes reduced) physical or temporal scale so as to replicate or mimic the processes and forms in an observable and reproducible form. This includes hardware models or physical analogs such as water flumes, wind tunnels, and wave tanks, where processes or properties are scaled in terms of their geometry (sizes), kinematics (velocities), or dynamics (forces), relative to the real-world system. An example of this is the investigation of subaqueous bedform development on moveable sand trays in small water tanks as an analog for understanding desert dune formation in the atmospheric boundary layer. This type of modeling relies heavily on the equivalence of dimensionless similarity parameters, such as the Reynolds number or the Froude number (e.g., White 1996). Haggett and Chorley (1967) refer to this type of scientific activity as translation, and it includes natural analogs as models: observable real-world systems that exhibit a behavior or characteristic that is similar in kind to (and thereby an explanation of) another geomorphic system, that is, using a known geomorphic phenomenon from a historical time sequence or from within a spatial hierarchy (e.g., a landform unit) as a model to understand another landscape or subset.

Quantitative models, lastly, quantify features, objects, and processes of a geomorphic system numerically as variables, parameters, and coefficients, representing the relationships between them as a collection of mathematical expressions. Such models range from single equations, such as the Universal Soil Loss Equation (USLE), to coded algorithms of varying levels of complexity running on computers. Quantitative models are usually developed out of initial conceptual models and often (partly) parameterized or tested against scale models and analogs. Malamud and Baas (2013) recognize three key distinctions in contemporary quantitative models of geomorphology: (i) traditional physically based computer models, (ii) cellular automata models, and (iii) statistical models of observations or simulated data.
MODELS IN GEOMORPHOLOGY

The first category of quantitative model, traditional physically based computer models, is grounded on an approach of what Haggett and Chorley (1967) refer to as dissection, to simulate geomorphic systems within a reductionist-deterministic context of quantifying small-scale physical processes, based on exact empirical or theoretical relationships (equations). The system is simulated within an explicit and discretized spatiotemporal domain (1-D, 2-D, or 3-D + time) and usually underpinned by the Exner equation, or the conservation of mass relating spatial gradients in sediment transport flux to topographic height changes, together with a diffusion- or advection-type transport forcing process. These are the most typical modern computer simulation models of geomorphic change, spanning a wide range of environments, including hillslope erosion by overland flow (e.g., WEPP, EUROSEM, MEDALUS), landscape evolution at a catchment or even continental scale (e.g., LAPSUS, SIBERIA), fluvial systems (meandering, braiding, river terrace deposits, etc.), and eolian dune development by wind. The detailed representation of small-scale physical processes usually involves a large number of parameters, complete definition of boundary conditions, and often a separate fluid-flow simulation component (e.g., for channel flow or surface wind), either as a complete Computational Fluid Dynamics solution or as a simplified flow theory, that require considerable computational resourcing.

The second category, cellular automata (CA), simulates geomorphic processes as a simplified set of rules of interactions between cells within a discretized spatiotemporal domain. The repeated application of interaction rules and corresponding changes in cell states over time between a multitude of elements produces larger-scale patterns, landforms, and collective behaviors that emerge as self-organizing phenomena. The number of parameters is usually small and the models can be run on ordinary computer systems. This type of modeling is also sometimes referred to as “reduced-complexity” modeling, and may also include Agent-Based Modeling (ABM) approaches (as yet rarely applied in geomorphology), where mobile agents such as animals move over a cellular domain interacting with each other and the domain environment. A key objective (and strength) of CA modeling is the identification and distillation of the most important, minimally necessary and sufficient, set of processes or rules (in their most fundamental form) required to reproduce certain geomorphic phenomena. They are often used to test or develop theories and hypotheses and produce generalized outcomes in terms of emergent patterns and behaviors, rather than customized site-specific projections. Typical examples of CA in geomorphology include sand dune models (Werner model, DECAL), models of river meandering (e.g., CAESAR), river braiding, coastal sand spit patterns, and landslide and forest fire models. Fonstad (2006) provides a comprehensive overview of CA modeling in geomorphology, as well as key issues and challenges.

The third category, statistical models, provides quantification and representation of relationships and structure found in data obtained from real-world geomorphic systems (or also sometimes in simulated data), without necessarily explaining the underlying processes or mechanisms. These models range from descriptive analysis, such as frequency–size distributions of events and processes such as landslides, to statistical tests that identify apparent relationships between variables (e.g., hypothesis testing and correlations), and the extraction of statistical trends in space and time (e.g., time-series models, fitted landscape surfaces). This category may also include sophisticated data models that use...
MODELS IN GEOMORPHOLOGY

statistical measures to optimize the representation of a geomorphic process or outcome, such as artificial neural networks (ANNs) and genetic algorithms (GA), where the internal realization of the working algorithm is essentially inscrutable (i.e., a black box situation). A GA has been used, for example, to optimize the parameter set of a traditional physically based simulation model of streamflow and sediment response in a river catchment (SWAT) calibrated to a specific real-world river basin.

The above gradation in quantitative geomorphic modeling approaches, in terms of the degree of specificity in representation as well as the differences in objectives, echoes a similar categorization by Dietrich et al. (2003). Within the realm of quantitative landscape modeling they propose four types of approaches or objectives: (i) detailed realism, which represents the – mostly unattainable – objective of exhaustively representing a geomorphic system with its unique mixture of site-specific details and general trends and processes operating at multiple scales of time and space – this type of modeling requires an unrealistic degree and detail of knowledge and data, but it is possible to reach detailed realism for some carefully circumscribed features or subsets of a landscape given sufficient information; (ii) apparent realism, which is the somewhat illusive quality of most large-scale spatially explicit landscape simulation models that generate detailed landforms or outcomes based on a distillation of key geomorphic processes on a coarse spatial resolution, but that should rightly only be considered as metaphors or qualitative representations of the real world; (iii) statistical realism, discussed by Dietrich et al. specifically within the context of self-organizing patterns and emergent behaviors, relating to the application of fundamental physical principles, such as minimized entropy production, and the general patterns and trends they produce that may be recognized across various different landscapes; and (iv) essential realism, which claims that geomorphic sediment transport laws can be identified and parameterized from empirical evidence and that model outcomes can be tested against field measurements – this type of modeling aims to understand differences between landscapes, as opposed to the search for commonalities across landscapes of statistical realism, and produces quantifiably testable outcomes, as opposed to the qualitative or metaphor representations of apparent realism.

A more extensive range of modeling approaches in geomorphology is distinguished by Odoni and Lane (2011), who place model types in a hierarchy of increasing complexity, but also recognize a differentiation between data-driven approaches and theory-driven approaches, as well as the interchange of data as inputs and outputs between these. On the data-driven branch, they recognize a sequence of modeling types starting at a basic level with data models, as capture and representation of empirical data (e.g., maps), moving on to hardware models, similar to the scale or analog models described previously, qualitative models, that is, conceptual representations, analytical models, mathematical analyses in continuous space and time, and finally, at the complex end, stochastic models, which provide probabilistic solutions. On the theory-driven branch, Odoni and Lane recognize a sequence starting at a basic level with theoretical models, based on logic and deduction, moving on to simulation models, as basic abstractions of some kind, quantitative models, relationships and properties as equations, numerical models, discretized time and space with computational techniques, and, at the complex end, deterministic models, which provide fully complete and repeatable outcomes. This theory-driven branch represents a progression of increasing degrees of specificity in inputs, parameters, boundary conditions, and outputs.
MODELS IN GEOMORPHOLOGY

There are many other model taxonomies (Odoni and Lane (2011) provide a comprehensive list of sources), and many different versions of classification have developed over the years, both in the past (e.g., those by Chorley (1967) and Huggett (1985), mentioned above) and more recently (Hooke 2003; Mulligan and Wainwright 2013). Another way of exploring attributes and underpinnings of different geomorphic models is to consider their characteristics along dimensions of dichotomy (e.g., Haggett and Chorley 1967; Slingerland and Kump 2011), such as:

- **static versus dynamic**: models that represent “equilibrium” features or structures as opposed to models that focus on processes and changes over time;
- **descriptive versus normative**: models that are concerned with a stylistic or simplified description of reality as opposed to models that attempt to predict outcomes under certain conditions;
- **stochastic versus deterministic**: models that represent aspects of a geomorphic system in terms of probabilities and statistics as opposed to models that quantify specific precise values;
- **process-based versus form-based**: models that simulate physical processes that are thought to operate in reality as opposed to models that represent shapes and forms found in the geomorphic landscape;
- **forward versus inverse**: models that attempt to predict a final or future state of a geomorphic system as opposed to models that aim to determine past initial or boundary conditions based on a current state;
- **black box versus white box**: models that use “invisible” or untraceable internal procedures (often involving advanced statistical methods) as opposed to models where all processes and relationships are transparent and precisely specified;
- **inductive versus deductive**: models that represent a system by generalizing and categorizing from empirical findings as opposed to models that assume a theory or framework to simulate consequent forms and processes.

Besides the characteristics and methods underlying different geomorphic models, another important question concerns what makes for a good model. Kirkby (1996) argues very precise criteria for a good model, stipulating four requisite attributes: (i) a physical basis, that is, that the selection of form/process equations, even if only in a black-box-style regression approach, is informed by some level of insight of the physical reality concerned, (ii) simplicity, that is, that the model includes only the necessary and sufficient number of processes and parameters for representing the geomorphic system, (iii) generality and richness, meaning that the model formulation is sufficiently general and versatile to allow application to a variety of areas and situations, and (iv) potential for scaling up and down, meaning that the model can be aggregated to represent geomorphology at a larger scale. There are some likely tensions between these criteria, however. The demand for generality and richness, for example, may require an extended number of input parameters and boundary conditions to enable representation of a wide range of situations, but this may conflict with the desire to keep the model as simple as possible. Pilkey and Pilkey-Jarvis (2007) argue on this score that many environmental models are bad, and indeed dangerous for end users, because they are too complex, with too poorly constrained parameters, yielding (unknowably) inaccurate predictions. Slingerland and Kump (2011) therefore maintain that a simple but properly validated model is much preferable over a more complex but less well-constrained model.
The meaning of the term “good” in a modeling context may involve various other considerations, ranging from practical utility, or the delivery of results that are useful and relevant to end users, through representation, or the synthesis and integration of concepts and understanding that help to consolidate knowledge, to inspiration, or the discovery of links and insights that lead to new research questions. A stochastic black box river flow discharge model, for example, may not offer much inspiration for novel research questions, nor a good representation of scientific understanding (and it would not meet Kirkby’s criteria either), but if it can predict a 50-year flood very accurately it is undoubtedly of good value to a water resource manager. Reflections on utility and representation are usually extensively considered in the context of model validity (Oreskes, Shraderfrechette, and Belitz 1994) and prediction (Wilcock and Iverson 2003), but the opportunities for inspiration are often only implicitly articulated. Some geomorphic models, such as reduced-complexity or CA models, however, can have a great capacity for inspiring new insights and research questions, even though they may not produce very accurate predictions for practical end users, nor represent particularly comprehensive integrations of detailed process-based understanding. Murray (2013), for example, argues that even though many researchers prefer models that resolve fine-scale physical processes and parameterizations, for simulation of large-scale landscape development and pattern formation emerging from sediment transport and biology interactions, for example, it may not be possible nor fruitful to pursue rigorous conservation of momentum principles at the small scale.

A final consideration for evaluating the merits of geomorphic models is their potential beauty or elegance. Some models may be considered beautiful because they combine, synthesize, and abstract a large and complex body of knowledge into a pinnacle of simplification, built on extensive foundations from various (often disconnected) areas of research. The opportunity for such beauty in geomorphic models is perhaps limited, but other ways of assessing elegance may be in terms of net change in information content (or Shannon entropy) between data inputs and model outputs, or in the formulation of the shortest, most efficient, algorithmic description (low Kolmogorov complexity) of a geomorphic system.

Models in geomorphology have a very long and rich history, with many reflections on their methods and merits, as the Further reading illustrates. Recent developments and future trends in geomorphic modeling include a widespread recognition and inclusion of biological components and controls (eco-geomorphic modeling), the pooling of expertise and resources in collective community modeling efforts, and the exploration and utilization of big data opportunities.

Modernity

Philip Howell
University of Cambridge, UK

“Modernity” periodically falls in and out of fashion. Its critics object to it as a portmanteau term that mixes up a range of phenomena, many of which are not especially new. Bruno Latour, sociologist of science and avowed contrarian, famously argues that *We Have Never Been Modern* (Latour 1993). In this view, modernity is no more than a matter of faith, a kind of “constitution” that draws fictitious divisions between object and subject, nature and society, premodern and modern. The whole idea should now be recalled, he has since gone on to say, much as one might recall a defective product. All the same, modernity continues to be a helpful, indeed essential, concept, and at least some objections can be met by keeping strictly separate modernity’s focus on technology, discourse, and experience. It is in this tripartite understanding of modernity’s multiple registers that its utility can be preserved, and the varied work accomplished by geographers under its sign highlighted.

First, for modernity as project, key technological innovations – steamships, railroads, and the electric telegraph are iconic – represent significant and non-negotiable advances in efficiency. They accompany a host of other putative features of modernizing societies – the growth of rationalism, individualism, secularism, scientific consciousness, and so on – that may be thought of as at least potentially liberating. Modernity as project does not have to be progressive in a political and ethical sense, however; technical advances were key “tools of empire,” for instance vital supports for the Western subordination of other peoples and cultures. Technologies and rationalities of modernity have also been linked to the greatest tragedies of the modern age, the Holocaust among them. Nevertheless, the sense of these developments as demonstrable, decisive, and unrecallable advances is crucial. The railroads, although they carried Jews and others to their deaths in the camps, also “annihilated space,” promoting mobility, communication, and trade. They were the age’s greatest symbol of modernity, a revolutionary rupture foretelling the wholesale industrialization of time and space. In the philosopher Charles Taylor’s (1995) words, they represent a “culture-neutral” definition of modernity. These technologies, and the associated phenomena of a rationalized, industrial, capitalist civilization, may have been foisted on the world by an increasingly powerful Western world, but they are not necessarily defined by that culture or tradition. It is impossible completely to divest ourselves of the idea that modernity, albeit in limited, carefully specified ways, represents calculable improvement, however incomplete and partial. David Harvey’s (1990) famous geographical thesis concerning time-space compression acknowledges these revolutionary technical achievements while decrying their role in the reorganization of capitalism.

These seemingly unimpeachable advances must be qualified by an understanding of the ways in which technology is embedded within particular cultures as well as technopolitical regimes. Charles Taylor noted that we cannot rely on “acultural” interpretations of modernity alone, for we would miss the ethnocentrism that,
for all this increased efficiency and economy, is installed at the heart of “modernity.” We may consider, then, in the second guise of modernity as discourse, the eminently contestable achievements of what have been often dubiously promoted as “modern.” So, while we might reasonably consider the railway an advance over the horse and carriage, we cannot make the same argument for, say, a Western-style suit in the colonial tropics as opposed to a loose-fitting robe like the Arabic *djellaba*. In terms of practicability, the latter, in its places of origin, is clearly preferable, but in the age of empire it still became the icon of a worn-out tradition as opposed to an up-to-the-minute modernity. In this discursive sense, then, modernity is no more than a claim to superiority, based on a particular provincial culture rather than on demonstrable rationality. In this geographic paradigm of modernity, Europe came to know itself, typically through the cultivation of superiority over other cultures, as the historical geography of “colonial modernity” shows (such as the role of mapping in the global, imperial gaze of modernity).

Modernity is both culture-neutral and culturally specific, then. But there is an additional element that needs to be recognized. This is the impact of modernity as project and modernity as discourse on ordinary as well as elite people’s consciousness and identity. For modernity as experience a whole series of lived phenomena in “modern times” have been put forward as part of the condition of modernity. In a justly famous analysis, Marshall Berman (1982) argued that the maelstrom of modern life opened up a contradictory and ultimately tragic tension between the possibilities and perils of the emerging modern world. Attempts to delineate this “structure of feeling” descend into cartoonish caricature when abbreviated, but the poet Baudelaire, in his well-known essay of 1863, “Le peintre de la vie moderne” (“The Painter of Modern Life”), helpfully puts the stress on the role of “the transitory, the fleeting, the fortuitous” in the life of the modern metropolis. This “lived modernity” has often attracted scorn from critics (by way of diagnoses of alienation, bureaucratization, commodity fetishism, narcissism, and so on). The sheer captivating excitement of those subjected to modernity’s thrilling disorientation should be registered, however, and it is captured in the aesthetic response to modernity’s pathos and delight. No less important is the mundane and complacent acceptance of modernity’s blandishments and material satisfactions.

The wider point is that myriad anthropologies of modernity are possible, often with the city as the crucial locus of concern for this mode of vital experience. The relationship between the making of the modern self and the modernization of urban environments and spaces has been an important theme for geographers (see, e.g., Dennis 2008). So, too, are the ways in which different groups of people (women, gay/queer men, immigrants, and people of color, say) responded to the challenges of modernity; here, the larger ethical dimension of modernity, its promise of individual as well as collective autonomy, is partially endorsed but also necessarily qualified, sometimes sharply.

What, then, is “modernity?” It is a concept that attempts to capture the acknowledged changes in technology (the growth of technical capabilities; scientific advances; the organization of economic, social, and political realms), the power of discourse (the normative, ideological, and aesthetic accompaniments of such “progress”), and, more simply, people’s experience of these destabilizing forces, operating from the sixteenth century but accelerating from the nineteenth. The tripartite schema suggested in this definition is far from exhaustive, and multiple modernities may be advanced. But it is worth emphasizing, in conclusion, that in the resultant dialectics or
trialectics of modernity, in the conjunction of modernity as project, discourse, and experience, a crucial spatial politics is always played out. Modernity is not about chronological newness; even less is it a well-defined period or state. It is best studied as a contextual and contingent historical geography, the product of a network of people, practices, knowledges, and objects that in their assemblage produce multiple “spaces of modernity” (Ogborn 1998). In these hybrid sites and landscapes, modernity is projected, planned, and programmed, hubristically celebrated as well as condescendingly denied, and at the same time lived and experienced, creatively represented, sometimes loved, sometimes loathed. To think of modernity in this multifaceted way is at least partly to address the critical concerns of Latour and other critics of the conceptualization of modernity, while retaining its unrivalled utility as description and provocation.

Modernization theory

Sudarshana Bordoloi  
*St Cloud State University, USA*

Raju J. Das  
*York University, Canada*

Modernization theory (MT) seeks to elaborate the differences between what it calls traditional and modern societies and to explain what impedes the transition of traditional societies to modernization. MT is a significant part of the “development project” that began in the late 1940s (Parpart and Veltemeyer 2014). The concept of modernization arose from the dichotomous categories, such as “backward versus forward,” “traditional versus modern,” or “barbaric versus civilized.” The Western world (Europe and later North America) was seen as the center of modernity characterized by social mobility, equal opportunity, the rule of law, and individual freedom, whereas, the rest of the world comprised traditional societies based on “ascribed status, hierarchy and personalized social relations” (Kiely 1995, 37). Implicitly, the Western model of development was therefore staged as the “norm” and the West was viewed as the pinnacle of what modernization meant in terms of civilized development and human progress.

**Historical context of modernization theory**

All ideas originate and spread in determinate historical-geographical contexts and reflect certain social interests. MT as a set of ideas is no exception. MT developed in the context of the postcolonial Cold War (Baber 2001) and de-colonization in which there were distinct threats to the economic and geopolitical security of the United States. These threats came from processes such as the spread of Stalinism (often called communism), which needed to be countered through strategies of economic and political development in the Global South. Thus from the vantage point of the United States in the 1950s, MT was the response of the West to rising global socialist tendencies in the aftermath of World War II, particularly the rising influence of the USSR on third-world countries (Preston 1996, 178). In addition, the rise of the national bourgeoisie in the postcolonial countries and the rising legitimate aspirations of their masses for economic welfare meant that these countries wanted to catch up with the West. Attempted transitions to the status of a developed or modern society largely meant transformation of the economy through technological uptake and rapid industrialization as well as widespread social changes able to disrupt traditional forms of social and political order (So 1990, 17; Moore 1963, 69). Such changes would also create a market for goods and surplus capital from the United States and other advanced Western countries.

While there was a need to promote development in the Global South from the standpoint of the United States and from the standpoint of the Global South itself, the extant economic theory was unable to fulfill this need in part because of its neglect of the noneconomic conditions for development. Modernization studies, encouraged and funded by the US government, became a growth industry and emerged as a multidisciplinary effort
MODERNIZATION THEORY

to examine the prospects for development. As discussed below, MT has come in different disciplinary forms: sociological, economic, psychological, political, and geographical.

Contours of modernization theory

Sociological theory of modernization

Sociological MT has its roots in long-established ideas in sociology and, especially, structural functionalism, which stresses the significance of social institutions, structures, and social norms that discipline and socialize people in their struggle for survival and progress (Peet and Hartwick 2009). Renowned Harvard structural-functionalist sociologist Talcott Parsons (1902–1979) played an instrumental role in shaping and establishing MT. His most important contribution was his conceptualization of “pattern variables” that distinguish modern from traditional societies. These variables offered a cultural explanation for why less developed countries are less developed and why traditional values should be transcended such that modernization can occur.

The first pattern has to do with the role of affect in shaping relationships, what Parsons’s conceptualized as affective versus affective-neutral relationships. In judging a person, one can directly express one’s feelings in relation to the person (affective) or can set the feelings aside (affective neutrality). Traditional societies have affective (face-to-face, emotional, etc.) social relationships as compared to affective-neutral (impersonal, detached, indirect) relationships in modern societies. For example, in traditional societies, employees of a firm will not be fired even if the employer is losing money because the firm is considered a family. This means lack of economic efficiency and lower level of development.

Second, there is the distinction between particularistic and universalistic relationships. One may judge a person according to criteria that are peculiar to the person (particularism) or criteria that are applicable to many. Social relations in traditional societies are particularistic in nature where people interact with each other through interpersonal trust. In modern societies, however, social relations adhere to universal or more generalized norms, where interpersonal relationships are not necessary. In traditional society, people tend to associate with members of the same social circle (e.g., they work for a relative’s firm or they buy consumption items in a neighborhood store), showing attachment to a locality. People treat each other particularly. Customs determine the manner of economic activities. Particularism prevails in the distribution of economic roles. In modern societies, however, people tend to interact with strangers treating them in universal terms: for example, bank clerks or state officials ask all clients/citizens for proof of identity. Workers are mobile and unencumbered by artificial restrictions and seek employment where they could be more productive and earn the best wages. Universalism prevails in the distribution of economic roles and underlies efficient allocation of labor and resources (So 1990).

Third, traditional and modern societies can be distinguished on the basis of whether collective or self-orientations are fundamental to social order. A person can focus on work/relations that benefit a society as a whole or just himself/herself. Traditional societies are collective in their orientation, tied together by communal goals. Modern societies stress individualism and the focus on self-development. In traditional societies, people are asked to sacrifice their own interests for the sake of collective obligations. In modern societies, the opposite values lead to technological innovation and economic productivity.
Fourth, there is a distinction with respect to whether social status is derived from ascription or achievement. One can judge a person by what she does (performance or achievement) or by what she is by birth (ascription). In traditional societies, a person is evaluated by his/her ascribed status (based on social norms and practices), but in modern societies, by his/her achieved status (based on education, experience, self-improvement, etc.). In a traditional society, during a job interview, a worker is asked about her relatives’ or parents’ names, because there is a lack of reliance of individual achievement in distribution of economic goods (one gets things because of one’s ascription). In modern society, if employers hire incompetent people based on who they are by ascription, they will go out of business.

Fifth, and finally, traditional and modern societies differ with respect to the type of functional roles that individuals play, understood by Parsons as being either functionally diffuse or functionally specific. A person may be related to another through multiple ways (diffuseness) or in specific ways. In traditional societies, employers have functionally diffuse relationships where they have multiple responsibilities: employers hire, provide housing, and act as a guardian, and so forth for the workers. This diffuse relationship is considered highly inefficient in MT. In modern societies the emphasis is on functionally specific roles of actors (e.g., of employers in relation to employees); relations do not cross the boundary of the private enterprise. Since they can avoid other obligations to each other, the employer and employee can pay more attention to increasing efficiency and productivity. Additionally, the division of labor is less developed in traditional societies: one person does one thing, so she becomes more efficient (Parsons 1960).

Economic modernization

One of the most significant contributions to economic modernization theory was made by the economic historian W.W. Rostow (1960) in his seminal book, *Stages of Economic Growth: A Non-Communist Manifesto*. Drawing from earlier stage theories and consciously taking an approach that is opposite to that of Karl Marx who wrote *Communist Manifesto* and argued for a non–capitalist society, where resources are to be controlled democratically for collective use via class-struggle, Rostow (1916–2003) identified five historical stages of efficiency and consumption through which each country will go. The first stage that is characteristic of traditional societies has primitive methods of production, low labor productivity, low technological development, a hierarchical social order preventing social mobility, and persistence of religious mysticism. As traditional countries expand internationally and come into contact with more advanced societies, changes occur in the former as a result of emerging agricultural and industrial economies, the rise of new entrepreneurs, the expansion of global markets, and so forth; thus leading to the second stage – precondition for takeoff. The third stage – takeoff stage – occurs when economic development processes finally take off from all previously encountered constraints. Economic take off in this manner could happen only with external geographic discoveries, internal development of modern science, rise of entrepreneurship, and growth of urban industry, but most importantly, mobilization of capital and resources to raise the productive investment to 10% of national income (So 1990; Peet and Hartwick 2009). This stage is followed by the fourth stage – drive to maturity – where economic development has become an automatic process, with growth in one sector leading to development in other sectors of the economy.
MODERNIZATION THEORY

Societies that have achieved all these four stages then become high mass consumption societies – the fifth and final stage – with rising consumer demands, strong domestic markets, durable and consumer goods services industries, and the development of an urban skilled professional workforce. Technological innovations and development were fundamental in Rostow’s historical stages of development (Larrain 1989; So 1990). A direct impact of Rostow’s theory was on the “dual economy” model forwarded by W.A. Lewis (1950) which drew attention to how traditional sectors of the economy (agriculture) in third-world countries are advantageous for an advanced sector (industry) due to the scope of unlimited labor supply from the former and how the latter could rapidly grow through foreign capital investments (Potter et al. 1999).

Psychological modernization

Scholars have also analyzed modernization from a psychosocial/psychocultural standpoint. The political scientist and economist Everett Hagen (1906–1993) links personality patterns to technological innovation and change. Whereas an authoritarian personality and lack of creativity among individuals in traditional societies impeded technological progress, modern societies are endowed with innovative personalities who seek creativity to satisfy their own needs (Hagen 1962). On a similar note, McClelland (1917–1998), in agreement with Hoselitz (discussed below) and Schumpeter, stresses that human motivation for achievement, power, and affiliation is the driving force behind entrepreneurship; entrepreneurs are seen as leading the route to rapid economic development (Larrain 1989, 95). Resorting to the theory of social deviance, Hoselitz saw entrepreneurs as the “social deviant” – innovations are initiated by people who think and act differently and thus contribute to generating “creative adjustments in situations of change” (Larrain 1989, 90). Inkeless (1964) considered education and values (through informal curriculum) – particularly disseminated from the Western tradition – as a valuable contribution for the development of the “modern man” in non-industrialized societies (So 1990).

Political modernization

Modernization theory was also a political discourse. Drawing primarily from the structural-functionalist perspective, works of Huntington (1968) and Coleman (1971) were instrumental in shaping US foreign policy and promotion of political institutions as pillars of modernization. In his influential work, Political Order in Changing Societies, Huntington indicated that rapidly modernizing countries could easily come into conflict with pre-existing cultures and local identities. This would lead to political instability – conflicts among different civilizations or cultures often backed by religious principles or what he called “clash of civilizations” – within nation-states, although they may remain the most powerful actors at the global scale (Peet and Hartwick 2009, 115). MT has also stressed the association between economic development and liberal democracy (for a recent illustration of this linkage, see Jacobsen 2015). Since the United States is an advanced country and liberal-democratic, it is thought that democracy is a necessary aspect of economic modernization. Other scholars argue, however, that modernization need not generate democracy but democracies survive in countries that are modern (Przeworski and Limongi 1997).

Geographical modernization

From its earliest formulations, modernity as a concept and modernization as a theory have
had a clear geographical perspective founded on principles of spatial differences and spatial diffusion. The works of Swedish geographer Hägerstrand (1952) and Gould (1964) emphasized that spatial diffusion of innovations (Hägerstrand 1952) and communicative possibilities (Gould 1964) were constrained by distance – the closer a place is to the center of
MODERNIZATION THEORY

modernity, the faster is its pace of modernization. Hägerstrand argued that waves of change move across space and gradually lose power, owing to the friction of distance. Gould argued that people are persuaded to adopt innovations through communication with each other. Geographical theories therefore emphasized the concept of modernization through spatial diffusion.

Modernization takes place as people act in response to foci of change, that is, towns and cities. The modernization diffusion process originates in contact situations such as port cities or colonial administration centers with patterns of change moving down the hierarchy of urban areas to interior areas and along transport routes (Taaffe and Gauthier 1973). This process can be measured by the spread of education, medical facilities, and mapped as modernization surfaces. Modern transportation, geographic mobility, development of education, and transformation of parochial social organizations to embrace modern values and ideas were emphasized as key factors that drive the modernization process. As the geographer Soja (1968) mentions, “modernization is not simply increase in a set of indices. It involves profound changes in individual and group behavior” (1968, 4). Various geographical studies also employed statistical analyses to reveal “modernization surfaces” – case studies of Tanzania (Gould 1964) and Malaya (now Malaysia, Leinbach 1972) – at the global scale. These works tried to project and analyze the extent of spatial diffusion of innovations at multiple scales. Diffusion theories presented a “top-down” or “trickle-down” approach to modernization (Stohr and Taylor 1981) and were widely accepted by the public due to the paternalistic approach of the West toward other cultures (Hettne 1995, 64).

Modernization theory of secular self-expression values

Inglehart has sought to refine MT in the light of recent research on the link between economic development and cultural change. Economic development is associated with shifts away from absolute norms and values toward values that are increasingly rational, tolerant, trusting, and participatory. Inglehart’s neo-modernization theory talks about two kinds of cultural values on the basis of which countries could be categorized: traditional versus secular-rational values and survival versus self-expression values (Figure 1). Protestant Europe and English-speaking North America are at one pole and South Asia and sub-Saharan Africa at another. Traditional societies are religious and are characterized by: close parent–child ties; deference to authority; traditional family values, and rejection of divorce, abortion, and suicide; and a nationalistic outlook. Modern societies have the opposite preferences on all of these topics.

There is another set of opposite values, that is, survival versus self-expression values, which are linked with the transition from industrial society to postindustrial societies. In modern societies, self-expression values are prioritized, and survival is taken for granted; there is a shift from an overwhelming emphasis on economic and physical security toward an increasing emphasis on subjective wellbeing, self-expression, and quality of life. Here there is a high priority to rising demands for participation in decision-making in economic and political life, tolerance of outgroups, including foreigners, gays and lesbians, and gender equality. There is also shift in child-rearing values, from emphasis on hard work toward emphasis on imagination and tolerance as important values to teach a child. There is a rising sense of subjective wellbeing that is conducive to an atmosphere of tolerance, trust, and political moderation. People place
a relatively high value on individual freedom and self-expression, and have activist political orientations. This is conducive to democracy.

**Modernization theory: a multidimensional critique**

MT does bring to attention uneven socio-economic development across countries and within countries. It seeks to shed light on noneconomic causes of such unevenness, such as the lack of development in the Global South. In so doing, it undermines to some extent environmental deterministic explanation of under- and uneven development. However, MT suffers from several crucial problems. Both mainstream social scientists (Nisbet 1969; Eisenstadt 1974; Huntington 1976, cited in So 1990, 53) as well as more progressive scholars (Frank 1969) have mounted numerous criticisms of MT.

To begin with, MT claims that traditional values are an obstacle to technological and other forms of change. Such claims are idealistic: they explain social processes merely in terms of ideas and ignore the fact that there are material origins and material (i.e., developmental) effects of traditional values. Whether values affect development depends on, for example, state policies and the social relations (of production and reproduction) under which people transform resources to produce things for use and exchange.

Persistence of traditional values may have material preconditions. For example, peasant conservatism may be a reality but it exists because of definite material conditions. Vulnerable to crop disease, weather changes, fluctuations in the price of their produce, and to exploitation by social and political systems, peasants may bear conservatism as an attempt to establish some order in these precarious conditions, that is, some safety mechanisms. Traditional values may also have positive developmental effects in some cases. While the traditional MT, which, based on the Western experience, says that family ties can hinder development as they promote nepotism, weaken work discipline, thwart the free market selection of labor, and dilute incentives to invest, recent development scholarship, based on the non-Western experience argues otherwise. For example, Wong (1988) asserts that patron–client relations of dependency between industrial patriarchs and their employees retard class-consciousness among workers and help employers exploit and incorporate family labor, which is cheap, pliant, and hardworking. These relations, in a state of highly fluctuating global capitalist production regime, help the firms remain competitive (see So 1990). Wong argues for an economically dynamic ethos of entrepreneurial familism, which involves family as the basic unit of economic competition, providing the impetus toward innovation and risk taking.

Similarly, while MT has argued that individualist values of modern societies promote development and that collectivist orientation in traditional societies hinders it, research on social capital makes a different argument: social capital understood as norms of trust, reciprocity, and cooperation increases the value of existing resources (Das 2004). Indeed, promotion of social capital, including by the World Bank, is now seen as a low-cost way of promoting development, which is partly why social capital has become a new cottage industry in academic circles. That social capital and MT share something in common is a different matter: both stress norms/values as fundamental factors explaining development issues, in abstraction from class relations.

MT further says traditional society must emulate modern values/ideas, but it never asks whose goals/values these are. Clearly, these values are those of the West and are considered superior...
MODERNIZATION THEORY

to those of the rest of the world and universal; thus MT suffers from a form of ethnocentrism. Frank found the prescribed way of high mass consumption as the ultimate goal of modernization highly problematic as it does not take into account cultural specificities which make societies think about goals and outcomes of development differently (Frank 1969). Indeed many would wish to live well without the social and environmental problems associated with high mass consumption societies. The problem, for us, is not necessarily that certain ideas reflecting European history are being considered universal and therefore are ethnocentric. The problem for us is much rather this: the interests of capitalist development, which originally happened to take place in Europe, and ideas that are reproductive of capitalist development, are made to appear to be universal interests and universal ideas.

There is also a spatial fetishism that occurs in MT, one that undermines its context sensitivity. Diffusion of technology and modern ideas, which is necessary, is not merely a question of communication but an ability to use information and maintain economic control over resources, including via access to state power. Modern seeds may be available but peasants may not have the money to buy and use them (Yapa 1977). Mere diffusion of ideas and technology from the West or a few metropolises within the Global South linked to the West may not be beneficial to the less developed world and may indeed produce increased inequalities given the structural conditions that shape livelihood possibilities.

Related to this spatial fetishism is the manner in which MT ageographically homogenizes less developed and advanced countries. For example, Rostow’s stage theory relegates all “backward” societies with the same typology and uniform traditionalism. Such typology obfuscates the diversity of cultures in the third world along with utter disregard for the long and troubled colonial histories to which these countries were subjected (Frank 1969). Tribal, feudal, and bureaucratic empires are so different from each other that one cannot put them under the category of traditional society. To do so is to deny specific pre-capitalist histories of these countries/territories and to hide the under-developing effects of their contacts with Europe. In fact, Eisenstadt, an internal critic of MT, says that there are many differences between traditional societies and there are many traditional elements in modern societies.

It is not just that there are differences between traditional societies at the national level. Even within the so-called traditional societies, there are different types of values. There are no homogeneous traditional values. “Great tradition” – of the elites – like reading poetry, painting, hunting, philosophy, and so forth, and “little tradition” (working in the fields, thrift, etc.) coexist. For example, Indian executives may try to improve efficiency in their firms by scientific means, may worship Lakshmi to protect their competitiveness, and may consult with astrologers to avoid a heart attack or to determine the day of launching a new branch plant (Singer 1972).

Advanced countries are also homogenized in MT, and their modernity is exaggerated. In modern societies, particularistic values – those concerning gender, age, ethnicity, sexuality, and so forth – are present and are deployed in recruitment and promotion of personnel. In the United States, there are vast differences in income and wealth (including homeownership), which are based on racial differences. America still has not had a female president, and all but one of its presidents are whites, which means that not all groups experience equal opportunity for achievement, which is an important criterion of modernity. In modern societies such as Japan, promotion and post-recruitment salaries depend on age, and so forth. On the other hand, less
Developed countries may be just as universalistic, achievement-oriented, and functionally specific in many ways as developed countries are and yet still remain less developed.

We argue that whether in poor or rich countries, when inequality is rapidly rising, there is a structural pressure on the part of the economic and political elite (so-called modernizing elites of MT) to promote obscurantist (i.e., traditional) ideas among the masses to weaken their solidarity and ability to fight for equality (i.e., to demonstrate achievement orientation of MT): ordinary people may use modern cell phones and laptops and still be ready to kill each other on grounds of religion, race, or caste in the name of their respective gods, superior skin color, or ritual purity. We also assert this: since modern values coexist with traditional values partly in order to reproduce existing inequalities in the Global North and South, MT is mistaken to believe that the agency of development is the modern elite or that the West is a paragon of modern values.

MT also suffers from its teleological unidirectionality, assuming that the progress of human societies is predetermined in that each society is aware of the ultimate destination it has to finally reach in the course of its development process (So 1990, 19). Thus MT is developmentalist in its belief that the history of Euro-America is generalizable into a sequence of states of economic growth that all countries must follow (Pieterse 2010, 19). It also assumes that countries in the periphery want to and will achieve the same kinds of societies and economies that exist presently in the more developed West, and that “any contemporary differences in levels of development are ... merely different locations along the same path to development” that the West has traveled (Taylor 1992, 12; see Figure 2). Further, MT’s assumption that modernization followed a unidirectional path – the rest of the world following the West – ignores alternative paths to development that countries based on their unique history and cultural patterns may pursue. So in MT, advanced countries have history, but less developed countries do not have that luxury.

Related to this teleology is the underlying assumption of MT that there is one original developmental state common to all countries. In particular, MT assumes that the currently more developed countries may have remained underdeveloped at some point in the past. It mistakenly classifies today’s underdeveloped societies in the Global South with preindustrial underdeveloped societies in the West. Frank has argued that today’s developed countries may have been underdeveloped, not underdeveloped. A country may be undeveloped because of lack of resources and technology. That is different from a country being underdeveloped, which happens when its potential to become developed is underdeveloped (i.e., blocked) due to exploitation of it by other countries.

The insufficient recognition of such blockages and interdependencies means that MT blames the so-called third-world societies (their cultural values) for lack of development and ignores their oppressive/exploitative external connections. MT ignores colonialism and imperialism, including imperialism in its old form as well as in its new form (symbolized by interventions of international organizations) (Peet and Hartwick 2009). Relations between traditional and modern societies, to the extent these are considered in MT, are seen as conflict free and mutually beneficial. Frank asked how the Euro-American model of development could be repeated by the Global South primarily when the West’s development had already altered the context in which the Global South has to develop (Frank 1969, as cited in Peet and Hartwick 2009). As Kiely (1995) points out, “modernization theory ...
separates the modern international division of labor from ‘traditional’ nation states, and fails to clarify the mechanisms by which the latter were integrated into the former” (Kiely 1995, 43).

Finally, but no less significantly, there is MT’s elitism and ideological character. In the first instance, MT argues that only the elites can bring about development. While MT appears to be a scientific theory, its class commitment is to society’s rich elites (Peet and Hartwick 2009, 119). The Parsonian synthesis was aimed at protecting the interest of the dominant property owning classes of the society, thereby ignoring aspects of social inequality and associated exploitation, power imbalances, and social resistances of the masses (Gouldner 1970, 240).

Ideologically, MT says that the Global South has a lower level of achievement orientation, but when political mobilization aimed at achieving a higher standard of living happens, it is seen as a revolution of rising expectations or a crisis of governance, prompting the same MT thinkers to propose a lowering of newly acquired aspirations and level of political activity (Bernstein 1971). This is not surprising given that one of the main aims of MT is to help identify the threat of anti-capitalism in the Global South as a modernization problem. Clearly, what is a modernization goal for the masses is not a modernization goal for MT. If the Global South has to modernize, it has only one choice: move along the path that the United States has moved and away from anti-capitalism. To help achieve this, MT suggests profit-driven economic development, replacement of traditional values by commercial values, and institutionalization of liberal-democratic state forms. Not surprisingly, universities (e.g., Chicago), foundations, and nongovernmental organizations are lavishly funded to discredit anti-capitalist and anti-imperialist politics among third-world intellectuals (who encourage achievement orientation on the part of the masses).

All told, MT helps to legitimate the ameliorative foreign aid policy of the United States and
other advanced countries. Rostow and others say, “anticipating” the post-1970s neoliberalism, that underdeveloped countries should welcome foreign capital, be export-oriented, and promote free enterprise (Peet and Hartwick 2009). By arguing that developed countries can have only benign influence via the ideas and interventions of development agencies, the MT justifies the activities of these agencies. Rostow, the author of the Non-Communist Manifesto and a master modernization theorist, indeed became one of the closest advisors to a US president (Lyndon Johnson). If environmental theory developed in the historical context of colonialism and to justify it, MT developed in the context of Cold War and to justify Western domination (and Western-style capitalism). Slater says that the occidental deployment of MT signifies a will to power, that is, geopolitical power, providing an ideological legitimization for a whole series of practical interventions and penetrations seeking to subordinate and assimilate the West’s third-world other (Slater 1993). The purpose of MT was to create “an international order as a system dominated and manipulated by certain industrial countries [primarily the US] in their own interests” (Larrain 1989, 100). Indeed, the categories of modern and traditional or civilized and barbaric, used in the overall framework of MT, are ideological labels to justify Western superiority as well as Western interventions in the third world – in one word, imperialism – in the name of lifting it out of underdevelopment.

**Conclusion**

MT is a project of multiple disciplines. Each discipline has identified key issues concerning modernization. Sociologists: cultural obstacles to modernization. Economists: speeding up of productive investments including through Western aid and investment and ideas of free enterprise. Political scientists: enhancing the capacity of the political system to cope with the stress associated with modernization (e.g., public mobilization). Geographers: spatial diffusion of modern ideas.

MT basically seeks to explain lack of development in terms of the absence of modern values in poor countries. These values are not conducive to profit-driven economic development. MT also says that people in traditional societies are resistant to change (they do not accept new technology and new ideas easily) and therefore lack modern scientific knowledge about nature and society. And, of course, these societies lack investment, which advanced societies should provide in the form of aid, FDI, and so forth. Modern ideas, modern technology, and capital from the West are needed in poor countries, which should have a hierarchy of cities and settlements through which these modern ideas and things will diffuse. The actors in the drama of modernization will be modernizing sociopolitical elites, commercial profit-seeking entrepreneurs, and innovative individuals. The role of the masses – workers and peasants – is mainly to change their ways of thinking and to receive modern ideas from the West and from the domestic elites.

Following in the tradition of the dependency theories, which critiqued modernization theory for its justification of exploitation, dominance, and creation of dependencies by the core countries on the peripheries, alternative strategies of development that were fundamentally opposed to the idea of Western models started to emerge from the 1970s. While Emanuel Wallerstein’s world-systems theory (1974) positioned capitalist relations of domination and subordination at a world scale involving core, peripheries, and semiperipheries (Amin 1976), other theories, in the tradition of postmodernism and postdevelopment philosophies, have focused on indigenous knowledge, civil society based
participatory practices, postcolonialism against colonial discourses, and so forth as alternative strategies of development from a third-world perspective.

Despite the critiques and alternatives, modernization theory has found a way to live on through neoliberalism, the economic discourse of development since the 1990s. The fundamental principles that characterize MT have been strikingly similar to the main tenets of neoliberalism. With its emphasis on rationality, free markets, achievement of high mass consumption, withdrawal from state welfare interventions and state regulation of companies, integration of countries into the global capitalist order through trade and foreign investment, and development projects based on high-cost Western technology, MT could be seen as a prototype – a “harbinger” – of present day neoliberalism (Kiely 1995; Potter 2004; Peet and Hartwick 2009). In conclusion, as Peet and Hartwick (2009) argue, “modernization theory formed the more general theory of history within which neoliberal economics could be situated” (Peet and Hartwick 2009, 140).

A given set of ideas will not disappear as long as the material conditions which give rise to it persist, whether these interests are international or domestic. The problem of development, of modernity, persists in that millions of women, men, and children do not have access to nutritious food, health care, housing, safe neighborhood, transportation, culture, science and technology, and so on. The need to explain this problem and to act on it still exists. Some scholars will continue to produce explanations that deal with the surface causes, including people’s ways of thinking, without aiming to understand the material, political-economic, roots of these ideas. The traditional MT and those ideas which appear to be critical of MT (e.g., social capital theory) have done precisely this: trying to explain unevenness in material conditions in terms of the ways in which individuals or groups of individuals think and behave, and are therefore reproductive of the current system of production which is behind that unevenness. The ideas informed by the postmodernist turn, as well, share something important with MT: they do not fundamentally challenge capitalism or imperialist economic exploitation as a material reality which exists independently of the people who are thinking about it now. That is, given their stress on everything as dominantly a discursive construction and given their neglect of the systemic character of society and its materiality, they do not and cannot argue for overturning the system and for the creation of a socioecological order where there is democratic control of resources and production to be achieved through a multiscalar revolutionary action of the masses. They essentially argue for a system that is reformed through, for example, local-level (community) actions and discursive destabilization (i.e., academic critique of some relatively trivial or less important parts of the system). This is why we continue to need a theory that goes beyond modernization theory and similar ideas, postmodern or not. This would be a theory which not only recognizes the consequences of sociocultural ideas (as well as local initiatives people take) for economic development issues, but which also emphasizes that such ideas (and such local initiatives) are heavily conditioned by deeper structures of unequal relations defined in terms of access to productive resources and the ways in which people earn their livelihood.

Modifiable areal unit problem

Paul A. Longley
University College London, UK

Geographic scale, or granularity, is fundamental to the fitness for purpose of a geographic representation. Yet the level of granularity with which we are able to represent the world may be restricted by constraints that lie beyond our control for reasons that are technical—such as the resolution of an airborne sensor or satellite—or societal and ethical constraints—as with the disclosure restrictions on individual level census or other survey data. The hypothetico-deductive approach to development of theory requires the specification of an appropriate scale range over which hypotheses can be tested, but it may happen that the researcher lacks either the technical equipment or the ethical mandate to record the phenomenon of interest in sufficient detail for the task in hand.

Other approaches are much more explicitly data driven, and inductive. Here, an insidious problem that characterizes much of geography is that, unlike many other scientific disciplines, there are few if any “natural” units of analysis into which elemental observations might be aggregated. What, for example, is the natural unit of analysis for measuring a soil “profile”? What is the extent of a “pocket” of unemployment, or a crime hot “spot”? In practice, the definition of objects of analysis in geography is often inherently ambiguous and, in practice, rarely precedes our attempts to measure or analyze their characteristics. In socioeconomic applications, the objects of study (or “geographic individuals” in the terminology of geographer Stan Openshaw) (Openshaw and Alvanides 2005) are usually aggregations, since the geographic locations that human subjects occupy are unique, and disclosure control usually requires that uniquely attributable information must be anonymized through aggregation. In natural environment applications, it may be tempting to think that all unique locations can be represented, but in practice the observable world is only viewed at a prescribed level of resolution. The accuracy of a land cover classification of a classified satellite image is only as good as the resolution at which reliable measurements were taken, for example. In each case, the fundamental problem is that the observable world is of seemingly infinite complexity and the units of analysis used in geographic analysis are often the outcome of choice, convention, and chance.

As a consequence, we cannot be entirely confident about ascribing even dominant characteristics of areas to true individuals or point locations in those areas. This source of uncertainty is known as the ecological fallacy, and has long bedeviled the analysis of spatial distributions. (The opposite of ecological fallacy is atomistic fallacy, in which the individual is considered in isolation from his or her environment.) The ecological fallacy problem is a consequence of aggregation into the basic units of analysis and is illustrated in Figure 1 (Longley et al. 2015). In this diagram, the function of a downtown central business district (CBD) has been usurped by a new neighboring retail center (not shown). This has resulted in high local levels of service sector employment. The operations of the factory located to the north of the CBD...
are unaffected, but its workers live in the same labor force zones as the service sector workers, generating the misleading impression that unemployment may instead be a blue collar (factory worker) phenomenon.

The likelihood of committing ecological fallacies such as this depends upon the administrative (or other) geography being used. If the units of analysis within each zone share the same characteristics or attributes, then the only geographic variation (heterogeneity) that occurs will be between zones. However, within-zone variation is usually the norm, and greater heterogeneity increases the likelihood and severity of the ecological fallacy problem. This said, it is also the case that geographers may have become over fixated about this potential problem over the years, and many general-purpose zoning systems are designed to maximize within-zone homogeneity in the most salient population characteristics – as with the UK Census geography, for example. Probably as a consequence, there are very few documented case studies that demonstrate the misleading consequences of ecological fallacy in practice.

The potential of aggregation to create problems in geographic analysis is compounded by problems arising from the different scales at which zonal systems may be defined. Gehlke and Biehl first identified this in 1934. It was subsequently demonstrated in a classic 1950 text

Table 1 1950 Yule and Kendall’s data for wheat and potato yields from 48 English counties.

<table>
<thead>
<tr>

</table>
by British statisticians Yule and Kendall, in an analysis that began by calculating the correlation between wheat and potato yields for the (then) 48 counties of England. Upon aggregating the data for the 48 counties to 24, then 12, then 6, and finally 3 zones, they demonstrated that correlation coefficients tend to increase with scale. Table 1 presents their results, ranging from near zero (no correlation) to over 0.99 (almost perfect positive correlation) — although subsequent research has suggested that this range of values is atypical.

Scale turns out to be important because of the property of spatial autocorrelation. A succession of subsequent research papers have reaffirmed the existence of similar effects in multivariate analysis. However, rather discouragingly, scale effects in multivariate cases do not follow any consistent or predictable trends. This has important implications for the analysis of big data and other secondary sources, where analysts rarely have control over the scale at which data are made available.

Further aggregation effects can arise because there is a multitude of combinations in which the mosaic of smallest available areal units can be assembled together into contiguous zones. This gives rise to the related aggregation or zonation problem, in which different combinations of a given number of geographic individuals into coarser-scale areal units can yield widely different results.

In a classic 1984 study, geographer Stan Openshaw applied correlation and regression analysis to the attributes of a succession of zoning schemes. He demonstrated that the amalgamation of elemental zones into larger areal aggregations could be used to manipulate the results of spatial analysis to a wide range of quite different outcomes. Moreover, using emerging geocomputational techniques, Openshaw was able to demonstrate that these outcomes could be prespecified by the analyst through careful, if usually contrived, zone design. These numerical experiments have some sinister counterparts in the real world, the most notorious example of which is the political gerrymander of 1812, in which the amalgamation of elemental voting districts was engineered to create an electoral constituency in Boston, MA, that would return Governor Gerry as its elected representative. The implication is that it is possible to assemble apparent spatial distributions that are unrepresentative of the scale and configuration of real-world geographic phenomena. The outcome of multivariate spatial analysis is also similarly sensitive to the choices and conventions that give rise to particular zonal schemes.

Taken together, the effects of scale and aggregation are generally known as the modifiable areal unit problem (MAUP). The ecological fallacy and the MAUP have long been recognized as problems in applied spatial analysis. Through the concept of spatial autocorrelation, they are also understood to be related problems. Geocomputational methods and big data analytics can be used to demonstrate the nature and potential extent of this problem, in particular empirical settings, and the results of experiments and simulations have focused interest on the effects of within-area spatial distributions upon analysis. This is an important contribution to balanced assessment of the quality of secondary datasets.

However, repeated scaling and aggregation experiments do not resolve the uncertainties inherent in spatial analysis. Zone-design experiments are merely playing with the MAUP, and do not provide any substitute for clear thinking about the validity of available units of analysis for particular investigations. There is no “solution” to the MAUP, but simulation of large numbers of alternative zoning schemes can gauge its likely effects. The imposition of
elemental zones that are to some extent arbitrary may be ad hoc, but it is rarely completely random. Measuring the range and variance of the MAUP in any particular case study does not really help us to accommodate its effects because there is no tenable analogy between “simple random zoning” and simple random sampling. Rather, the way forward is likely to lie in clearer application-centered thinking about the nature of within-zone heterogeneity that is concealed in aggregated data. In this view, MAUP will disappear if analysts understand the particular areal units that they wish to study.

Three other important considerations flow from this discussion. First, application-centered thinking implies a focus upon the uniqueness of places. Second, areal objects are not time-invariant but ever changing, and our perceptions of what is appropriate zonation will also change over time as a consequence. Third, at least within the socioeconomic realm, the act of defining zones can be self-validating if the allocation of individuals affects the interventions for which they are eligible (e.g., eligibility to apply for a place at a school, or eligibility for workfare incentives). Spatial selectivity affects spatial behavior, and so the principles of zone design are of much more than academic interest.

The abiding message of all of this is that the MAUP is not best thought of as an empirical problem but instead poses a theoretical requirement to hone statistics to the geographic context in which they are applied. The problem should not be considered in isolation, but rather as part of a grander design to develop explicitly geographical representations of the accumulated effects of historical and cultural processes upon unique places.

Monitoring and evaluation

Camille Gaskin-Reyes
George Washington University, USA

Monitoring and evaluation (M&E) methodologies are used in many fields to record and assess the performance of organizations, plans, and projects, and to involve the identification, measurement, and assessment of outputs, outcomes, and impacts. In the field of regional development M&E embraces activities in the economic, educational, health, and environmental sectors. In this entry the health sector will be used as an analogy to understand the basic concepts underlying monitoring and evaluation, and attention will focus on development projects, although the principles and methods have more general applicability.

In the health sector, physicians perform periodic and systematic checkups on their patients to assess their health status. Based on the interpretation of the symptoms that the patients report and the results of medical tests, the physicians make diagnoses and prescribe treatments. They usually monitor the situation for a while, and then ask patients to come in for follow-up visits to evaluate changes. From this example, one sees that monitoring involves an ongoing process of supervision and oversight during an event or intervention, whereas evaluation has to do with reviewing and assessing outcomes after a process of monitoring has been completed.

Monitoring can be defined more formally as a systematic procedure for checking for the effectiveness (outcomes) and the efficiency (outputs and impacts) of an intervention during implementation. Its main purpose is to identify progress and shortcomings and to recommend corrective measures to optimize desired results. In the health sector, the health professional monitors the patient and makes evaluative judgments. In development projects, the project manager or executing entity is responsible for monitoring the development intervention to gauge project progress.

Performance indicators are a key aspect of monitoring, whatever the sector or area. They are defined as metrics to track the progress of an intervention and the attainment of targets that a project is expected to meet. Their use also enables a comparative look at the situation, whether in a sector, project, or country over a specific time period. Using a baseline as a point of departure, project managers are expected to use the project information generated by the system to update and review project status on a periodic basis. The frequency of reviews varies from project to project, situation to situation; as a general practice, such reviews are carried out quarterly, yearly, and at the mid-term point.

In project design, the entire results framework and architecture are usually set up at design stage, using for example, a methodology such as the logical framework. The logical framework is an instrument that pulls the entire project results chain together: from inputs (resources) and processes to outputs, outcomes, and finally impacts. No logical framework is useful if it does not incorporate a sound monitoring and evaluation plan, including defined performance indicators.

While monitoring takes place during the life of the project, evaluation is the objective, largely third-party valuation of the impacts of an intervention after project completion and
final disbursements. Evaluation also uses pre-
determined criteria, focusing on factors such
as relevance, efficiency, effectiveness, impact
(understood as changes to beneficiaries’ health,
welfare, or living standard), sustainability, and
lessons learned for feedback into new design.
Hence, evaluation is about recording and
demonstrating change: changes over time for
the same group, changes in living conditions in
a geographical project area, changes in overall
poverty as a result of poverty reduction interven-
tions or strategies through the appropriate use of
project resources.

To sustain an evaluation system, however, and
for it to be valuable and valued, there must be
demand for the information. Other important
factors are an established, formal structure;
the timeliness, accessibility, and cost-efficiency
of the system itself; and the institutional and
technical/information technology capacity
to run and maintain it. A further important
hallmark of a sound evaluation system is the
credibility, transparency, and utility of the
information that it generates.

In development projects, monitoring and
evaluation go hand in hand like oil and vine-
gar. They have become indispensable tools for
project managers, officials, project stakeholders,
and civil society to assess the ongoing status of
interventions or activities under execution.

It cannot be overstated that project managers
can know if projects are really on the right
track only if the performance indicators and
data collection systems are set up and function-
ing smoothly. Much in the same way that the
physician monitors the vital signs of a patient,
the system helps the project manager to analyze
information and understand important changes,
in particular emerging issues, risks, or red flags
within the project context. Failure to address
problems that come to light through monitoring
could derail implementation and the attainment
of project results. A steady and reliable stream of
information also facilitates the ongoing review
and quality assurance of the project’s path toward
results.

Results consist of both outputs and outcomes.
Outputs are products and services delivered (i.e.,
health clinics, schools, training seminars, learning
materials) and outcomes represent the initial and intermediate effects of the use of those
outputs on the intended beneficiaries of projects
(improved health care, learning outcomes, etc.).
Projects also have impacts, defined as medium-
to longer-term welfare gains or improvements to
society. These impacts are the focus of the eval-
uation process, long after the completion of the
intervention or project.

Based on their in-depth knowledge of the
issues surrounding the project, project man-
agers should make timely decisions to resolve
problems. A project that exhibits continuous
bottlenecks must be closely monitored until
improvements are noted. Monitoring devel-
opment projects requires, in particular, the
participation of key stakeholders and beneficia-
ries. These groups are well positioned to provide
feedback on the quality and relevance of the
project’s products and services.

There are a number of steps to achieve success
in the monitoring, reporting, and ultimately the
evaluation of projects:

• plan for the monitoring and evaluation
  framework from the time the project is an
  idea, and set it up early;
• be rigorous in the implementation of a mon-
  itoring plan and cover any associated costs of
  the plan;
• conduct a readiness assessment with develop-
  ment partners and establish agreements on
  results and the factors for project evaluation;
• choose project performance indicators that are specific, measurable, achievable, relevant, and time-bound;
• anticipate and address risks throughout the monitoring process;
• pay attention to baseline data, data sources, data collection frequency, targets, and responsibilities for monitoring and results reporting;
• report results on achievements candidly, and supervise for risk management and course correction;
• use quantitative and qualitative information for timely decision-making by managers;
• make provisions for mid-term assessments and post-completion impact evaluations.

Once a project is completed, project managers usually prepare a project completion report. This report is a stock-taking exercise. It represents a preliminary assessment of initial or intermediate outcomes of the project, the use of budgetary resources, the outputs acquired, and preliminary outcomes.

At this point, the process of monitoring ends, and the evaluation phase begins. The evaluation of final outcomes usually takes place about four years after project completion, and involves persons not operationally linked to the project. The emphasis of this evaluation, sometimes called an ex post evaluation, is to generate final, objective conclusions with respect to the attainment of project goals, and recommendations for the improvement of future operations.

There are many methods and approaches for consideration. The specific choice of an instrument depends on a number of factors, such as the demand for the information, the costs involved, the technical capacity, and the time available for the evaluation exercise. Mostly, formal surveys are used for information gathering from a sample of beneficiaries or households to understand changes due to project interventions. For example, if a project manager wants to assess the project’s impact on how living standards of the population have improved, the type of survey selected would be a living standards measurement survey. The latter includes such aspects as spending, household composition, savings, and household income. Given the fact that evaluation is about trying to measure change in a target population, another tool used is a household survey, which assesses changes in a population’s access to social services such as health, education, clean water, and sanitation.

Client satisfaction surveys and focus groups are very useful to measure beneficiary satisfaction with goods and services delivered by the project. In focus groups of beneficiaries, people are asked about their experiences with the project, their perceptions about quality, timeliness, and usefulness of the services, as well as any bottlenecks experienced.

The information from these different surveys complements quantitative information provided by the monitoring system in place during the execution period. These findings help assess outcomes, the institutional performance of project managers, government entities, and funding agencies, and are also critical for accountability purposes. In recent years, accountability for results has become a critical component or even a condition for funding by international agencies. The latter rely on the information generated to exercise their own fiduciary oversight.

A well-established monitoring and evaluation system from start to finish and beyond project completion is, therefore, one of the main ways to track project progress and verify results. In fact, having a monitoring and evaluation system is now perceived as a key safeguard to manage fiduciary risks. In addition to providing project officials, managers, and the public with a tangible
MONITORING AND EVALUATION

way to corroborate project results, monitoring and evaluation delivers valuable lessons to improve future planning and budgeting, and demonstrate outcomes. Tangible evidence on outcomes reduces subjectivity and makes it easier for project managers to distinguish failure from success.

Monsoons

Shouraseni Sen Roy
University of Miami, USA

The word “monsoon” originates from the Arabic word “mawsim” for season. It was originally used by seafarers centuries ago to describe the alternating system of winds over the Arabian Sea. The most widely used definition of monsoons is the seasonal reversal of winds caused by differential heating of the land and sea, most frequently over southern and eastern Asia. This is primarily caused by the differing response of land and water vis-à-vis incoming solar radiation. The specific heat of water is much larger than that of dry soil. For instance, during the summer months heat conduction in soil takes place very slowly and only the few topmost centimeters of the land surface are heated. Thus, solar energy absorbed by land surfaces produces rapid warming, which, in turn, heats the air in contact with it. In contrast, the solar radiation absorbed by oceans is able to penetrate to a much greater depth, of at least 200 m, due to the vertical mixing of the uppermost water layers, which results in the turbulent transfer of heat. Therefore, land surface temperatures are considerably higher than the ocean along the same latitude, by about 5–10°C (Das 2002). Spatially, monsoons are mainly confined to tropical latitudes within 20° of the equator; temporally, monsoons are most pronounced in the summer months – June–August in the northern hemisphere and January–February in the southern hemisphere. Specifically, at the regional scale, the monsoonal circulation is most prominent over the Indian landmass, with similar seasonal wind reversals recorded above northern Australia (Hendon and Leibmann 1990), western and eastern Africa (Sultan, Janicot, and Diedhiou 2003), and the southwest USA (Adams and Comrie 1997). The focus here is on causal processes, patterns, and variability related to the wet Indian summer monsoon, locally known as the southwest monsoon season.

The majority of the precipitation across the Indian subcontinent occurs between June and September. During these summer months, conditions favorable to triggering the southwest monsoon result from the northward migration of the inter tropical convergence zone (ITCZ) to its northernmost position (30°N), the greatest annual contrast in land and sea temperatures, and the atmospheric steering effects of major physiographic barriers in the north, particularly the Himalayas. These forces set up a strong pressure gradient between the equatorial latitudes and the subtropical region to the region of maximum heating and lowest pressure, which is accompanied by a quasi-geostrophic westerly wind, deflected by surface friction towards the equatorial low pressure trough (Pant and Rupa Kumar 1997). The result is a weakening of the prevailing northeast trade winds, overpowered by southwesterly winds flowing from the opposite direction (Figure 1), the southwest monsoon.

In the upper atmosphere, the subtropical westerly jet stream moving across the Indian subcontinent shifts north to flow over the Tibetan plateau and is replaced by an easterly jet stream whose core overlies the equatorial Indian Ocean and extends westward into East Africa. The formation of this easterly jet stream is linked to the development of an upper level high-pressure ridge above Tibet. This anticyclone extends...
MONSOONS

Figure 1  Southwest summer monsoon circulation over the Indian subcontinent. Yellow arrows represent the Arabian Sea branch and green arrows represent the Bay of Bengal branch. The purple line represents the approximate location of the ITCZ during the summer months. The development of an intense center of low pressure in northwestern India is represented by the red circle with the letter “L” in the center.

vertically from the middle to the upper tropospheric levels of the atmosphere and is associated with mid-oceanic troughs over both the Pacific and Atlantic Oceans. Besides large scale, land–sea heating contrasts, the monsoon circulation also results from the marked sea-surface temperature contrasts and releases of latent heat that help to maintain strong horizontal and vertical wind shear (Pant and Rupa Kumar 1997). Given the relative significance of the summer monsoon in meeting the huge and growing water demands across the Indian subcontinent, it is of special interest in the explanation and prediction of the physical processes that shape monsoons. Ramage (1971) observed four principal features of the monsoon:
Figure 2  Normal dates for the onset of the southwest monsoon season across the Indian subcontinent. Source: IMD 2013.

1. A change in prevailing wind direction of at least 120° between January and July.
2. The average frequency of prevailing winds in January and July should exceed 40%.
3. Mean wind speeds in at least one month should exceed 3 m/s.
4. There should be less than one cyclone–anticyclone alteration every two years in either month within a 5° latitude–longitude grid.

Monsoon onset

The seasonal transition from premonsoon to monsoon is so abrupt that it is commonly referred to as the “burst” of the monsoon over the Indian subcontinent. The typical conditions that establish monsoonal circulation include surface winds blowing from the southwest, a sudden decline in near-surface air temperatures,
and a sharp increase in cloudiness and precipitation (Pant and Rupa Kumar 1997). The first monsoon rains occur over the southwestern state of Kerala, marked by a sustained increase in precipitation around the first week of June (Figure 2). More specifically, the main processes associated with the onset of the monsoon and factors affecting its performance are:

1. **Formation of a heat low and monsoon trough:** as the sun migrates northwards from the Equator, the land areas surrounding the Arabian Sea receive increasingly larger quantities of heat both from the sun and heat releases from the Earth’s surface. This produces a trough of low pressure that extends northward from Somalia across Saudi Arabia, Pakistan, and northwestern India (Das 2002). This trough is also a zone of intense horizontal wind shear.

2. **Mascarene anticyclonic system:** The Mascarene High located over the southwestern Indian Ocean around 30°S and 50°E near Madagascar, generates a significant outflow of air. This airstream moves across the Equator as a southwesterly flow known as the East African or Somali jet, reaching its peak between June and August (McGregor and Nieuwolt 1998). The intensity of this jet stream plays an important role in the intensity of the monsoonal rainfall over the Indian subcontinent.

3. **The Tibetan high:** this large cell of high pressure is centered above the Tibetan Plateau that lies poleward of the surface monsoon trough over northern India, and triggers upper-level divergence as well as lower-level convergence. The outflow of air from the Tibetan high is vital to the formation of the tropical easterly jet stream that lasts from June to September.

4. **Change in kinetic energy:** observations from several field experiments show the development of a sudden and rapid increase in kinetic energy over the Arabian Sea, which is associated with the formation of a vortex off the coast of southern India (Das 2002).

Accurate forecasting of the summer monsoon is critically important for this region. The Indian Meteorological Department (IMD) currently employs a two-stage approach for issuing southwest monsoon forecasts. The first seasonal rainfall forecast is issued in April, followed by an updated forecast in June for July rainfall across the entire country. Detailed information about long-range weather forecasts issued by the IMD can be found elsewhere (Rajeevan et al. 2007). The guidelines used to determine the onset and advance of monsoonal precipitation in India are (IMD 2013):

1. **Rainfall:** if after May 10, 60% of the 14 available weather stations report rainfall greater than 2.5 mm for two consecutive days, then the onset over Kerala is declared on the second day, provided the following criteria are also met.

2. **Wind field:** the depth of westerlies is maintained at 600 hPa in the area extending from the equator to 10°N and 55–80°E, and the zonal wind speed over the area bounded by 5–10°N and 70–80°E is maintained at or above 15–20 knots at 925 hPa.

3. **Outgoing long-wave radiation (OLR):** the OLR values derived from INSAT are below 200 W m\(^{-2}\) within the area bounded by 5–10°N and 70–75°E.

**Monsoon withdrawal**

The change of air circulation associated with the weakening of the monsoon is far more gradual than its onset. The withdrawal begins in northern
India around mid-September, and by the end of October it is complete across the entire subcontinent (Figure 3). This withdrawal is accompanied by the reassertion of the subtropical westerly jet stream and the dissipation of the easterly jet stream. The criteria currently used to determine the withdrawal of the southwest monsoon season by the IMD (IMD 2013) are:

1. Withdrawal from far northwestern India is not analyzed before September 1.
2. After September 1, the synoptic features analyzed for the withdrawal from the western part of northwest India are:
   i. Absence of rainfall activity over the area for five consecutive days.
   ii. Emergence of an anticyclone in the lower troposphere (850 hPa and below).
   iii. Substantial decrease in atmospheric moisture content as detected by satellite water vapor imageries and tephigrams.

Principal branches of the southwest monsoon

The progress of the southwest monsoon across the subcontinent is governed by the formation of two branches: the Arabian Sea branch and the Bay of Bengal branch (Figure 1). The Arabian Sea branch monsoon accounts for most of the intense heavy precipitation over the west coast, whereas the Bay of Bengal branch of the monsoon accounts for most of the precipitation occurring over the Gangetic plains. The two branches converge over northwestern India, resulting in renewed precipitation in the vicinity of Delhi. The Arabian Sea branch steadily advances northward to Mumbai in about 10 days by June 10. The Bay of Bengal branch moves northward into the center of the Bay of Bengal and expands into most of Assam state in northeastern India by the first week of June. After reaching the nearby Himalayas, the Bay of Bengal branch spirals upward and is deflected to the west, where it keeps advancing over the Gangetic basin while another branch hives off toward the northeast. The southwest monsoon months are also characterized by the formation of a monsoonal trough, which extends east–west over the northern plains of the subcontinent and is useful for determining the path of the rain-bearing winds. Several smaller low-pressure cells form during the monsoon season in the Bay of Bengal and they generally move along the axis of the trough paralleling the foothills of the Himalayas. These monsoonal depressions typically consist of 2–3 closed isobars at 2 hPa intervals (Pant and Rupa Kumar 1997), producing substantial precipitation in the northern plains, transporting heat and moisture upwards, and reinforcing the structure and activity of the monsoonal trough. Although these depressions usually weaken after crossing central India as their moisture supply wanes, some can be reinvigorated by the addition of moisture from the Arabian Sea branch, thereby restoring their intensity to produce heavy, sustained rainfall above western India (Pant and Rupa Kumar 1997).

Another important force shaping monsoonal rainfall is the impact of orography on spatial patterns of precipitation, such as in northeastern India where moisture-laden air is forced to rise against steep slopes, leading to some of the planet’s highest rainfall totals, as in Cherapunji (1087 cm of mean annual rainfall) and Mawsynram (1141 cm of mean annual rainfall) (Das 2002). A similar effect occurs along India’s west coast, where saturated onshore winds are forced up the Arabian Sea facing slopes of the Western Ghats, producing copious rainfall along
The amount of precipitation taking place over the Indian subcontinent varies over time and space, ranging from arid conditions in the northwest to a moist tropical regime in the far northeast and the western coastal strips, as is evident from the distribution of normal rainfall (Figure 4). Moreover, the amount and frequency of precipitation can be highly variable from year to year (Figure 5). The monsoons also undergo periodic pulses of active and weak cycles. For instance, Murakami (1977) discovered that the Indian monsoon has two significant peaks in its intra-seasonal periodicity, one at about five days (related to cyclonic systems embedded in

the Malabar and Konkan coasts as far north as Mumbai.
Figure 4  Spatial patterns of normal seasonal rainfall June–September. Source: IMD 2013.
the monsoonal flow) and another at around 15 days (related to the strength of the monsoon itself). Krishnamurti and Ardanuy (1980) found a 10–20 day westward propagating modes and rainfall over India. Other studies that found significant periodicity in the monsoon rainfall, including 30–40 episodes of period in cloudiness and precipitation (Yasunari, 1979) as well as recurrence period of 40 days (Singh and Kripalani, 1986).

As well as the intra-seasonal variability observed in monsoon rainfall, there are substantial inter-annual variations in such rainfall across the subcontinent as shown in Figure 5. The analysis of 31-year moving averages of all India monsoon rainfall revealed two multidecadal periods of deficient rainfall (1901–1930, 1961–1990) and two unusually wet periods (1871–1900, 1931–1960) (Pant and Rupa Kumar 1997). Furthermore, significant spatial variations in monsoon rainfall have also been observed, such as the presence of a decreasing trend in monsoon rainfall across most parts of the country that ended in 1962 in northeastern India and West Bengal in 1972, while persisting in north-central India. According to the latest report of the Intergovernmental Panel on Climate Change (IPCC) there is medium confidence that the Indian monsoon precipitation is projected to increase (Stocker et al. 2013). The report also mentions the overall weakening of the monsoon circulation, which is compensated for by elevated levels of moisture leading to great precipitation. It is important to understand the possible causes for these temporal and spatial variations in rainfall over the years, because the amount and timing of rainfall is of crucial importance to socioeconomic conditions in this region. Some of the major driving forces

Figure 5  Average all India monsoon rainfall 1901–2010. Source: IMD 2013.
controlling the performance of monsoon rainfall across the region are as follows.

1 *Teleconnection and monsoonal precipitation*: one of the most widely researched teleconnections in relation to the southwest monsoon rainfall over the subcontinent is the El Niño–southern oscillation (ENSO). One of the first studies to link the southern oscillation and monsoon rainfall was undertaken by Walker (1924); it was further validated by later studies (Parthasarathy and Sontakke 1988). There is now a general consensus about the occurrence of droughts during El Niño events (the warm phase of the ENSO) in comparison to La Niña events (the cold phase of the ENSO). However, the relationship between the ENSO and Indian monsoons is not always the same, such as the occurrence of normal rainfall during the 1997 monsoon season that signaled a weakening association between the ENSO and monsoon rainfall during the final decade of the twentieth century (Kumar, Rajagopalan, and Cane 1999). Going further, Torrence and Webster (1999) noted substantial decadal-level changes between the ENSO and monsoon rainfall. More recently, the modifying roles of the Pacific decadal oscillation (PDO) (Krishnan and Sugi 2003; Sen Roy, Goodrich, and Balling 2003) and the Madden Julian oscillation (MJO) (Kane 2000) concerning the influence of the ENSO on Indian precipitation has been observed. Some other teleconnections that appear to play a role in the performance of the Indian monsoon include the quasi biennial oscillation (QBO), arising from the interaction between nonlinear intra-seasonal oscillations and annual cycles (Chattopadhyay and Bhatla 2002), the Indian Ocean dipole mode (IODM) (Gualdi et al. 2003), and the North Atlantic oscillation (Sen Roy 2011). For instance, during the developing phase the heat content and sea surface temperature variability associated with the IODM are modulated by a local response of the ocean to winds as well as a long-distance response to the agitation of Kelvin and Rossby waves (Gualdi et al. 2003).

2 *Eurasian snow cover*: the Eurasian snow cover is increasingly regarded as one of the driving forces of the monsoonal circulation across the subcontinent. The presence of extensive snow in northern Asia during the premonsoon months implies significant regional energy consumption in snow and ice melt plus the evaporation of water from melt-saturated ground. This leads to reduced premonsoon surface heating and results in weaker thermal lows (McGregor and Nieuwolt 1998). Analyses of empirical data underscore the delayed arrival of monsoon when Eurasian snow cover is greater (Barnett et al. 1989), and the negative correlation between them has increased markedly since the mid-1970s (Liu and Yanai 2002).

3 *Sea surface temperature (SST)*: variations in SSTs in the adjacent arms of the Indian Ocean play a major role in the overall monsoon rainfall across the Indian subcontinent. In general, the warm SSTs of the Arabian Sea result in above-average rainfall and vice versa (Shukla and Misra 1977). Additionally, the study of 10-day and monthly mean evaporation rates over the Arabian Sea and Bay of Bengal has revealed that evaporation was higher above those water bodies during a low-rainfall year (1987), indicating minimal influence of SSTs on subsequent monsoon activity on the subcontinent. In contrast, evaporation above the southern Indian Ocean was greater in July and September 1988 when compared to
the same months of 1987 (Ramesh Kumar and Schlüssel 1998). In yet another recent study Sen Roy, Goodrich, and Balling (2003) showed substantial spatial variations in the relationship between SSTs and monsoon rainfall, in the form of positive coefficients in peninsular India, while predominantly negative coefficients were observed across most of northern and eastern India.

Aerosols: recently, the Indo-Asian region has received substantial attention for its significantly higher concentrations of aerosols and their projected impacts as a result of several major field studies, which include the Indian Ocean Experiment (INDOEX) (Rasch, Collins, and Eaton 2001), the Arabian Sea Monsoon Experiment (ARMEX) (Moorthy, Suresh Babu, and Satheesh 2005), periodic observations carried out in the Bay of Bengal, and the recently concluded Gangetic Valley Experiment (GVAX). Some of the main findings from the INDOEX were the significant role of the Indian subcontinent in the circulation of anthropogenic aerosols from the landmass to adjacent oceanic areas (Reddy et al. 2004). The results from this experiment also revealed the growing impact of increased levels of aerosols on precipitation patterns across the subcontinent (Satheesh and Ramanathan 2000). The spatial patterns indicate a high concentration in the Gangetic basin, raising concerns about aerosol impacts on both social and physical processes (Kaufman, Tanré, and Boucher 2002), seasonal temperatures (Sen Roy, 2008), and the monsoon precipitation (Lau and Kim, 2006). Specifically, an increased loading of absorbing aerosols over the Indo-Gangetic Plain during the premonsoon season is directly related to the increased heating of the upper troposphere. This results in the formation of a warm-core upper level anticyclone over the Tibetan Plateau in April to May, which leads to increased rainfall over the Indian subcontinent (Lau and Kim, 2006). In another study, by Meehl, Arblaster, and Collins (2008), the role of black carbon aerosols in decreasing precipitation trends over parts of India was revealed.

In conclusion, it is evident that the monsoonal rainfall, which is extremely critical for this region, has significant spatial and temporal variations that are the focus of ongoing research studies. The role of processes at the global scale and processes related to global climate change need to be taken into consideration for the full understanding and accurate forecasting of monsoon in the subcontinent.

Moral geography

Philippa Williams
Queen Mary University of London, UK

Moral geography concerns the relationship between geography and moral philosophy. It is about the intersections between morality, space, and power within both the human and the nonhuman, and the material and the symbolic, dimensions of life. Some would say that it is the idea that people, things, and practices belong in certain spaces, places, and landscapes and not in others. To appreciate the meaning of moral geography, it is important to outline its key concepts. The idea of morality refers to the prevailing understanding by which things are judged to be right or wrong in an absolute sense, or better or worse in a relative sense. Such ideas often underpin the values by which individuals, institutions, or communities judge principles or standards in behavior, as well as what are understood to be important aspects of life. This capacity to reflect on and to reason about normative values, about how things should or ought to be, which things are good or bad, and which actions are right or wrong is what distinguishes humankind from other creatures. This practice of reflecting on such moral questions is also referred to as ethics, and forms a part of moral geography. Geographers, unlike moral philosophers, are less preoccupied with understanding whether something is judged to be right or wrong, moral or immoral, and more concerned with the ways in which moral meaning and value become produced and reproduced in particular places and articulated through space and time.

Moral geography therefore involves uncovering the social and spatial politics of morality, interpreting how moral meaning is infused with practices of power, and examining the implications of this reality for different people and different environments, both today and in the past. Moral geography connects to both the realities that geographers seek to know (ontology) and the way that geographers go about acquiring that knowledge (epistemology). And it concerns both the descriptive content of geography, as well as the actions of geographers, as researchers, practitioners, and teachers. Academics and students of geography often celebrate the discipline’s potential to change the world for the better, but, it is important to recognize that the meaning of “better” is highly subjective and depends on normative values produced through society. What is better for some people may not be better for others. Acknowledging the ways in which moral values or norms suffuse all research, practice, and teaching is therefore of paramount concern for all geographers.

Geography and the “moral turn”

The shift toward applying a “moral lens” (Philo 1991) within geography should be understood in the context of the “normative turn” in social theory, and geographers’ response to empirical realities during the 1970s and 1980s. During the “quantitative revolution” of the 1960s, the dominant way of seeing and understanding the world in social science was through a positivist lens that clearly demarcated the factual from the nonfactual, and rested on the capacity to determine the “truth” through a quantitative,
MORAL GEOGRAPHY

often technological, approach to social matters. The 1970s was a period shaped by the specter of poverty and uneven development, and not just for the “third world.” Notions of difference and identity, in particular race and gender, were becoming prominent political issues alongside growing concerns about an environmental crisis caused by rising pollution and the depletion of resources in the name of economic growth. These concerns underpinned a growing moral crisis that provoked a normative reaction in radical geography for greater social relevance within the discipline. Geographers began to place increasing emphasis on the ways in which social meanings and categories come to take on the appearance of truth or objectivity.

Although geographers already had deep attachments to topics charged with moral meaning, such as race, ethnicity, gender, and sexuality, the ethical or moral import of this work had not been the primary intellectual focus. This changed in the early to mid-1990s when the discipline underwent a moral turn that was reflected in the tabling of conference panels in the United Kingdom and the United States with explicit links between geography and ethics, such as the panel on “A/moral geographies” at the 1995 IBG–RGS conference, as well as the establishment of a new journal Ethics, Place & Environment. This intellectual shift was further augmented by the publications of geographers such as Sack (1997), Smith (1997), and Proctor (1998) whose work developed more explicit dialogues with moral philosophy and ethics in order to advance critical perspectives on the ways in which the spatial is implicated with moral meaning, such as justice, fairness, and difference.

These geographers engaged with different dimensions of moral philosophy such as metaethics, descriptive ethics, and normative ethics to inform their approaches to moral geography, and these continue to represent an important framework for understanding moral geography today. First, metaethics involves the big questions about what it means to think or do ethics. This is a hugely varied and contested area within moral philosophy but one that prompts important questions for geographers about the potential to accept the universality of certain grand moral values, and to recognize the spatial (and temporal) particularity of their application. Proctor (1998), for instance, distinguished between a “thin,” minimalist, or universal morality, captured by such grand values as justice and truth, and a “thick,” particular, or local morality that is culturally sensitive and situated. Drawing on this work, Smith argued that the task of the geographer is to “examine the contextual thickening of moral concepts in the particular (local) circumstances” of contrasting human contexts (1997, 587). Second, descriptive ethics identifies actual moral beliefs and practices and, as such, constitutes one of the most productive avenues for geographical research into spatial and social patterns and relations that invite a “moral reading” (Smith 1997, 587). In the context of geography’s rediscovery of the importance of context to geographical enquiry, Philo (1991, 19) proposes that an understanding of local culture alerts us to the geography of everyday moralities “which ‘glue’ together the assumptions and arguments of particular peoples in particular places.” And, third, normative ethics concerns the study of ethical action: how one ought to act. This prescriptive aspect of moral geography underpins concerns that geographers have a moral obligation to improve the world, and to effect positive change; some go so far as to say that geography should be a moralizing force within school and higher education. At a conference in 1990 on social and cultural geography Philo presented the case for geographers to consider the moral positions that they and other people take in and toward their lives without
becoming moralizers themselves. His views echo those of other scholars who caution that all geography is underpinned by certain norms and values that may not be universally constructive.

While moral issues were not entirely new to geographers, the moral turn did represent a shift toward a more coherent and visible relationship between geography and moral philosophy within the discipline. This agenda revolved around two key axes, first, geographers’ commitment to examining morality—the “geographies of morality”—and, second, the recognition that there are also ethical and moral dimensions to these geographies—the “moralties of geography.”

Places, spaces, and scales of moral geographies

The topic of moral geography has implications across the discipline of human geography and has developed significantly since the moral turn, reflecting changes within the discipline as well as responses to global experiences and transformations that have prompted new ethical questions concerning justice, equality, and power. It is possible to identify three key interlocking threads of inquiry that have attracted significant geographical attention.

The first of these concerns the application of a moral lens to questions of development, justice, and difference. Early precedents of work in this area include the place of justice and the spatial in urban and regional planning, as well as the relationship between people, nature, and matters of social justice in the city. As a key architect of the moral turn, David Smith (2000) built on these studies and directly applied questions of morality, ethics, and geography to understand how notions of difference and social justice were differentially experienced in contrasting places. Focusing on South Africa after apartheid, the changing moral landscape of an East European city, and conflict over land and settlement in Israel/Palestine he showed how such divisive histories and contested presents fundamentally shape human experience. This scholarship emphasized the significance of context for understanding morality and recognized that different places inform different moral geographies. It also highlighted the importance of applying a geographical lens to these questions.

Geographers’ engagement with notions of justice and the city have transformed over time. Scholars have shown how the focus has shifted beyond conceptions of wealth and poverty to more explicit concerns about difference. Second, geographers have become increasingly concerned with the value of identifying and constructing normative agendas for justice and with questioning the extent to which this is productive for challenging specific injustices. Third, there is growing debate around the ontological status of the spatial where some scholars see the spatial as a derivative of the social. More generally, it is interesting to note that geographers have typically documented instances of injustices rather than searching for examples of where justice is being realized.

Other scholars have considered ethics in development geography to debate whether, and in what ways, people in more privileged locations should intervene in the lives of less privileged people elsewhere. Shifting geopolitical relations underpinned by the rise of Brazil, Russia, India, and China have challenged US hegemony and prompted scholars to examine how different norms underpin different development partnerships. For instance geographers have examined the ways that North–South aid is often portrayed as unreciprocated charity to those less fortunate, whereas a positive moral tone of reciprocity is attached to development aid transacted between South–South partners. In the field of geopolitics scholars have also taken issue with the ways that geopolitical analysis has perhaps unwittingly
been infused with normative moral judgments concerning the “just” war, even while geopolitics itself eschews the adoption of normative political positions. The contention of some is that geopolitics has failed to imagine nonviolent alternatives and consequently needs to demonstrate greater reflexivity concerning the normative reasonings that underpin its analysis of war. As a result, the impact of geography on debates concerning military intervention outside of the discipline is arguably limited.

In other areas, the economic expediency of moral values such as justice, equity, and fairness has not been lost on scholars. A number of geographers have pointed to the political work done by certain value agendas and how these have become standardized in the neoliberal market economy. One example of these value agendas pertains to fairtrade, which was established on an ethic of care to alleviate poverty and economic injustice through a market-based form of solidarity exchange, but in reality these objectives are rarely realized on the ground. Scholars have revealed how the ideological power of fairtrade’s moral claims lies in the normalizing agenda of neoliberalism that obscures the unequal practices of power that sustain its existence and makes it both apolitical and irrefutable.

The second strand of geographical inquiry is linked to the notions of difference and justice, and concerns the complex relationship between distance, care, and responsibility. David Smith (2000) critiqued earlier calls by geographers to transcend local particularism in favor of universal values, and instead highlighted the productive tension in seeing moral universalisms and particular moralities together. This revised approach ultimately shifted the scale and scope of moral inquiry and action, and prompted geographers to re-evaluate perspectives with respect to ideas about “care at a distance” and “geographies of responsibility.” The question that animates geographical approaches concerns how attention to ethics can motivate a sense of responsibility toward different and distant others, as well as toward the people with whom we have more intimate and everyday encounters. Jeff Popke (2006) recognizes two responses to this position, first by linking care to more or less universal notions of justice against which acts of judgments can be made. In this context, responsibility toward others is ensured through collective rules, policies, and practices that embody and nurture an ethic of care. A second response emphasizes care as a fundamental activity of humanity and locates responsibility in the recognition of our intersubjective being. Scholars have turned their attention toward ethical consumption, which can be conceptualized as an act that links local practice with care at a distance, and embodies a form of ordinary or everyday ethics.

In her work on the geographies of responsibility Doreen Massey (2004) proposes that we need to go beyond the local and the politics of propinquity to think seriously about how our lives and actions are connected to and have implications for faraway places, and vice versa. She urges us to understand distant space in the same way that we think about distant time or “the past,” and therefore as something that is intrinsic in the present, and so too in place. As she argues, “we are responsible to areas beyond the bounds of place not because of what we have done, but because of what we are” (Massey 2004, 16). Other scholars have drawn on Kant’s notion of the perpetual peace and the imperative that we tolerate one another as neighbors to stress the spatially extensive sense of our responsibility toward others, our cosmopolitan responsibility. This political and ethical stance is particularly important with respect to an increasingly urban world that augments the thrown-togetherness of people, a world patterned by migration that demands certain forms of hospitality and the
legacy of postcolonial difference. Within these contexts the ethical imperative for dialogue, negotiation, and openness to and with the other are argued to be paramount.

The third strand of moral geography concerns “moral landscapes” and relates to the ways in which particular spaces and their social relations become imagined and organized in conjunction with moral meanings and values. This area of study owes much of its intellectual inheritance to an article by Driver (1988) on social science and the urban environment. Through an analysis of sanitary science, moral statistics, and medical geography, Driver pointed to the inherent moral concerns of human and social sciences, and proposed that, rather than simply reflecting patterns of urbanization, social science is in itself a moralizing force for the organization of space and society. Another important dimension concerns how landscape becomes linked to ideas about morality and how schemes of moral value are located in particular environments. Scholars had examined how space and society are organized to reveal the hierarchical constructions of “moral order” in the city that excludes morally marginal communities, the lower economic classes, and areas beyond the reach of economic planning. Largely focusing on urban and nineteenth-century concerns, historical geographers have explored a wide range of subjects from the moral locations of soldiers and sailors in nineteenth-century Portsmouth and mid-nineteenth-century New York fashions to attempts to regulate gender and consumption, alcohol, and prostitution in different sites. Other geographers have shown how rurality can be a repository of moral values and normative assumptions, and mark the people who live there as well as their dispositions toward life. David Matless (1997) has explored how visions of the English landscape promote various forms of order in contrast to disorderly characteristics associated with “untidiness” or “bungalows” that are simultaneously connected to appropriate forms of behavior and ultimately to national identity and citizenship. Meanwhile Duncan and Duncan (2003) show how aesthetics in an American suburb inform “landscapes of privilege” that constitute identities and promote patterns of distinction and exclusion.

Further developing this understanding of sociospatial inclusion and exclusion, scholars have shown how certain people are marked or stigmatized as outsiders deemed to be “out of place” because they do not conform to expectations about what the norm is. Geographers have examined these kinds of processes and their implications for different groups of outsiders, notably mad people, political protestors, non-white people, those who are homeless, deviant, or disabled, and homosexuals, among others. More recently geographers have focused on the moral dimensions of social encounters in our everyday lives to explore the moral evaluations we make about others concerning their social, economic, and cultural worth and how these give rise to different forms of class-based prejudice. This analysis shows the ways that poverty is deemed to be a personal moral failing rather than an intrinsic part of capitalism. Some have argued that, in the contemporary context of superdiversity and supermobility, this kind of prejudicial behavior is structured by a hegemonic ethic of individual self-interest that threatens the existence of socialized processes such as care, compassion, and responsibility.

Practicing moral geography

As well as applying a moral lens to geographical issues, a number of geographers have also highlighted the importance of both employing professional ethics during the research process and
teaching about ethical actions through geography education. Many argue that human geography, and its concern for the interactions between people and their relationship with the environment, is well placed to instruct students about their moral accountability as responsible citizens.

As Sack (1997) has argued, geography is now a discipline oriented toward improving the lives of others rather than in terms of self-interest or traditional practices. As such, he cautions that research should not be exploitative but should make a practical contribution to the lives of the people being studied. Others contend that geography should go further than simply “doing no harm” and instead actively contest hierarchies of power and enact transformative practices. Indeed, there is a rich history of social activism in geography motivated by an ethical commitment to make a difference or achieve social change; however, Cloke has expressed a degree of skepticism about the level of actual transformations and practical action that is realized by geographers, for, “whilst it is easy to think and write about ethical and moral issues, it is much more difficult to actually do something about acts of injustice in our everyday lives” (2002, 587). Cloke suggests that geographers are adept at recognizing difference and differentiating processes, but are less well equipped with the imaginative and practical guidelines required to address inequalities.

In his own research career Cloke has worked closely with homeless people and associated organizations, in both intellectual and practical capacities, and urges other scholars to forge stronger connections between their academic and nonacademic lives. It is becoming increasingly difficult, however, for scholars to live ethically and to act politically in the context of a neoliberal university system that increasingly values scholarly activity in terms of research output and funding grant incomes. Some scholars are finding ways to create opportunities within this environment, aligning their intellectual, political, and ethical commitments.

In order to act politically and effect change, geographers have been encouraged to identify appropriate ethical and political practices among the issues they study and to propose normative orientations. Some scholars have hesitated at the notion that geographers should be proposing their own moralizing frameworks, while others argue that geography has not done enough to inform political and moral philosophy and to shape notions of universal practice. The role of geography in documenting everyday moralities and proposing normative moralities is therefore contested.

Beyond the moral turn

Recent geographical debates about morality have turned inward, to reflect on how geographical scholarship deals with moral concerns and to consider the implications of particular normative assumptions for the production of geographical knowledge and understanding. Barnett and Land (2007) highlight the value of scholarship concerning care at a distance and geographies of responsibility. However, they take issue with the assumptions that underpin this work, in which placed-based local relationships are prioritized as the sites in and through which care happens and knowledge is produced, whereas caring at a distance is more problematic. Barnett and Land reorient these normative positions and suggest that people are already motivated to care by all kinds of factors, and that more knowledge does not necessarily drive responsible actions but can also create feelings of powerlessness. Instead, they propose generosity as a political concept that can help to challenge these assumptions about how we relate to others and expand a view around how responsible actions are both received and
responded to. In response to these ideas, scholars have suggested the need for a metaethical approach that brings together a theory of justice and virtue ethics.

In a series of reports for *Progress in Human Geography*, Barnett (2011, 2012) returns to contemporary moral and political philosophy to critically evaluate the relationship of geographical approaches to normative concepts, including justice, reason, and worth. He is concerned that a good deal of debate in geography has involved whether it is possible to develop normative foundations for critique, and yet contemporary moral and political philosophy has shifted toward more pragmatic, intuitive, and socialized understandings of ethics and practical reason. In line with this approach, Barnett proposes that theorizing justice, for instance, demands a more expansive approach that recognizes the situated and relative experiences of justice or injustice, rather than be constrained by the search for an absolute notion of the term. This approach might also encompass the importance of feelings about justice and injustice and turn attention to an emotional geography of justice. Meanwhile, other scholars have cautioned against seeing situated interpretations of justice as entirely independent of broader theoretical constructions of the concept, and emphasize the need for a dialogical understanding of justice.

More generally, Barnett has proposed that geographers would do well to rethink their disposition toward normativity. Moral geography’s concern has revolved around two axes – proposing normative moralities and charting everyday moralities; both approaches reflect a degree of skepticism about the degree to which normativity structures everyday life and the destructive role of power. And yet, Barnett contends, if we learn from shifting interests in moral philosophy, it may be possible to go beyond an excessively cynical view of the social as regulated by power, and instead expand our perspectives about why things matter to people, the nature of worth, and ultimately a broader view of the normative dimensions of social life in ordinary, routine, and practical ways.

MORAL GEOGRAPHY

Mortality

James A. Tyner

Kent State University, USA

Mortality is commonly understood as the state or condition of being dead. So defined, the term acquires a particularly biological – and individual – quality. Mortality is what happens when a living organism, say a man or woman, dies. In actuality, though, mortality is a much more complex concept in that many political, economic, and cultural practices pivot on the conceptualization of death. Indeed, as Todd May (2009) explains, from an anthropocentric viewpoint, the fact that we die is the most important fact about us. Not only does death negate our mortal, material existence, the awareness of this inevitability is profound. For accompanying the inevitability of death – of our own mortality, as well as that of all other living creatures – is the uncertainty of death. We know that death will arrive; we just do not know when. Together, the inevitability and uncertainty of death has generated much scholarship toward the study and objectification of mortality.

Our understanding of death is far from simple. In many societies, throughout time, death has been understood as the termination of vital signs: the beating of the heart, the cessation of breathing. Ultimately, and most clearly, death was marked by the decomposition of the corporeal body. With advances in science and medical knowledge, however, the clear-cut separation between “life” and “death” has become blurred. This is more visible in the case of “brain death.” Beginning in the 1950s, but especially following a seminal report prepared by an ad hoc committee at the Harvard Medical School, the concept of brain death, and of a patient being brain dead, became established. This singular concept has arguably transformed our understanding of mortality more than any other development.

Prior to the twentieth century, when a person’s heart stopped or he/she stopped breathing, death was all but inevitable. With the advent of techniques for artificial respiration, coupled with advances in resuscitation techniques (e.g., cardiopulmonary resuscitation, CPR), death could be (temporarily) prevented. Later, with the development of “iron lungs” and the successful transplant of organs, death was once again delayed. The concept of “brain death,” however, and the attendant condition of being brain dead, changed forever how life and death were to be understood. Of fundamental importance is the fact that death has in some situations become relational. Whereas CPR is a practice conducted on one body, with the intent of saving that body’s life, the practice of organ transplantation is dependent upon two bodies: the organ “donor” and the organ “recipient.” This co-relational condition of life and death created a “demand” for organs – but also the necessity for a class of corporeal bodies that would occupy a threshold between “life and death.”

Biomedical advances made heart, lung, and kidney transplants (among others) possible. However, a major cause of failure in organ transplants was the use of cadaver organs that had deteriorated during or after the conventional death of the organ donor – waiting too long for a donor to die risked damaging viable, transplantable organs and thus an inability of saving the recipient-patient. For many medical
practitioners, therefore, interest was focused on those patients who were being kept alive via artificial means. The argument was that if a patient was irreversibly “dead” – meaning that he or she had suffered permanent brain damage; or was in a permanent “vegetative” state, it should be possible to retrieve those organs to save the life of another person. The concept of “brain death” subsequently entered the medico-legal lexicon and remains a contested ethical and legal minefield with a unique geography. In the United States, for example, there is no universally recognized medical consensus on the definition of brain death. Four different criteria are in use and individual states determine which criteria to follow. The result is that when someone is pronounced dead may be a function of where that person is pronounced dead.

Brain death as a concept calls attention to the fluidity to which life and death are understood and measured. There are many scientific terms and measures related to mortality. Life span, for example, refers to the oldest age to which any living organism can survive: in effect, a biological ceiling or limit to life. Biologists estimate that the life span for humans is approximately 120 years. By way of comparison, elephants are premised – under natural conditions – to live between 60 and 70 years. The qualifier “natural” is important in that it directs attention to the observation that most humans do not live to be 120; nor do most elephants live to be 70. For this reason, demographers and other social scientists refer to a concept known as “longevity,” which is the ability to remain alive from one year to the next. Longevity is expressed by a measurement known as “life expectancy” – the statistical average length of life. Currently in the United States of America, for example, the life expectancy of females is 81 years while that of males is 76; this compares to Somalia, where the life expectancy of females is 56 and that of males is only 53.

Differences in mortality, as indicated by life expectancy, are explained in part by biological factors (e.g., genetics); however, most inequalities in mortality result from societal conditions, such as a lack of access to health care and adequate nutrition. Geographic variability of observed and documented patterns of mortality, in other words, reflects unequal opportunities for life. Men and women, on average, live longer in the United States than their counterparts in Somalia not because of inherent or essential biological differences but rather because of deeper structural conditions that result in disproportionately higher rates of mortality in the latter.

The existence of inequalities in mortality has prompted geographers and other social scientists to confront “premature death” as an indicator of social injustice. Ruth Gilmore (2002), for example, argues that the cause of premature death is an application of violence. The salience of Gilmore’s argument is that it places the study of mortality squarely within the growing body of scholarship on violence (Tyner 2012). Here the purpose is to identify the direct and indirect causes and conditions – the myriad forms of violence – that result in death. It is common, for example, to distinguish between “direct” forms of violence and “structural” forms of violence. The former refers to interpersonal actions, such as hitting, stabbing, or shooting whereas the latter includes those actions (or inactions) where there is no identifiable actor. Poverty and malnutrition are considered forms of structural violence; mortality subsequently results from indirect conditions that may not be linked to any particular individual.

Recent scholarship has blurred the distinction between direct and structural violence; many alternative concepts and theories have been forwarded, including institutional violence, administrative violence, cultural violence, epistemic violence, and so on. Of note is that most conventional studies of mortality continue
to focus primarily on “direct” violence (e.g., homicide), secondarily on “structural” violence (e.g., famine); decidedly little on mortality has engaged in the broader debates on what exactly is captured by the term “violence.”

Beyond directing attention toward violence, an engagement with premature death is informative for a second reason, namely the politics of vulnerability. To begin, however, it is necessary to consider more closely the conceptual origins of premature death. Prior to the eighteenth century, and notably in Western societies, the knowledge of life and death were located within the realm of cultural and religious traditions. Death was a singular “moment” that marked the passage from one form of existence (life) to another (after-life). During the Enlightenment, however, a new demographic approach to the concept of mortality emerged, a transformation that coincided with the foundation of the modern state. What emerged was a biologics, a science that positioned the knowledge of life within a broader context of statistical patterns and regularities. Significantly, premature death was conceptualized as a “preventable risk”; this risk depended on the development of new scientific techniques for measuring longevity and mortality rates and for identifying the most common causes of death (Bayatrizi 2008). Moreover, premature death was inseparable from the growing political and economic interest in the management of life and death – exemplified best by the creation of life insurance. Simply stated, underlying the biological understanding of mortality – and the myriad demographic concepts of life expectancy, life span, and other vital measures (e.g., infant mortality rates, material mortality rates) – is a form of governance that continues to inform political practice.

The governance of mortality is well-illustrated in the voluminous work being conducted in on biopolitics, necropolitics, and even security studies (Rutherford and Rutherford 2013). These bodies of scholarship direct attention to the calculated management of life and death. Crucial here are considerations of how sovereignty, the law, and violence interact in generating those structures of inequality that result in empirically observed differences in mortality. “Biosecurity,” for example, is frequently understood as the prevention or elimination of infectious diseases in crops, livestock, and humans. More recently it has been applied to encompass broader governmental mandates to protect and secure human health (Hinchliffe and Bingham 2008). According to some geographers, for example, biosecurity is emerging as a new expression of sovereignty. To this end Eugene Thacker (2005) argues that sovereignty today derives its legitimacy from its ability to continually identify potential and actual “diseases” that threaten the body-politic. And while these diseases are commonly understood in a literal fashion (e.g., influenza, HIV/AIDS), it is important to note that biosecurity threats assumed – or, more properly, are constructed as – many different forms. Both obesity and aging, for example, have emerged as biopolitical threats that are presumed to jeopardize the national security and financial solvency of states. Here, both corporeal conditions – of excess weight and excess age – are premised by some pundits as contributing to a drain on the costs of health care with vastly different endpoints. Obesity, as a case in point, is framed as personal failure; but a failure that threatens to bankrupt the nation. From this position, premature death – which is held to be preventable through exercise and diet – is viewed not as an indicator of violence but rather as an indicator of a private failure to prevent one’s own death.

A biopolitics of mortality would appear to take us far afield from the realm of the biologic. In fact, recent scholarship indicates not a separation but rather a greater elision between the two.
MORTALITY

Consider the truism that – regardless of governmental intervention and prevention – all living organisms will die. Expanding on this idea, Judith Butler (2004) posits mortality as an equalizing possibility, one that hinges on the distinction between what she terms “precariousness” and “precarity.” Given that all humans, regardless of gender or sexual orientation, ethnicity or nationality, must at some point die, mortality holds the potential to create a shared morality. Recognition of mortality, Butler premises, constitutes an appreciation of “precariousness”; a form of corporeal vulnerability in which the fragility of life is shared by all mortals – including the privileged. As the empirical accounting of mortality, that is, differences in life expectancy, indicates, however, not all humans are equally vulnerable. In opposition to precariousness is the concept of precarity – the particular vulnerability imposed on the poor and disenfranchised: those living bodies endangered by war, natural disaster, and poverty – in short, the many structures of violence that unevenly affect life. Butler (2004) maintains that we are all subject to potential precarity through our common precariousness. In making this controversial argument, Butler effectively re-centers mortality into the political-economic realm and views our shared mortality as a path toward the promotion of a more socially just society.

While Butler’s optimism is perhaps debatable, the awareness of the finitude of death has contributed to a widespread engagement by geographers, anthropologists, sociologists, and other social scientists on the cultural meanings of mortality (May 2009). This research highlights that the fear of death and the awareness of mortality significantly inform the organization of all societies. Zygmunt Bauman (1992) explains that the fact of human mortality and the necessity to live with the constant awareness of that fact go a long way toward accounting for how societies interact. Geographers, for example, have long engaged in the study of “mortal geographies” – of how different cultures remember the dead. This is seen in the numerous studies that have documented the location, distribution, and cultural significance of cemeteries and other deathscapes (Maddrell and Sidaway 2010). This research has highlighted, among other aspects, the significance of “death” for the living and the politics of mourning. A related body of literature has focused on the remembrance and memorialization of death. Here the emphasis is on the contested meanings of death itself. More than simply a biological indicator of death, mortality is again revealed to be a peculiarly human condition informed by cultural, political, and economic factors.

Mountain biogeography

Zehao Shen
Peking University, China

The discipline

The idea that Earth life originated from a mountain island has been in the tradition of Western culture tracing back to the Deluge. In accord with the legend from the Genesis, the greatest botanist and biogeographer before the nineteenth century, Carolus Linnaeus (1707–1778) hypothesized that Noah’s Ark landed at the Paradisical mountain – Mt. Ararat in Armenia. This mountain, with a significant elevational spectrum of climate types, harbored the animal and plant species adapted to different environments, and became the origin center of all creatures, which came down the mountain after the flooding and migrated around the Earth.

The voyages of exploration in the eighteenth century helped to establish a global perspective of modern biogeography. Covariation of climate and vegetation along elevational gradients, as well as the resemblance to the latitudinal pattern, were first elaborated by Alexander von Humboldt (1769–1859), the founder of phytogeography, after his field expedition to Mt. Chimborazo of tropical South America. In the same period, Augustine de Candolle (1778–1841) first pointed out that mountains act as one of the barriers to the migration of plants and animals, resulting in the boundaries of species ranges. Although the pioneers of this field invested their major efforts in the mountainous regions around the world, the most fascinating questions and insights in biogeography clearly came from the observations of insular biota, as did the Galapagos Archipelago for Darwin and the East Indies Archipelago for Wallace. Limited area, isolation from continents, and highly endemic biota combine to make an island (or a group of islands) a model system to all insular habitats for studying the patterns and causal factors of biodiversity, a fundamental question of not only biogeography, but ecology and evolution as well.

The equilibrium theory of island biogeography (MacArthur and Wilson 1967) provided the first theoretical model of biogeography. During the past half century, this dominant model has received hundreds of tests for the role of the spatial factors (i.e., area and distance) and processes (i.e., immigration and extinction) in the dynamics of island biodiversity. Mountains, among other locales, were taken as a typical insular context for testing MacArthur and Wilson’s theory. This is verified by the term of “sky islands” coined by Marshall (1957) to describe the mountains of southwestern North America, and its later applications to other mountains.

Although there is no such field specifically defined as “mountain biogeography” in the framework of modern biogeography, mountains are undoubtedly a special case of islands in the sense of spatial configuration, environmental pattern, and processes as well as biogeography itself. Given the equilibrium theory of island biogeography as the foremost theoretical paradigm of this discipline, the unprecedented environmental challenges in terms of climate warming, land use change, and biodiversity, conservation at global scale ask for an update of the
framework for biogeography, for which mountain biogeography seems to be an ideal candidate.

Environmental properties of mountains

Characterized by prominent topographic relief, mountains are only one type of geomorphology or terrain, however they are no doubt the hotspot of biodiversity of terrestrial ecosystems. Mountains cover about 25% global land area, while conserving 95% of vascular plant species, and 95% of bird, mammal, reptile, amphibian, and fish species (Kapos, Lysenko, and Lesslie 2000). Mountains possess distinct environmental properties that are critical in terms of biogeography.

Elevation gradient

Representing environmental variations independent of latitude, the primary biogeographical dimension, mountains are important for their elevation gradient, with the maximum of 8848 m in Mt. Everest of Himalaya, and the minimum of −392 m in the surface of the Dead Sea. Elevation gradient is accompanied by multiple environmental factors that are critical for the distribution of organisms:

Air pressure. Because of the effect of gravity, air density and also atmosphere pressure decreases as altitude increases, rapidly at first and then more slowly. Atmospheric pressure decreases roughly 50% (to around 500 mb) within the lowest 5500 m, above which, the pressure continues to decrease, at an increasingly slower rate, to about 10% (≈100 mb) at 12000 m.

Solar radiation. Reflected and absorbed by the atmosphere, solar radiation is weakened in total intensity and in the fraction of UV-B radiation, with the red/infra-red fraction increased, toward lower altitudes. But because clouds and fog often increase with altitude, there is not a consistent altitudinal pattern of solar radiation intensity or spectral composition, but a consistent global trend for maximum intensity of solar radiation and the UV-B fraction is found.

Climate gradient. The greenhouse effect of the atmosphere helps to keep a globally consistent lapse rate of temperature of about 0.6°C/100 m elevation, with regional and seasonal variability. In contrast, the altitudinal gradient of precipitation is more variable, although it generally increases (or at least keeps stable) from the lower elevations, but with the maximum precipitation height sometimes occurring at mid-elevation. Mountains as a whole are less windy on average, owing to the topographic shelter between or within mountain ranges, except for exposed crests, summits, and island mountains. Altitudinal climate gradient is often treated as an analog of the latitudinal gradient, although it is unique with regard to the latitude-related daily and seasonal cycles of climatic dynamics, and the 1000 times spatially compressed results compared with the latitudinal gradients.

Area distribution. The surface (or horizontally projected) area of altitudinal zones have a variable elevational gradient, depending on the relief and shape of the specific mountain.

Mass elevation effect

Mass elevation effect (or Massenerhebung effect) describes variation in the tree line (or other temperature-based biogeographical boundaries) based on mountain size and location. In general, mountains surrounded by large ranges will tend to have higher tree lines than more isolated mountains, due to heat retention and wind shadowing. This effect was first pointed out by A. de Quervain who found the treeline or snowline occurs at higher elevation at the central part of the Alps than at the outer margins.
Topographic variations

Dominated by geological structure and bed rock type but also reshaped by the climate, highly variable mountain physiography reveals heterogeneous environments at multiple spatiotemporal scales and dimensions, and provides habitat diversity for the organisms, in terms of solar radiation, soil moisture, wind velocity, snow accumulation, and so on. On the other hand, slope steepness acts as a primary driver of geomorphological and hydrological processes, regulates the pattern and dynamics of surface disturbance, as well as mountain landscape evolution.

Elevational geometric constraint

Measured by altitude, the range of mountain has geometric constraints on both ends of the elevation range, especially for the isolated mountains. Area decreases with elevation, and the upper end of mountains always means a hard boundary for distribution of the species.

Spatial isolation and connectivity

The spatial isolation within and between mountain ranges is ubiquitous. However, as the mountain bottoms are connected via lowland terrestrial ecosystems rather than water as in a real insular context, the media for terrestrial organisms should be much more permeable between the sky islands than water surrounding an archipelago.

Mountain uplift and evolution

Mountains (and mountain islands) have life cycles that are jointly determined by the agents of both the geosphere and atmosphere. On the one hand, inner-Earth energy uplifts mountains through the geological processes folding, faulting, and volcanisms. On the other hand, mountains are continuously worn by gravity-driven erosion. The height and configuration of a mountain, its area and elevation gradients, are the dynamic output of these interactive processes.

Patterns of mountain biogeography

Attitudinal zonation of vegetation and ecotone (treeline) dynamics

Zonation of altitudinal vegetation spectrum is a basic and prominent pattern of mountain biogeography, dominated by the compressed climatic gradient along the elevation. As first uncovered by von Humboldt, altitudinal vegetation zonation, including the type composition, altitudinal limit, environmental determinants, regional variation of mountains, as well as the global pattern of the altitudinal vegetation spectrums have been a fundamental part of mountain biogeography. The climatic determinants of altitudinal distribution of vegetation zones, as well as the response of vegetation types, particularly the vegetation boundaries (e.g., treeline) to climate change, have always been a contentious topic in mountain biogeography.

Elevational distribution of species and species richness

Although species distributions respond to climate gradients in an individualistic manner, at least two macro-ecological patterns reveal the holistic aspect of the response. First is the altitudinal vegetation zonation with significant boundaries (e.g., treeline) as indicators. Second, a consistent pattern, Rapoport’s rule, is speculated to regulate the altitudinal distributions of organisms, that is, species elevational ranges increase along with elevation itself (Stevens 1992).
The altitudinal pattern of species diversity, analogous to the latitudinal pattern, has been a core question of biogeography. After a half-century of study, four altitudinal patterns of species richness have been summarized, that is, decreasing, platform plus decreasing, hump-shaped, or insignificant (Rahbek 1995). The occurrence of a particular pattern and the contribution of the underlying mechanisms are still in discussion, based on mounting empirical and theoretical studies.

Species range disjunction, fragmentation, and endemism

Fragmentation within a mountain and disjunction within mountain ranges are normal patterns of intraspecific population distribution, providing higher probability of speciation. Endemism – restricted species distribution – is more common in mountainous regions than other areas, even though a general model for the elevational pattern of endemism is still elusive. The elevational pattern of endemism is generally different from that of species richness. However, in the insular environment, the rate of endemism tends to increase along the elevation gradient (Steinbauer et al. 2012).

Roles of mountains on species distribution and biodiversity

In the framework of island biogeography, species diversity in an insular environment is the sum of three processes: immigration, extinction, and speciation. These processes occur in ecological or evolutionary time scales and are affected by factors of these two categories, respectively. Contemporary mechanisms involve those factors hypothesized to play a role in the ecological time scale, while historical mechanisms are speculated to affect at evolutionary time scale and have cumulative impacts, through the interaction of three basic biogeographic processes.

Contemporary mechanisms

Climate limit on species distribution. The niche concept holds that each species occupies a preferred position and range width along the altitudinal gradient, regulated by the altitudinal climate gradient. Three basic hypotheses exist about the climatic constraint on species distribution: (i) productivity regulated by the combination of energy and water supply; (ii) ambient energy as a constraint on the rate of metabolic activity, generation duration, as well as genetic mutation probability; (iii) extreme low temperature limit and the distribution of different freezing tolerances. In the accumulated studies on the altitudinal pattern of species richness, climatic factors are able to account for more than 60% of variation in general.
