In a thirty-year period from 1974–2004, the Sierra de Guadarrama mountain range in central Spain has had a mean annual temperature rise of 1.3 °C, which has increased the lower elevational limits of 16 species of butterflies an average of 212 m. A study of Costa Rican cloud forests suggests that anthropogenic warming has elevated the cloud heights reducing moisture from cloud contact. Many plants and animals are dependent on these moisture inputs and with its decline, changes have occurred in both distribution and abundance of these species.

A meta-analysis of numerous animal taxa from Europe, North America, and South America found a median rate of poleward migration of 16.9 km/decade (Chen et al. 2011). In a study of 166 global latitudinal treeline sites, 52% experienced poleward advancement since 1900 (only 1% exhibited recession); with the probable cause linked to local winter warming. Saplings of tree species preferring higher temperatures have, over the past century, begun to germinate 50–300 km northward in northern Sweden.

A survey of more than 100 bird ranges in the United Kingdom found that from 1968 to 1991 the bird’s northern range margins shifted an average of 18.9 km. In 35 years, the sachem skipper butterfly (Atalopedes campestris) has expanded its northern boundary hundreds of kilometers from California into Washington State (Crozier 2003). The change in distribution corresponds with an increase of 2–4 °C over a 50-year period, and the butterfly’s persistence in these new areas is possible due to the warmer winters at the northern edge of their margins. A study of British dragonflies and damselflies found that all 37 nonmigrating species exhibited northward range shifts, attributable to a warming climate, from 1960 to 1995; the mean northward shift was 74 km.

While examples of poleward limits shifting to higher latitudes are common, there is much less evidence that low-latitude limits are changing due to anthropogenic climate change, particularly for woody species. Finally, it must be noted that globally elevational and latitudinal range shifts are variable, about one quarter of species analyzed moved downslope or toward lower latitudes.

General patterns

The impact of climate change on terrestrial ecosystems may encompass considerable
geographic variability. Projections of anthropogenic climate change generally suggest that warming will be greatest at higher latitudes. However, analyses of global data sets of insects, birds, frogs, lizards, and turtles suggest that future species extinction risk is greatest in tropical ecosystems. Tropical species typically have narrow thermal tolerances compared to higher latitude insects and vertebrates which have broad thermal tolerance and often are living in environments below their physiological optima, so warming may enhance their fitness.

Marine environments are also being altered as a result of a changing climate. Rising levels of atmospheric CO₂ absorbed by the oceans increases acidification which impedes marine animals from producing calcareous skeletal structures, and may directly impact the food web and species distributions. Water temperature increases of 0.79 °C between 1931 and 1996 in Monterey Bay, California led to increased abundance of invertebrate species from southern areas and decreased abundance of species from northern areas. In the North Sea, where water temperatures have risen 0.6 °C from 1962 to 2001 there have been detectable impacts to the distribution of bottom dwelling fish due to climate change. Roughly two thirds of the species exhibited a northward shift in mean latitude, and further temperature changes may influence community interactions and effect commercial fisheries in the region.

Rising sea temperatures can cause bleaching of coral reefs and frequent or severe occurrences may impact their survival at large geographic scales. Fossil records indicate that reef-building corals were once present at higher latitudes during warmer periods, and then retreated equatorward as temperatures cooled. Following this trend, a northern range expansion into the northern Gulf of Mexico and along the Florida Peninsula has been documented for two species of reef-building coral, coinciding with climatic warming and increased sea-surface temperatures. However, there is no clear evidence that the world’s coral reefs can adapt to moderate future warming. Coral reef communities may experience a number of changes; increased mortality may reduce the age structure, more tolerant coral species may replace those more sensitive to environmental stress, and coral species may be replaced completely by other groups of organisms as coral communities are unable to keep pace with projected warming.

An earlier breakup of sea ice on western Hudson Bay in Canada has been correlated with rising spring air temperatures from 1950–1990. Polar bears living at their southern range boundary in this area have demonstrated a decline in their mean body weight, as well as their population numbers. These animals hunt from the ice shelves, and as the lengthening of ice-free periods on Hudson Bay causes their feeding grounds to disappear, they are forced to live off their reserves. If these conditions persist, it is possible that the bears will move into areas of human habitation, threatening human life and property.

Multiple factors may alter species distributions in polar regions. Warming temperatures at these higher latitudes may raise soil and permafrost temperatures as seen in Alaska in the late 1980s to early 1990s, which has the potential to dramatically alter or even destroy the ecosystem as a whole. Evidence seen in northern Canada and Alaska as well as parts of Russia show that shrubs have been expanding into areas of tundra, coinciding with three decades of rising temperatures. Much of the warming has occurred during the winter months and has created a positive feedback loop, as shrubs trap and hold snow to insulate the soil. An increase in microbial activity and plant-available nitrogen allows for increased shrub establishment and growth, which may
impact animals such as caribou, which prefer tundra species.

Although accessibility in Antarctica still limits the locations and organisms selected for investigation, the establishment of research stations in the late 1950s and satellite imagery have greatly increased information available from this important area. Trends found in 244 marine glaciers on the Antarctic Peninsula show that 87% have retreated southward toward the pole and the pattern is comparable with warming temperatures in the region and it appears that the most significant changes are taking place along the coast. Penguin species in the Antarctic have been impacted due to changes in climate conditions. Adélie penguins are found throughout the Antarctic and have appeared and disappeared throughout the paleocological record in response to changing ice cover. Regional warming has reduced the extent of sea ice, thus limiting the wintering habitats for individuals on the Antarctic Peninsula. In contrast, Gentoo penguins generally establish in ice-free areas and are able to expand their breeding ranges as the changes in climate reduce the extent of sea ice and provide more suitable habitats.

On the western side of the Antarctic Peninsula, there has been a decline in krill stocks, which depend on the sea ice to breed successfully. These shrimp-like crustaceans serve as a primary food source for many species in the area and feed on phytoplankton, a community that is also changing as the diatoms are being replaced by less mineral-rich cryptophytes as their regional habitat changes. These changes may alter the food web and impact the species that are able to inhabit the area. Anticipated results of climate change in Antarctica will most likely encourage the establishment of new taxa to the region and increase their chances for survival by providing more favorable environmental conditions; however, they may also provide direct competition to local species already living at the edge of their physiological limits.

Finally, considerable uncertainty surrounds biological responses to climate change at the community level. As numerous studies have shown there is a common directional pattern in plant and animal taxa response to recent changes. However, given the complex interactions (e.g., predator–prey, plant–pollinator, etc.) that occur between species, it might be difficult to predict future ecosystem trajectories.

**Biogeography and climate change: models**

Given the numerous and growing documented cases of species range shifts over the past several decades biogeographers and ecologists have applied a long-standing interest in understanding the distribution of species toward predicting how species’ ranges might shift under future climate change. Looking to the next century, modeled climate change scenarios predict that global mean surface temperatures may increase 1.4°C to 5.8°C, a more rapid rate than the gradual warming at the end of the last glacial period, which took place over a period of 5000 years (IPCC 2007). Precipitation contrasts will likely continue to increase between wet and dry season and among regions. While global average temperatures are modeled to increase, the average values mask considerable geographic variation. Generally, temperature increases are most likely to be greatest in high northern latitudes, particularly in the winter months. Although tropical regions are modeled to see smaller increases in air temperature, the tropics are most likely to experience novel climates (lacking modern analogs). Since most ecological models are based on modern observations, predicting ecological responses to these no-analog climates might be challenging.
In recent decades biogeographers have used quantitative models to predict vegetation patterns under modeled future climate change conditions. The models fall into two broad classes: vegetation-type models (dynamic global vegetation models) and species-specific models. The vegetation-type models operate at the global scale and generalize vegetation into plant functional types or biome type, not focusing on single species or their individual range shifts. The species-specific models focus on individual species. The species-specific models are best divided into two broad categories: correlational (empirical) models and mechanistic (processed-based) models. Recently, several researchers have advocated a hybrid (combined) approach which incorporates the strengths of the correlational and mechanistic models.

**Dynamic global vegetation models**

Static global biome models were initially developed to model global vegetation distribution patterns under constant climate conditions based on eco-physiological constraints and resources limitations. The dynamic global vegetation models (DGVMs) are a natural extension of these in that they can be used to predict the dominance of plant life forms (or plant functional types) at large spatial scales under changing climate conditions over decades to centuries. These complex models typically incorporate vegetation dynamics (e.g., nutrient cycling, competition, disturbance), soil-vegetation-atmosphere transfer, biogeochemistry (e.g., canopy physiology, soil processes), land management change, and soil conditions. In part, DGVMs are designed to track vegetation changes driven by climate variability. DGVMs have proven to be useful when modeling global scale vegetation response to modeled anthropogenic climate change because DGVM output can be coupled with general circulation model (GCM) predictions. In contrast to correlational models, DGVMs do not take into account the behavior or responses of individual species, and generally don't perform well at regional scales; rather they are designed to provide predictions at the global scale, necessarily sacrificing detail. An advantage of DGVMs is they can be applied where anthropogenic environmental changes may have already altered species observed ranges or in cases where a species may be absent from a previous portion of its range due to human activity – both scenarios cause problems for correlational models.

**Correlational models**

This category of model is known by several names including: species distribution models (SDMs), empirical models, bioclimatic niche modeling, niche envelope modeling, and habitat suitability models. Correlational models identify statistically significant relationships between species occurrences and a number of environmental variables thought to predict suitability of the habitat for the species (e.g., temperature, precipitation, solar radiation, soil nutrients, and topography). Provided the species’ geographical distribution is correlated with the environmental predictor variables then the model can be employed to make spatial predictions based on maps of the predictor variables (including future climate maps). The generated maps can identify areas of potential species occurrence based on the suitability of those locations. Moving beyond single species modeling, “stacked” SDMs can combine modeled distributions for multiple species in a geographic space to create community-level predictions. SDMs require little understanding of the mechanistic (ecological or physiological) links between the organisms and their environment,
which can be advantageous if the analysis involves numerous species and/or large geographic areas. However, predictions from these models might be limited in their biological realism and transferability to novel environments. Studies have found that dispersal capacity and response to disturbance affected predictive strength of a correlational mode.

There are a number of important assumptions of these models: (i) species location data is representative of the species’ true distribution which is problematic if spatial occurrence data is incomplete or limited, (ii) species are in equilibrium with the environmental factors used in the model, and (iii) the correct environmental predictor variables are included in the model. Furthermore, other assumptions of correlational models include that the processes controlling range limits are fixed in space and time – this is not likely to be the case under future climate conditions, and that genetic and/or phenotypic plasticity of species being modeled is low. Finally, correlational models are typically defined as static models in that they do not incorporate the ability of a species to migrate to the predicted geographic space, which can be remedied by including realistic rates of species migration.

Mechanistic models

Process-based or mechanistic models focus on the role that functional traits such as physiological, behavioral, and morphological limitations and life history characteristics such as development, growth, and reproduction have on species distributions. These factors, which are not included in correlational models, can influence a species distribution and abundance, potentially constraining a species’ geographic distribution to a subset of locations that might otherwise be deemed suitable by correlational models. Mechanistic models require a large number of parameters to be estimated which may be of limited availability particularly at high spatiotemporal resolution.

Hybrid models

These models are a middle ground between the high data demands and complexity of a full mechanistic model and less data intensive mechanistic models. Hybrid models combine the static spatial predictions from correlational models with some process-based factors (e.g., dispersal, phenology, population dynamics, trophic interactions, and community dynamics). The inclusion of these factors will likely constrain predicted future species ranges compared to correlational models, and might allow for predictions of species distributions under changing climatic conditions.

Problems and limitations – DGVMs

While climate has long been recognized to be a major determinant in vegetation distributions it is possible that under future (anthropogenic) climate change conditions vegetation might not respond as it has in the past. There are numerous factors that lead to this conclusion. In the future, habitats will be more fragmented than they were in the past potentially limiting species dispersal, dispersal vector models are not fully developed, elevated atmospheric CO₂ levels may have unknown impacts on plant physiology, disturbance regimes may differ from current conditions, and biotic interactions may be altered.

As is often the case with climate or ecological models, the generalizations necessary to model global phenomena can create problems. For example, DGVMs represent competition poorly as they focus on identifying the dominant plant functional type, not accommodating species coexistence well and poorly representing
CLIMATE CHANGE AND BIOGEOGRAPHY

ecosystem heterogeneity. Additionally, based on evidence of vegetation response to Holocene warming it is clear that seed dispersal and migration of species is a critical response to environmental changes. Yet, DGVMs might not represent plant migration processes well, such that replacement of an extinct plant functional type by a new plant functional type would likely not occur immediately as modeled by DGVMs; rather a lag of several decades to 150 years might occur due to dispersal limitations or competitive interactions.

Problems and limitations – correlational models

The strength of correlational models is almost entirely dependent on the availability of correlational data. When using correlational models to predict vegetation response to climate change there is little regard for the dynamics of potential shifts from one species’ dominance or vegetation type to another. As described above for DGVMs a correlational model does not account for lags in vegetation change. Additionally, correlational models focus on the factors most highly correlated with species distributions, but it is possible that critical climate factors, which are rare or not directly measured, may not be included in the predictive model undermining the predictive power of the model. Interspecific interactions (e.g., competition) which might lead to a species being absent from geographic space within its climatic envelope complicates correlational associations and can lead to inaccuracies in predicted distributions under future climate conditions. While perhaps desirable to combine single species SDM predictions to model community-level patterns (S-SDMs), stacking results often leads to an over prediction of species richness. To resolve this, researchers have combined SDM output with macro-ecological variables and ecological assembly rules to constrain species richness predictions. Finally, novel climate conditions might develop yielding future climate conditions for which there is no current analog and therefore for which we lack correlative data.

Problems and limitations – mechanistic models

Mechanistic models require more time, effort, resources, and data than correlational models as they often require specific information about a species’ traits. As above, any geographic variation in a species’ physiological limits proves a challenge for mechanistic models. Similar to the issues described above, the parameterization of processes is based on correlative models and the causality of the observed correlations is not assured.

Quantitative models have been used to project likely impacts of climate change on species distributions and biomes since the early 1990s. DGVMs, correlational, mechanistic and hybrid models differ in both the geographic and taxonomic scales at which they’ve been applied. At global scales climate dominates distributions, whereas at finer scales factors such as topography and geology affect microclimate, nutrient availability, and water availability, which in turn influence species distributions.

Local and regional scales

Correlational, mechanistic, and hybrid models are most commonly used for modeling species shifts at scales ranging from hillslopes to continental scale and are useful for conservation planning in light of anthropogenic climate change. The primary concern with modeling over small scales, however, is the requirement of fine resolution climate and species data which is not readily available.
Myriad studies have been published modeling climate change impacts on single taxa (including terrestrial animals, plants, and aquatic organisms). Other studies are based on overlapping geographic distributions (stacking) of multiple species to assess community-level patterns (species diversity and forest type changes) likely to occur under future climate conditions. However, simply assessing species richness patterns by overlapping ranges of individual species may lead to an over prediction of species richness since no constraints are placed on species coexistence that might naturally arise through resource competition.

A DGVM analysis (Bachelet et al. 2001) of potential changes to vegetation in North America showed a general northward shift in biomes. Generally coniferous forests expanded slightly, temperate deciduous forests shifted northward, being replaced by southeast mixed forest or savanna. Tropical forests appeared as a new vegetation type in Louisiana where they replaced the northward shifting southeast mixed forest. Shrubland was lost in the Great Plains, being replaced by savanna. The greatest reduction was for the tundra biome, decreasing by more than 80% by the end of the twenty-first century.

Global scale

DGVMs have been typically reserved for continental to global scale modeling efforts where biome level patterns are of primary interest given that output is fairly coarse. Scholze et al. (2006) modeled changes in land-cover type (forest vs. nonforest) at the global scale. Depending on the level of temperature increases over the coming century there is a high risk of forest loss in Eurasia, eastern China, Canada, Central America, and Amazonia. The models suggest forest expansions into the Arctic and semiarid savannas around the world.

Definition, occurrence, and basic processes of permafrost

Definition

Permafrost is a thermal phenomenon and is defined as ground (soil or rock and included ice or organic material) that remains at or below 0°C for at least two consecutive years. According to this definition, the occurrence of permafrost does not necessarily require the existence of ice.

Permafrost consists of an active layer, which is the surface layer of soil that thaws each summer after the snow cover has melted and refreezes each winter (Figure 1). The active layer thickness refers to the annual maximum thaw depth at the end of the summer. It ranges from less than a few decameters in continuous permafrost along the arctic coast, to a few meters in discontinuous permafrost (e.g., Southern Siberia), and several meters in mountain ranges such as the European Alps or the Qinghai-Tibetan Plateau.

The main permafrost body is bounded at the top by the permafrost table and at the bottom by the permafrost base (Figure 1), as a result of the balance between heat conduction from the surface (MAGST; mean annual ground surface temperature) and thus the atmosphere, and the ground thermal heat flux from the Earth’s interior. The position is determined by the vertical temperature profile of the ground and only varies over very long time periods, depending on the permafrost thickness and the ice content (Figure 1). Permafrost temperatures at depths reflect variability of climate conditions as heat diffuses slowly through the ground.

The depth of zero annual amplitude (ZAA) is where the permafrost temperature shows no seasonal variation, that is, below the depth of ZAA, long-term changes in average climate conditions are reflected. The depth of ZAA varies from a few meters in discontinuous permafrost to 20 m or more in continuous permafrost or in bedrock.

Occurrence

The occurrence of permafrost is determined primarily by the regional climatic and the site-specific surface and subsurface properties and in general is to be expected where the MAAT (mean annual air temperature) is below 0°C. About 20% (or 25 × 10⁶ km²) of the global land surface is characterized by permafrost. These areas are located mainly at high latitudes and/or at high altitudes (Figure 2). Regional permafrost occurrence is classified into three zones, based on the fraction of land area underlain by permafrost: (i) the continuous permafrost zone, where 90–100% of the area contains permafrost; (ii) the discontinuous zone, with 50–90%; and (iii) the sporadic zone, with 10–50%. Isolated occurrence is given in regions where less than 10% of the area is underlain by permafrost.
CLIMATE CHANGE AND PERMAFROST

Figure 2  Worldwide occurrence of permafrost. Reproduced from GTN-P, http://ipa.arcticportal.org.
As an example of permafrost occurrence, this entry showcases the Swiss Alps. In Switzerland, about 5% of the land surface is characterized by mountain permafrost, and the permafrost bodies reach depths of a few decameters in debris (Von der Mühll and Haeberli 1990) and up to more than 1 km in the bedrock of the highest summits. Its position varies only over very long time periods, depending on the permafrost thickness and the ice content.

Low temperature conditions, as well as the occurrence of ground ice, are the most effective drivers for mechanical weathering, geomorphic dynamics, and related landform evolution (Swift et al. 2014). Pingos are the most prominent landforms in high latitudes (e.g., in North America, Svalbard), developing and persisting only in permafrost landscapes. They are characterized as ice-cored hills with a height of about 60 m and a lifetime of up to 1000 years. Closed-system pingos (hydrostatic processes) occur in lowland settings within continuous permafrost, while open-system pingos (hydraulic processes) are more common in valley bottoms and footslopes in both discontinuous and continuous permafrost. They are characterized as peaty frost mounds consisting of alternating layers of segregated ice and peat or mineral soil material. In high mountain regions, rock glaciers (Figure 3) are among the most prominent landforms and indicators for the occurrence of permafrost. They represent climatological boundary conditions with a MAAT below $-1$ to $-2 \, ^\circ C$, and annual precipitations of $<2500 \, \text{mm}$ (Swift et al. 2014). Rock glaciers commonly occur at the foot of free rock faces (talus rock glaciers) or below moraines (debris rock glaciers), and form tongue- or lobe-shaped bodies with lengths of several hundred meters. Active landforms contain ice and move at rates of $>0.1 \, \text{m year}^{-1}$, whereas inactive ones still contain ice but do not move any more. Relict rock glaciers indicate former permafrost conditions.

Key processes

The present state of permafrost occurrence (as well as its future development) is influenced by climatic conditions. Permafrost is a thermal system with a relatively slow response to climatic changes (compared, for instance, with glaciers). The response time of permafrost depends on the thermal conductivity, the ice content, and the thickness of the frozen ground. In fact, the thickness and some marginal occurrences of alpine permafrost most probably still reflect maximum Holocene cooling during the Little Ice Age, which culminated in the nineteenth century. Temperature profiles observed in boreholes have proven permafrost thicknesses in excess of values expected from present-day mean annual ground temperature (MAGT).

In general, the thermal boundary conditions of the uppermost layers of the lithosphere are determined by atmospheric energy fluxes and the heat flow from the Earth’s interior. The geothermal heat flux is relatively low and quite constant in space and time. In the context of permafrost, its variations caused by mountain topography can be neglected. As a consequence, the ground thermal regime and, in particular, its potential changes are determined mainly by the atmospheric net heat exchange at the surface, which is controlled by the local topography, by the surface and subsurface conditions, and by the ground properties.

The surface energy balance, equation 1, describes the energy exchange of heat and moisture between the atmosphere and the ground surface. According to the conservation principle,
the sum of all fluxes must be balanced for any timescale and every location.

\[ Q^* + Q_H + Q_{LE} + Q_G + Q_M = 0 \] (1)

where \( Q^* \) (net radiation) = \( K \downarrow + K \uparrow + L \downarrow + L \uparrow \) and where \( K \downarrow \) = incoming shortwave radiation, \( K \uparrow \) = reflected shortwave radiation, \( L \downarrow \) = incoming longwave radiation, \( L \uparrow \) = outgoing longwave radiation, \( Q_H \) = sensible heat flux, \( Q_{LE} \) = latent heat flux, \( Q_G \) = ground heat flux, and \( Q_M \) = latent heat of fusion.

From equation 1 it is evident that solar radiation is the most important energy source of the surface (if geothermal heat is neglected; see above). Therefore, the surface temperature at a specific location depends significantly on the amount of incoming shortwave radiation, which varies on an annual cycle with latitude and topography. Furthermore, the partitioning of the energy balance components also varies significantly due to site-specific factors, such as ground properties, snow cover regime, and so on (see below).

In general, the propagation of the ground surface temperature into the ground depends on the ground thermal properties for heat transfer.
The response of permafrost to atmospheric changes is furthermore dependent on the ice and liquid water content of the ground, which can be spatially highly variable, particularly in mountain topography. Ice and water in the ground determine the rate of temperature change by the effect of latent heat, that is, ice-rich ground slows down and damps temperature change because of heat absorbed by partial melting of interstitial ice. Ice content, however, is difficult or impossible to measure directly, and quantification must typically be based on geophysical methods such as electrical resistivity tomography or refraction seismic tomography (Hauck 2013).

Finally, glacier retreat may lead to permafrost aggradation in regions where the current MAAT still favors the development of frozen ground.

**Observed changes**

In general, permafrost is sensitive to changes in temperature and other controls, such as snow cover, ice content, and vegetation (Voigt et al. 2010). First of all, permafrost conditions are strongly dependent on atmospheric changes. In the following, a short overview of observed changes of major atmospheric parameters (air temperature and precipitation, including snow) is thus provided before observed changes in permafrost temperatures are further discussed.

**Observed atmospheric changes**

For air temperature, the past decades show a clear positive trend at the global scale, with an average increase of about 0.85°C for the period 1880–2012 (Figure 4). The warming is spatially heterogeneous and regional variations diverge in magnitudes of between about 0.2 and 2.5°C. Also note that in particular in cold regions,
Figure 4  (a) Observed global mean combined land and ocean surface temperature anomalies, from 1850 to 2012 from three datasets. Top panel: annual mean values. Bottom panel: decadal mean values including the estimate of uncertainty for one dataset (black). Anomalies are relative to the mean of 1961–1990. (b) Map of the observed surface temperature change from 1901 to 2012 derived from temperature trends determined by linear regression from one dataset (orange line in panel a). Reproduced from IPCC (2013).
meaning high altitudes and high latitudes, data coverage is usually sparse.

For precipitation there is no clear overall global trend observed. There are regions that show an increase while others show a decrease of annual precipitation (Figure 5).

For permafrost, more important than the annual precipitation rate is the annual distribution of precipitation in relation to air temperature, that is, in particular, whether precipitation reaches the ground in the form of rain or snow. As outlined above, the duration of the snow cover extent is of major importance. In general, there is a decrease in spring snow cover extent observed (Figure 6), which typically increases the exposure of ground to strong radiation during springtime.

**Observed changes in permafrost**

In general, climate change indications are given by alterations of the permafrost in its spatial extent, thickness, and temperature, as well as by landform changes. However, due to the lack of long-term data series and the large heterogeneity of the different sites (continuous, discontinuous permafrost), the observation and monitoring of the response of permafrost to climate change can be rather complex. Nevertheless, recent warming in the polar and mountainous regions has resulted in documented generally warmer permafrost, deeper active layers, and the development of taliks. While warming of permafrost is distinct in northern Europe and North America, trends are less clear for mountain regions, for instance for the European Alps, because of large variations in snow conditions and complex

heat exchange mechanisms in warm permafrost close to 0°C. For most other mountain ranges worldwide, including large mountain ranges such as the Himalayas, systematic monitoring and observation of permafrost conditions do not exist.

Changing active layer thicknesses represent the direct response to annual climate conditions and show interannual variations between +20% in Svalbard (Janssonhaugen) and +100% in the Alps (Schilthorn), depending on site-specific conditions (Voigt et al. 2010). On Svalbard, significant near-surface warming was reported as the result of a strong temperature anomaly during winter and spring 2005/2006, resulting in a 1.8°C higher mean ground temperature at the permafrost table as compared to the mean of the six previous years. A similar anomaly occurred in summer 2003 in the Alps; a relatively direct response was recognized in the acceleration of rock glaciers (Roer, Kääb, and Dikau 2005) and destabilization of rock walls (Gruber, Hoelzle, and Haeberli 2004).

Permafrost temperatures have risen over the past several decades in Alaska; coastal sites show continuous warming since the 1980s and this warming trend has propagated south toward the Brooks Range, with noticeable warming in the upper 20 m of permafrost since 2008 (see Figure 7; Romanovsky et al. 2011). Permafrost in the Alaskan interior warmed in the 1980s and 1990s, but has generally stabilized during the past 10 years. Northern Russia and northwest Canada show increases in permafrost temperature similar in magnitude to those in Alaska during the past 30–35 years. Recent permafrost temperature records from three boreholes in Sweden, Norway, and Svalbard suggest rapid warming, with rates of 0.04–0.07°C year⁻¹ at the permafrost table. In the Swiss Alps, there is evidence for warming at rates of about 0.01°C year⁻¹ at a depth of 48 m in bedrock (Harris et al. 2009).

**Landform changes**

Changes in permafrost extent, thickness, and temperature are used as first diagnostics of climate change. However, since these changes are not visible and not easily detectable, topographic or landform transformations are often the first indicators for ongoing changes. The increase in temperatures leads to warming and thawing permafrost, thus initiating the degradation of single landforms or entire landscapes, visible for example in the expansion of thermokarst lakes in the high latitudes of Russia. The occurrence of thermokarst mirrors the decay of permafrost in soils and sediments and features sink holes, slumps, and lakes caused by the disturbance of the thermal equilibrium brought about by
CLIMATE CHANGE AND PERMAFROST

geomorphic, vegetation, or climatic changes, or a combination thereof (Swift et al. 2014). Another geomorphological indicator of climate change in permafrost regions is the increased erosion of arctic coastlines, as a complex of the ocean–land surface system. The smaller, shorter, and thinner distribution of sea ice allows for the longer activity of waves at the shore. Also, in high mountain systems, the warming ice, as well as the occurrence of unfrozen water, leads to changes in the thermo-hydrological system and related processes. This is reflected by the increasing number of accelerated and destabilized rock glaciers (Figure 8), active layer detachment slides, and rockfalls. During recent decades it has been observed that several landforms are moving at increased rates, probably related to warming permafrost temperatures. The monitoring of seasonal and interannual changes in rock glacier

Figure 8  Collapsing tongue and development of deep cracks of rock glacier Grueo1 (Valais, Switzerland) between 1975 and 2001. The cracks started to develop on the orographic right side, while later (between 1993 and 2001) the landslide-like failure extended over the entire tongue. Between 1975 and 2001 the rock glacier advanced about 60 m ($\approx$2.3 m year$^{-1}$). (See also Roer 2007, Kääb et al. 2007.) CLIMATE CHANGE AND PERMAFROST

dynamics indicates regionally synchronous patterns, reflecting response to varying ground surface temperatures. In addition, destabilized rock glaciers are also described; they show very high deformation rates and often display crevasse-like features at the surface indicative of shear mechanisms similar to those known for landslides.

Monitoring of permafrost

International permafrost data such as borehole temperatures and active layer thicknesses are made available in the Global Terrestrial Network of Permafrost (GTN-P), which aims to manage a global network of permafrost observatories for detecting, monitoring, and predicting climate change. The basis is a database with open access permafrost data from all over the world. Beside this superordinate network, some thematic as well as national networks exist (see Figure 9). A well-established national network is PERMOS (Permafrost Monitoring Switzerland; www.permos.ch), which was formally implemented in 2007, after a 6-year pilot phase. The aim is the systematic, long-term documentation and investigation of permafrost in the Swiss Alps, as compiled at different sites with varying topographic settings (mountaintops, crests, talus slopes, rock glaciers) based on three different types of observations: (i) ground temperatures measured in boreholes as well as near the ground surface, (ii) changes in subsurface ice and water contents, and (iii) velocities of creeping permafrost landforms. A good example of a more thematic network on permafrost is the

Figure 9 Permafrost borehole temperatures at depths of around 10 m, from the Alps (Switzerland), Norway, and Svalbard (Janssonhaugen). Voigt et al. 2010. Reproduced by permission of the authors.
Circumpolar Active Layer Monitoring (CALM) program, which coordinates measurements of active layer thickness at 260 sites, measurement of 168 of which has been ongoing since the 1990s.

Impacts of permafrost thawing for society

Thawing of permafrost can lead to increasing active layer depths, the development of taliks, and generally a decrease in the spatial extent of permafrost areas. There are several second-order impacts associated with permafrost thawing, some with adverse impacts for human societies and/or positive feedback mechanisms.

In the following some selected examples of impacts related to permafrost thawing are outlined.

Instabilities related to permafrost thawing

Loose ground, debris slopes, or steep rock walls are stable when pores and cracks are filled with permanent ice (permafrost conditions), and infrastructure constructions are stable when anchored in permafrost areas. When permafrost thaws, steep slopes can destabilize and infrastructure such as roads, railways, and houses in arctic or high-altitude areas can lose their stability.

In relatively warm permafrost, air temperature anomalies or heavy precipitation events can provoke rockfalls and landslides. Among the most prominent anomalies was the extraordinarily hot summer of 2003 in central Europe, which caused an enlarged active layer thickness or permafrost thaw in the Alps, contributing to increased rockfall activities (Gruber, Hoelzle, and Haeberli 2004). Also, short high-temperature anomalies or precipitation events, it is suggested, are able to trigger large slope failures, as observations from different mountain regions of the world have shown. Increasing permafrost temperatures also pose engineering challenges of infrastructure stability in arctic regions or, for instance, for the railway on the Tibet Plateau.

Changing landscape features

Degradation of permafrost changes geomorphologic features and can lead to the formation of thermokarst terrain, expansion of thaw lakes, or erosion of arctic coastlines. These impacts that mainly occur in arctic regions can affect construction work and infrastructure stability.

Feedbacks (carbon cycle)

The two examples above describe impacts at the local or regional scale, but permafrost thaw in the arctic regions can have a significant global impact, and is among the greatest fears regarding global climate change. Frozen organic soils, including the subsea areas on the shallow shelves of the Arctic Ocean, some relics from the last glaciation, contain considerable quantities of carbon (Figure 10). In fact, these areas hold more than twice the amount of carbon dioxide (CO$_2$) currently present in the atmosphere. Permafrost thawing exposes previously frozen carbon to microbial degradation and releases radiatively active gases, such as carbon dioxide (CO$_2$) and methane (CH$_4$) or nitrous oxide (N$_2$O). These gases are very strong radioactive forcing gases and create positive feedbacks, which amplify significantly global warming.

Modeling (future) permafrost conditions

There is a range of models (from simple to complex) available to simulate permafrost. Each model approach has its own advantages and
disadvantages, and the objective of a study determines which modeling approach is most appropriate.

Assessments for large areas are typically modeled by using **empirical-statistical models**. These models provide probabilities for permafrost occurrence as a function of topo-climatic parameters and statistical relation, for example between potential direct solar radiation and MAAT.

**Process-based models** focus on a detailed understanding of the energy fluxes between the atmosphere and the permafrost ground. They explicitly parameterize the energy balance at the surface and require a correspondingly large amount of measured or computed data. These models also consider subsurface characteristics and surface layers such as seasonal snow. Due to their large computational demand and the extensive input of observational data, these models are restricted to modeling only relatively small regions or specific sites. However, only with process-based models can ongoing processes related to climatic changes be studied.

Several thermal modeling approaches and studies have been conducted and developed in Norway for regions with gentle topography (Westermann et al. 2013), and the use of climate model output for permafrost modeling in alpine environments is among the most promising techniques for scenario generation (Salzmann et al. 2007). For the Swiss Alps, a recently finished large project (funded by the Swiss National...
Science Foundation) on The Evolution of Mountain Permafrost in Switzerland (TEMPS) made a particular effort in assessing future permafrost evolution. By combining various methods, including scenarios from regional climate models and a one-dimensional coupled heat and mass transfer model (COUP), it was shown that air temperature change has the strongest impact on permafrost in the Alps. Also, there is an overall degradation of permafrost observed, which will very likely continue. Furthermore, the changing snow cover regime could be associated with the high variance found in permafrost time series, and ice content is responsible for the rate of permafrost thawing.

Climate change is widely recognized to be one of the major challenges facing humanity in the twenty-first century. The Intergovernmental Panel on Climate Change (IPCC) has provided increasingly clear signals that human actions are contributing to growing concentrations of greenhouse gases in the atmosphere which, if unchecked, may lead to an increase in global average temperatures of more than 2°C above preindustrial levels by 2030 and a 5–6°C rise in the longer term (IPCC 2013). The IPCC describes the consequences of even the lower increase as “dangerous” and warns of rapidly rising sea levels, greater climatic variability (e.g., increased drought occurrences and severity), more frequent extreme weather events, and acidification of the world’s oceans caused by the accelerated uptake of atmospheric carbon dioxide.

Such cautions have transformed climate change from a relatively narrow scientific concern into a high-profile political issue. However, governing climate change is intensely challenging for a number of reasons. First, limitations in current understandings of natural and human-induced effects on the Earth’s climate system create significant problems for assessing the costs and benefits of different courses of action. Second, greenhouse gas emissions are integral to virtually all human activities, including energy production; transport and mobility; land use; planning; building design; waste and, ultimately, individual behavior. As such, climate change is a classically “wicked” environmental problem, the management of which requires high levels of scientific knowledge, major economic restructuring, and strong coordination across tiers of governance, industry, finance, and civil society.

Such complexities and uncertainties have prompted serious disagreements over methods for addressing climate change and how to apportion responsibilities for reducing greenhouse gas emissions. Within United Nations discussions, many countries from the Global South that have contributed relatively little to current atmospheric greenhouse gas concentrations argue that developed countries in North America and Europe should reduce their emissions first and that their development should not be impeded by efforts to decarbonize the world economy (Falkner, Stephan, and Vogler 2010). However, many developed countries have been unwilling or unable to show strong climate leadership. Inequality in the distribution of the effects of climate change has been another source of dispute. Although climate change is projected to produce global impacts, some regions stand to be more severely affected than others. Examples of disparities include: the magnified dangers of sea-level rise for low-lying territories in Bangladesh and major coastal cities; faster-than-average warming in polar regions caused by losses in albedo (created by snow and ice melt, reduced reflection of sunlight, and increased heat absorption by the ground); and desertification in semiarid areas in sub-Saharan Africa caused by altered
CLIMATE CHANGE POLICY

weather patterns. Such physical differences are compounded by differences in vulnerability to climate stresses. Low-income areas in the Global South with high reliance on agriculture, seasonal water availability, or fisheries, for example, face particular difficulties and even the prospect of climate-related conflicts and climate-induced migration.

Climate change thus raises serious issues about fairness and responsibility between nations, communities, and generations that are further aggravated by ongoing rapid industrialization and spiralling emissions in countries like Brazil, India, and China. Geographical perspectives are therefore crucial both to understanding climate change itself and to developing strategies to combat and adapt to climate change. Climate policy must contend not only with the grand project of decarbonizing the global economy in aggregate but also with how to do this while addressing rather than reinforcing inequalities and enabling rather than impeding economic development. It must also grapple with how to help societies and communities adapt to a more unstable climate.

The entry begins its review of these debates by examining the main types of climate policy and general problems within the idea of governing climate change. It then discusses climate policy developments at the global and national levels, and the emergence of transnational climate-governance networks comprised of public and private sector actors as a major (and, some argue, leading) force in climate governance and critical scholarship on carbon markets as a means of reducing emissions. The entry concludes by examining emerging debates on adaptation and loss and damages policy.

Defining climate policy

Climate policy traditionally divides into adaptation and mitigation measures, where adaptation encompasses initiatives to help societies adjust to the effects of climate change and mitigation comprises policies to counteract the causes of climate change by reducing emissions. Adaptation policy can be further divided into autonomous initiatives (e.g., households protecting their dwellings from local flooding) or government initiatives (e.g., funding and constructing flood defenses for areas threatened by sea-level rise), while mitigation policy can be either direct (e.g., measures to reduce the carbon intensity of an industrial process or vehicle fuels) or indirect (e.g., policies to promote renewable energy that reduce emissions by reducing demand for fossil fuel energy generation).

Adaptation policy is sometimes argued to be geographically distinctive from mitigation policy in the sense that although adaptation can be instigated at any spatial level (e.g., international, national, and regional assistance programs), physical adaptation activities generally take place locally to ameliorate local climate-related stresses. In contrast, mitigation policy has more of a global dimension because greenhouse gases diffuse rapidly over the atmosphere. As such, mitigation actions anywhere in the world theoretically lessen overall global impacts. Conversely, mitigation is also local because emissions sources themselves come from local point sources (e.g., individual power stations, factories, vehicles, and people). The implications of these distinctions are discussed further later in the entry.

A further subcategory of climate policy concerns compensation for loss and damages caused by climate-related impacts. Loss and damages first gained official status within the United Nations Framework Convention on Climate Change following the 16th Conference of Parties in Cancún, Mexico, in 2010 and broadly differentiates between loss and damages on the basis of whether reparation or restoration for negative impacts is impossible (e.g., loss of freshwater
resources) or possible (e.g., damages to buildings from storm events) (Surminski and Eldridge 2013). Although commonly associated with adaptation policy, loss and damages can also be incorporated into mitigation policy, for example, where governments provide transitional assistance to industries affected by a national carbon tax if this creates competitive disadvantages compared with companies operating in countries that have not implemented equivalent carbon pricing measures.

Beyond these basic categories, the character and boundaries of climate policy become hazier. Although the physical processes associated with climate change are essentially environmental, tackling the causes of increased atmospheric greenhouse gas concentrations is an economy-wide issue, not just an environmental policy problem. Mitigation and adaptation efforts are thus unlikely to succeed unless climate issues are integrated into all major policy areas and there is clear policy programming to ensure mitigation and adaptation operate cohesively. Viewing climate change solely as an environmental issue also makes it susceptible to being marginalized in government or to attack by groups whose interests are negatively affected by mitigation or adaptation policies (Newell and Paterson 2010). Policy integration also poses major challenges for compartmentalized models of government, where each department has its own priorities against which climate concerns must compete and where departmental boundaries limit information flows and impede coordinated action.

Some authors go further and question the fundamental goals of climate mitigation policy. Hulme (2008) criticizes what he sees as the intellectual hubris behind the idea that humans can or should attempt to stabilize the Earth’s enigmatic and dynamic climate system. Beyond the practical difficulties of defining the idea of “a normal climate” and mechanisms that might achieve climate stability, Hulme suggests that the mindset of climate stabilization raises deeper ethical issues about who has the right to determine desired climate outcomes and how costs and benefits should be distributed, on what authority, and in whose interests they should act. Among the questions he asks is: on what grounds is it defensible to stabilize the climate to lessen economic losses in developed countries if this sacrifices development and poverty reduction in the world’s poorest nations?

Despite the undoubted value of such critiques and the need for greater reflection on the balance between mitigation and adaptation, mitigation has tended to occupy a dominant position in political and social science debates on climate policy. One explanation for this is that it aligns with the general orthodoxy that public policy can essentially solve or manage policy problems within acceptable limits. This outlook has a particular tradition in environmental policy, where considerable successes have been achieved in controlling ozone-depleting substances, sulphur dioxide, and other pollutants, and could also be regarded as more politically acceptable than resigning humanity to potentially devastating changes in the climate system. The growing emphasis being placed on adaptation, loss and damages, and nonstate forms of climate governance nevertheless suggests that climate change is severely testing deeply held beliefs in the problem-solving abilities of nation-states and public policy. The entry now examines some of the main developments in scholarship on international, national, and transnational modes of climate policy and carbon markets.

**International climate policy**

Anthropogenic impacts on the Earth’s climate system are a global problem in three important
respects: (i) greenhouse gas emissions anywhere in the world contribute to accumulating stocks of greenhouse gases in the atmosphere and, by extension, to climate impacts across the world; (ii) all nations stand to be affected by climate change, though in different ways and with differing levels of severity; and (iii) no one country can tackle climate change single-handedly. Many commentators have concluded from this that effective mitigation can only come about through global cooperation and interstate dialogue under the auspices of the United Nations.

Reflecting this viewpoint, the United Nations Framework Convention on Climate Change (UNFCCC) has worked since the 1992 Rio Earth Summit to establish a global climate regime and targets, timetables, and mechanisms for reducing greenhouse gas emissions and enabling adaptation. This global deal approach built upon an established model that enjoyed considerable success with other transboundary environmental problems. The 1985 Vienna Convention and 1979 Geneva Convention have been particularly hailed as creating effective legal frameworks for subsequent protocols limiting or prohibiting long-range transboundary air pollution and ozone-depleting substances (Falkner, Stephan, and Vogler 2010). It also aligned well with a state-centered view of geopolitics that assumes nation-states possess the capacity and willingness to work cooperatively through the United Nations to combat commons threats.

The international climate negotiations have, however, exposed serious shortcomings in state-hierarchical approaches to climate diplomacy. Although the 1992 Framework Convention provided the political and legal foundations for the 1997 Kyoto Protocol, negotiations on a successor treaty were hampered by the refusal of the United States to ratify Kyoto and ongoing disputes over how the burden of reducing emissions should be shared between developed and developing countries, with particular attention focusing on rapidly emerging economies such as China and India. Two main reasons can be proposed for these difficulties: (i) the UN’s inability to force agreement between countries; and (ii) a lack of willingness by governments to compromise national interests (whether related to economic competitiveness and development or to the provision of financial and technological assistance to mitigate and adapt to climate change) (Falkner, Stephan, and Vogler 2010).

Most major developed countries nevertheless agreed legally binding emissions reduction targets in the Kyoto Protocol (the main exceptions being the United States and, until 2007, Australia, though Canada withdrew from its Kyoto commitments in 2011). Additionally, the Kyoto agreement incorporated the Clean Development Mechanism and Joint Implementation, two instruments designed to leverage investment in overseas emissions-reduction projects to ease the costs of meeting emissions targets whilst promoting sustainable development in host countries. However, the 2009 Copenhagen Accord only managed to secure loose commitments on targets and funding and fueled fears that the UN process could collapse as a result of disagreements on how to apportion responsibilities for reducing emissions and the provision of funding.

Work by subsequent Conferences of the Parties to retrieve this situation led in December 2015 to the adoption of the long-awaited and hard-won successor to the Kyoto Protocol, the Paris Agreement. Among the key undertakings made in the agreement are: (i) to hold the increase in global average temperatures to well below 2°C above preindustrial levels and to pursue efforts to limit this to 1.5°C; (ii) to achieve a net balance between anthropogenic greenhouse gas emissions and removals between 2050 and 2100; (iii) pledges by over 180 countries to cut or curb their emissions, although these take the form of Intended
Nationally Defined Contributions (INDCs) and are not legally binding; (iv) the creation of a five-yearly review mechanism to enable countries to increase their INDCs to close the gap between current commitments and the emissions reductions needed to remain below the 2°C target; and (v) to accelerate finance flows alongside a mechanism for addressing financial losses faced by vulnerable countries from climate impacts.

Although the Paris Agreement appears to represent a significant step forward in the intensity and timescale of action being taken to avoid dangerous climate change, and in the levels of cooperation between countries in the Global North and Global South, its real value will only be known as governments develop hard-and-fast policies to reduce emissions, support adaptation, and provide for loss and damages.

**National and transnational climate policy**

National climate politics has been a somewhat underexplored topic within geographical research on climate policy, particularly mitigation policy. Early research on this topic was instead dominated by environmental economists analyzing the use of carbon trading and carbon taxes to reduce emissions (Helm 2005). One chief attraction of this research was that it directly addressed the question of how to mitigate climate change without harming prosperity or competitiveness, and so aligned strongly with traditional state economic interests. However, the rather normative approach of environmental economics has been criticized for treating greenhouse gas emissions as a purely technical question of correcting market distortions and for ignoring broader social and political debates on how societies should both mitigate and adapt to climate change (see discussion by Hulme (2008) above).

The political dimensions of national climate policy have been addressed more directly by comparative research by political scientists examining how national characteristics such as per capita wealth, education, dependency on fossil fuels, press freedoms, and the strength of domestic environmental groups affect the strength or weakness of national mitigation policies. Harrison and Sundstrom (2007) conclude from studies of the European Union, the United States, Russia, Canada, Australia, and China that compliance costs were a consistent influence, but they also acknowledge that the impact of many factors was mixed in both direction and extent. For instance, public opinion has been important in persuading politicians to introduce mitigation policies in the European Union but has been less influential in the United States, Canada, and Russia, while shifts in public opinion and electoral competition in Australia have both driven and constrained mitigation policy, in turn shaping the emphasis on and nature of adaptation policy.

Structural explanations for why some countries adopt more ambitious mitigation policies nevertheless still fail to capture the multi-issue, multi-actor and partisan nature of political debates on climate policy in many countries. Bailey and Compston (2012) attempt to counteract this by investigating the tactics used by industry groups, electorates, the media, and national legislatures to oppose new climate policies and political strategies that governments can utilize to counteract such opposition. Examples of these strategies include: (i) taking action early during a new government to allow time for political disputes and concerns about new mitigation and adaptation initiatives to fade before the next election; (ii) offering policy concessions to influential groups such as major industries and electorates to dissuade them from opposing climate measures; (iii) using persuasion...
CLIMATE CHANGE POLICY

techniques, such as stressing the moral imperatives for mitigation and adaptation actions and emphasizing climate policy as an opportunity to develop competitive advantages in low-carbon industrial sectors; and (iv) employing manoeuvres to strengthen climate policy relative to more powerful government departments, such as finance and industry. Compston and Bailey, however, stress that the political, economic, and social conditions shaping climate policy in different countries are often highly specific and that such frameworks only provide a figurative toolkit for how governments might deal with nationally distinctive barriers to climate policy. Detailed studies of national mitigation policies and politics nevertheless remain relatively sparse and have emanated mainly from political science rather than geography. A noteworthy example of such research is Carter and Jacobs’s (2014) investigation of factors aiding the creation of the United Kingdom’s Climate Change Act between 2006 and 2010. In particular, they stress the importance of interparty competition for climate leadership and policy entrepreneurship by individual politicians who opt to make issues like climate change part of their “narrative identity” and political legacy.

The question still remains why greater geographical scholarship has not been directed towards analyzing national climate policy, particularly given the difficulties geographical differences present for identifying general factors affecting mitigation and adaptation efforts. A major explanation for this trend is a more general shift in geographical thinking away from conceptualizing places and spatial scales as rigid and independent phenomena (e.g., the international and national “layers”) and towards modes of enquiry that emphasize the fluidity of economic, social, and political interactions being brought about by globalization and economic liberalization. This has led to increased questioning of the idea that nation-states are pre-eminent political actors and growing interest in multi-actor, multilevel, and transnational forms of environmental governance. Geographers have been particularly energetic in exploring how climate leadership is increasingly being exerted by regional and city administrations, multilateral institutions (e.g., the World Bank and World Trade Organization), businesses, nongovernment organizations, and individuals through their everyday conduct and opinions.

This trend is further reflected in the growing diversity of mechanisms through which climate change is being governed. Rather than mitigation policy being dominated by state regulations and financial incentives, research shows that nonstate initiatives such as corporate sustainability reporting (e.g., the Carbon Disclosure Project), industry-led certification schemes (e.g., the Forestry Stewardship Council), and grassroots initiatives are rapidly becoming mainstream forms of climate governance. Geographers have also analyzed the growth of transnational climate governance networks led by non-nation-state actors and involving cooperation between multiple actors from the public and private sectors. One prominent example is the International Council for Local Environmental Initiatives (ICLEI), an association of over 1000 cities and towns in 86 countries working to promote local action for global sustainability (www.iclei.org/). Another is the Transition Network, founded in 2007 to encourage and support communities to develop grassroots initiatives to reduce emissions and build local resilience (www.transitionnetwork.org/). By 2013, over 1000 Transition initiatives had been established in the United Kingdom, mainland Europe, Australasia, and North America.

Geographical thinking about the spatialities of climate governance thus raises important questions about the changing nature of climate
policy. Pivotal among these are the implications of transnational and nonstate forms of climate governance for the role of the state. To what extent are state functions being “bypassed” or are states being left behind as climate-governance actors because of the slow progress made by UNFCCC negotiations and state-led climate policies, or are states simply changing how they govern, with greater focus on creating regulatory frameworks to support and steer more dynamic and less encumbered nonstate and transnational initiatives? Most analysts agree that “governing beyond the state [does not mean] governing without the state” and that many – though by no means all – nonstate governance arrangements (particularly within the adaptation sphere) involve state intervention in establishing ground rules and enabling and monitoring mechanisms for nonstate-led initiatives (Bulkeley and Jordan 2012, 564). At the same time, geographical analysis has demonstrated that state authority over the governance of socioenvironmental problems is being replaced by more polycentric and autonomous modes of governance.

Further questions concern the effectiveness and legitimacy of public–private climate networks. Although most commentators agree that interstate negotiations and state actions have made limited progress in establishing effective climate governance regimes, will greater nonstate actor leadership yield more effective outcomes, and what mechanisms exist to ensure their accountability to those affected by nonstate initiatives? There are few definitive answers to these questions, not least because of the number and diversity of nonstate initiatives; however, the fragmentation of governing authority within nonstate climate governance networks creates obvious challenges for coordination and coherence. Additionally, transnational climate-governance activities cannot be assumed to place reducing emissions or promoting adaptive capacity above the private interests of the actor groups involved. The nonstate network approach thus relies on climate goals coalescing with other motivations. For example, the World Bank is a major actor in climate governance through its involvement in the Climate Investment Funds and its influence over development policy in many developing countries. Some of its investments may therefore work to reduce emissions or finance adaptation while others, particularly those linked to economic growth, may undermine these goals. Although tensions also exist between state climate and economic strategies, corporate motivations for becoming involved in climate governance depend on them genuinely acknowledging the impact of their activities on the social and physical environment and their willingness and capacity to dedicate resources to promoting collective mitigation and adaptation actions (Newell and Paterson 2010).

**Carbon markets**

Carbon markets have become a core element of both state-led and private responses to climate change in recent years. The essential logic underpinning carbon markets is that markets are the main driving force for innovation and productivity within economies; therefore, if markets can be designed that internalize the social and environmental costs of carbon emissions, in theory they can provide a mechanism for achieving effective and cost-effective reductions in emissions. Three main types of carbon market can be distinguished.

“**Cap and trade**”

“Cap and trade” is where a governing body sets an overall emissions cap, distributes emissions allowances to affected industries (typically
large power generators and energy-intensive manufacturers), and allows companies to trade allowances in order to help achieve emissions targets. The purpose of trading in this instance is to give emitters with lower emissions-abatement costs a financial incentive to sell their surplus allowances to those with higher abatement costs so as to produce net overall welfare gains at reduced cost compared with other policy approaches. The European Union Emissions Trading System (EU ETS) is the world’s largest cap-and-trade scheme. In 2014, the scheme covered all 28 EU member states plus Iceland, Liechtenstein, and Norway, and around 45% of the European Union’s total greenhouse gas emissions. From 2013 onwards, the scheme was expanded to incorporate aviation to and from participating countries.

**Government-led project schemes**

Such schemes involve governments or organizations investing in emissions-reduction projects elsewhere in the world to generate emissions credits for sale on international markets. The most prominent example of this type of scheme is the Clean Development Mechanism (CDM), which allows developed nations that ratified the Kyoto Protocol to buy credits generated from projects in developing countries to meet a proportion of their UNFCCC targets. In addition to enabling countries to source emissions cuts at lower cost compared with decarbonizing their domestic energy or transport systems, the CDM aims to promote investment, technology transfer, and sustainable development in host countries. Typical investments permitted by the CDM include wind and solar energy, methane capture from landfill gas, and the destruction of potent synthetic greenhouse gases.

Most project-based schemes utilize a *baseline-and-credit* methodology, where the number of credits issued represents the difference between measured emissions from activities and estimates of business-as-usual emissions if the project had not been implemented. Because calculations are based around a hypothetical comparison, baseline-and-credit systems need robust oversight by the CDM Executive Board and Designated National Authorities to determine the types of project permitted, approve projects, and verify the number of credits generated.

**Voluntary carbon offsets (VCOs)**

VCOs utilize a methodology similar to that of government-led project schemes but provide mechanisms for private individuals, companies, and governments to purchase carbon credits to offset their greenhouse gas emissions. Credits are again generated from remote abatement projects funded by credit sales, for example, where an individual buys carbon offsets from a tree-planting initiative to compensate for emissions from personal air travel. However, because VCOs are run by private organizations (e.g., Future Forests, ClimateCare, and the CarbonNeutral Company) rather than governing bodies, VCOs are generally subject to less strict controls, meaning that a broader range of projects is utilized and projects are not always screened as rigorously.

The philosophy and practice of carbon markets have provoked intense academic debate. Most environmental economists see them as valuable mitigation mechanisms because of their cost-effectiveness and flexibility in reducing emissions. Geographical research has, however, highlighted two main sets of difficulties: (i) the political and practical problems of translating economic theories on carbon pricing into effective policy; and (ii) a tendency for carbon markets to enable the commodification and expropriation of aspects of nature in ways that sustain uneven
CLIMATE CHANGE POLICY

and crisis-prone development patterns at the expense of justice-based approaches to climate governance. These arguments are now examined in turn.

A crucial challenge for carbon markets is how to translate different greenhouse gases into common units so that they can be traded. Greenhouse gases do not possess the intrinsic value or tangible qualities of normal commodities, so creating markets requires estimates of the carbon savings gained, for example, from replacing wood-burning stoves with gas stoves in India, and methodologies for converting gases with different climate-forcing potentials into carbon dioxide equivalents so as to create a tradable commodity. Such proxy commodification is inherently susceptible to pressures from political and economic actors with vested interests in the profitability of carbon markets.

Other research stresses the political difficulties of governing carbon markets. Most economists agree that cap and trade depends on setting strict emissions caps to create strong incentives for businesses to innovate and reduce emissions. However, the European Union has struggled to agree targets for its emissions trading scheme because some member states have pressed for less challenging targets to protect major industries and shield consumers from higher energy prices (Bailey, Gouldson, and Newell 2011). The CDM has also encountered difficulties in: ensuring rigorous rules for monitoring, reporting, and verifying emissions reductions; resisting pressure to relax rules on whether projects are judged to be additional to business as usual; and structuring carbon markets so that they direct finance and technology to countries according to their development needs. Surveys of the CDM indicate that investment has been instead concentrated towards rapidly industrializing countries, particularly China, where more lucrative projects exist, while Africa has benefited least from CDM finance despite having more pressing development needs (Newell and Paterson 2010).

Problems with the EU ETS and the CDM also underscore the geographical challenges facing carbon markets. In particular, they reveal tensions between a general regulatory logic that sees carbon markets as effective and efficient mechanisms and the territorial logic of governments seeking to safeguard consumers and strategic industries. The governance problems encountered by the CDM, meanwhile, illustrate the difficulties of reconciling market imperatives for profitable investments with promoting sustainable development and a just apportionment of costs and benefits between countries that have industrialized by burning fossil fuels and those in greatest need and most vulnerable to climate change.

Marxist critiques of carbon markets express similar concerns about their potential to reinforce unequal power relations and inequitable development, but draw broader connections between carbon markets and the history of global capitalism. Central to this approach is the idea that capitalism must continually find new modes and sites of wealth accumulation in order to avert periodic crises in an economic system that is structurally organized around perpetual growth as it encounters resource limits. Harvey (2006) argues that capitalist systems feed value production through accumulation by dispossession – the commodification and privatization of new resources at the expense of pre-existing rights irrespective of whether they were previously regarded as common heritage or property. The commodification of greenhouse gas emissions is seen as a key instance of such dispossession wherein carbon markets assign property rights to, and essentially privatize, aspects of the atmosphere and livelihoods to fuel capital speculation. Böhm, Misoczky, and Moog (2012) describe how the use of rice husk in a CDM biomass power generation project in Thailand denied
local peasants a traditional source of fertilizers and forced them to buy chemical fertilizers from transnational corporations. Newell and Paterson (2010) similarly portray carbon markets as effecting a redistribution of wealth and access to resources under conditions of unequal exchange, where markets create and sell cheap credits to the Global North obtained from the Global South. Such projects often have limited regard for delivering benefits to host regions and mainly enable high-emitting countries to avoid forgoing carbon-intensive lifestyles.

Bailey, Gouldson, and Newell (2011), meanwhile, examine connections between carbon markets and ecological modernization, the influential school of thought which suggests that climate change can be addressed through technological and market innovation without sacrificing societies’ ideological commitment to market capitalism and economic growth. The innate compatibility of capitalism and environmentalism proposed by ecological modernization provides one reason for the political acceptance of carbon markets by mainstream political and business actors. However, the concern again is that the preference for carbon markets within such interpretations of ecological modernization effectively locks out alternative – and perhaps more effective and equitable – ways of mitigating climate change. In particular, ecological modernization’s emphasis on efficiency pays limited attention to distributional equity and the possible need to limit demand for energy and emissions-producing activities. This in turn raises questions about whether ecological modernization thinking enables political and business elites to recognize and respond to structural problems within carbon markets. In essence, does ecological modernization involve genuine reflection on how to reduce the environmental impacts of capitalism or does it simply reinforce “business-as-usual” modes of thinking?

Policies on adaptation and loss and damages

So far, the discussion has focused chiefly on mitigation policy or issues common to both mitigation and adaptation. However, geographers have also been heavily involved in studying the ways in which human adjustments to climate risks operate across spatial and societal scales. An obvious foundational question for adaptation research concerns visions of adaptation. Pelling (2011) argues that climate adaptation should not be limited to interpretations of resilience that emphasize preserving pre-existing states and practices (e.g., the use of new seed varieties to sustain existing agricultural practices). Although resilience in its broader interpretation incorporates multiple and dynamic visions of change in response to shocks and stresses, Pelling also emphasizes the role of transitional adaptations that promote incremental changes to prevailing economic, political, cultural, and social relations, over time, to produce more radical change. Transformational adaptation, in turn, stresses the possibility of utilizing climate risks consciously to reform or replace dominant societal objectives and political-cultural regimes.

Recognizing that adaptation policy is equally about responding to and creating new realities, and not just about preserving the present, raises further questions about the processes used to evaluate the effectiveness, efficiency, equity, and legitimacy of adaptation policy. Adger, Arnell, and Tompkins (2005) argue that these are again geographical issues because adaptation operates at different spatial and societal scales and involves a broad landscape of actors, including individuals, corporations, civil society, local, regional, and national governments, and international agencies. Of particular importance is the potential for operational adaptation decisions to be influenced and constrained by higher-level institutions.
involved in developing adaptation frameworks, but at the same time, for local interpretation of higher-level decisions to have a significant bearing on adaptation outcomes. Equally important are the perspectives held by different actors on the goals of adaptation policy (if these are even defined) and, thus, what effective, efficient, equitable, and legitimate adaptation means and entails. Recognizing and responding to such interconnections can be critical in avoiding maladaptation, that is, impacts that adversely affect the vulnerability of other regions, sectors, or social groups (Barnett and O’Neill 2010).

Recognition that mitigation and adaptation efforts cannot avoid all the impacts of climate change has also prompted growing attention to loss and damages as a means of addressing climate impacts. The UNFCCC responded to this emerging agenda in 2010 by initiating a work program to assess current knowledge of climate-related loss and damages, mechanisms for addressing loss and damage, and the UNFCCC’s role in enhancing the implementation of loss and damage policies. Approaches to address loss and damage from extreme events and slow-onset processes can be divided into four categories: risk reduction; risk retention (e.g., social safety nets and contingency funds); risk transfer (e.g., insurance); and approaches for managing loss and damage from slow-onset processes.

While loss and damages approaches seek to promote the principle of distributive justice within adaptation policy by ensuring that regions and communities’ ability to adapt to climate change is not constrained by resource limitations, implementing the concept can be problematic. First, severe difficulties lie in attributing individual weather events to climate change and even more so in pinpointing culprits from whom to seek compensation. Second, the unpredictability and magnitude of certain climate risks mean that insurance contracts and claims for some climate events may become exorbitantly expensive. As such, the willingness of governments and other actors to contribute is likely to depend on the establishment of multilateral and bilateral “no-liability” financing mechanisms, while further challenges lie in ensuring local communities have a genuine say in international, national, and local planning and decision-making processes and in establishing governance arrangements for the identification and management of climate loss and damages.

Conclusion

Climate policy and governance have become increasingly important themes in recent geographical research on human–environment relations. This interest reflects both the growth of climate change as a policy concern and its intersections with core geographical interests in environmental and economic futures, development and equity, and the changing character and spatialities of governance. The debates reviewed reveal a multitude of uncertainties and disputes about human influences on the climate system, the feasibility and ethics of “governing” climate, different strategies for mitigating and adapting to climate change and their coexistence with development and justice priorities, and even definitions of climate policy itself. Geographical perspectives play a valuable role in probing the complexities lurking within the idea of climate policy, while the epochal and uneven effects of human-induced climate change provide a compelling case for continued geographical investigations of the challenges of developing effective and equitable climate policy.

Climate change, concept of

Mike Hulme
King’s College London, UK

In 1966, the World Meteorological Organization (WMO) published a technical report on climatic change in which the statistical properties of different meteorological time-series data were systematically compared. Climatic change was proposed as the term to embrace all forms of climatic inconstancy on timescales longer than 10 years, irrespective of cause. Although climates were understood as changeable on all timescales, most scientific attention was paid to past changes which had occurred on multi-century to multi-millennial timescales. The favored term was “climatic change,” climatic being used as an adjective to describe this particular type of change (as opposed to, say, political or economic change). Thus the first academic journal dedicated solely to the study of climate change was launched in 1977 with the title *Climatic Change*.

From the 1970s onwards, understandings of climatic change began to change. There was a growing appreciation that a wide range of human activities, from energy use to food production, had the potential to alter the physical functioning of an interconnected global system. “Climate change” – a noun – now became “an issue” rather than the technical description of changing weather it had been for the WMO in 1966. It took its place in public life alongside other “issues” like global poverty, human rights, or water pollution. With the establishment of two new international institutions – the Intergovernmental Panel on Climate Change (IPCC) in 1988 and the UN Framework Convention on Climate Change (UNFCCC) in 1992 – climate change supplanted climatic change as the dominant linguistic term. Climate change became a phenomenon caused by complex chains of human actions (and natural processes), but also an agent which could influence far-reaching sets of material and imaginative phenomena. As this “new” idea of climate change traveled around the world, it became inscribed with multiple and complex political and cultural meanings. In this sense, the idea of climate change has never fully escaped older cultural readings of climate and its changes which have been retained in many non-Western cultures.

Historical and cultural perspectives

The idea of climate change – whether of natural or human origin – has a genealogy that can be traced back to Greek civilization. Not only were changes in climate discerned by Greek scholars, but these early observers were also able to trace causation to human actions in the world. For example, in the third century BCE, Aristotle’s student Theophrastus observed and documented local changes in climate induced by human agency: the clearing of forests around Philippi in Greece warmed the climate, while the draining of marshes cooled the climate around Thessaly. Non-Western cultures also had accounts of climate change, often captured in linguistic expressions for climate which combined both descriptive and causative elements of change. Thus the Inuktitut word *sila* or the Marshellese phrase *oktak in mejatoto* are both expressions which capture the enveloping climate of a place.
CLIMATE CHANGE, CONCEPT OF

and a causative account of cosmological stability or change.

Western Enlightenment discourses about climate change from the seventeenth century onwards frequently turned to the effects of deforestation. For example, the historian Edward Gibbon could see the beneficial warming effects of tree-clearing, both in changes of climate through time and in differences in climate caused by geography. In the late eighteenth century, Gibbon claimed that the “improvement” in European climate since classical times was due to the clearing of “immense woods” and he believed that contemporary forests in Canada subjected that land to a climate as fierce as that of ancient Germany. Empirical support for such understanding seemed to emerge from the land practices of colonizing Europeans in America. Within half a century of large swathes of forest being cleared along the eastern seaboard, observers were able to remark that winters had become less harsh and summers cooler. Climate had not just changed, but had been changed.

The idea of climate change also occupied the imagination of European colonists in the tropics and subtropics. Here, the destruction of forests was believed to exacerbate the droughts that many settlers in the eighteenth century found endemic in subtropical regimes. Climate change was thus not only a phenomenon that humans induced in the physical world; the resulting changes in climate could also challenge the economic wellbeing of a colony and the health of its exogenous inhabitants. Climate change functioned both as an index of change, but also a putative cause of wider environmental and social change.

In western cultures, the temporal horizons over which climates were believed to change were massively extended in the nineteenth century through the combined work of geologists and physicists. Huge swings in global climate were implied by massive and ancient glaciations, the traces of which were newly diagnosed in the landscape by scientists such as Louis Agassiz in the 1830s. But alongside these emerging radical ideas of global climatic instability occurring over previously unimagined timescales, some observers were still grappling with the extent to which human activities could alter contemporary regional climates. The prominent Austrian geographer Eduard Brückner maintained that statistical evidence could be found for contemporary changes in regional climates. In the 1880s he demonstrated that average temperature and precipitation for areas of central Europe and Russia when measured over successive 35-year periods differed substantially, claiming that such changes in climate would have implications for rivers, lakes, agriculture, and human migration.

Despite the work of Brückner and a few others at the time, the dominant Western view during the first decades of the twentieth century was that climates were basically constant on timescales that mattered to human planning and action. The British climate historian Hubert Lamb was thus able to remark in 1959, “not so very long ago … climate was widely considered as something static, except on geological time scale[s], and authoritative works on the climates of various regions were written without allusion to the possibility of change” (Lamb 1959, 299).

The globalization of climate change

Into the 1960s, the dominant approach to understanding climate – and hence climate change – remained through the comparative analysis of meteorological statistics. The WMO’s technical report on climatic change published in 1966 (WMO 1966), systematically compared the statistical properties of different meteorological time series data. Climatic change was defined
as “all forms of climatic inconstancy, regardless of their statistical nature (or physical causes),” although inconstancies over less than a decade in length were to be regarded as climatic variations. Thus climatic change encompassed climate periodicities (regular and irregular), fluctuations, oscillations, vacillations, discontinuities, and trends. With few exceptions, most scientific attention and public interest at the time was paid to (natural) worldwide changes which had occurred in the distant past on multi-century to multi-millennial timescales. Climatic change that originated through human activities and which occurred on the timescales of human generations was confined to local and regional scales.

The preconditions for a new understanding of global climate change began to emerge in the 1960s, as evidenced in a joint UNESCO/WMO symposium on changes in climate held in Paris in 1963. First, a few scholars such as Hubert Lamb in the United Kingdom and Emmanuel Le Roy Ladurie in France began publishing accounts of historical climate change based on long climatic reconstructions derived from documentary and environmental evidence. Lamb in particular helped to popularize the notion of a Medieval Warm Epoch (in the late Middle Ages) and a Little Ice Age (in the early Modern period) – both of which were imagined to be hemispheric, if not global, in reach (Lamb 1966).

Second, new developments in scientific monitoring of the planet, boosted by the International Geophysical Year in 1957/1958 and by new satellite technologies, prompted a new conception of climate as an interconnected system of atmosphere, ocean, biosphere, and cryosphere. Local and regional understandings of climate largely gave way to global understandings, facilitated by early computer simulation models of the newly imagined “Earth system.” This opened the way for numerical experimentation using these models through which the global climatic effects of volcanoes, sunspots, carbon dioxide and, later, nuclear explosions could be safely simulated.

Third, this idea of a human-induced change in global climate found sympathy in the broader currents of intellectual thought of the 1960s and 1970s. The emergence of a new environmentalism focused attention on the planetary scale effects of human activities on the physical world. One of the first associations of anthropogenic climate change with notions of danger was in a 1963 conference of scientists convened by the Conservation Foundation of New York which warned of a “potentially dangerous atmospheric increase of carbon dioxide.” And the first governmental and international assessments of the prospects of climate change were conducted during this period. In the United States for example, the President’s Scientific Advisory Committee in 1965 published a report on “Restoring the Quality of our Environment,” which included a specific section on “the climatic effects of pollution.”

The possibilities of changes to the “global climate system” – driven by human activities – therefore began to be articulated. The first use in a scientific journal of the term “global warming” occurred in June 1971 (Russell and Landsberg 1971) and a major focus of the WMO’s First World Climate Conference in 1979 was on climate change. During the “greenhouse summer of 1988” the idea of anthropogenic climate change – commonly depicted as the enhanced greenhouse effect – penetrated deeply into popular culture in the West, although more superficially or not at all in other parts of the world. The growing political resonance of climate change was partly explained by the dissolution of the Soviet Union between 1989 and 1991. Fears of Cold War destruction were displaced by those associated with climate change, prompting the observation at the time from cultural theorist Andrew Ross that, “apocalyptic
fears about widespread droughts and melting ice caps have displaced the nuclear threat as the dominant feared meteorological disaster” (Ross 1991, 8).

The evolving scientific definition of climate change can be discerned through successive assessment reports of the IPCC. In its First Assessment Report in 1990, no very precise definition of climate change was offered, although it was stated that the “climate change we are addressing in this report is that which may occur over the next century as a result of human activities” (IPCC 1990, xxxvi). In fact the report discussed both natural and human changes in climate. A few years later, the Second Assessment Report was more explicit. Climate change meant “climate fluctuations of a global nature … and which includes the effects due to human actions … and those due to natural causes” (IPCC 1996, 56). By 2001 the IPCC had settled on a definition which also prevailed for its Fourth and Fifth Assessment Reports: “Climate change refers to statistically significant variation in either the mean state of climate or its variability, persisting for an extended period (typically decades or longer). Climate change may be due to natural internal processes or external forcings, or to persistent anthropogenic changes in the composition of the atmosphere or in land use” (IPCC 2001, 788).

While the IPCC understood climate change to embrace both natural and human causes, for the UNFCCC – signed in 1992 – climate change was to mean “a change of climate which is attributed directly or indirectly to human activity that alters the composition of the atmosphere and which is in addition to natural climate variability observed over comparable time periods.” The contrasting definitions between these scientific and political usages have resulted in considerable strategic ambiguity in the public meaning of climate change.

Meanings, imperatives, and language

Since the 1960s, climate change has moved from being a technical description of a physical phenomenon (climatic change) to becoming a political (i.e., a contested) issue. Thus, each December since 1995 has witnessed a two week meeting of the Conference of the Parties (COPs) to the UNFCCC, where politicians, diplomats, business leaders, and civil society organizations have gathered to negotiate political responses to climate change. Further evidence of this shift includes how some government ministries have been reconstituted around climate change. For example, since 2008 the United Kingdom has had a Department of Energy and Climate Change, while in 2010 the European Union appointed its first Commissioner for Climate Change Action.

At the most generic level climate change now acts as a synecdoche for the collective impacts of humanity on the physical process and sustainability of the Earth. This reading of climate change has helped give rise to the idea of the Anthropocene, a new geological era which marks the global impact of human activities on the Earth’s ecosystems. But as the idea of climate change has traveled around the world through scientific, political, and civic networks it has become inscribed with complex meanings each carrying different local resonances. It is not possible to view climate change “from nowhere.”

Contrasting accounts of climate change offer different interpretations of cause, significance, and responsibility, even while anchoring the idea of climate change in the changing weather attributes of the climate system. Thus Ban Ki-Moon, the UN Secretary-General describes climate change as “the defining challenge of our age … the time to act is now,” while the economist Lord Nicholas Stern describes it as “the greatest example of market failure the world
has seen.” Contrasting meanings can be found in the work of ethicists and anthropologists. So theologian Michael Northcott sees climate change as “the Earth’s judgement on the global market Empire and the heedless consumption that it fosters” and cultural anthropologist Jerry Jacka, writing of the Porgeran tribe in Papua New Guinea, explains climate change as “due to societal breakdown between [the Porgerans] and the rituals oriented toward powerful spirits that control the cosmos.”

The proliferation of linguistic terms used to express the idea of climate change lends further variety to these multiple meanings. With climate change (noun) having replaced climatic (adjective) change it became necessary to describe what sort of climate change the world was facing. Climate change is therefore described as natural, anthropogenic, and/or human-induced. It is portrayed as gradual or rapid, smooth, or abrupt (see Table 1). For example, the term “climate catastrophe” first appeared in the context of anthropogenic climate change in the German language in the cultural magazine Der Spiegel in April 1986. The phrase “catastrophic climate change” (Klimakatastrophe) continues to be used to deliberate effect in certain discourses. And other linguistic entrepreneurs have sought to find more persuasive formulations than the dominant expression “climate change.” So “global warming,” “weather weirding,” “the climate crisis,” “global heating,” and “climate disruption” have all been used as alternative, more vivid, descriptions of the idea of anthropogenic climate change.

**The future of climate change**

There are few issues in the world today that can match the salience and cultural reach of climate change. Books dealing with climate change now appear at the rate of more than one a day in the English language alone, compared to less than one a week a generation ago. They cover topics such as climate change and architecture, diet, football fans, gender, theology, visual art, time, forests, justice, democracy, disasters, trust, law, aviation, migration, and capitalism. Not only is the reality of climate change contested, but so too are its causes, consequences, and meanings. Climate change today therefore needs to be understood as an emergent phenomenon that is simultaneously a physical transformation of the climate system and an evolving cultural symbol. The insights of anthropologists, psychologists, sociologists, literary critics, historians, theologians, and philosophers are needed to do justice to the idea of climate change, as much as those coming from natural and physical scientists.

All of human life is now lived out not just in the presence of a physically changing climate, but...
CLIMATE CHANGE, CONCEPT OF

but in the new discursive and cultural spaces that have been created by the idea of climate change. Most human practices and disputes can now be expressed through the language and symbolism of climate change. Thus photography, music, cartoons, literature, theater, poetry, dance, religious practice, architecture, educational curricula, personal identity, politics, and so on, use climate change as a medium of expression. And disputes about flood management, landscape aesthetics, child procreation and child rearing, trade tariffs, development aid, industrial patents, social justice, taxation, even democracy itself, are formulated in the language and argumentative spaces of climate change. As suggested by the eco-critic Greg Garrard, we “feel there might not be any narrative whose meaning we cannot re-evaluate in relation to climate change” (Garrard 2013, 183). Climate change has become a new condition through which human life now takes shape.

Climate change communication

Susanne C. Moser  
*Susanne Moser Research & Consulting, USA  
Stanford University, USA*

Communicating climate change – as a special case of science and risk communication, and as an opportunity for civic engagement with global environmental change – is among the greatest communication challenges in contemporary society. The social-scientific interest in climate change communication has risen over the past decade in response to the growing understanding in the problem and the lagging societal response (Moser 2010, 2016). Over this period, understanding of climate change communication has grown significantly, although it remains difficult because of the nature, scope, scale, and speed of the problem, the enormous political and financial stakes involved, and the changing societal context that shapes people’s receptivity of the issue (Whitmarsh, O’Neill, and Lorenzoni 2011; Moser and Dilling 2007).

For some, communicating climate change is a matter of science education and as such a desirable goal in itself; for others, it is a means to increase scientific literacy so as to increase people’s capacity to participate in an informed manner in the decisions of a democratic society. For yet others, communicating climate change serves advocacy, that is, informing and mobilizing society for or against certain courses of climate action. The resulting politicization of climate change science has also created considerable interest in how to effectively counter disinformation campaigns and overcome societal and political polarization on the issue (McCright and Dunlap 2011).

Geographers’ interest in climate change communication

Given both physical and human geographers’ long-standing involvement in the study of global (climate) change, communication is a central concern for them. As humans modify the climate, environment and life support systems of the planet, and thus cause a fundamental shift in human–environment interactions, including in the availability of natural resources and the occurrence of climatic hazards, climate change communication becomes a foundational skill and tool for geographers. Geographers are interested in conveying and explaining observed and projected changes in the environment – a task made more difficult by the fact that the causes and early impacts of climate change are difficult to see, slow to emerge, and challenging for lay audiences to connect systemically. This makes climate change communicators part of the “early warning” system of a society and thus part of the human response to climate change.

In addition, for many geographers, effectively communicating the causes, risks, and response options to climate change is a matter of practical necessity and ethical obligation. Not only as educators and researchers in multidisciplinary teams, but as expert informants of policy debates or management responses, as consultants, and as individuals participating in civil society, geographers are grappling with how best to communicate the issue to different audiences.
CLIMATE CHANGE COMMUNICATION

With the expertise inherent in the field of geography, in earth science and human-environment interactions, its unique interest in linking phenomena across space and scale, and its ability to understand change in the richness of place-based and regional contexts, geographers are well positioned to help society understand climate change, facilitate meaningful interpretation of the science, and foster an informed debate about possible responses.

Focal areas for climate change communication

The practice and study of climate change communication have centered on different aspects of climate change. Early on, interest was primarily in articulating the science of climate change, that is, establishing its existence, providing multiple lines of evidence for its reality, explaining its causes, particularly the growing understanding of its human causation and how scientists have come to know and become confident in this conclusion, as well as illuminating the complex challenge of global climate modeling and future projections of climate change. Much of the communication challenge with regard to climate science has been in simplifying complex science for audiences with varying levels of science literacy. This involves identifying useful mental models that help individuals understand the fundamental aspects of the problem, and to help audiences sort out (scientifically unsubstantiated, but nevertheless frequently repeated) counterclaims asserting that climate change is not real, not human caused, and not significant or certain enough to warrant action.

A second major focus of climate change communication is the emerging and future impacts of climate change, and the ecological and societal vulnerabilities in different regions and sectors to these consequences. For communicators, there have been both opportunities and challenges in that focus. Climate change impacts as the concrete manifestations that “bring climate change home” (Slocum 2004) offer communicators an opportunity to make the abstract topic of concern visible, tangible and meaningful to audiences (Moser 2014). Years ago, communicating impacts typically involved pointing to the future, to places far from where the majority of humanity lived, and to other species – such as polar bears on melting ice floes or low-lying islands in the Pacific ocean being inundated by the rising sea. These science- and necessity-driven ways of “distancing” climate change in space and time matched the human propensity for psychological distancing (Spence, Poortinga, and Pidgeon 2012), that is, the common desire to keep threats at arm’s length as a way to manage the psychological impact of taking the magnitude and profundity of global climate change seriously. More recently, the early consequences of climate change have become evident in every region of the world and thus offer opportunities to link the observed with the scientifically understood and with future projections. In turn, this challenges communicators not only to find ways to communicate what is (and is not yet) understood in scientifically credible ways, but also to help people process their affective responses (e.g., worries, fears, guilt, denial, hopelessness) to these emerging and projected impacts (Swim et al. 2011).

The third major focus in climate change communication (as in the climate change science field more generally) is on response options. With regard to communicating climate change mitigation, that is, efforts to reduce the causes of anthropogenic climate change, one major challenge has been to persuade society of the human causation of contemporary climate change, and thus of humanity’s responsibility for minimizing future climate change. Concurrent
is the challenge of conveying just how substantial the reductions in emissions from energy consumption, transportation, land use, and industrial activities need to be if society wishes to avoid significant disruption of life support systems, economies and livelihoods, human safety and wellbeing, and place identity. A third set of challenges in communicating mitigation lies in translating complex policy mechanisms and associated responsibilities and roles for different actors at different scales of governance into understandable approaches and clear actions.

Communicating the complementary response of adaptation, that is, the diverse set of strategies and options for preparing for and minimizing the risks of negative impacts from climate change and for taking advantage of possible positive consequences, is a more recent challenge. Many view this as a growing opportunity to “make climate change real,” to take actions that produce immediate and tangible results (as opposed to the delayed climate-related benefits of emission reductions), and to address local challenges that diverse interests may be able to rally around. However, the concept of adaptation is still unfamiliar to people, and to some it signals passivity, defeat, and competition to mitigation. Research on whether or not these assumptions and perceptions are borne out in reality and on how best to communicate adaptation is only beginning to emerge (Moser 2014).

A range of related but more specific issues have emerged, such as the deliberate modification of the climate system through various geo-engineering approaches, or carbon capture and storage, that communication researchers are also beginning to examine. In all of these instances, common communication concerns revolve around public perceptions and understanding, linguistic preferences, mental models, beliefs and attitudes toward responses, the willingness to fiscally or politically support a particular course of action, and what roles different actors may (or should) play in any of them.

**Messaging, language, and imagery**

While the categorical areas of climate change communication directly mirror the concerns of climate change researchers more generally, it is far from obvious exactly what, how much, and in what words and imagery the substance of climate change should be communicated. Information needs, levels of understanding, cognitive processes, cultural values, and the context in which information is being communicated are among the key influences on what information different audiences take up, accept, understand, and perceive as persuasive, how they interpret and retain it, and whether or not and how it influences their behavior (Swim et al. 2011; Hulme 2009; Moser and Dilling 2007).

Particular attention in this context has been paid to mental models, that is, the conceptual, symbolic, often intuitive ways in which we represent real-world processes in our minds. Mental models are simplified explanations, constructed and reinforced by language, images, symbols, sounds, colors, and tone of voice. They predispose us to think about problems and associated solutions in certain ways, for example, the “greenhouse effect” offers a mental model of global warming that likens the effect of heat-trapping gases in the atmosphere to the panes of a greenhouse, which allow sunlight to come through, but heat to be retained inside the greenhouse (Figure 1).

Considerable applied research thus has also gone into research on messaging, that is, what and how best to communicate climate change, including:

- how to avoid the conceptual confusion of weather and climate;
The greenhouse effect

Some solar radiation is reflected by the Earth and the atmosphere.

Some of the infrared radiation passes through the atmosphere. Some is absorbed and re-emitted in all directions by greenhouse gas molecules. The effect of this is to warm the Earth’s surface and the lower atmosphere.

Most radiation is absorbed by the Earth’s surface and warms it.

Infrared radiation is emitted by the Earth’s surface.

Figure 1 The greenhouse effect has long served as a mental model to explain how certain natural and human-generated gases trap heat closer to the Earth’s surface and warm up the planet. Reproduced from US Environmental Protection Agency, 2012. © US Govt/EPA.

- word associations and preferences such as climate change vs. global warming, or adaptation vs. preparedness;
- the benefits and drawbacks of different mental models such as carbon pollution vs. greenhouse effect; and
- resonance of different frames, such as economic vs. national security vs. moral reasons for acting on climate change (Whitmarsh, O’Neill, and Lorenzoni 2011; Moser and Dilling 2007).

More recently, communication researchers have also become interested in the use of imagery, especially iconic imagery and graphics, in conveying climate change messages (O’Neill and Smith 2014) (Figure 2).

Communicators and trusted messengers

Historically, scientists in academia and other research institutions were the primary communicators of climate change — a logical result of scientists discovering and working to understand this global, but at first “invisible,” problem. With growing understanding of the far-reaching implications of climate change, however, spokespersons...
Figure 2  Research into the use and impact of iconic imagery on issue salience and people’s personal sense that they are able to do something about climate change (self-efficacy) has revealed that images of climate change impacts (such as extensive flooding – photo in (a)) can increase salience but undermine self-efficacy. By contrast, images that help envision a clean energy future (photo in (b)) promote self-efficacy (O’Neil and Smith 2014).

from non-governmental organizations, politicians, government agency representatives, and influentials from other sectors of society (e.g., faith and business communities, entertainment) have become common messengers in the public arena. Communication researchers have examined the various roles they play with regard to science translation, advocacy, agenda setting, education, moral suasion, and political influence. A key factor in the amount of influence is the degree to which the messenger is perceived as a trusted source of information (and judgment) among a given audience (Moser and Dilling 2007).

Communication channels and the role of traditional and new/social media

Another focus in climate communication research is the pathway through which different audiences hear and learn about climate change and through which they communicate about it. The strongest focus has been on mediated forms of communication. In particular, the important roles of the media as communicators, translators, and explainers of emerging science, as shapers of public and policy agendas, as influentials on public understanding of science and the scientific consensus on climate change, but also as amplifiers or attenuators of influential voices in the public debate are key research foci (for ongoing tracking and analysis of climate change media coverage see: http://sciencepolicy.colorado.edu/media_coverage/). A critical understanding of these roles of the media requires a consideration of the political economy of the media industry, journalistic norms, editorial and professional influences on what, how often, and how climate change is being communicated, and of the influence of technology on social interactions, cultural expectations, and changing civic behavior (Boykoff 2011). This has also led to a growing interest in the role and potential/limits of non-traditional media (new and social media, internet, Web 2.0).

An important, if quantitatively smaller, body of work on the topic of communication channels focuses on direct interpersonal, face-to-face, or virtual communication. As the oldest form of communication, the research and practical focus on face-to-face, direct communication and dialog were somewhat neglected in the face of the rapidly rising technology-based, mediated forms of communication. A range of disciplines (from neuroscience to psychology and beyond) have contributed to a better understanding of the observed politicization and polarization in public opinion on climate change, that is, the ideologically and values-driven divergence in public understanding and opinion about climate change, and the resulting antagonistic exchange among divergent factions of society. Based on these insights, dialogic approaches to communication of climate change (use of active, two-way conversation as opposed to one-way information delivery) are being increasingly studied and explored in practice.

Understanding audiences

Deliberate or strategic communication, that is, communication aimed at achieving an intended outcome (such as a certain level of climate literacy, or public support for a certain climate policy), aligns the contents to be communicated with the communication channel(s) and messenger(s), as well as with frames, mental models, and language that are meaningful and resonant with a particular audience. This requires communicators to move away from thinking of a generalized “public” and instead clearly define and understand particular publics so that climate communication can be tailored accordingly.
In fact, considerable research has gone into understanding different audiences. The longest-standing strand of research in this regard has focused on tracking public perceptions of and attitudes toward climate change, as well as public understanding of climate change (science), including identifying dominant beliefs and key gaps in understanding (e.g., Gallup, Pew, and Stanford opinion polls). Because different messengers have come under attack over time, public opinion surveys also commonly now track attitudes toward scientists and other prominent communicators (e.g., on trustworthiness). Opinion surveys are also used to track public preferences among response options. Mostly, these have focused on mitigation such as different energy sources or particular policy mechanisms, for example, energy efficiency standards, a carbon tax, a cap-and-trade system, and so on, but increasingly they also ask about adaptation and geoengineering.

Communication researchers are interested in better understanding different audiences’ belief systems, worldviews, and values that shape how and to what extent climate change information is taken up and how it is interpreted (e.g., cultural cognition of risk, www.culturalcognition.net). Another audience-focused research interest is gaining traction among climate communication researchers as the limits of an exclusively cognitive approach to engaging publics are becoming more apparent: affect and emotional responses to climate change play an important role in people’s responses to this global problem; worry, fears, anger, grief, guilt, hope, and other feelings affect people’s valuation of the seriousness and urgency of climate change, their assessment of the need for and possibilities of personal and societal response, and their level of cognitive, behavioral, civic, and political engagement (Swim et al. 2011).

The cumulative insights on differences among publics have led to different audience segmentation studies. For example, early approaches focused on demographic variables (e.g., age, gender, ethnicity), finding, for example, that women across cultures appear to be more concerned about climate change than men and wish to see a more urgent and comprehensive response. Others have differentiated audiences mostly along political ideological lines, finding that more liberal, left-leaning audiences tend to be more convinced about the science of climate change, show greater concern, and feel greater urgency to take strong action on climate change than their more conservative, right-leaning counterparts. They also have tracked the growing polarization in climate change attitudes and beliefs, particularly in the US. A more recent variant of audience segmentation research distinguishes audiences by prevalent cultural worldviews and belief systems (e.g., Leiserowitz and colleagues’ ongoing survey since 2008 on “Global Warming’s Six Americas,” which is based on cultural theory; Leiserowitz, Maibach, and Roser-Renouf 2008; for regular updates see: http://environment.yale.edu/climate/).

In summary, different audiences share different convictions about the reality, human causation, urgency, and severity of climate change; they trust different messengers, and preferentially use different media channels; and they share different concerns, emotional responses, and preferences for responses (e.g., level of government involvement, regulation vs. free-market, voluntary or individual actions). The notable polarization over the past 20 years of climate change communication, resulting in a self-reinforcing process of opinion hardening, without necessarily increasing climate science literacy, has resulted in a very challenging communication environment. This has led to a growing interest among both researchers and communicators in the
CLIMATE CHANGE COMMUNICATION

possibilities of reducing that polarization, bridging differences and finding common ground among divided societal factions and elevating climate literacy to reduce the gap between the ever-stronger scientific consensus on the reality, causation, and urgency of climate change and lay audiences’ and policymakers’ understanding and responses to climate change.

Climate literacy

Lesley-Ann L. Dupigny-Giroux
University of Vermont, USA

Climate literacy refers to both a body of knowledge and a way of understanding and acting in light of this knowledge. It is a distinct subset of science literacy, or the knowledge, skills, and attitudes needed to apply inquiry or problem-based approaches to new situations and decision-making. Climate literacy involves a deep appreciation of the complexity and interconnectedness of the climate system over space and time; the role that humans exert in modifying and interacting with the climate system; the ability to “act accordingly” having understood the above; and the recognition of bias or the change in behavior due to insights gained about an issue or concept (Dupigny-Giroux 2008, 2010). The Essential Principles of Climate Science Literacy (US Global Change Research Program 2009), which were developed through a collaborative process among a number of science agencies, scientists, educators, nongovernmental agencies, and US governmental agencies including NOAA (National Oceanic and Atmospheric Administration), AAAS (American Association for the Advancement of Science), and the National Science Foundation (NSF), state that “People who are climate science literate know that climate science can inform our decisions that improve quality of life. They have a basic understanding of the climate system, including the natural and human-caused factors that affect it. Climate science literate individuals understand how climate observations and records as well as computer modeling contribute to scientific knowledge about climate. They are aware of the fundamental relationship between climate and human life and the many ways in which climate has always played a role in human health. They have the ability to assess the validity of scientific arguments about climate and to use that information to support their decisions.”

One of the keys to unlocking climate literacy is understanding the distinction between weather, climate, the climate system, climate variability, and climate change. The interchangeable usage of these terms in the public lexicon not only leads to confusion and bias, but also erodes the fundamental underpinnings of science literacy in general. Weather refers to the “short-term (minutes to days) variations in the atmosphere” of such variables as “temperature, humidity, precipitation, cloudiness, visibility, and wind” (American Meteorological Society 2000). Climate, on the other hand, refers to “The slowly varying aspects of the atmosphere–hydrosphere–land surface system. It is typically characterized in terms of suitable averages of the climate system over periods of a month or more, taking into consideration the variability in time of these averaged quantities” (American Meteorological Society 2000).

The climate system refers to the processes occurring in the Earth’s spheres, as well as the interaction between them that determines a region’s climate. These spheres are the atmosphere, hydrosphere (lakes, rivers, oceans), cryosphere (frozen ground, glaciers, ice, and other frozen parts of the hydrosphere), biosphere (vegetation on land and marine biota in the oceans), and the lithosphere (crustal matter). The interconnectedness of the climate system suggests
CLIMATE LITERACY

that a systems-based approach be applied to understanding and quantifying climate processes.

It is important to appreciate the nuances of the related concepts of climate variability and climate change. Climate variability encompasses “variations in the mean state and other statistics (such as standard deviations, the occurrence of extremes, etc.) of the climate at all spatial and temporal scales beyond that of individual weather events. Variability may be due to natural internal processes within the climate system (internal variability), or to variations in natural or anthropogenic external forcing (external variability)” (IPCC 2012, 557–558).

Climate change refers to: “A change in the state of the climate that can be identified (e.g., by using statistical tests) by changes in the mean and/or the variability of its properties and that persists for an extended period, typically decades or longer. Climate change may be due to natural internal processes or external forcings, or to persistent anthropogenic changes in the composition of the atmosphere or in land use” (IPCC 2012, 557).

These definitions highlight the timescales involved, the tight coupling between the atmosphere and the other spheres on Earth, and the role of both anthropogenic and natural drivers. What is missing from these definitions is the awareness that uncertainty exists in observations of changes in the climate system, certain drivers of climate change (e.g., aerosol and cloud forcing), recent changes in the climate system, and projections of global and regional climate change (IPCC 2012). While the presence of uncertainty makes it challenging to be “responsive to policymakers’ needs for expert judgment at a particular time, given the information currently available, even if those judgments involve a considerable degree of subjectivity” (Moss and Schneider 2000), uncertainty should not be misconstrued as unreliability or the complete lack of scientific climate knowledge. The 2013 American Meteorological Society’s (AMS) policy statement “Climate Science is Core to Science Education” states that “uncertainty is a natural component of the all scientific endeavor” and “provides a sound example for the broader instruction of the scientific method.” An incomplete appreciation of uncertainty, feedbacks, and scale in the climate system leads to weather and climate becoming either interchangeable concepts or synonymous with only one process (e.g., climate change) or variable (e.g., temperature and precipitation) (Dupigny-Giroux 2010).

As with any discipline or language, climate understanding hinges upon terminology. Core concepts or processes such as teleconnections, electromagnetic radiation, and the hydrologic cycle are not always well understood by nonpractitioners. After learning the rubrics of the climate language, undergraduate students report having a “more cohesive comprehension” and being less likely to question the legitimacy of science in general due to a lack of understanding. Disconnects in terminology and physical processes often exist between the public and climate spheres. For example, Choi et al. (2010) outlined the ways in which the term “air pollution” (soot, aerosols, particulate matter) has become confused with and is now interchangeable with greenhouse gases, and ultimately global warming. Another disconnect lies in statistical climate averages and the usage of the term “normal.” The World Meteorological Organization (WMO) mandates that climate variables be averaged over a consecutive period of 30 years, producing 30-year statistical averages that are also called climate normals. A misconception that only 30 years of data are needed to define climate, or that climate is only relevant to the last 30 years, may have arisen from the layperson’s use of the term “normal” – meaning “the expected value” or “according with, constituting, or not deviating
from a norm, rule, or principle” (Merriam-Webster 2012). Related concepts such as the probability of an event’s occurrence, the mean or average of observations over time, and the fact that these averages change with the length of the observational record and length of time being averaged, are key to quantifying the characteristics and changes of a region’s climate. Finally, the importance of cultural norms and linguistic choices is often overlooked in the translation of science and mathematical concepts or results from one language to another.

Achieving climate literacy can only occur in the context of interdisciplinarity, ranging from the mathematical sciences, through the natural and social sciences, and into the cognitive sciences and psychology. The communication of climate understanding and knowledge must hinge on the lessons derived from cognitive and neuroscience literature on how humans learn and assimilate new information. Social constructivist theory reveals that new knowledge is socially constructed from previous cultural and epistemological experiences and knowledge acquisition, especially at the pre-high school levels. Varying degrees of climate illiteracy emerge when this prior knowledge is riddled with misconceptions about the climate system. Climate misconceptions are held by both students and lifelong learners alike. Many of these misconceptions are related to global climate change, while others point to a fundamental flaw in science literacy in general. Hendriques (2000) identified possible sources of misconceptions in textbook diagrams, verbal explanations, personal observations, and the stories recounted to young children. In summarizing 41 of the most commonly held misconceptions among middle and high school students, Choi et al. (2010) focused on the role of textbooks in contributing to the initial formation of climate misconceptions around types of radiation, the nature of selective absorption, greenhouse gas emission, stratospheric ozone depletion, and the distinction between particulate air pollution and gases.

Perhaps the most pervasive of all climate misconceptions is the notion that stratospheric ozone depletion (which is important for short wavelength ultraviolet radiation) causes tropospheric atmospheric warming (which is a function of the absorption and emission of long-wave radiation). Not only is this misconception particularly resistant to instructional remediation (Chi 2005), but it has been reported worldwide and has its roots at the middle school level. The multiple inaccuracies convolved in this misconception are exacerbated by students’ inability to think or visualize in three dimensions (which affects their understanding of where in the vertical profile of the atmosphere the processes occur) and their flawed notion that stratospheric ozone is a single species while tropospheric ozone is composed of other gases such as carbon dioxide, methane, nitrous oxide, and oxygen.

Dupigny-Giroux (2010) highlighted six challenges to achieving climate literacy. These included the language of the climate sciences (or scientists speaking in code; see also Somerville and Hassol 2011); the persistence of misconceptions; the timing of curricular interventions; the importance of learning styles; the importance of formal educators; and the role of life experience. In the formal academic setting, achieving climate literacy (and science literacy in general) is intricately linked to student preparation in terms of academic content and lifelong learning skills. Undergraduate students report being better able to grasp atmospheric and climate concepts when they had taken either earth science or physics at the pre-baccalaureate level. Similarly, lack of familiarity with the scientific method and scientific habits of the mind (e.g., observation, quantitative analysis, and deductive reasoning) also poses barriers for those who do not consider
themselves as being predisposed to science. Achieving climate understanding will involve targeting both the analytical and the experiential processing systems of the human brain (Center for Research on Environmental Decisions 2009). Climate literacy demands the ability to view connections over time and space, and in the language of Bloom’s taxonomy, to move beyond simple knowledge or remembering to higher orders of applying, analyzing, evaluating, and creating new information. Climate understanding relies on process-based approaches and the ability to synthesize different elements of the land surface. Finally, achieving climate literacy calls for a paradigm shift away from a student-centric world view on the part of students in which they “forget the big picture,” to a broader temporal and spatial view of the climate system around them. This is facilitated by helping students shift from a “fixed intelligence mindset” in which they tend to avoid challenging material, to a “growth intelligence mindset” (Dweck 2006) where they have acquired the habits of the mind needed to embrace and persist in overcoming their personal barriers to climate literacy.

Climate policy

Paul A.T. Higgins
American Meteorological Society, USA

Climate policy is decision-making that relates to the climate system. This can include efforts to increase understanding of weather and climate events or to manage risks and realize opportunities associated with current weather patterns, climate variability and climate change (whether natural or caused by humans). Increased knowledge and understanding of the climate system results primarily from scientific observations and research. Weather and climate services help apply that knowledge and understanding for societal benefit (American Meteorological Society Policy Program 2012).

Weather and climate observations reveal dangers from severe weather, create a long-term record for assessing climate variability and change, and provide a rigorous basis for the development, testing, and validation of the models used for forecasts, projections, and predictions. Weather and climate observations provide information on temperature, precipitation, humidity, cloud cover, and other atmospheric conditions. Observations also record physical conditions at the Earth’s surface (e.g., coastal inundation, the status of water resources, timing of lake and river freezing and thawing, etc.) and biological characteristics (species ranges and the timing of seasonal events such as bud burst, flowering, leaf drop, and migration). These observations come from surface (terrestrial, oceanic, and cryospheric), airborne, and satellite-based instruments.

Weather and climate science consists of basic and applied research (analysis and experiments). It may be conducted in the laboratory, the field, or in computer models and is intended to expand our knowledge and understanding of the characteristics and functioning of the climate system. The information that results helps identify and characterize risks and opportunities associated with the climate system, which can enhance commerce and help society minimize (or avoid altogether) weather- and climate-related dangers. Scientific research on the climate system is conducted in academic institutions, government agencies, and the private sector (for-profit and not-for-profit organizations).

Weather and climate services help us to apply knowledge and understanding to benefit society. For example, services can help improve public health and safety, expand economic opportunities, protect environmental resources, and promote national security. Weather and climate services include weather forecasts and warnings, flood and drought prediction and monitoring, natural hazard preparedness and response, public health monitoring, disease prevention and control, assessment and management of fire risk, and decision support for water resources, agriculture, transportation, and other key economic sectors.

For example, weather and climate forecasts support agricultural decision-making such as which crops to plant, when to plant them, and how best to irrigate, fertilize, or control for pests. Weather forecasts and climate projections can also help identify when social challenges or unrest may occur because of crop failures and reduced yields.
Policy choices with respect to the climate system can include decisions about how much to invest in (and how best to conduct) observations, science, and services or specify building codes, land-use patterns, disaster insurance requirements and subsidies, and efforts to monitor, prepare for, respond to, and recover from disasters. These choices influence vulnerability and resilience to weather and climate events.

Government agencies at all levels (national, regional, and local) fund scientific research, determine the balance of investments among disciplines and between basic research and applied objectives, establish and maintain observations, provide weather and climate services, and create weather- and climate-related regulations.

The National Meteorological and Hydrological Services (NMHSs) such as the National Weather Service in the United States provide data, forecasts, and warnings. For-profit companies and humanitarian institutions also provide weather and climate services. These services inform and support routine activities for people and businesses and help protect life and property from extreme weather events.

Climate change as a policy issue

As a policy topic, climate change boils down to four overarching issues: (i) climate is changing, (ii) people are contributing to climate change, (iii) the societal consequences of climate change are highly uncertain but include the potential for serious impacts, and (iv) there are numerous policy options for climate change risk management, most of which are well characterized (i.e., have known strengths and weaknesses) (Higgins, 2014b, from which portions of this section are adapted. © American Meteorological Society. Used with permission.)

Climate is changing. The scientific conclusion that climate is changing is overwhelming because there are many separate lines of evidence that all agree and that have been verified by many different experts. Think of it this way: if you feel heat, smell smoke, hear a fire alarm, and see flames then you have independent confirmation from four senses that there is a fire. The evidence is conclusive. The same is true for climate change. The evidence that climate is changing comes from more than a dozen independent measurements, including: (i) temperature increases in the air measured over land and the oceans using thermometers, (ii) temperature increases in the air measured by satellites, (iii) warmer ocean temperatures (i.e., greater ocean heat content), (iv) melting glaciers throughout the world (the vast majority), and (v) species moving where they live and shifting the timing of their key life events (e.g., migration, reproduction, and periods of activity). These, and other, independent lines of evidence demonstrate that climate is changing.

People are contributing to climate change. Multiple independent lines of scientific evidence demonstrate this as well. Basic math and a growing chemical signature of carbon from fossil fuels demonstrate that people are causing carbon dioxide concentrations to increase in the atmosphere. The warming influence of greenhouse gases is clear based on laboratory experiments, evidence from past changes in climate due to greenhouse gases, and the role of greenhouse gases on other planets (e.g., that Venus is much hotter than Mercury despite being further from the sun).

Additional lines of evidence to link human activities with climate change relate to the patterns of change underway. Think of it like a whodunit where the suspects each have a unique fingerprint – a pattern of climate change they cause. The changes in climate we have witnessed over the past several decades match the patterns expected from greenhouse gases well and do not match the characteristics we would expect from the usual suspects: the sun, volcanoes, aerosols,
land-use patterns, or natural variability. That, in addition to what we know about greenhouse gases, is conclusive evidence that humans are contributing to climate change.

The societal consequences of climate change in the decades ahead are hard to predict because exactly how climate will change and how capable human society will be at absorbing climate impacts are issues characterized by deep uncertainty. This deep uncertainty will almost certainly remain for the foreseeable future.

Notably, different experts reach different conclusions about the seriousness of climate risks. Some experts think the consequences of climate change over the next several decades are likely to be relatively small – perhaps a few percent of GDP. They tend to foresee some combination of stabilizing climate feedbacks, relatively low sensitivity of physical systems, biological resources, and social institutes to climate changes, and a large capacity for society to deal with climate impacts (due, in part, from humanity’s considerable scientific and technological capabilities).

Other experts see climate change as a very serious risk to society. The rationale for this view may include that: (i) the expected changes over the next several decades are unprecedented over the past 10,000 years (i.e., since the start of human civilization); (ii) relatively small changes in climate in the past have, at times, had large societal consequences locally or regionally; and (iii) the physical characteristics of our planet, the biological resources on which society relies, and the social systems that we have developed are often heavily adapted to existing conditions. This increases the potential for changes in climate to be disruptive.

Even in the absence of deep uncertainty over climate change’s specific consequences, policy responses necessarily integrate both objective information about the climate system and our relationship with it, and subjective value judgments (e.g., whether we are more averse to the risks of changes in climate or the policy responses, the ways we assess issues of fairness among nations and peoples, and the consideration we give to cultural heritage or nonhuman species). This creates a complex and often contentious risk management challenge.

Policies relating to climate change can be thought to fall into four broad categories (Figure 1): (i) mitigation – reducing greenhouse gas emissions, (ii) adaptation – increasing society’s capacity to cope with changes in climate, (iii) geoengineering or climate engineering – deliberately manipulating the Earth system to counteract at least some of the impacts of greenhouse gas emissions, and (iv) knowledge base expansion – learning and understanding more about the climate system, which can help reveal risks and opportunities and support risk management efforts.

Reducing emissions is a little like disease prevention (e.g., exercise, eat well, and don’t smoke). Adaptation is like managing illness (e.g., take medicine to cope with symptoms and alleviate problems). Geoengineering is a little like organ transplantation – best avoided but potentially better than the alternative even if you happen to be the first (or only) patient.

Each category of response consists of a family of possible options (described in greater detail below). In some cases the boundaries between the categories become fuzzy (e.g., efforts to reduce emissions might influence adaptive capacity in some cases, and vice versa). Indeed, some consider geoengineering approaches as falling under either mitigation or adaptation. Furthermore, none of the proactive risk management options are mutually exclusive – we could simultaneously enact policies intended to mitigate, adapt, and geoengineer in a range of combinations. Comprehensive climate change risk management almost certainly includes a
Climate change risk management consists of three proactive risk management strategies (mitigation, adaptation, and geoengineering) and efforts to expand the knowledge base with respect to the climate system through research, observations, technology development, and scientific assessments (Higgins 2014a).

### Mitigation

By reducing emissions, mitigation decreases society’s future contributions to greenhouse gas concentrations in the atmosphere. This translates into smaller future changes in climate, which increases the chance that societal impacts will remain manageable. However, the climate has already changed and will continue to warm due to past emissions, which makes some climate impacts unavoidable. Mitigation does little to help with changes in climate that have occurred or are already entrained.

Mitigation could also create risks. Some approaches could reduce access to energy or cause excessive energy price increases. Adverse secondary consequences are also possible. For example, policies to promote biofuel production could lead to inefficient uses of land, water, or agricultural crops. Biofuel use could also reduce air or water quality.

However, mitigation might also confer benefits unrelated to climate change (often called co-benefits). For example, reducing emissions of greenhouse gases is expected to reduce more traditional forms of pollution associated with coal-fired power plants (e.g., mercury emissions, smog, and acid rain), which would benefit public health. Similarly, mitigation would likely lead to a reduction in oil consumption. This would help reduce impacts associated with oil drilling, transport, and use, and lessen foreign oil dependence, which could improve the environment, the economy, and national security.

Approaches to reducing emissions fall into several broad categories. These include: (i) regulation; (ii) research, development, and deployment of new technologies; (iii) conservation; (iv) efforts to increase public awareness; (v) positive incentives to encourage choices that lower emissions; and (vi) adding a price to greenhouse gas emissions, which creates an overarching incentive to reduce emissions.

Regulations often specify what activities are permitted and the manner in which they may be conducted. This can include (among others) specifying fuel efficiency standards for vehicles, determining land-use practices, establishing mandates to use specific emission control technologies, making harmful practices illegal, establishing renewable energy requirements, or enacting building codes and construction practices that help reduce energy consumption (e.g., requiring the use of energy-efficient appliances and minimum amounts of insulation).

Research, development, and deployment can help create or improve next-generation technologies, including those that might reduce emissions. Conservation of energy or biological resources (e.g., forests and wetlands) can help reduce emissions associated with energy use or
land-use practices. Public awareness campaigns can help ensure that the public understands the implications of their choices and encourage individuals to adopt practices that reduce emissions. Similarly, positive incentives such as tax breaks or subsidies can help shape consumer preferences toward products and choices that result in lower emissions.

Adding a price to greenhouse gas emissions is a particularly noteworthy policy option because it would be expected to have a broad-reaching impact on emissions, has received a great deal of attention from the research community, and has been a focus of policy discussions since climate change emerged as a public issue.

Three economic principles suggest that adding a price to greenhouse gas emissions might be a beneficial way to manage climate change risks. The first economic principle relating to emission pricing is that having less of something (greenhouse gas emissions, in this case) almost certainly requires an increase in the price of those activities that cause it. This is because a price increase for emitting activities causes emissions reductions by encouraging efficiency (a reduction in emissions for a given amount of the activity) and also frugality (more sparing engagement in the activity) (Daly 2007). Critically, increasing the efficiency of an activity without a corresponding increase in the price makes engaging in the activity cheaper, which encourages more of the activity. As a result, efficiency gains without an increase in the price of an activity may not lead to emissions reductions.

The second economic principle is that incorporating the costs associated with climate change into the price emitters pay for their emissions (i.e., through an additional price on emissions) would be expected to increase overall economic wellbeing. This is because maximum economic benefits are realized when individual decision-makers (the entity choosing to emit, in this case) pay all costs and receive all benefits associated with the activity.

Currently, the societal consequences of climate change are distributed across the entire population, including future generations. As a result, potentially significant economic costs associated with greenhouse gases (i.e., the societal costs of climate damage) are not paid for by those who emit. Instead, the people who endure the consequences of climate change pay those costs. This constitutes an economically harmful subsidy that emitters receive from the broader society. Incorporating the costs of climate damage into the price paid by emitters would reduce that subsidy and therefore bring net economic benefits.

Note, however, that greenhouse gas emissions result, in part, from six separate market failures (Higgins 2010). These include: (i) that the cost of climate damages associated with emissions are not included in the price paid by the emitter (i.e., a negative externality is unaccounted for, as described above); (ii) split incentives, in which the narrow interests of a decision-maker are maximized when creating much higher costs for someone else (e.g., a landlord’s incentive to minimize capital investment expenses even when doing so ensures that their tenants’ excess energy expenses will be greater than the landlord’s savings on capital equipment); (iii) imperfect information, in which decision-makers do not know or understand their options and the implications of their choices; (iv) monopoly power, which limits consumer choices for low-emission alternatives; (v) long-lived (fixed or immobile) factors of production, which locks in less efficient technologies because the existing capital stock makes emitters less responsive to market signals; and (vi) the absence of a market for climate stability (a public good) because the private sector cannot provide and price public goods.

Adding a price to emissions addresses the first market failure (the externality) but is insufficient
or ineffective at addressing the other market failures. This means that including a price on emissions that accounts for climate damages associated with emitting would likely be insufficient for fully addressing all the relevant market failures that contribute to human caused climate change (i.e., greenhouse gas emissions).

Furthermore, we cannot quantify precisely the cost of climate damage associated with emitting greenhouse gases because the consequences of climate change are characterized by deep uncertainty, as described above. This means we cannot know the economically optimal price to add to emissions. In practice, adding a price to greenhouse gas emissions will either be too high or too low to maximize economic benefits.

A price that is too high (i.e., exceeds the cost of climate damage associated with emissions) would sacrifice some economic wellbeing relative to a lower price because energy prices would be too high. A price that is too low (i.e., fails to account for the costs of climate damage) would sacrifice some economic wellbeing relative to a higher price because too much climate damage would occur. Risk aversion to climate change implies erring on the side of a price on emissions that is more likely to be too high than too low, whereas risk aversion to price increases for energy implies erring on the side of a price that may result in excessive climate damage.

The third economic principle related to emissions pricing is that market mechanisms are generally the most economically efficient way to reduce emissions. This means that a price-based approach can be expected to result in the greatest amount of emissions reduction for the least cost or, equivalently, the most emissions reduction for a given cost. An important caveat to this basic conclusion is that it applies when the externality constitutes the dominant market failure because the additional market failures described above are not entirely responsive to the emissions price approach and therefore may be more effectively addressed through regulation or another policy option.

Despite these basic economic principles, adding a price on emissions may be insufficient or undesirable. As noted above, the price on emissions will necessarily be too high or too low because we cannot know what the actual damage to the climate system will be from a given amount of the emissions, and a price-based approach cannot address the full range of market failures.

Furthermore, adding a price to greenhouse gas emissions could have significant distributional consequences (i.e., there would be winners and losers) even while overall economic benefits would be expected to increase. Depending on the specific details of the policy design, those distributional consequences could be particularly significant for heavy emitters or low-income families. In addition, losses are likely narrowly distributed whereas benefits are broadly distributed. This creates both legitimate questions of fairness and political challenges for climate policy (described below).

Some policy options for mitigation also require allocating scarce resources toward emissions reduction efforts (e.g., investing in low-emission technologies). In the event that the consequences of climate change turn out to be less harmful than expected, investments in mitigation could constitute an inefficient use of limited resources. Note, however, that this does not apply to approaches that reduce market failures (e.g., adding a corrective price on emissions). Although emission pricing at first seems to require the use of scarce resources because energy prices may rise, it is actually reducing a hidden subsidy (i.e., reducing societal investments in climate damage) as previously described.

Notably, societal values other than maximizing economic efficiency also matter, perhaps
more than economic efficiency, in some cases. For example, fairness, the role people play in determining the Earth’s characteristics and functioning, and how to weigh the impacts on cultural heritage or other species are all questions outside of economic efficiency.

In general, there are two market-based approaches for adding a price on emissions (Higgins 2010). Policymakers can set a limit on the amount of emissions (a cap or limit on the quantity of emissions) and allow emitters to buy and sell permits to emit. This approach (often called cap-and-trade) leaves it to the market to determine the price of emitting. Alternatively, policymakers can determine the price that emitters must pay when they emit (a fee or a corrective tax). This approach leaves it to the market to determine the quantity of emissions. Notably, these two approaches have much in common because emission prices and quantities are linked. Both are market mechanisms for addressing climate change.

Hybrid approaches that combine elements of both approaches are also possible. For example, cap-and-trade can include a price ceiling (an upper limit on prices at which additional permits are always sold) or a price floor (a minimum price on emissions at which permits are always purchased). Similarly, fee-based hybrids can include automatic increases in the price if emissions quantities exceed an upper limit, thereby ensuring a minimum level of climate protection.

Policy deliberations for these approaches must determine the initial price (or quantity) of a pricing mechanism and the rate that it changes over time (Higgins 2010). Higher prices (or lower quantities) translate into larger, faster emission reductions, but may trigger larger price increases for energy and transportation.

Emission fees or permits can be collected at the oil well, coal mine, or point of entry for imports (often called “upstream”), closer to where the actual emissions occur, such as the tail pipe or power plant (downstream), or in between (e.g., petroleum refineries). Upstream implementation helps ensure comprehensive coverage of emissions, generally reduces the administrative burden placed on regulators and emitters, and minimizes transaction costs. Downstream implementation more closely aligns the point of regulation with the point where emissions occur. However, where the fee is collected likely does not affect who pays the fee, because market forces generally determine the relative burden on producers and consumers.

Revenues generated from adding a price on emissions could be used in a wide range of ways. For example, revenues can be used to lower existing taxes, returned in a lump-sum payment to citizens, used to promote research and development of low-emission technologies, or assist those most heavily hit by the fee, among other options. How these revenues are used can reduce or exacerbate distributional consequences of emission pricing. For example, a tax shift – one that applies the revenue generated from emission pricing to lowering existing taxes – or the lump-sum return of revenues to citizens on an equal per capita basis could increase the progressivity of the approach. Similarly, the disproportionate impact on heavy emitters can be softened by providing a small number of permits freely (under cap-and-trade) or by directing some of the revenue generated by a fee to hard-hit sectors.

Emissions pricing can include offsets or credits for emissions reductions that occur elsewhere (e.g., carbon capture and sequestration, forestry projects, and international mitigation efforts) and the banking or borrowing of permits in the case of cap-and-trade. Offsets can encourage emission reductions and reduce the costs of achieving a given level of climate protection. However, offsets also pose challenges because seemingly legitimate reductions may not last over
time. Borrowing and banking can also help even out price fluctuations in a cap-and-trade system.

Adaptation

Adaptation involves planning for climate impacts, building resilience to those impacts, and improving society’s capacity to respond and recover. This can help reduce damage and disruptions associated with climate change. Adaptation might also help with existing threats due to current weather patterns (e.g., routine and severe weather events) or from other natural and human-induced disasters unrelated to climate changes. This represents an important potential co-benefit of efforts to build adaptive capacity to climate change.

Adaptation also has limits or downsides. It is possible that some climate impacts will be too severe to manage through adaptation. Efforts to promote adaptive capacity could also prove maladaptive (counterproductive) due to uncertainties over future climate projections and the expected impacts of climate change on physical systems, biological resources, and social institutions.

Adaptation policy can include regulation to decrease vulnerability (e.g., through land-use planning and building codes), response planning, disaster recovery, impact assessment for critical systems and resources (e.g., water, health, biological systems, agriculture, and infrastructure), observations and monitoring, and efforts to minimize compounding stresses such as traditional air pollution, habitat loss and degradation, invasive species, and nitrogen deposition.

Implementing adaptation policies successfully may require detailed consideration of location-specific factors because climate change impacts will vary geographically and depend on the uneven distribution of societal resources and institutions. As a result, centralized policy responses may be somewhat more limited for adaptation than for mitigation or geoengineering.

Nevertheless, centralized regulations have the potential to promote adaptive capacity by altering land-use patterns on a wide scale (e.g., floodplain development, management of coastal zones, and insurance practices) in ways that increasingly account for future climate change impacts. Similarly, centralized approaches to disaster relief efforts, the establishment and design of wildlife reserves, and management of water and agricultural resources could all help account for vulnerabilities anticipated by climate change.

Centralized adaptation policies can also potentially promote decentralized efforts by creating broadly useful sources of: (i) scientific information about climate change impacts and vulnerabilities; (ii) information about the advantages and disadvantages of particular adaptation measures and the specific conditions under which different options work best; (iii) support for (or incentives to encourage) local and or regional-level adaptation planning and implementation, including the provision of technical expertise and/or financial resources; and (iv) monitoring and reporting on the effectiveness of adaptation efforts.

Geoengineering

Geoengineering refers to deliberate, often global-scale, manipulations of the climate system (American Meteorological Society 2009). In general, the goal of geoengineering would be to counteract the effect of human greenhouse gas emissions or some of their consequences. Geoengineering could help to lower greenhouse gas concentrations in the atmosphere, counteract the physical impact of increasing greenhouse gas concentrations, address specific climate change impacts, or offer desperation strategies in the event that abrupt, catastrophic, or otherwise
unacceptable climate change impacts become evident.

Geoengineering could also create new sources of risk because attempts to engineer the Earth system on a large scale could lead to unintended and adverse consequences. Notably, the complexity of the Earth system (which couples numerous physical and biological systems and processes) and society’s relationship to the Earth system (which involves further coupling with social institutions) makes it challenging for scientific research to fully identify and quantify the potential consequences associated with geoengineering. As a result, the possible impacts from geoengineering could inadvertently compound the dangers associated with climate change.

Even to the extent that potential consequences of geoengineering can be well characterized, those consequences would almost certainly differ among countries and individuals. This raises complex legal, ethical, diplomatic, political, and national security concerns. The use of geoengineering as a desperation strategy could also distract from mitigation and adaptation, either of which may have a higher probability of contributing positively to risk management efforts.

Nevertheless, two categories of geoengineering are most prevalent within scientific and policy discussions: solar radiation management and carbon removal and sequestration. These, and other approaches, likely wouldn’t address all possible impacts associated with greenhouse gas emissions. For example, solar radiation management will not reduce the amount of carbon dioxide in the air or the ocean, and would therefore have no impact on ocean acidification or other direct effects of carbon dioxide enrichment on biological systems.

Policy options for geoengineering generally fall into five categories. We could conduct research and analysis in order to develop or vet options. We could study the impacts and likely unintended consequences. We could create punitive measures to discourage unilateral (or what might be considered reckless) attempts to geoengineer. We could create policies that promote cooperation and transparency or help ensure that governance issues would be addressed. Of course, policies could also seek to implement geoengineering approaches. To date, policymakers have rarely considered geoengineering explicitly.

Expanding the knowledge base

Policies can also be designed to expand the knowledge base relating to the climate system (described above) or to reveal information relating to the management of risks associated with climate change.

Research, observations, scientific assessments, and technology development can help reveal risks and opportunities associated with the climate system and support decision-making with respect to climate change risk management. Expanding the knowledge base allows policymakers to understand, select, and refine specific risk management strategies, and to thereby increase the effectiveness of risk management efforts. Knowledge base expansion can, in some cases, also reveal entirely new opportunities for protecting the climate system or reducing the risks of climate change impacts. As a result, policies to expand the knowledge base can underpin and support the proactive risk management strategies described above (mitigation, adaptation, and geoengineering).

Climate system research spans numerous disciplines and subdisciplines, including those within the atmospheric sciences, oceanography, hydrology, biology, cryology, and paleoclimatology, among others. Determining the societal consequences of climate variability and change depend on understanding how human systems depend on and will respond to potential impacts on
physical systems, biological resources, and social institutions. That also requires information from disciplines in the social sciences, including (but not limited to) economics, sociology, history, and political science (Steinbuck and Higgins 2013).

The political landscape

There are several political obstacles to climate change risk management in general and to pricing greenhouse gas emissions in particular. Climate change can be characterized as a “wicked problem” (Rayner 2006). This means that climate change, as a public and policy issue, is characterized by: (i) contradictory certitudes (i.e., different people believe – as fact – different things that are actually incompatible), (ii) having redistributive implications for entrenched interests, (iii) being related to deeper problems (e.g., the scale of human activities relative to the Earth system’s capacity to withstand disturbance), (iv) having relatively little room for trial-and-error learning, and (v) tending to be incompletely solvable (i.e., we must live with climate change in some sense).

As a result, policy deliberations (and public debates) about climate science are often at odds with the assessments of the relevant subject-matter experts (Leiserowitz et al. 2014). This is because the complexity of the issue and the underlying science increases the potential for nonexperts to be unaware of expert assessments and more prone to believing rhetorical arguments that seem convincing, even when those arguments do not withstand the scrutiny of subject-matter experts. This contributes to political polarization with respect to climate change. Furthermore, those who would tend to be hurt by climate change risk management (particularly through emission pricing) often know that policies could harm them, care about a relatively small number of issues other than climate policy, and tend to be politically powerful and well organized. In contrast, the winners from emission pricing often do not realize they will benefit (i.e., because they take the climate system for granted and do not recognize the risk emissions pose for climate). Winners also tend to care about a wide range of other issues more than climate change. Because benefits are broadly distributed, the constituency for climate protection is a relatively disorganized group that is politically weak. These differences between the winners and losers create significant political obstacles to enacting policy solutions.

To some degree, these challenges are exacerbated at the international level because the contribution to (and risk exposure from) climate change are unequal among nations. For example, many of the impacts of climate change are expected to be most severe for countries and peoples who have contributed minimally to the atmospheric stock of greenhouse gases (e.g., low-emitting small island states, which face limited options for adaptation, and developing countries, which may be highly vulnerable to climate change and possess limited adaptive capacity). This separates the sense of urgency to respond to climate change from the capability of doing so. Of course, these differences also contribute to the complex ethical dimensions of climate policy.

The global nature of climate change also creates future challenges for climate policy. There is a genuine need for a coordinated global effort to reduce emissions because atmospheric greenhouse gas concentrations are well mixed (i.e., they are based on emissions anywhere in the world). This makes unilateral action more difficult and potentially less effective. It also contributes to powerful rhetorical arguments against mitigation efforts. Why should nation A begin to reduce its emissions when nation B has no similar plan to do so?
There are policy solutions to these challenges. For example, unilateral action by one nation could be conditional on other countries making similar efforts, or could include incentives for cooperation such as border tax adjustments to account for those who do not incorporate climate damage into prices paid by emitters (which constitutes a subsidy).

Voluntary emission targets and actions taken by individual nations may also encourage similar efforts by other nations and thereby create a positive feedback cycle for emissions reductions. This is a central component of the current international approach to reducing greenhouse gas emissions, as established by the Copenhagen Accord in 2009 and further implemented through the Paris Agreement in 2015.

Climate variations, climatic modes, and teleconnections

Temporal departures from the long-term means of climate variables such as temperature, precipitation, humidity, cloud cover, and winds, tend to be organized spatially and to be internally consistent for a given climate region (e.g., warmer than normal, drier than normal, reduced cloudiness, etc.). Climatic modes are recurring climate anomaly patterns on regional to hemispheric and even global scales accompanying intraseasonal, interannual, and multiyear variations of the atmospheric circulation. Intraseasonally (i.e., 30–90 days), these modes often are linked to deep convection pulses over the tropical Indian Ocean that spread both eastward and poleward to influence the weather and climate of extratropical latitudes, and which help modulate the interannual climate modes. Prominent examples of the latter include the opposite-signed climate anomalies in western versus eastern North America in the colder months, and between Greenland/Iceland and western Europe. On hemispheric and larger scales, important interannual climatic modes include the opposing anomalies of temperature between middle and high latitudes of the Northern Hemisphere, and of precipitation between the western and eastern tropical Pacific Ocean.

The spatial coherence of climate anomaly patterns (i.e., alternating positive and negative departures) on regional to global scales, expresses their association with atmospheric circulation as a teleconnection, or long-distance (tele-) repetitive association (connection) of climate variations. For example, the European heat wave of summer 2003 was accompanied by persisting cool anomalies further eastward in western and central Russia. A teleconnection is primarily the statistical manifestation of a climatic mode but also implies a physical explanation for such modes. Thus, in the foregoing examples, the tropical Madden–Julian Oscillation (MJO) comprises the dominant source of intraseasonal climate variability for the globe; the Pacific–North America (PNA) pattern accompanies the opposition in climate anomalies between western and eastern North America; the North Atlantic Oscillation (NAO) expresses the Greenland–Europe anomaly couplet; the Arctic Oscillation (AO) projects onto opposite-signed temperature anomalies in middle versus higher latitudes; and the El Niño Southern Oscillation (ENSO) explains tropical precipitation anomalies between the western and eastern Pacific, and both temperature and precipitation anomalies for the extratropics of both hemispheres (Table 1). On decadal and multidecadal timescales, climatic modes and teleconnections express the dominant roles of temperature, salinity, and wind stress in the ocean gyres; the Pacific Decadal Oscillation (PDO – or “ENSO-like” pattern – has a period of about

40–60 years (i.e., each phase is 20–30 years), while the Atlantic Multidecadal Oscillation (AMO) has a periodicity of around 70 years.

Any teleconnection comprises two extreme phases marked by a reversal in sign of the sea level pressure (SLP) or tropospheric height anomalies defining the pattern in the key region. These phases are typically denoted as positive and negative. For example, the AO extreme phases comprise the “high index” (colder high latitudes, warmer middle latitudes) and “low index” (warmer high latitudes, colder middle latitudes), whereas the ENSO extreme phases are named La Niña (cold event or intensified...
normal pattern) and El Niño (warm event or dry western Pacific, wet central and eastern Pacific).

Teleconnection patterns can be classified into two broad types: zonally symmetric–annular–and zonally varying, or meridional. In both the Northern and Southern Hemisphere extratropics, the dominant modes are annular, comprising the AO and the Antarctic Oscillation (AAO), both of which are expressed in the stratosphere as well as troposphere. Meridional patterns involve longitude and amplitude anomalies of the tropospheric long (i.e., stationary or Rossby) waves and may be embedded within – and highly correlated to – the annular modes; prime examples being the NAO in relation to the AO and the Southern Hemisphere’s Trans-Polar Index (TPI) and AAO (Table 1). Thus, although usually defined as discrete (i.e., independent) phenomena, a teleconnection can correlate significantly with others; for example, the PNA, NAO, and AO in the North America sector during certain winters, and their modulation by the MJO, thereby increasing their area of influence. Winter climate anomalies in western North America often are of the same sign as those in the Labrador–Greenland area, while those in eastern North America can have the same sign as Europe.

The reduced land–sea contrasts in Southern Hemisphere middle latitudes versus the Northern Hemisphere impart a lower amplitude to the stationary waves. Thus, teleconnection characteristics can be quite different between the Northern and Southern hemispheres (e.g., the Pacific–South America (PSA) pattern versus the PNA), with shorter duration times for intraseasonal “blocking” episodes. Conversely, the semi-annual (interseasonal) oscillation – SAO – of middle and subpolar latitudes is much stronger in the Southern Hemisphere than in the Northern Hemisphere, where the annual cycle dominates.

The persistence of climatic modes and teleconnections on timescales ranging from weeks to months and even across seasons and years, results primarily from positive feedbacks – reinforcing nonlinear interactions – between the atmosphere and Earth surface climate variables; notably the sea surface temperature (SST), soil moisture and vegetation activity, snow–cover latitude extent and depth, and sea ice conditions (extent, concentration). The Earth surface climate anomalies and their atmospheric interactions often are evident as departures in large-scale satellite-retrieved variables of the outgoing longwave radiation (OLR), and Normalized Difference Vegetation Index (NDVI). Indeed, fluctuations in these and other variables frequently are used to monitor teleconnections and their accompanying climate anomalies. Much of the pioneering work on teleconnections – particularly that by Jerome Namias (1969) and J. Bjerknes (1969) – used the association with anomalies in surface conditions to help predict circulation climate on monthly to seasonal timescales, or “medium- and long-range weather forecasting.” The interactions are thermal (involve the radiation and energy budgets), hydrologic (involve the moisture budget), and dynamical (involve the atmospheric circulation). Anomalies in the number, position, and amplitude of the tropospheric troughs and ridges accompanying teleconnections, and their associated jet streams and synoptic circulation systems of high and low pressure, impart a juxtaposition of positive and negative surface climate anomalies over space.

History of teleconnections research
and teleconnections in climate history

Teleconnection studies have a long history. The term dates back to Ångström (1935) but studies of climatic fluctuation patterns include H.H.
Hildebransson’s (1897) discovery of inverse SLP variations between southeast Australia and southern South America (Barry and Carleton 2001), Sir Gilbert Walker’s pioneering efforts nearly 100 years ago to link Indian monsoon rainfall with SLP variations over the tropical Pacific Ocean (the “Southern Oscillation”) and elsewhere, and J. Bjerknes’ work in the 1960s linking tropical Pacific sea surface temperature (SST) variations to fluctuations in the extratropical westerlies. During the 1980s and 1990s, an explosion of research identified a large number of teleconnection patterns either accompanying extratropical climate anomalies or modifying the influence of tropical teleconnections. In the 2000s came the realization that improvements in both weather and climate prediction occur with explicit consideration of the MJO phase. Additional advances included numerical modeling that attempted both to reproduce the dominant teleconnections and to clarify the physical processes linking the atmospheric circulation fluctuations with the Earth surface anomalies. Much recent work assesses the long-term stability of teleconnection–climate associations given the contemporary climate changes related to trace gas increases (“global warming”) or other human activities (e.g., tropical deforestation, irrigated agriculture), including proposed climate geoengineering solutions.

In terms of climate history, the Medieval Climate Anomaly (MCA) and subsequent Little Ice Age (LIA) are partly explained by teleconnections: during the MCA, an extended La Niña-like pattern with some resemblance also to positive (+) NAO, especially in the Europe sector; during LIA, an extended El Niño-like pattern and one resembling the meridional (−) NAO. Spatial patterns of Northern Hemisphere temperature trends in the last quarter of the twentieth century also suggest a strong association with teleconnections, only comprising an El Niño pattern in the Pacific and + NAO. However, trends since about 2000 indicate more the global warming signal, especially in higher northern latitudes, superimposed on a greater frequency of the low index (−) AO pattern.

### Teleconnection indices

A number of statistical methods can extract the dominant spatial pattern(s) of variation in, for example, SLP, geopotential height, or OLR, on regional to subcontinental and larger scales, although these have favored empirical orthogonal function (EOF) analysis. More recently, self-organizing map and artificial neural networks have clarified and extended the impact of different synoptic circulation regimes in teleconnection phases. The role of a given teleconnection in climate anomalies often is quantified using correlation or composite (map average) approaches for the extreme phases.

Once a teleconnection pattern has been confirmed as robust (e.g., from time series analysis of eigenvalues), it is useful to depict it as an index that can be updated monthly or seasonally for climate monitoring purposes. Indeed, in areas lacking long-term mapped atmospheric data – the Southern Hemisphere oceans in particular – teleconnection indices have been crucial for assessing climate linkages to large-scale SST and sea ice variations. Although both qualitative and quantitative indices exist (e.g., for ENSO), the majority of teleconnection indices involve measurements of climate variables that express the phenomenon. Because most teleconnections involve anomalies in SLP or geopotential height of the major circulation “centers of action,” their related indices typically utilize monthly or seasonal values or their differences from the long-term (climatological) normals.
For example, the NAO index (NAOI) traditionally comprises the SLP anomaly difference between Portugal or the Azores (North Atlantic High) and Reykjavik (Icelandic Low). From the geostrophic wind equation, the NAOI thus captures variations in the strength of the westerlies over the North Atlantic. These winds are stronger during +NAO, and weaker for −NAO, with concomitant variations in temperature and precipitation anomalies for western and northwestern Europe (i.e., milder and wetter in +NAO, colder and drier in −NAO). Somewhat analogously, the PNA pattern was originally defined by Wallace and Gutzler (1981) as simultaneous variations in 500 hPa heights at four grid points representing the waves over North America and the northeast Pacific, although it can also be defined using three grid points. Both the AO and AAO are defined using zonally averaged SLP anomaly differences between middle and high latitudes (Table 1). The tropical Quasi-Biennial Oscillation (QBO) is defined primarily by the lower-stratospheric winds; either in their easterly or westerly phases. Regional-scale teleconnection indices can depict variations in meridional winds; for example, the M1 index captures fluctuations in the trough in the Tasman Sea, whereby a weakened trough (i.e., anomalous ridge) often accompanies El Niño.

Recent improvements to teleconnection indices include, for example, consideration of spatial variations in location of the centers of action that may not be captured by station SLP observations; a monthly NAOI that considers the grid points of lowest and highest pressure in the Icelandic Low and Azores High, respectively. Other teleconnection indices may be refined using additional climate variables involved in the pattern. Thus, the traditional ENSO index is the SLP anomaly difference between Tahiti (i.e., South Pacific High) and Darwin (northern Australia monsoon low), or Southern Oscillation Index (SOI). Because the ENSO is primarily a tropical ocean–atmosphere interaction mode, fluctuations in tropical Pacific SST and OLR improve upon the SOI; notably in the Multivariate ENSO Index, MEI (Figure 1).

Associations between teleconnections may be either constructive (i.e., reinforcing or amplifying) or destructive (damping), with concomitant impacts on the climate signal. Thus, a positive or warm phase of the PDO tends to enhance the frequency and/or intensity of El Niño events, while a negative (cool) phase enhances La Niñas. These relationships can be evident in the frequency and area burned by wildfires in the western United States, for example. Finally, analysis of longer-term Pacific SST data can refine the subregion of greatest sensitivity to ENSO, consideration of which improves ENSO forecasting (e.g., the Niño 3.4 vs Niño 1 + 2 regions).

**Physical processes and mechanisms**

Because the tropics experience an annual surplus of solar and net radiation, they are the Earth’s heat reservoir; energy and moisture move poleward on average, typically along relatively narrow corridors in the atmosphere that are influenced by synoptic phenomena on weather timescales and by climate teleconnections. Extratropical to tropical atmospheric interactions may also occur, such as East Asian cold-air surges that help trigger enhanced convection in the western tropical Pacific, and which may, in turn, propagate out of the tropics as moisture plumes or “atmospheric rivers.” Despite their persistence in a given phase, teleconnections can shift quite abruptly to the opposing phase, resulting in a similarly abrupt reversal of climate anomalies in region(s) influenced by the teleconnection. This behavior manifests the “almost intransitive”
character of Earth’s climate system, whereby large fluctuations or changes may occur with only minimal changes in boundary conditions.

The dominant global-scale teleconnection pattern – ENSO – arises from strong ocean–atmosphere interactions in the tropical Pacific that are transmitted to the extratropics by standing waves and the subtropical jet stream (STJ). During neutral and also cold (i.e., La Niña) events, negative anomalies of SST (−SSTA) occur in the eastern and central tropical Pacific, positive anomalies in the western (“warm pool”) area. However, during El Niño events the SST anomaly pattern is reversed and features an area of +SSTAs near the International Date Line, extending eastward and along the west coast of South America (Figure 2). The basin-wide pattern of tropical Pacific SSTAs evident in Figure 2 combines two “flavors” of El Niño: that which develops primarily near coastal Peru (or traditional El Niño, 1st EOF), and that which develops in the central tropical Pacific, or Modoki El Niño. This 2nd EOF features −SSTAs both to the east and west of the +SSTAs, and occurs in summer and winter. Its extratropical climate impacts can also differ from the traditional El Niño.

Over +SSTAs and upper-ocean warmth (i.e., depressed thermocline) in the tropics, atmospheric convection is enhanced (negative OLR anomalies) due to increased evaporation and instability of the air, and SLP tends to be low. Conversely, over −SSTAs and upper-ocean coolness (thermocline near the surface), convection is suppressed – air sinks and cloud dissipates (positive OLR anomalies) – in the more stable atmosphere, with corresponding higher SLP. Precipitation anomalies, such as those retrieved from the tropical rainfall measuring mission (TRMM) satellite, accompany the OLR anomalies: negative OLR with higher daily rain rates; positive OLR with low or zero rain rates. Thus, when the SOI or MEI (Figure 1) is either close to the long-term normal or indicates La Niña, most deep convection is located in the western tropical Pacific – an intensified North Australian summer monsoon – with subsiding air in the eastern tropical Pacific. At these times, the Walker (west–east) Circulation is enhanced relative to normal. During both traditional and Modoki El Niño events, subsiding air in the western tropical Pacific weakens the Australian monsoon, whereas the +SSTAs in the central and eastern tropical Pacific during traditional

Figure 1  Time series of the MEI from 1950 through February 5, 2016. Positive values (red) indicate El Niño events, negative values (blue) indicate La Niña events. Source: http://www.esrl.noaa.gov/psd/enso/mei/.
El Niño promote increased convection and precipitation (Figure 3).

SSTAs in the central North Pacific tend to be of opposite sign to those in the central and eastern tropical Pacific (i.e., negative in El Niño, positive in La Niña: Figure 2), although they may have the same sign in Modoki events. As shown by Namias, −SSTAs in the North Pacific help anchor a strong trough there because of the reduced surface insolation receipt (more cloud cover) and greater wind stress that brings up colder water from depth. A tropospheric ridge tends to be enhanced downstream (i.e., in western North America), both because of vorticity advection and by the warmer water along the coast (weakened California current), which increases the tropospheric thickness. Thus, the extratropical SST-OLR anomalies of the teleconnection are opposite those in the tropics (i.e., −SSTA with −OLR, +SSTA with +OLR). Moreover, the enhanced latitude gradients of SST and air temperature in traditional El Niño events intensify the “thermal wind,” helping produce a stronger STJ that advects moisture into the southwestern, southern, and southeastern United States. Accordingly, more cloudiness and precipitation usually accompany El Niño along the Gulf...
Coast and in southeastern states (Figure 3). When an El Niño is accompanied by $+\text{PNA}$, drier and warmer than normal conditions occur in the northwest United States and southwest Canada, with colder and wetter than normal conditions in the northeast. The atmospheric associations may be intensified in winter by snow cover–circulation positive feedbacks. Over more extensive snow cover, the greater net radiation deficit refrigerates the air relative to a no-snow situation, reducing the tropospheric thickness, and thereby helping “fix” a long-wave trough longitudinally that encourages further snowfall along and near its equatorward margin. Thus, the $+\text{PNA}$ typically is marked by positive snow extent anomalies in the eastern United States, but $-\text{PNA}$ has positive snow extent anomalies in the western United States, helping promote persistence in the two patterns. Somewhat analogously, more extensive snow cover in Eurasia may be involved in the onset and amplification of ENSO.

Certain teleconnection patterns – the PDO in particular – are not yet explainable physically, although the positive (warm) and negative (cool) phases are accompanied by a suite of climate anomalies along the west coast of North America. The PDO probably represents a “slow
teleconnection” with the upper ocean that involves the North Pacific Gyre, somewhat similar to that proposed for the Southern Hemisphere’s Antarctic Circumpolar Wave, although the ACW is a more mobile pattern. Accordingly, the PDO appears to influence the occurrence and character of El Niño and La Niña events. For example, the frequency and intensity of El Niño events increased starting around 1976/1977 with the transition from cool to warm PDO; before that, El Niños and La Niñas occurred with about equal frequency (Figure 1). It is interesting that the late twentieth-century warm PDO was also marked by the longest El Niño on record (1991–1995) and by the very strong 1982/1983 and 1997 events; the last marking a peak in globally averaged temperature the following year and the start of the so-called “climate warming pause.” This most recent period has seen increased oceanic uptake of heat, perhaps due to the stronger surface wind stress promoting greater vertical mixing within the water column that has accompanied more frequent La Niña events, and/or the AMO’s interaction with the global ocean “conveyor belt.” The slowed atmospheric heating may also be the result of increases in atmospheric particulates resulting from the rapid industrialization of China and India.

Climate impacts

Temperature anomalies

Globally, El Niño events tend to accompany positive (i.e., warmer) anomalies of surface temperature while La Niña tends to accompany negative (cooler) anomalies. However, considerable regionality occurs for both phases. For example, the US Gulf Coast and southeastern United States typically experience cooler conditions in El Niño winters owing to greater cloud amount and precipitation (Figure 4a). Conversely, this region typically sees warmer conditions during La Niña events, due to reduced cloudiness (Figure 4b).

Colder winters in eastern North America are more likely with an intensified or larger West Pacific Ocean “warm pool” (i.e., in La Niña or neutral ENSO and/or cool PDO phases) because these favor the +PNA pattern, with the timing of cold-air outbreaks influenced by the MJO (greater convection over the tropical Indian Ocean).

The opposition in sign of SLP anomalies between the Arctic and middle northern latitudes expressing the AO has associated surface temperature anomalies as follows: colder (warmer) in the Arctic (middle latitudes) for the high index phase, and warmer (colder) in the Arctic (middle latitudes) for the low index phase. Accordingly, winter sea ice conditions tend to be milder – less ice – for low index than high index AO, and trends in the AO (e.g., from lower to higher index values between about 1968–1997) explain a proportion of the wintertime trends in surface temperature over the extratropical Northern Hemisphere.

Regional anomalies of temperature are favored by teleconnection modes comprising meridional atmospheric circulation (e.g., +PNA, −NAO/AO). They tend to be expressed subseasonally as increased blocking activity. Blocking refers to the high amplitude wave – and therefore very slow moving, or even retrograde – phase of the intraseasonal “index cycle.” At its most extreme, the meridional phase resolves into an Omega Block comprising a blocking high and positive temperature anomalies in higher latitudes (e.g., the Greenland–Scandinavia region), flanked by “cutoff” lows in lower–middle latitudes (e.g., Southeast United States, western Mediterranean). Because this pattern represents a reversal of the normal latitudinal pressure/height
Figure 4  United States climate division composite surface temperature anomalies (°F) for (a) nine El Niño events and (b) eight La Niña events, with respect to the 1971–2000 climatology. Note: 1.8°F = 1.0°C.  Source: Reproduced from NOAA.
CLIMATIC MODES AND TELECONNECTIONS

and temperature/thickness gradients, the thermal wind also is reversed; hence, the westerlies slow – and may become easterly – in the region of the blocking high, and the Polar Front Jet (PFJ) splits (“split flow”) upstream of the block. An Omega Block is more likely to accompany negative NAO/AO; it results in milder than normal conditions in Labrador–Greenland but colder conditions in western Europe and the eastern United States (e.g., the winter of 2009–2010). The NAO is not restricted to wintertime and can be responsible for extreme climate anomalies in other seasons. For example, the highly anomalous surface melt that occurred over 97% of the Greenland ice sheet in mid-July 2012 was accompanied by a strong blocking ridge, with cutoff lows and negative temperature anomalies over Labrador and the British Isles (Figure 5a), during a −NAO for the month (Figure 5b).

Droughts and floods

Because the ENSO “cycle” involves relocations of the centers of rising and sinking air and their associated Walker circulations, El Niño events favor drying – even drought – accompanying the South Asian and Australian summer monsoons, and in the Brazilian Nordeste, but an increased incidence of flooding rains in Peru, Ecuador, and eastern Africa. The opposite is generally true for these regions during La Niña. In the extratropics during boreal winter, El Niño brings increased precipitation – sometimes flooding – to California, the Gulf Coast, and southeastern United States (Figure 3). The accompanying split-flow regime along the US West Coast can induce atmospheric rivers of extreme moisture (cloud, precipitation) that result in flooding and mudslides in California. In the Northwest US states and southwest Canada, the weakened PFJ and strengthened ridge typical of El Niño reduce precipitation in that region.

Increased precipitation typically characterizes El Niño events in parts of East Asia. ENSO-related precipitation anomalies are sensitive to the strength of the El Niño, the type of event (traditional vs Modoki), as well as to MJO phase. The US Midwest extreme drought of summer 1988 resulted from a tropical–extratropical teleconnection as the El Niño of 1987 transitioned to a La Niña, establishing a strong ridge over central North America that was intensified by land surface–atmosphere interactions (e.g., dry soil, lowered evapotranspiration rates).

Wildfire

Wildland fires occur when an ignition source (e.g., lightning, human activities) causes combustion of dry fuels in grassland or forest eco-types, and windy, low humidity conditions prompt a rapid expansion of the burned area. Because fine fuels – from dry soils and vegetation – are a necessary prerequisite for wildfires, there are strong associations of fire frequency, intensity, and burned area with climatic modes and teleconnections. Thus, El Niño events tend to accompany increased bush-fire activity in eastern and southeastern Australia, and more severe forest fire conditions in Canada’s Yukon, northern Prairie Provinces, and central Quebec. Lag relationships also are evident: in the southwestern United States, the positive anomalies of precipitation associated with El Niño increase vegetation growth that then dries out in the subsequent La Niña or neutral ENSO episode, providing fuel for large fires. A PDO influence is superimposed, whereby wildfire area burn or intensity may be increased in constructive phases (i.e., El Niño during warm PDO, La Niña in cold PDO). Subseasonally, the MJO modulates wildfire variations of the western United States, partly via its influence on dry lightning. Of course, the encroachment of human settlements
Figure 5  (a) Average 500 hPa heights (m) for the four–day period of the Greenland ice sheet major surface melt event in mid-July 2012; (b) monthly average 500 hPa height anomalies (m) for July 2012. Source: Reproduced from NOAA.
into wildland areas increases the risk of fire hazard, as likely also does global warming.

**Tropical cyclones**

Intense rotating synoptic-scale vortices originating in tropical latitudes from strong sea–air interactions (i.e., warm-cored cyclones) also vary in their frequency and tracks of movement due to teleconnections. The primary response is to the SST anomaly pattern, whereby tropical cyclogenesis increases over +SSTA and decreases over −SSTA. The climatic relationship is most evident in association with ENSO: more frequent and/or intense tropical cyclones develop in the tropical eastern Pacific in El Niño than in La Niña, with the reverse being generally so for the western Pacific. During the Australian monsoon (October–April), tropical cyclone activity in the southwest Pacific and eastern tropical Indian Ocean shows a close association with the monsoon trough, which tends to be more (less) active in La Niña (El Niño) years. Subseasonally, however, there is strong modulation by the MJO on both ENSO extreme phases in most tropical cyclone regions. In the Caribbean Sea, Gulf of Mexico, and western Atlantic, the relationship to ENSO is more indirect. There, hurricane activity decreases, on average, in El Niño years relative to La Niña and also neutral years, because the +SSTAs in the eastern tropical Pacific enhance the latitude gradient of temperature and, thereby, a stronger STJ. The associated greater vertical wind shear in El Niño years is unfavorable to intensification of tropical cyclones. Fluctuations in longitude of the North Atlantic High – partly a function of the NAO – influence the steering of hurricanes and tropical cyclones; into the Gulf of Mexico for westward displacement, versus along the US Atlantic coast with eastward displacement. On longer (interdecadal) timescales, increased versus decreased hurricane activity in the North Atlantic shows some association with the AMO.

**Extratropical synoptic systems and extreme weather events**

Because teleconnections represent low-frequency variations of the atmospheric circulation, the associated higher-frequency (synoptic-scale) circulation regimes can be quite different for the extreme phases as well as between events of the same sign (e.g., weak versus moderate versus strong El Niño). Thus, “nor’easter” winter storms bringing heavy snowfall along the US East Coast are more likely during El Niño, +PNA, and −NAO/AO because of the phasing of the STJ and PFJ that accompany a deep trough in those longitudes. Conversely, intense mid-latitude cyclones bringing heavy precipitation to Britain and western Europe are favored by +NAO/AO patterns. Accordingly, decadal and longer-period variations in the prevalence of NAO extreme phases are accompanied by quite different synoptic regimes and their associated regional surface climate anomalies (e.g., the 1960s and 1970s versus the 1980s and 1990s). In the Tasman Sea, atmospheric blocking – more frequent in El Niño than La Niña years – favors winter–time persistent cold-air outbreaks over New Zealand that often contain intense meso-scale cyclones (“polar lows”) bringing snowfall to the South Island.

The frequency and intensity of tornadoes (especially the more violent vortices) in the central and Midwest United States show some association with ENSO; somewhat greater in La Niña than in El Niño events, because of the stronger PFJ – and more cold air aloft – in the former, and the fact that higher SSTs in the Gulf of Mexico are maintained over winter by the lack of cloud and precipitation (cf. El Niño). Recent work suggests that the springtime
transition between a La Niña and El Niño sees strong increases in tornado activity in the central United States. Superimposed on these and other synoptic–teleconnection associations as to the timing of events is the role of MJO.

**Teleconnections and global warming**

Contemporary climate changes, such as the reduced Arctic sea ice extent and thickness, may be influencing teleconnections and the frequency and intensity of synoptic and subsynoptic weather events over middle latitudes, via “Arctic Amplification.” This positive feedback involves greater absorption of solar radiation by the Arctic Ocean in summer (due to the reduced surface albedo) and stronger upward fluxes of latent and sensible heat in winter (more open water or thinner ice), which decrease the latitude–temperature–thickness gradient, slow the zonal winds, and increase the amplitude of Rossby waves and incidence of blocking; all expressed as more frequent – NAO/AO patterns.

Finally, given their important roles in climate prediction and the development of climate change scenarios, it is pertinent to consider how well global climate models (GCMs) capture the circulation variability comprising teleconnections and climatic modes. As might be expected when simulating ENSO, the performance has improved substantially with better coupled (i.e., ocean–atmosphere interaction) models, although there is some dependence on El Niño type – traditional versus Modoki – and the model convective scheme. For teleconnections of extratropical origin, particularly the AO, GCMs generally confirm their intrinsically atmospheric character; that is, coupled models tend not to significantly improve the simulation of these teleconnection patterns relative to atmosphere GCMs.

Climatology: history

Cary J. Mock  
University of South Carolina, USA

Early developments

Climatology as an academic and professional discipline has increased in popularity in the last few decades. This is also clearly evident in popular culture such as television, newspapers, and blogs and forums on the Internet. It is in contrast to what Carleton (1999) noted for much of the twentieth century, when climatology was viewed more as an ugly duckling of statistics and applied services. Much of the increased visibility of climatology can be traced in several historical themes that have impacted the development of the discipline. This entry summarizes themes of climate data and technological advances, methods in climatology, interdisciplinary linkages, scale aspects, and societal relevance. It focuses more on the geographic aspects and contributions, but also notes linkages with other disciplines (notably meteorology) and concepts that extend back to before the twentieth century. Important events on geographical climatology are noted in Figure 1.

Daily weather observations, both instrumental and verbal, have provided a framework for climatological research since the ancient Greeks. Very early weather and climate descriptions also include those written by Muslim scholars in the Middle Ages which were used in climate classification. However, instrumental observations did not begin until after the Renaissance, and widespread observational data networks in North America mostly began in the early nineteenth century. Thus, climatological research in the nineteenth century based on these data was mostly basic description, which enabled the construction of the first large-scale climate maps and climate classifications (e.g., by Koeppen). Some climate and weather processes were debated, such as the law of storms and potential relationships between climate and health. During this era, both meteorological and geographical climatology were not official academic disciplines, and thus were not distinguished from one another.

Modern developments to the mid-twentieth century

By the end of the nineteenth century, expanding observational networks of weather data began to be more evident at the global scale, while regional-scale data networks became denser. The first geography (and meteorology) academic departments in the United States were established at the University of Chicago and at the Massachusetts Institute of Technology in 1903 and 1928 respectively. Physical geography and climate studies from the early- to the mid-twentieth century assessed the relationship of the Earth and its inhabitants, probably because of the popularity of environmental determinism at this time, partly through the work of Ellsworth Huntington (Skaggs 2004). This included mostly descriptive climatology in the form of climate as “averaged weather,” as well as some climate classification. From the 1910s to the 1940s, climatology started to move beyond observation
toward the analysis of processes and synthesis, as more detailed meteorological observations became apparent from aircraft and the upper atmosphere. In particular, aviation-related observations increased sharply in the United States during the 1920s and 1930s. Thus research incorporated new meteorological theoretical advances such as the Bjerknes mid-latitude cyclone model and Rossby’s model of atmospheric circulation. During much of the “regional era” of the 1920s–1940s, research advances in the processes in climatology were made mostly in the physical sciences (Skaggs 2004). These advances subsequently led to the development of synoptic and dynamic meteorology by World War II.

Skaggs (2004) regarded the “modern era” of geographical climatology as beginning after 1945. Prior to the modern era, the notion of climate in relation to the environmental determinism paradigm that prevailed in geography earlier in the twentieth century, and to the decline of the regional geography paradigm, had a huge impact on society. The research perspective on climate classification continued, but influences from meteorological advances were increasingly introduced into academic geography. By around 1950, climatology in some university geography departments was taught by meteorologically trained scholars employing concepts derived from meteorological technology and developed prior to and during World War II. During this time, physical geography specialty areas, including climatology, started to subdivide into more specialized fields (definition of fields vary up to today); for example, climatology could incorporate the fields of micro-,
CLIMATOLOGY: HISTORY

regional, and synoptic climatology. The quantitative revolution in geography was apparent during the mid-twentieth century as well, with the increase of the application of statistical and hypothesis testing approaches in physical geography. In separate activities outside American academic geography in the 1950s, applied meteorology and climatology and climate data collection and archiving increased in popularity with the advent of the State Climatologist Program; the establishment of what eventually became the National Climatic Data Center in Asheville, North Carolina; the establishment of the National Hurricane Center at Miami, Florida; and the advent of the era of satellite meteorology.

Developments of recent decades

The 1960s into the 1980s saw further developments and ideas from other fields influencing mainstream geographical climatology, including chaos theory. Data management and monitoring accelerated with the creation of the National Oceanic and Atmospheric Administration (NOAA) in 1970 and the National Aeronautics and Space Administration (NASA) shortly after. The National Climate Program Act in 1977 renewed governmental state climatological public services, and regional climate centers also contributed to data management activities. Geographical climatology continued with its traditional positivist, deductive approach, with different climatological subfields still largely based on observational data, statistics, and hypothesis testing but becoming a bit more diverse in the spatial scale of study. Many of the subfields in climatology (e.g., synoptic climatology) developed within academic geography, aided by the development of faster computation, with applications utilizing objective as well as subjective methods. Some studies adopted new perspectives to examine climate processes (e.g., the air-mass climatology approach). Urban and energy balance climatology, and arctic and alpine climatology became prominent at some academic geography centers (Brazel et al. 1991). The development of Thornthwaite’s concept of potential evapotranspiration merged hydrological data with climatic data and linked the processes between climate and the hydrosphere.

By the mid-1980s geographically trained climatologists were analyzing various components of the climate system in greater detail, and much research was integrating climate processes at various time (from meteorological subdaily to paleoclimatic) and spatial (from microscale to global) scales. At the close of the twentieth century there were still distinctive characteristics of how geographical climatologists conducted research compared to meteorologists; for example, they placed more emphasis on classification and less on forecasting (Carleton 1999). However, given the need for a strong holistic approach in analyzing and linking climate processes at different spatial and temporal scales, geographical climatologists began collaborating and borrowing more ideas from meteorology as well as other Earth, physical, and natural science disciplines. The mapping and analyses of numerous climate variables from NOAA’s 20th Century Reanalysis project have enabled much more detailed studies of climate variability and change. Quiring (2007) noted that a shift occurred around 1998, with climatologists publishing less in geography journals and more in nongeography journals, perhaps for greater interdisciplinary visibility, to reach more of a mainstream climate audience, or as a result of the culture of funding agencies or the growth of more journals. From 2000 onward, while positivism and empirical generalization remained popular in climatology, the development and increased popularity of numerical modeling as a result of faster computers also focused more
CLIMATOLOGY: HISTORY

attention on processes. Up to the present, not many modelers trained in dynamic climatology are in academic geography departments, but some are in geography departments that include atmospheric science programs. However, an increasing number of geographical climatologists are utilizing data from global climate model simulations, including for downscaling studies to link larger-scale processes with smaller-scale ones. Climatologists started to use new innovative applications with climatology from geographical information science and spatial statistics developed in the last few decades. The need to calibrate and verify climate models with observational data continued to be a common theme in geographical climatology, covering a range of time scales from the interannual to the paleoclimatological, and some geographical climatologists continued to analyze the data quality of weather and climate observations.

Study of the human dimension in climatology dates back to the ancient Greeks; thus the idea of humans modifying the climate and the physical environment is not new. The idea of humans causing increased global warming can be traced back, for example, to the work of George Perkins Marsh in the mid-nineteenth century. However, with the advent of the Intergovernmental Panel on Climate Change (IPCC) in the 1980s, climate change and detection studies from the regional to the global scales became increasingly popular and gained in importance, including among geographical climatologists. This activity has led to increased interdisciplinary research between climatologists and social scientists and humanities scholars on climate impacts, adaptation, and policy (Kates 2011). The result has been something of a renewal of environmental determinism concerning the role of climate on premodern societies, since the turn of the century (Diaz and Trouet 2014), prompting more activity in high-resolution paleoclimatology. The increased popularity of extreme climate events, such as years of unprecedented extreme droughts and heat waves, in recent times and potentially in the future, have also led to more case study approaches and interdisciplinary climate research. Geography, with its unique interdisciplinary tradition and linkages to the natural, physical, and social sciences as well as the humanities, will likely continue to play a prominent role in continuing climatology’s increased visibility well into the twenty-first century.

Climatology

Julie A. Winkler
Michigan State University, USA

Climatology is a key component of contemporary physical geography. In this contribution to The International Encyclopedia of Geography, the evolution of climatology as a field of inquiry is summarized. In addition, the data sources available to climatologists, along with their limitations, are described, and the wide range of statistical methods and numerical models used in climatological research is highlighted. The various subfields of climatology are grouped into two categories, those that represent an analytical perspective and those that are thematic in focus, and are briefly described. Particular attention is paid to recent developments in applied climatology. Finally, the growing popularity of the terminology “climate science” and the consequent implications for the meaning of “climatology” are noted.

Evolution of climatology as a field of inquiry

Climatology is often described as either “the study of climate” or “the science of climate.” These broad definitions, however, mask the evolution through time in the perceptions of what constitutes “climate,” and the impact of these changes on the foci, objectives, and approaches of climatology. Danish science historian Matthias Heymann argues that climate “cannot be reduced to a clear, neat, and unequivocal definition;” but, rather, “its interpretation is closely linked not only to a state of scientific knowledge, but also to the broader cultural contexts of its time” (Heymann 2010, 82). Changes in the perception and interpretation of climate have not only influenced the nature of climatology as a field of inquiry, but also the positioning of climatology among, and within, other disciplines, including geography.

Climatology before 1900

The term climate originates from klima, a Greek astronomical term for the length of the longest day at different latitudes. In the third century BCE, Greek philosopher Eratosthenes described five latitudinal zones (two frigid zones, two temperate zones, and a tropical zone), distinguished by similar sun angles and day lengths, which he referred to as climates. Early climatological thought was strongly influenced by the philosophy of weather and climate espoused in Meteorologica, authored by Aristotle around 340 BCE. Another influential treatise was On Airs, Waters and Places, published around 400 BCE by Hippocrates, who attributed common diseases to locations, seasons, winds, and air.

The scientific era of climatology begins in the 1600s, when, as succinctly described by American mathematician H. Howard Frisinger, the study of climate moved “beyond the natural philosopher into the hands of the natural scientist” (Frisinger 1966, 444). Scientific breakthroughs that furthered an understanding of the Earth’s climate included French mathematician Blaise Pascal’s observations in the seventeenth century of the relationship between atmospheric pressure and elevation, and the
development in the mid-eighteenth century of a conceptual model of the general circulation by British amateur meteorologist George Hadley. The invention, beginning in the late sixteenth century, of key meteorological instruments (e.g., thermometer, barometer, hygrometer, anemometer) led to systematic measurements of the atmosphere and also to the sharing of observations. Observational networks date to the mid-1600s and were commonplace by the late 1800s. According to geographer David Miller, these measurements provided climatology with numerical data for analysis before most other environmental sciences, and the term climatology became synonymous with the “ordering of any variable displaying an annual regime” (Miller 2005, 284). Science historian Heymann (2010) argues that with these new measurements, the intellectual focus of climatology shifted to climate’s changeability (i.e., the temporal dimension of climate), with less emphasis on the spatial (i.e., geographical) dimension. Notwithstanding the strides made in providing a foundation for the physical explanation of climate, climate determinism also gained popularity during this period. The underlying belief of climate determinism is that the physical environment, particularly the climate, has a controlling influence on the development of human societies and cultures.

Substantial shifts in climatological thought occurred during the nineteenth century. Alexander Humboldt is often credited for refocusing climatology on the spatial, rather than temporal, variations in climate and, early in the 1800s, Humboldt prepared the first isoline map of the spatial distribution of annual temperature. The introduction in the late 1800s of long-term averages as a reference for comparing typical conditions between locations is attributed to Austrian meteorologist Julius von Hann. Climate classification also was used to describe the spatial variations of climate, and the well-known classification by German geographer Waldimir Köppen was first published in 1884. In the nineteenth century, climatology was primarily a subdiscipline of geography and meteorology and, to a lesser extent, of geology. Climate determinism remained popular among some groups throughout the nineteenth century.

The modern era of climatology

The modern era of climatology begins in the late nineteenth and early twentieth centuries. Early in this period, Norwegian meteorologist Vilhelm Bjerknes outlined the primitive equations (i.e., equations for the conservation of mass, momentum, and energy) for predicting large-scale atmospheric motion, and British mathematician Lewis Fry Richardson provided initial numerical techniques for solving these equations. Bjerknes and his colleagues, including his son Jacob Bjerkness and Halvor Solberg, also were responsible for the first conceptual models of extratropical cyclones, air masses, and frontal systems, providing a platform for relating the climate at a location to the frequency of different types of weather systems. Atmospheric teleconnections, defined as the relationships between distant atmospheric and sea-surface temperature anomalies, were first introduced by British physicist Gilbert Walker in the late nineteenth century, and by the second half of the twentieth century were widely used to explain interannual climate variability.

Energy and water fluxes between the atmosphere and Earth surface were another focus of twentieth century climatological research. The initial conceptualization of the energy budget is attributed to the work of Swedish physicist Anders Ångström in the 1920s, although numerical models of the energy balance were not developed until the late 1960s. In 1955,
geographers Charles Thornthwaite and John Mather published their seminal monograph *The Water Balance*, outlining methods to estimate water surpluses, runoff, and recharge. Improvements in observations also contributed to advances in climatology. Regular balloon soundings of the upper atmosphere began in the 1930s and, from the 1970s onward, climatology benefited from the greater spatial and temporal coverage of satellite observations of the atmosphere and land surface.

In the second half of the twentieth century, concerns about anthropogenic contributions to climate change spawned an enhanced interest in climatology. In the 1850s British physicist John Tyndall discovered that atmospheric molecules such as carbon dioxide and water vapor absorbed thermal energy, and in the first half of the twentieth century global temperature was theoretically linked with changing carbon dioxide concentrations by Swedish physicist Svante Arrhenius and British engineer Guy Callendar. Yet, concern regarding the impact on climate of increasing greenhouse gases did not become widespread until after Carl Keeling initiated in 1958 systematic measurements of atmospheric carbon dioxide at the Mauna Loa Observatory in Hawai’i. Soon after, anthropogenic-induced land cover change was recognized as an additional forcing of local, regional, and global climate. With this heightened interest in the anthropogenic influences on climate came a greater interest in the temporal, rather than spatial, variations of climate. Although initial attempts to estimate trends in global surface temperature date to the early work by Köppen in 1881, published time series of globally averaged temperatures were not available until the 1970s and 1980s. These include, for example, the temperature time series produced by scientists at the University of East Anglia Climatic Research Unit in the United Kingdom, and at the US National Aeronautics and Space Administration Goddard Institute for Space Studies.

Climate models became essential tools for studying climate. Meteorologist Norman Phillips is credited with developing, in 1956, the first general circulation model of the atmosphere, and in the late 1960s and early 1970s climatologist Syukuro Manabe and oceanographer Kirk Bryan constructed and refined a coupled atmosphere and ocean model. By the early twenty-first century, global models were widely used to project future climate conditions, and archives of model simulations were established. Interest in paleoclimatic approaches to studying climate also increased during the modern era, in line with an evolving focus of climatology on the temporal variations of climate. As early as 1837, Swiss geologist Louis Agassiz proposed that the Earth had experienced past ice ages, and in 1941 Serbian astronomer Milutin Milankovitch related long-term climate change to cyclic variations in Earth motion (orbital eccentricity, obliquity, and precession). Beginning in the 1800s, proxy measures of climates, such as the growth bands in trees and deposits in lake beds, were recognized as a means to extend the climatological record backwards in time. Ice cores were first drilled in the 1950s, and, around the same time, analyses of deep-water corals suggested variations of ocean temperatures over glacial time scales.

**Philosophical paradigms of climatology**

The philosophical paradigms of climatology, particularly as practiced within geography, have shifted considerably over time. In the early twentieth century, climatology was heavily influenced by environmental (climatic) determinism, which at that time was a central theory of the discipline of geography. After environmental determinism fell out of favor in the 1920s, climatology as practiced within geography returned to a focus
on the spatial differences in climate that was popular during the previous century, whereas the focus of climatology practiced within the discipline of meteorology was on the time-averaged components, or synthesis, of weather. From the mid-twentieth century until recently, philosophical paradigms were not extensively debated by climatologists, whatever the discipline with which they most closely identified. For the most part, climatologists comfortably worked within a positivist framework and employed the scientific method. American geographer Richard Skaggs contends that the lack of a widely accepted orthodoxy during this period, and the diversity of subject matter and methods, contributed to the rapid advancement of climatology from the 1950s onward (Skaggs 2004). But beginning with the early twenty-first century, climatologists became more cognizant of the paradigms that guide their work. Climatologists Gavin Schmidt and Steven Sherwood, for example, recently commented on the influence of climate models on climatological thought, pointing out that these models have led to the dominance of “the paradigm of understanding emergent properties of the complex system via the bottom-up agglomeration and interaction of small scale processes” (Schmidt and Sherwood 2015, 165). Interest in the coupling of climate and human systems also has grown and British geographer Mike Hulme has argued that geography should “reclaim climate from the natural sciences,” where it is defined in physical terms only, and, instead, “treat it unambiguously as a manifestation of both Nature and Culture” (Hulme 2008, 6).

Data sources for climatological analyses

A large number of climate variables are used to describe the many facets of climate. Observations of these variables are essential for analyzing the spatial and temporal variability of climate. Climate variables can be measured directly or they can be estimated using remote sensing techniques. Worldwide routine in situ measurements include surface air pressure, maximum and minimum temperature, precipitation, humidity, wind direction and speed, and visibility. A global network of balloon soundings provides upper-air measurements of pressure, temperature, humidity, and wind speed and direction for multiple levels in the upper atmosphere. Satellite observations of the atmosphere began nearly fifty years ago. Observations are obtained from both Earth-orbiting satellites and geostationary satellites. Retrieved variables include, among others, surface land temperature, sea surface temperature, soil moisture, snow and ice cover, and precipitation estimates.

Although climatologists often collect atmospheric observations as part of field campaigns and maintain specialized observational networks for specific applications, the extensive use of historical climate data archives is a hallmark of climatology. Most often, these archives are maintained by national organizations, such as the US National Oceanic and Atmospheric Administration’s National Centers for Environmental Information (formerly the National Climatic Data Center). Working with these archived observations can be challenging. Most observational networks were initially designed for short-range weather prediction, where the focus is on the accuracy and precision of measurements. While these qualities are also a consideration for climate monitoring, the temporal and spatial consistency of observations is as, or even more, important. Heterogeneities introduced into the historical climate record by changes in instrumentation, observation protocols such as time of observation, and station location complicate the use and interpretation of climate observations, particularly the
interpretation of temporal trends. Consequently, identifying and adjusting for biases in time series of climate observations has been, and continues to be, an important aspect of climatology.

In addition to archives of “raw” observations, gridded fields of historical climate observations also are available. Gridded fields can be obtained by: (i) averaging anomalies or climatological values for stations located within a specified grid box (e.g., the Global Historical Climatology Network (GHCN) global gridded temperature and precipitation products); (ii) spatial interpolation of anomaly and climatological fields based on distance between observing stations, such as the global gridded monthly time series and climatological values of terrestrial air temperature and precipitation developed by the University of Delaware; or (iii) spatial interpolation that, in addition to distance, considers elevation (e.g., the WorldClim and Daymet datasets) or elevation and slope (e.g., the PRISM (parameter-elevation relationships on independent slopes model) gridded fields of temperature and precipitation). As noted by PRISM developer Christopher Daly, an important consideration when using gridded observations is that the fine resolution of many of these datasets can give an appearance of realism that is often not consistent with the spatial resolution of the initial observations (Daly 2006).

Reanalysis fields, first introduced in the late 1990s, are another popular data archive for climate research. These gridded fields are a “blend” of observations and model output. Very generally, for a particular time, the value of a parameter at a location is initially obtained from the short-term forecast of an operational weather forecast model and then modified by the surrounding current observations of the atmosphere. The spatial coverage of reanalyses ranges from regional (e.g., the North American regional reanalysis) to global (e.g., ERA-40 from the European Centre of Medium Range Forecasting), and the horizontal resolution varies from fine (e.g., about 38 km for the Climate Forecast System reanalysis) to coarse (e.g., 2.5° latitude × 2.5° longitude for the NCEP/NCAR reanalysis). Reanalysis fields are affected by biases associated with the operational weather forecast model and from the number and type of available climate observations; thus, they can deviate from observations especially in data-poor regions.

Archives of simulations from global and regional climate models are another important resource for climatological analysis. These simulations are useful for numerous applications, particularly for assessments of climate change impacts and adaptation. Simulations of historical and future climates obtained from global climate models developed by more than twenty modeling groups from different countries are available from the Coupled Model Intercomparison Project, phase 5 (CMIP5). Archives of finer-resolution simulations from regional climate models are also available. For example, the ENSEMBLES project distributes climate simulations for Europe for the period 1950–2100, that were obtained from regional climate models driven by reanalysis fields and multiple global climate models. For North America, multiple regional climate model simulations for two time slices (1960–1990 and 2040–2070) are available as part of the North American Regional Climate Change Assessment Program (NARCCAP).

Research methods in climatology

Climatologists employ a plethora of research methods, ranging from the simple to the complex, that are constrained only by the researcher’s innovation. Statistical techniques and numerical modeling are, in particular, widely employed in climatological research and applications.
Statistical techniques

Statistical techniques are used for the extraction, quality control, and synthesis of climate information, and for establishing associations between variables. The calculation of long-term averages and the use of composite mapping are some of the first, albeit relatively simple, usages of statistical methods in climatology. For example, climate standard normals of temperature and precipitation, introduced by the World Meteorological Organization in the 1930s, are defined as 30-year averages, updated every decade, for individual stations. Composite maps, on the other hand, display the ensemble average of spatial fields of climate variables, and have frequently been used to identify the typical circulation patterns associated with a particular weather phenomenon, such as severe weather, or the typical temperature and precipitation patterns under different atmospheric teleconnections. Other early introductions of statistical methods to climatology include the use of parametric probability distributions to estimate the magnitude and return frequency of climate extremes. A classic example, dating to the 1960s, is the *Rainfall Frequency Atlas of the United States* authored by hydrologist David Hershfield, which provided extreme precipitation estimates for hydrologic design. Time series analysis also has been a cornerstone of climatological analysis. Linear and nonlinear regression methods have been, and continue to be, used to estimate temporal trends in climate variables, and techniques such as harmonic, spectral, and wavelet analysis are helpful for detecting interannual and interdecadal climate variability.

Climate classification also employs statistical techniques. The goal of any classification is to minimize intraclass variation while maximizing interclass variation. Classification has been used within climatology to summarize the spatial variations of climate and to identify frequently-occurring atmospheric circulation patterns. Early classifications were developed subjectively, such as the aforementioned Köppen classification scheme, which grouped locations based on average temperature and the amount and seasonality of precipitation, and the well-known catalog of circulation types for the British Isles developed by climatologist Hubert Lamb in the early 1970s. Over the past several decades, subjective classification methods have, for the most part, been replaced by computer-assisted approaches based on multivariate statistics. In particular, cluster analysis is frequently used to identify climate regions. Statistical approaches for identifying circulation types include correlation analysis, empirical orthogonal functions (i.e., principal components analysis), and self-organizing maps. A classic example is the use of empirical orthogonal functions by meteorologists John Wallace and David Gutzler in the early 1980s to identify wintertime teleconnection patterns for North America.

Statistical techniques are also used in climatology to downscale simulations from global and regional climate models to finer spatial and temporal resolutions, and to adjust for biases in the model simulations. An extensive literature exists that evaluates the efficacy of a range of techniques for this purpose, including regression procedures, canonical correlation analysis, artificial neural networks, support vector machine algorithms, and weather generators (Winkler et al. 2011 provides a review). The resulting empirically-downscaled and bias-corrected climate projections are frequently used in climate change assessments. Other uses of statistical techniques within climatology include the development of transfer functions to estimate climate parameters from proxy records of climate-dependent phenomena, such as the

Statistical techniques are also used in climatology to downscale simulations from global and regional climate models to finer spatial and temporal resolutions, and to adjust for biases in the model simulations. An extensive literature exists that evaluates the efficacy of a range of techniques for this purpose, including regression procedures, canonical correlation analysis, artificial neural networks, support vector machine algorithms, and weather generators (Winkler et al. 2011 provides a review). The resulting empirically-downscaled and bias-corrected climate projections are frequently used in climate change assessments. Other uses of statistical techniques within climatology include the development of transfer functions to estimate climate parameters from proxy records of climate-dependent phenomena, such as the
growth rings of a tree, quality control of observational data including tests for heterogeneities, and the spatial and temporal interpolation of atmospheric observations.

**Numerical modeling**

Numerical models are physically-based models developed using the principles of conservation, the first law of thermodynamics, and the laws of motion. Models are an important tool for improving the scientific understanding of the processes and internal dynamics of the climate system, evaluating responses of the system to perturbations, projecting future climate conditions, understanding the processes contributing to paleoclimates, and translating climate processes into useful information for applications and policy. Climatologists employ a variety of numerical models that differ in terms of their dimensionality and resolution, and by the number and types of the components of the climate system that are included in the model. The choice of model depends on the questions to be addressed or the applications for which the simulations are intended.

Examples of 1-D models include energy balance models, which are typically used to investigate latitudinal variations in surface temperature as a function of the Earth's energy balance, and radiative-convective models, which are single column models focusing on vertical variations but ignoring horizontal variations. Early 3-D climate models were atmosphere-only general circulation models. Although a coupled atmosphere–ocean model was first introduced in the 1960s, it was not until the late 1980s that atmosphere–ocean general circulation models (AOGCMs) were widely used. AOGCMs simulate the dynamics of the climate system, rather than only the atmosphere, and incorporate feedbacks between the atmosphere, ocean, and land and sea ice, allowing for more realistic modeling of interannual and longer-term variability of the coupled system. Earth system models (ESMs) expand on AOGCMs to include additional components of the climate system (e.g., the carbon cycle) and represent the current state-of-the-art in 3-D climate modeling. ESM simulations are routinely run for periods of a century or longer. In addition to ESMs, Earth system models of intermediate complexity (EMICs), are available. These models have more idealized representations of the climate system components, and are particularly useful for long (i.e., millennial) model integrations. As climate models became more complex, the acronym “GCM” evolved from its original meaning of “general circulation model” to the more general term “global climate model” that broadly refers to 3-D models of the global climate system. In addition to GCMs, limited-area 3-D climate models are also available. Referred to as regional climate models (RCMs), as they only examine a portion of the Earth's surface, RCMs typically have a higher spatial resolution than GCMs and can simulate sub-GCM-scale processes and distributions of climate variables. Lateral boundary conditions to drive a RCM are obtained from reanalysis fields or from GCM simulations.

The immense effort expended by climatologists to develop, evaluate, and apply climate models cannot be overstated. Through the efforts of climatologists and others, these models continue to increase in skill and scope. Furthermore, extensive effort has gone into producing the inputs needed for the initial and boundary conditions of climate models and the long-term, spatially-extensive datasets used for diagnostic evaluations. Maintenance of archives of multimodel simulations is another hugely cost and labor intensive effort, but archives such as
CLIMATOLOGY

CMIP5 are essential for assessing model differences and uncertainty. In addition, climatologists have written extensively on the challenges of interpreting multimodel ensembles, which in effect are “ensembles of opportunity” with interdependent rather than independent members (Knutti 2010). Much effort also has been expended in developing procedures for downscaling climate simulations to scales appropriate for applications and for accounting for biases in simulations. A glimpse of the potential use of model simulations for climate assessments and decision-making was provided by geographer Linda Mearns and her colleagues who summarized the diverse applications of the RCM simulations from the NARCCAP archive (Mearns, Lettenmaier, and McGinnis 2015). Climate models are also a primary tool for evaluating the influence of land use/land cover change on local, regional and global climate. Thus, it is not difficult to understand why Schmidt and Sherwood (2015) refer to numerical simulation as the “new pillar of inquiry” in climatology.

Subfields of climatology

Climatology is routinely divided into subfields. Many different subfields have been proposed, representing differences in scale (e.g., microclimatology), techniques (e.g., statistical climatology), and thematic focus (e.g., building climatology), although there is usually considerable overlap between an individual subfield and other subfields. The subfields also differ considerably in the number of adherents, and the popularity of different subfields has waxed and waned with time. For this entry, subfields within climatology are grouped by whether they represent a different perspective on climatological research or whether they are primarily distinguished by a thematic focus.

Subfields as analytical perspectives

Several subfields of climatology reflect different perspectives to climatological inquiry; namely, physical climatology, dynamic climatology, synoptic climatology, and paleoclimatology. Physical climatology is primarily concerned with the interactions between the Earth’s surface and the atmosphere, including the spatial and temporal distributions of energy, moisture, and momentum exchanges. One focus area of current significance is the role of surface cover types on climate. Physical climatologists are interested in energy and mass exchanges from the micro to the global scales. Physical geography is characterized by the extensive use of numerical models, ranging from simple to complex, although other analytical procedures including statistical techniques are also employed.

Dynamic climatology and synoptic climatology are closely related. In general, dynamic climatology refers to the climatology of atmospheric dynamics and thermodynamics. Dynamic climatologists often, but not exclusively, focus on atmospheric circulation at the global scale and are concerned with climate variability at longer (i.e., interannual) time scales. Synoptic climatology, on the other hand, is concerned with the relationship between the atmospheric circulation and local or regional climate. Synoptic climatology takes the viewpoint that climates differ because their component weather types and the frequencies of these weather types differ, which in turn are affected by atmospheric circulation at a range of scales from planetary to regional. Historically, dynamic climatology has emphasized the use of numerical modeling, whereas empirical methods, particularly classification methods, were widely used in synoptic climatology. This distinction has blurred, however, with statistical techniques (e.g., empirical orthogonal functions) frequently used in dynamic climatology and with numerical models (e.g.,
GCMs, RCMs) now an essential tool in synoptic climatology.

The historical perspective on climatology is provided by paleoclimatology. Here the focus is on reconstructing past climates (usually before the start of the instrumental record) and linking these proxy records to atmospheric circulation. Climate reconstructions make use of pollen analysis, tree-ring dendrochronologies, lake and river sediments, stratigraphic variations in the chemical and dust content of cores obtained from ice caps, and other proxy measures. Statistical techniques are used to develop the transfer functions between the proxy measures and other time series of climate variables (e.g., temperature and precipitation), and climate models are used to simulate past climates in order to understand the mechanisms for past climate changes and to extrapolate between the local and global scales of paleoclimates.

Thematic subfields

Innumerable thematic subfields of climatology can be defined. Of these, urban climatology, hydroclimatology, bioclimatology, and agricultural climatology are particularly active areas of climatological inquiry.

Urban climatology originated in the late 1800s and initially was descriptive in nature, primarily focusing on observational studies and the characterization of the urban heat island (i.e., the elevated temperatures of urban areas compared to surrounding rural environments). With the development of numerical models, the focus of urban climatology shifted to energy and momentum exchanges in the urban environment at all spatial scales, although micro- and mesoscale environments such as urban canyons have been of particular interest. Other areas of active research in urban climatology include air quality, urban forestry, biogeochemical cycles, water movement and storage, and the potential impacts of climate change on the urban environment.

Hydroclimatology, often described as the study of the influence of climate on hydrologic events, emphasizes the interface between the atmosphere and terrestrial water. All aspects of the hydrologic cycle, including precipitation variability, floods and droughts, snowfall and snow cover, river discharge, and groundwater recharge, are investigated, using a range of methods from descriptive summaries to numerical simulations.

Bioclimatology focuses on the interactions between the atmosphere and living organisms. Interest in the influence of climate on biota dates to Hippocrates; thus, bioclimatology is one of the oldest subfields of climatology. Bioclimatology is a diverse subfield, with research ranging from changes in plant development, including trends and interannual variability in the timing of the spring emergence of plants, to the influence of extreme heat events on human mortality. The analytical approaches used in bioclimatology are as diverse as the topics studied. Although agricultural climatology can be considered a part of bioclimatology, it is often singled out as a separate subfield because of the extensive work in this area and its economic significance. Research within agricultural climatology ranges from climate-crop interactions at the field and subfield scales to climate influences on global food security.

The “new” applied climatology

Applied climatology is often considered to be a subfield of climatology. In his classic textbook General Climatology, which was published in 1960, geographer Howard Critchfield claimed that applied climatology is one of three major subdivisions of climatology, along with physical climatology and regional climatology. Since
then, few textbooks and other references have been published without specific mention of applied climatology. However, this distinction as a subfield masks that applied climatology, or at least modern-day applied climatology, draws on, and incorporates, any of the analytical perspectives of climatology and, moreover, can be situated in any of the thematic subfields of climatology. In other words, applied climatology crosses all the subfields (analytical and thematic) of climatology and even extends into the social and policy sciences.

British geographers John Thornes and Samuel Randalls argue that, in spite of considerable interest in applied climatology in the mid-twentieth century, and even calls by prominent climatologists such as Werner Terjung and Stanley Changnon for climatology to address real-world problems, it was not until the late 1990s, with rising concern about climate change, that applied climatology became an interdisciplinary endeavor involving both natural and social scientists (Thornes and Randalls 2014). Prior to this, climate had primarily been treated as a hazard or risk, and applied climatology involved mostly natural scientists. Geographer Marc Tadaki and his colleagues explain that the aim of applied climatology in the 1960s and 1970s was “not to explain social life, but the far more pragmatic one of optimizing economic returns and biophysical indicators” (Tadaki, Salmond, and Le Heron 2014, 397). They contrast this with the current status of applied climatology, arguing that “climate applications have never been more embedded into human organizations than at present” (Tadaki, Salmond, and Le Heron 2014, 399).

Much of the early work in applied climatology could also be thought of as applied in potential but not necessarily in practice, with the choice of problem often selected by the climatologist and findings simply handed off to potential users. Recognition of the limitations of this top-down approach is leading to greater calls for the coproduction of knowledge by climatologists, stakeholders, and representatives from other relevant disciplines, who work together to outline concerns and goals, jointly identify options for mitigation and adaptation, and then evaluate the potential co-benefits and negative externalities of different options. This strategy is much more time consuming than top-down approaches but offers an exciting new direction for applied climatology and increased potential for more informed decision-making.

The future of climatology

Over the last few decades, the study of climate has expanded dramatically. Geographer Andrew Carleton contends that “climatology has become a subject of active research in disciplines that formerly either eschewed it (e.g., meteorology and atmospheric sciences) or had little need for such studies (e.g., geology)” (Carleton 1999, 714). Moreover, climatologist Hervé Le Treut and his colleagues note that, in addition to greater interest in climatology, the scope of climatology also has expanded and is “now far more wide-ranging and physically comprehensive than was the case only a few decades ago” (Le Treut et al. 2007, 98).

Much of this expansion can be attributed to increased interest in, and concern with, natural and anthropogenic climate change. Environmental scientists Michael Grieneisen and Minghua Zhang recently queried the Web of Science database to identify publications related to climate change during the period 1997–2009 and found that the number of publications had increased exponentially with over 100,000 publications reporting climate change-related research during this period (Grieneisen
They point out that this total is equivalent to the research output of major scientific disciplines. Climate is now studied across a range of disciplines, although Grieneisen and Zhang found that, with the exception of economics, the social sciences remain underrepresented compared to the natural sciences. Furthermore, Andy Reisinger argues that, in spite of cross-disciplinary interest, climate-related research has been slow to integrate the insights and contributions of different disciplines within an individual research program but, instead, remains primarily “multidisciplinary” rather than fully “interdisciplinary” in character (Reisenger 2011).

Even though the future for the study of climate is bright, the future of the term “climatology” is in question. More and more, the study of climate is referred to as “climate science” rather than “climatology,” with the meaning of “climatology” instead constrained to the description, often using statistical methods, of the spatial and temporal characteristics of climate. This change mirrors nomenclature changes occurring in meteorology, where “meteorology” is being replaced as the umbrella term for the study of the atmosphere with “atmospheric science.” Propo-

nents of this nomenclature change argue that the “climate science” terminology is more encompassing and better portrays the increased use of numerical models, more frequent multidisciplinary participation, and greater recognition of the human dimension in the study of climate. Further evolution in the meaning and usage of “climate science” and “climatology” can be expected in the future.

Background and rationale

Geographic information continues to proliferate in both quantity and type, thus presenting significant impediments to its effective management and analysis. Cloud computing is being used to meet such challenges by providing access to capacious storage and high-performance computing resources. In its most general form, cloud computing is an evolving construct that refers to the provision of distributed, configurable computer services, such as applications, compute cycles, and storage, over a network. A key advantage of the cloud model is its inherent flexibility, or what is sometimes termed “elasticity”; users and organizations are easily able to adapt to rapid and uncertain changes in demand, thereby reducing the capital expenditures that are required if infrequent demand peaks must be satisfied. Commonly used sobriquets of this adaptability feature are “pay-as-you-go,” “on-demand,” and “utility” computing. This represents a rather dramatic organizational shift, from an approach involving substantial capital expenditures, which have often taken the form of single-user, powerful personal computers individually configured with software (requiring routine upgrades), to one that incurs operational expenses based on lightweight, networked clients (Garrison, Kim, and Wakefield 2012). Other benefits of cloud computing accrue as a consequence of increased ease and reliability of software and hardware maintenance, thus reducing support costs and risks to organizations.

Cloud services are provided using three primary deployment modes that vary in terms of their accessibility and levels of security. Major commercial vendors, such as Amazon and Microsoft, currently provide open-access public cloud services. In other cases, institutions may opt to develop private cloud resources to support their particular computing objectives. Such services are typically developed by large organizations and are hidden behind a firewall. In yet other cases, hybrid services are provided. For example, public services, such as geographic information system (GIS) applications, may be used with proprietary data held in a secure repository.

Cloud services are often viewed as a set of layers in a stack. The layer closest to the end user is often termed “software as a service” (SaaS) and is generally manifested as managed, network-enabled applications. A good example is Google Apps, and GIS software and services vendors are also rapidly embracing this model. Beneath that layer the “platform as a service” (PaaS) refers to configurable foundational software components such as databases and the middleware that handles flows of information among applications. At the lowest level, “infrastructure as a service” (IaaS) provides the physical
CLOUD COMPUTING

computing resources that are configured by the user to meet variable needs. This layer is often viewed as being centralized, but in reality may be highly distributed as location independence is an important objective of the cloud model. Authoritative discussions about cloud computing concepts, including definitions, architectural issues, and service models, are provided by Armbrust et al. (2010), Garrison, Kim, and Wakefield (2012), and Liu et al. (2011). Research articles focused specifically on emerging technical issues related to cloud computing are published in IEEE Transactions on Cloud Computing.

Geospatial applications

Many geospatial computing tasks are data and computation intensive (Armstrong 2000). Cloud environments are an appealing way to achieve high performance in the form of scalable, massive parallelism, at low cost. One major cloud services vendor, for example, enables buyers to purchase cycles in compute-optimized, memory-optimized, and graphics processing unit (GPU) (massive parallelism) instances. Though researchers are in the early stages of reporting on advances in the use of clouds for geospatial applications, the results show promise (Yang, Xu, and Nebert 2013).

Spatial data reduction and transformation

Like most sensor technologies, LiDAR instruments continue to increase in spatial, spectral, and temporal resolution, thus driving up data volumes (in this case, point clouds). Hegeman et al. (2014) demonstrate how a cloud environment (Amazon EC2) is used to extract topographic information from raw point clouds. Tang and Feng (2014) develop a private cloud and exploit GPU-based parallelism to process LiDAR point clouds; their implementation scales well across the limits of their evaluation process.

Remote sensing

Remote sensing requires significant computer power to process high-resolution multispectral imagery, though such processing is rarely time-critical. Nevertheless, several researchers have developed cloud-based strategies for unsupervised image classification. Sugumaran et al. (2015) provide an overview of remote sensing applications in cloud computing environments. Wang et al. (2013) implemented a maximum likelihood classifier that uses MPI (message passing interface) and MapReduce. When compared to a single node, their approach boosts performance considerably.

These two domains represent only a partial perspective on possible geospatial applications. Other areas that can benefit from low-cost on-demand parallelism include spatial optimization and various forms of spatial statistical analysis, particularly those employing Bayesian methods.

Current cloud computing challenges

Though the advantages of cloud computing are widely touted, it is not a panacea. In some cases, particularly those involving invariant demand for resources, seemingly attractive economic advantages fail to materialize. General cloud computing challenges are emphasized in Yang et al. (2011). There are two common problems with important geospatial implications worth mentioning here.

Network latency

Though computer network bandwidth continues to increase in both wired and wireless
forms, latency can occur if significant traffic volumes are encountered, or when applications are data-intensive, requiring substantial input/output. In such cases, preservation of data locality may become important.

Security

Some applications, health applications of GIS being a prominent example, require fastidious attention to security details, as any lapse can be catastrophic. Cloud computing, by definition, requires storage off-site (and therefore out of local control), with data often being transported across commercial networks. As a consequence of this openness, institutional data policies may prohibit the use of cloud services. Such concerns might be misplaced, however, since the security of many enterprise systems, including those located on university campuses, is highly variable, as can be seen in the accounts of data breaches that appear regularly in the press.

Summary

Cloud computing is emerging as an important computing model that is supported by rapid advances in network infrastructure and bandwidth, as well as innovative software architectures. The approach provides flexible, configurable computer resources to end users. GIS applications are increasingly taking advantage of the opportunities afforded by cloud environments and it is likely that the approach will become commonplace over the course of the next decade.

Clouds

Lin H. Chambers
NASA Langley Research Center, USA

Clouds are familiar to all of us from our youngest days. They can bring gloom or bright, fanciful shapes; they can bring gentle, life-giving rains or flood-inducing downpours, dancing snowflakes or driving blizzards. Anyone who flies regularly has seen how quickly one can go from the gray, rainy underside of clouds to the sunny, fantastical landscape of cloud tops. Despite this familiarity, many people know very little about clouds.

What are clouds?

Clouds are collections of liquid water droplets or ice crystals suspended for a time in Earth’s atmosphere. Clouds form when conditions are cold and moist enough to condense or freeze water vapor, and disappear when conditions are warm and dry enough to evaporate water or sublimate ice. In terms of moisture, this condition is referred to as saturation – the point at which the atmosphere holds as much water vapor as it can in a gaseous form; beyond the saturation point, moisture will begin to condense out of the atmosphere (dew on the ground comes from this source). But the formation of clouds is most often mediated by tiny particles in the atmosphere called cloud condensation nuclei (CCN) through a process called heterogeneous nucleation. This is the process whereby gas molecules of H₂O (water vapor) first stick to a condensation nucleus – a small particle floating in the atmosphere such as dust, smoke, sea salt, even small bits of biological matter kicked up by the wind – then clump together to form water droplets if enough water vapor is available to do so. Without these nuclei, clouds would only form in the coldest parts of the atmosphere, below −40 °C/F, where homogenous nucleation (water vapor directly with water vapor) can occur. This is because very high supersaturation levels (humidity above 100%) are required to overcome the surface tension of tiny, pure water droplets and allow more molecules to adhere and grow the droplet; but the presence of a foreign substance within the water enables the droplet to grow at much lower supersaturation levels. Ice nucleation – allowing the formation of ice crystals – requires very specific nuclei that facilitate water molecules arranging themselves in a crystalline structure to create solid ice. More details on these processes can be found, for example, in Rogers and Yau (1989).

How are clouds classified?

While clouds are infinitely variable, certain patterns recur and are meaningful. Luke Howard (1772–1864) created a useful and enduring classification of clouds first published in 1803 (Howard 2011/1865/1803; Hamblyn 2001). His classification used Latin terms to identify three primary classes of clouds:

- cumulus – heap, pile, mound: describes puffy, convective clouds;
- stratus – spread, laid out: describes flat, featureless cloud layers;
- cirrus – curl, fringe: describes wispy, high ice clouds.

### Clouds

#### High-level clouds:
- **Cirrus (Ci)**, **Cirrocumulus (Cc)**, **Cirrostratus (Cs)**

- **Cirrus** (Ci): in the form of filaments, strands or hooks, not progressively invading the sky.
- **Dense Cirrus** (Ci): in patches or entangled sheets, which usually do not increase, and seem to be the remains of the upper parts of a Cumulonimbus.
- **Dense Cirrus** (Ci): often in the form of an oval, being the remains of the upper parts of a Cumulonimbus.
- **Cirrus** (Ci): in the form of filaments, strands or hooks, progressively invading the sky and generally becoming denser. Cirrus and/or Cirrostratus progressively invading the sky, generally growing denser, but does not reach 45° above the horizon.

#### Mid-level clouds:
- **Altostratus (As)**, **Alto cumulus (Ac)**, **Nimbostratus (Ns)**

- **Altostratus** (As): the greater part of which is semitransparent; through which the sun/moon may be weakly visible, as through ground glass.
- **Thick Altostratus**, greater part sufficiently dense to hide sun (or moon), or Nimbostratus.
- **Alto cumulus**, the greater part of which is semitransparent; the various elements of the cloud change only slowly and are all at a single level.
- **Alto cumulus undulatus** (lens-shaped); most of which is semitransparent; occurs at one or more levels and continually changing in appearance.
- **Semi-transparent Altostratus** in bands, or Alto cumulus as one or more layers (semitransparent or opaque), progressively invading the sky.

#### Low-level clouds:
- **Cumulus (Cu)**, **Stratus (St)**, **Stratocumulus (Sc)**, **Cumulonimbus (Cb)**

- **Cumulus** (Cu): of fair weather, little vertical development and seemingly flattened.
- **Cumulus of moderate extent** with protrusions in the form of cones or towers, may be associated with Cumulus, Stratocumulus with bases at the same level.
- **Cumulonimbus**, the summits of which, at least partially, lack sharp outlines but are neither clearly fibril or in the form of an anvil.
- **Stratocumulus formed by the spreading out of Cumulus.** Cumulus may also be present.
- **Stratocumulus not resulting from the spreading or flattening of Cumulus**.

#### More weather phenomena:
- **Mammatus** are the drooping underbelts of heavy, rain-saturated clouds.
- **Tornadoes** are extremely destructive whirlwinds extending from the base of a thunderstorm.
- **Wall cloud**: Lowering from rain-free base of thunderstorm indicates area of strongest updraft. Tornado may form.
- **A shelf cloud forms in association with a cold front from a squall line or thunderstorm.**
- **Waves generated by a nearby thunderstorm ripple through the base of Stratocumulus.**

---

Figure 1 continued
These three primary cloud classes could then be combined to describe further variations in clouds, such as stratocumulus: a vertically restricted layer of extensive cumulus, and so forth. The cloud chart in Figure 1 provides one example of a modern classification based on this system. Many of these cloud types are associated with the occurrence or approach of a particular type of weather system, as noted in the figure. Thus, familiarity with cloud classification...
CLOUDS

is useful for anyone who spends substantial amounts of time outdoors, or whose work is in some way impacted by weather events.

How do clouds form?

There are a number of ways that the atmosphere can reach the saturation conditions to form clouds; these involve either a drop in temperature or an increase in the water content of an air mass, or both. This can occur in several ways, as follows.

- By wind forcing air upward over surface topography such as a mountain range. As air rises, it cools. This mechanism is called orographic lifting and explains how mountains can create a rain shadow on the downwind side of a range by causing most water to condense and precipitate out of the atmosphere on the upwind side of the range.
- By frontal lifting, in which air in a warm air mass is forced upward over an equally invisible, but denser, cold air mass. As the warm air rises, it cools, and water vapor may condense to form clouds. Thus, the arrival of a warm front often signals precipitation.
- By the simple process of heat rising, or convection. As sunlight warms a surface during the day, it in turn heats the air above it, which becomes less dense and begins to rise. If sufficient heating occurs, for example, on a summer day, this can cause air to rise and cool enough to reach saturation and form clouds. Often under these conditions a collection of cumulus clouds will form with their bases all at essentially the same level – the point at which the air has risen and cooled to the dew point temperature where water begins to condense. If heating continues, stronger convection will occur in the atmosphere, resulting eventually in towering cumulonimbus storm clouds.
- By radiative cooling, which occurs after the sun has set and is no longer warming the Earth’s surface. The air now cools due to emission of thermal or infrared radiation (heat) to space, and may drop below the dew point temperature. Fog often forms by this mechanism.
- By advective cooling in which air flows over a cooler surface and cools to its dew point. This may lead to coastal fog in regions where the land and water temperatures differ.
- By mixing some source of moisture into a cold, dry atmosphere.

A common question is “Why don’t clouds fall from the sky?” The answer, of course, is that they do – they are subject to gravity like everything else. However, because individual cloud particles are tiny, they fall very slowly against the resistance of the air: approximately 0.6 m/min. for a typical 10-micron diameter cloud particle (smaller than the width of a human hair). This allows even gently rising air currents (convection) to keep a cloud at a near constant altitude for quite some time. It also creates the distinctive appearance of cirrus clouds, in which falling ice particles drift downward through upper atmosphere winds into shapes that look like horses’ tails. And of course, individual droplets or crystals form and evaporate at different times in different parts of the cloud due to environmental conditions, including entrainment, the process by which drier air from outside the cloud gets mixed into the cloudy air. For example, droplets may evaporate at the edge of a cumulus cloud due to heating by the sun, while new droplets condense at the cloud base as convection lifts air upward to the dew point.

Once water or ice particles form, they can begin to clump together and grow into larger particles, and eventually some may become large enough to fall from the sky as rain, snow, sleet,
or hail. Raindrops, which are approximately 20,000 times larger than cloud droplets, fall about 400 m/min.; large hail falls even faster. Such precipitation provides a second mechanism by which clouds disappear or lose mass. Rogers and Yau (1989) provide more details.

How do clouds affect weather?

The connection between clouds and precipitation is clear and obvious to humans everywhere. While clouds may or may not bring precipitation, the absence of clouds is a near-perfect predictor of dry weather (although occasionally a few droplets may be blown by the wind from a nearby cloud to fall in an area of blue sky) – note the more cloud-free regions in Figure 2 correspond generally to drier areas of the surface. In effect, clouds are a visible massing of water in the atmosphere, which sooner or later will fall to the ground somewhere. In addition, clouds modulate the surface temperature of the Earth: cloudy or overcast days are generally cooler than clear days within the same season, while cloudy nights are warmer than clear nights.

Where precipitation falls is governed largely by the large-scale circulation of the atmosphere, which is in turn controlled by the movements of the sun and the rotation of the Earth. Several large-scale features resulting from these governing forces can be observed in Earth’s cloud patterns. The *intertropical convergence zone* (ITCZ) is a persistent band of cloudiness near the equator that results from convection near the subsolar point. It moves seasonally with the sun. In the

---

CLOUDS

mid-latitudes, Coriolis forces create moving air masses and generate comma-shaped fronts that are associated with clouds in various ways depending on their relative temperatures. Satellite observations have revealed that the bulk of Earth’s precipitation falls on the oceans. Salby (1996) provides more details on these processes.

How do clouds affect climate?

One of the least appreciated roles that clouds play is in their modulation of the Earth’s energy budget. While human experience leads us to appreciate the cooling shade of a passing cloud on a hot sunny day, few people understand the global importance of clouds in controlling Earth’s climate. Clouds reflect sunlight – thus cooling the Earth – and also modulate the heat emitted from the Earth system, depending on their altitude (and thus their temperature). This combination of factors means that different cloud types can have different effects.

- High, thin ice clouds (cirrus, cirrostratus, etc.) reflect some sunlight but also reduce the amount of heat emitted to space because of their extremely cold cloud top temperatures (−40 °C/F and below) at high altitudes above 5 km. Taken together, this results in a local warming effect from such clouds.

- In contrast, low, thick water clouds (cumulus, stratus, etc.) reflect lots of sunlight but also emit large amounts of heat because of their relatively warm cloud top temperatures (just a little cooler than the nearby ground surface). Taken together, this results in a local cooling effect from low clouds.

Satellite measurements of the entire planet were necessary in order to understand the global impact of clouds (Ramanathan et al. 1989). Measurements beginning in the mid-1980s show that low clouds dominate in terms of the radiative effect of clouds, due in large part to the existence of persistent marine stratus cloud decks on the west side of land masses (such as San Francisco’s or the United Kingdom’s famous fogs). On balance, clouds have a huge impact on the Earth’s energy budget: were it not for their presence, the average global temperature on Earth would be 20 °C warmer.

The competing effects of different cloud types also explain why clouds remain one of the most important and challenging variables in the prediction of future climate. A successful model must be able not only to predict whether clouds will increase or decrease in a changing climate, but also how each type of cloud (high or low) will increase or decrease, as well as whether the clouds will thicken or thin, last for longer or shorter periods of time, and so forth (for more information, see Randall 2012).

How do humans affect clouds?

Clouds, driven by energy from the sun and the resulting water cycle, transport vast amounts of water and energy around the planet, so it might seem unlikely that humans could affect them. However, since the scale of each cloud particle is tiny, human activities can and do affect clouds. For example, adding condensation nuclei to the atmosphere (e.g., through the burning of renewable or fossil fuels) provides more locations for water to aggregate and results in clouds with more and smaller particles. These small particles grow more slowly and thus suppress precipitation, with the result that such clouds last longer than natural clouds. They also are brighter – another way of saying that they reflect more sunlight – because they contain many more small particles rather than fewer large particles (an example of this effect resulting
from ship traffic impacting low marine stratus clouds over the ocean can be seen online at http://earthobservatory.nasa.gov/IOTD/view.php?id=80203).

Airplanes can also affect clouds. By adding hot water vapor to the atmosphere, a product of fuel combustion within airplane engines, airplanes can “seed” the formation of a special type of mixing cloud, called a contrail – short for condensation trail. This occurs when conditions (temperature and humidity) in the atmosphere where the plane is flying are right: that is, it must be cold enough – typically −40°C/F and below – and moist enough that the addition of the plane’s exhaust brings the atmosphere to or beyond the saturation point (Schumann 1996). Because of the extremely cold temperature, this condensed water immediately freezes into ice crystals, which will remain until they sublimate. In areas with extensive air traffic, observation of the sky can thus provide clues to the moisture content of the upper atmosphere: if the atmosphere is too dry, the moisture in the exhaust will simply humidify the air slightly, but remain invisible vapor.

With only a little ambient water vapor present, condensation can occur but sublimation will proceed quickly as the water returns to a vapor state in the atmosphere. This leads to short-lived contrails – a short tail that follows the plane but quickly dissipates. When more ambient water vapor is present, the additional vapor and energy from the passage of the plane can generate a persistent contrail that may remain in the sky long after the airplane has passed. When the atmosphere is nearly saturated (perhaps due to emissions from other airplanes in high-traffic areas), the plane’s passage can create a persistent spreading contrail, which grows by condensing and freezing water vapor from the nearby atmosphere. Eventually such contrails can grow into extensive cirrus sheets, nearly indistinguishable from natural cirrus clouds.

On the other hand, airplanes can also cause existing clouds to dissipate. This can occur when heat from a plane’s exhaust causes cloud particles to evaporate, a phenomenon referred to as a “distrail,” short for dissipation trail (an example of this effect can be seen online at www.spc.ncep.noaa.gov/cooling/distrail/). Since clouds affect the Earth’s energy budget, these human impacts on clouds also mean that humans impact the energy budget and, like high and low clouds, some effects are toward warming and others toward cooling.

How do scientists characterize clouds?

Beyond simple visual observation and classification, scientists now use a variety of techniques to quantitatively measure and characterize clouds.

- The cloud fraction is a measure of the amount of sky covered by cloud. Its meaning is slightly different for an observer at a point on the ground who is affected by perspective and foreshortening, compared to a satellite remote sensing instrument which obtains a nearly two-dimensional view.
- The cloud height can be measured in a variety of ways, depending on point of view. From the ground a ceilometer – a device that sends a light or laser beam upwards, and then detects its reflection from the cloud – can be used to measure cloud base (referred to by pilots as the ceiling). From space, passive remote sensors can infer an effective cloud top height by measuring the temperature of the cloud. Active remote sensors (radar or LiDAR) can determine the cloud top height by ranging methods.
- The effective temperature of a cloud, typically measured by satellite remote sensing, provides a measure of the amount of heat
Clouds

released to space by the cloud top (and is also used to estimate cloud height as above).

- The liquid (or ice) water content of a cloud, as its name suggests, is a measure of the total amount of water contained in the cloud, or in a segment of the cloud. This is often measured by satellite remote sensing, which allows scientists to measure the total water content in a vertical column of the atmosphere.

- Cloud phase describes whether the particles in the cloud are predominantly liquid droplets, ice crystals, or a mixture of the two.

- The cloud particle size is a measure of how big the water droplets or ice crystals in the cloud are. Typically particles will be distributed across a range of sizes and one can characterize the particles with a variety of statistical measures such as mean or effective size and various moments of the size distribution. Different size particles interact differently with light and heat of different wavelengths traveling through the cloud.

- Optical depth is a measure of the visual opacity of a cloud – how opaque it is – as well as characteristic of the mean free path of light photons within a cloud. Mean free path is, statistically, the average distance a photon (or light ray) travels within the cloud before being scattered, absorbed, or reflected. Light transmission through the cloud falls off as \( \exp(-\text{optical depth}) \). Experience in heavy fog can illustrate just how quickly visibility can be reduced.

How can individuals observe clouds?

Clouds and citizen science

As a uniformly accessible but highly changeable part of the Earth system, clouds have inspired a variety of forms of citizen science and other types of observation projects. These include the following.

- The Global Observations to Benefit the Environment (GLOBE) Program, a global student program of environmental observation. Its cloud observation protocol – one of more than 50 observation protocols – has been popular since the program began in the mid-1990s. Thus GLOBE has a large amount of cloud observation data in its database. With the launch of CloudSat, a satellite carrying the cloud profiling radar instrument, in the mid-2000s, a subset of GLOBE participants have been involved in more in-depth cloud observations, which are used to help validate the CloudSat retrievals.

- The Students’ Cloud Observations On-Line (S’COOL) project, a similar, but more focused, project to obtain ground truth observations of clouds and sky conditions at the time that a NASA satellite carrying the Clouds and the Earth’s Radiant Energy System (CERES) instrument passes overhead. Since 1997, students around the world have provided tens of thousands of observations to this project. Participants are provided with matching satellite cloud retrieval data (where applicable) to allow them to pursue further scientific inquiry around clouds and remote sensing.

- The SatCam iPhone app developed over the past few years to enable mobile device users to provide photographic validation of clouds for the Moderate Resolution Imaging Spectroradiometer (MODIS), an imager on the Terra and Aqua satellites. This app uses geolocation features on the iPhone to precisely locate an observer in the satellite image, which it returns to the user after a photo is submitted.

- The Cloud Appreciation Society was established in the United Kingdom as a place for
cloud lovers to unite. Apart from its website, it has also created a CloudSpotter iPhone app, which allows users to submit and classify photos of clouds, then receive expert confirmation on their cloud classification.

Cluster detection

David C. Wheeler
Virginia Commonwealth University, USA

Background

Investigating a spatial pattern of events or event counts to find a geographic area with statistically significantly increased likelihood of event occurrence is known as spatial cluster detection. A spatial cluster, therefore, may be defined as a statistically unusual collection of events in a geographic area when compared with the pattern expected under a particular event-generating process (Besag and Newell 1991). Cluster detection is used frequently in many disciplines where a spatial analysis is conducted, including archeology, biology, criminology, health services, and epidemiology, among others. Spatial cluster analysis has been used in archeology to determine if there are clusters in ancient grave sites of different time periods, and also to identify clusters of individuals in grave sites according to a common characteristic, such as extracted wisdom teeth. In biology, cluster detection may be used to determine if there is a cluster of a certain disease among a species of trees, or to determine if there is a cluster of a particular species of tree in a forest. In criminology, cluster detection is used to identify hotspots of crime within a city. Cluster detection has been used in health services to demarcate catchment areas for hospitals. In spatial epidemiology, cluster detection is used to identify areas of significantly elevated or decreased risk of disease incidence or mortality, potentially to reveal etiologic clues.

A major motivation for performing cluster detection in spatial epidemiology is that many diseases have risk factors that are distributed unevenly in the environment. Examples for cancers include lung cancer and radon, bladder cancer and arsenic, and leukemia and benzene. The uneven distribution of known or unknown risk factors can lead to spatial patterning in disease risk. When risk factors are unknown, studying spatiotemporal patterns in disease events may reveal clues about disease etiology. In fact, there is a long history of research analyzing geographic patterns in disease incidence and mortality with the objective of discovering environmental determinants of disease. Examples of risk factors revealed by analytic epidemiologic studies that followed upon observations of geographic patterns of cancer include exposure to asbestos from shipyards as a risk factor for lung cancer among men along the southeastern United States seaboard and chronic use of snuff as a risk factor for oral and pharyngeal cancer among women in the southern United States.

Due to the relationship between disease risk and known risk factors that may exhibit a spatial pattern, it is crucially important to adjust for known covariates when conducting cluster detection analysis. Failing to account for known risk factors may lead to detection of an uninteresting cluster, one that would be expected to occur if the risk factors were considered. For example, age is often positively associated with cancer risk and could lead to a detected cluster of disease in an area with a relatively large elderly population. To focus this discussion of cluster detection, the following review of methods is
limited to a few probabilistic models that allow for adjustment for covariates. This review is not intended to be comprehensive.

Methods

Contemporary cluster detection methods assess the statistical significance of the elevated risk in some area to evaluate the area as a cluster. Of interest is the question of how likely the area of elevated risk is under a certain null hypothesis. A typical null hypothesis is constant risk, where all areas are assumed to have the same risk after adjusting for pertinent, known risk factors. The null risk level may be taken to be the overall risk in the entire study area. Under the null hypothesis, the disease risk does not vary within the study area. An area with an elevated risk well over the null risk may be detected as a cluster if the statistical test has good power in the area, where power is the probability of the test to reject the null hypothesis when the null hypothesis is false. The methods to detect clusters operationalize the null hypothesis through probability statements of a particular quantity of interest to summarize how unusual the observed risk is in some area. The methods develop a distribution of the quantity of interest under the null model and then compare the quantity of interest for the observed data to the distribution under the null model. In this way, cluster detection is conducted in a statistical hypothesis-testing framework by comparing the observed risk measure to the expected risk measure or statistic under the null hypothesis. Rejecting the null hypothesis in some area by finding an unlikely risk measure compared with the expected value under the null leads to cluster detection. For example, a county in the United States with eight diagnosed cases of esophageal cancer in one year when only two cases were expected based on the national rate of esophageal cancer incidence may be determined to be a cluster in a nationwide study. In this example, cancer incidence in the local area, the county, is compared with the national incidence rate in a relative risk (null value of 1) to determine what is unusual assuming that the national rate applies equally to all areas.

The method one uses for cluster detection depends on the type of data under study. Different methods exist for individual-level data and aggregate data. Individual-level data are defined by the geographic coordinates for some location for each subject in the study. The type of location is typically the residence, but it could also be a place of employment. In either case, the geographic coordinates are determined from an address-matching process of reported addresses. Individual-level data also include an outcome variable value, which is often a binary disease status indicator (disease present or absent). Covariate values for individuals are typically available for case-control and cohort studies used in cluster detection and commonly include age, gender, and race. Lifestyle factors, environmental exposures, and socioeconomic status variables such as income and education may also be available for individuals. In contrast to individual-level data, aggregate data are counts of the outcome variable and measures of the covariates within defined geographic areas. The geographic unit is often an administrative boundary, such as a census tract or county in the United States, or a postal code, such as a ZIP Code in the United States. Importantly, aggregate data also include a measure of the at-risk population that is used to calculate the disease rate or proportion in each area. It is crucial to consider the size of the at-risk population when conducting cluster detection because areas with larger populations will be expected to have more counts of the outcome variable under the null hypothesis. For example, an area with 10 new
cases of childhood asthma and 1000 residents will be less likely to be classified as unusual than would an area with 10 new cases and 100 residents. In case-control studies, the controls are a sample from the at-risk population and are used as a contrast with the cases in terms of spatial location in a cluster detection analysis. Advantages to using individual-level data over aggregate data include more precise spatial information and more specific information on risk factors, particularly for levels of environmental exposures. With aggregate data, it would be necessary to use a mean environmental exposure in each area instead of individual-based exposures.

One method for cluster detection with individual data is the generalized additive model (GAM), which provides a flexible approach to modeling spatial residual variation in risk after considering known risk factors. This type of model is a natural fit for a case-control study with individual-level spatial information. Consider \( i = 1, \ldots, n \) subjects located within a region \( A \), each with known residential location \( s_i \) at a particular time \( t \) and a binary label \( Y_i \) for disease status. Defining the spatial risk function as \( r(s) \), equal to the probability that a person at location \( s \) will be a case, the general spatial log-odds function is \( l(s) = \log[r(s)/(1 - r(s))] \). We can model the log-odds of disease through an adjusted generalized additive model as:

\[
\log \left[ \frac{P(Y_i = 1)}{P(Y_i = 0)} \right] = \alpha + X_i \beta + l_i(s_i) \tag{1}
\]

which adjusts for covariates \( X_i \) parametrically with coefficients \( \beta \) and an intercept \( \alpha \). This model could include known environmental exposures as covariates. The model includes a nonparametric term for the spatial log-odds using residential locations at lag time \( t \). The spatial log-odds is a bivariate function of spatial coordinates and models residual spatial variation in risk. The residential locations at only one time are used in this model specification. In a typical study, the time would be the time of diagnosis of disease or time of study enrollment. If spatial information for other times is available, through residential histories for example, then the spatial risk component at time lags can be evaluated. The residual odds ratio surface may be calculated through the spatial log-odds and the mean of the spatial log-odds by \( \exp[l(s) - \bar{l}] \). The spatial component estimated by the GAM can be visualized by mapping the log-odds or odds ratios, or by mapping risk using a logarithmic base 2 scale where each unit increase corresponds to a doubling in risk. Two convenient forms of the spatial log-odds function are a locally weighted scatterplot smoother (LOESS) and a thin plate regression spline (TPRS) smoother (Wood 2006). These smoothing functions contain a smoothing parameter than can be estimated by minimizing the Akaike Information Criterion (AIC).

The null hypothesis of primary interest in this type of analysis is that the risk is constant over space, that is, \( r(s) = r \). An approach to evaluate the significance of the spatial component in the GAM for both types of the smoothing function is to use a Monte Carlo permutation test. This test has conditions based on the number of cases and the locations of subjects at one time point, performs randomization of the case labels among the locations, fits the model to the randomized data, and calculates the change in deviance with the spatial component in the model. Typically, 999 randomizations are used to build the permutation distribution for the test. Random labeling of subjects as cases or controls is equivalent to the null hypothesis of constant risk over space. Thus, the random labeling process is akin to repeatedly generating data from the null hypothesis. The \( p \)-value for the overall spatial term is calculated by dividing
CLUSTER DETECTION
the rank for the observed data of the change in
deviance among the permutation distribution
by the number of randomizations. Statistical
significance of the local log-odds or odds ratio
can also be evaluated with the Monte Carlo
permutation procedure. The local log-odds or
odds ratio, either calculated at each data point
or predicted for each cell of a grid overlaid
on the study area, is regarded as statistically
significant if it is outside the 2.5% and 97.5%
ranked values from the local permutation dis-
tribution. These areas of statistically significant
risk are the detected clusters. When multiple
locations for subjects are available over a range
of time, this randomization procedure may be
used to determine the temporality of the spatial
component that is most associated with risk of

A method for cluster detection with aggregate
data is to use Bayesian hierarchical modeling.
This can be done for outcome counts assum-
ing either a binomial or Poisson distribution.
Cluster detection with Bayesian hierarchical
models may be performed using either the
model residuals or the exceedence probabilities
for a quantity of interest, such as a relative risk,
compared with some threshold value (e.g., 1 for
relative risk). Focusing on a model for Poisson
distributed counts, one can denote the counts
in each area as
\[ Y_i \sim \text{Poisson}(E_i \theta_i) \]
where \( E_i \) represents the expected number of cases and \( \theta_i \) is the relative risk in area \( i \). The expected
counts are based on an overall risk in the study
area. One can specify a log-linear model for
the relative risk that includes area-specific risk
factors \( X_i \) as:

\[
\log[\theta_i] = \alpha + X_i \beta + v_i
\]

where \( \alpha \) is the intercept and \( v_i \) denotes spatially
unstructured random effects. The model param-
eters can be estimated with Markov chain Monte
Carlo (MCMC) simulation in software such as
WinBUGS. The Bayesian residuals for this model
are calculated as
\[
\hat{r}_i = (y_i - e_i \hat{\theta}_i) / \sqrt{e_i \hat{\theta}_i},
\]
where \( \hat{\theta}_i \) is the mean estimate of the relative risk from
the MCMC samples. Mapping the probability
that the residual exceeds some threshold value,
say 2 or 3, can identify hotspots of elevated,
unexplained risk. Another approach is to define
an exceedence probability as the probability that
the relative risk exceeds a threshold level \( c \). The
exceedence probability is estimated from the
MCMC samples as:

\[
\text{Pr}(\theta_i > c) = \frac{\sum_{g=1}^{G} I(\theta^g_i > c)}{G}
\]

where \( I() \) is an indicator function that returns
1 if the expression in the function is true and
0 otherwise, \( \theta^g_i \) is the relative risk from the
\( g \)th MCMC sample, and \( G \) is the number of
MCMC samples. This exceedence probability
is the proportion of the MCMC sample values
of the relative risk in the \( i \)th area that exceed
the threshold value, where the threshold is
frequently set to 1. Hotspots may be identified
by selecting the exceedence probabilities that are
greater than a conventional level, such as 0.95
or 0.99.

A method that can be used for cluster detec-
tion with either individual-level or aggregate
data is the local spatial scan, which scans over the
study area with circles of varying sizes to find the
most unusual area of elevated risk. The method
compares the null hypothesis of constant risk
to alternative hypotheses where the disease rate
inside a scanning window is greater than outside
the window. The scanning window size is set
to contain no more than a certain proportion
of the total population in the study area, for
example 50%. A test is calculated based on the
maximum likelihood ratio statistic across all
circles as:
where $Y_j$ and $E_j$ represent the observed and expected number of cases inside circle $j$, $Y_+$ is the total number of observed cases, $Y_+ - Y_j$ is the number of cases outside the circle, and $I()$ is an indicator function taking on the value of 1 if the observed number of cases exceeds the expected number in the circle. The sampling distribution of the test $L$ under the null hypothesis is constructed using a large number (e.g., 999) of Monte Carlo randomizations of the case labels, and then the observed $L$ is compared with the null distribution to calculate a p-value associated with the window with the maximum likelihood ratio statistic. The most likely cluster can be identified using the software SaTScan (www.satscan.org), and then mapped using other statistical or geographic information system software. It is not possible to directly adjust for covariates with the local spatial scan method implemented in SaTScan, but one can perform analyses stratified by a categorical variable, where a spatial scan test would be calculated for each level of the covariate.

There are several issues that are problematic for cluster detection. One of the important issues for cluster detection in spatial epidemiology is residential mobility. Most cluster detection analyses assume that pertinent unknown exposures occur in and around the home, but use only one reported address per individual, which is typically the address where subjects were diagnosed with disease. This makes the assumption that subjects do not move, or that all environmental exposures relevant for disease occur at only the most recent location. This is a major assumption that becomes increasingly wrong as disease latency increases, and as population mobility increases. The power of cluster detection tests to identify a spatial signal in risk will suffer as the assumption becomes more tenuous. For other applications of cluster detection, such as crime hotspot analysis, population mobility is much less of a concern. The power to detect a cluster generally varies from test to test, and also depends on the magnitude of the risk in the potential cluster, the shape of the elevated risk area, and the location of the elevated risk area within the study area (Waller, Hill, and Rudd 2006). The spatial scale of the cluster detection analysis is an issue with aggregate data, as a small area of significantly elevated risk at one spatial scale (e.g., census block group) may not be detected when using a larger spatial unit (e.g., county). This is related to the well-known modifiable areal unit problem. Of course the results of a cluster detection analysis will depend on the address–matching completeness and spatial accuracy of the geocoded addresses. Using many addresses matched to a centroid of a large geographic unit may result in a relatively uninformative cluster if relevant exposures are thought to occur at the neighborhood level.

Coastal depositional processes and landforms

Nancy L. Jackson
New Jersey Institute of Technology, USA

Coastal depositional environments are generally located on low gradient passive margins where there is sediment of a size that can be moved by waves or wind. The combined effects of the processes of winds, waves, tides, currents, and sea level give rise to a number of emergent depositional landforms including barrier islands and spits, and associated beaches, dunes, and marshes, as well as sedimentary features at the shoreline such as salients and tombolos (Figures 1 and 2). The spatial and temporal scales of processes and landform adjustments range from broad-scale evolution of barrier islands in response to long-term sea level and sediment supply variation, to small-scale adjustment of beaches and dunes in response to episodic storm and non-storm conditions. Human processes also have a direct influence on the evolution and adjustment of coastal depositional landforms by changing the size, shape and location of these features via beach nourishment, dune building, and inlet dredging and filling activities.

Barrier islands and spits

Barrier islands are wave-built, emergent, shore-parallel elongated sedimentary accumulations of unconsolidated sand and/or gravel that generally form chains separated by tidal inlets. They comprise about 5–10% of the world’s coast and are generally associated with passive margin shorelines. The longest barrier island chains are located on the US Atlantic and Gulf coasts but barrier islands can be found throughout the world, including South America, India, and Europe.

Barrier islands are found in micro- (<2 m) and meso- (2–4 m) tidal environments but not in macro- (>4 m) tidal environments, where the lack of wave energy concentration at a single elevation prohibits their formation. The planform morphology of barrier islands is a function of wave height and tidal range. Barrier islands in wave-dominated environments are generally long, narrow, and straight with a pronounced flood tide delta, few tidal inlets, and prominent overwash deposits. Barrier islands in mixed-energy environments (wave and tide processes) tend to be short and wide with large, well-developed ebb tidal deltas and numerous tidal inlets.

Barrier islands are important as a buffer from storms to the mainland and protection for the ecologically productive back-barrier lagoon or bay environment. Barrier islands are defined separate from other barrier formations because they comprise a system of distinct interactive sedimentary subenvironments. The subaerial portion of the barrier includes a beach and dune system and back-barrier shoreline and is underlain by a subaqueous platform fronting the shore face. The barrier is bounded by tidal inlets and associated ebb and flood tidal deltas on their ends, and is backed by a low-energy lagoon or estuarine system. Marshes are present on the sheltered reaches of the back-barrier and mainland shorelines of these basins (Oretel 1985). Although barrier islands are commonly associated with oceanic environments, the
existence of barriers on estuarine shorelines has sparked recent debate on whether these estuarine landforms can be classified as barrier islands (Otvos 2012).

Formed during the Holocene transgression, there are four explanations for the genesis and development of barrier islands (Davis and Fitzgerald 2004). The first explanation involves the presence of nearshore sand barriers that subsequently migrate inland with sea level rise to form emergent barrier islands. The second explanation is that barrier islands begin from
the development of sand spits due to longshore sediment transport from an existing headland. Breaching of the spit during storm activity and development of an inlet establishes the barrier island. The third explanation is that barrier island formation is the result of sea level rise and subsidence of mainland shorelines drowning low elevation areas adjacent to beach and dune ridges on the mainland. The low elevation areas backing the beach and dune ridges form lagoon systems with marsh environments. The fourth explanation is that barrier island development involves a combination of all three explanations.

Barrier islands can migrate based on available sediment supply and sea level variation. Transgressive migration occurs where sediment supply is limited or relative sea level rise is high. Transgressive barriers are narrow, low in elevation and characterized by numerous washover deposits. These deposits form when waves and surge overtop or breach the dune ridge during storms and result in the landward transport of sediment from the ocean side toward the back-barrier environment. Regression occurs where sediment supply is ample or the rate of sea level rise is low. A prominent feature on regressive barriers is multiple beach or dune ridges, which can be vegetated and indicate the position of former shoreline positions.

Barrier spits are emergent, elongated, narrow, and composed of sand and/or gravel but differ from barrier islands in that they are attached to the mainland or an island. They develop on the downdrift end of littoral cells and, thus, evolve by longshore transport of sediment from the mainland. The shape and orientation of barrier spits are a function of wave angles and local water depths. The distal end of a spit terminates in open water and is often the location of multiple beach ridges that develop in response to an alternating increase and decrease in longshore sediment transport. Transport of sediment into deep water leads to the growth of a spit platform at the distal end. Wave refraction leads to a curvature at the distal end and transport of sediment bayward. Barrier spits that prograde completely across entrances to bays or lagoons are referred to as baymouth barriers (Otvos 2012). Barrier spits may breach during storms forming an inlet, separating the landform from the mainland, to form a barrier island.

Beaches

Beaches are located on exposed oceanic shorelines as well as on back-barrier shorelines or within estuarine or lagoon systems. Beaches are sloping unconsolidated deposits of sand and/or gravel that form at the land/water intercept where there is sufficient wave energy to rework available sediment. The beach profile extends from the position where the subaerial backshore intersects the upland or dune toe to the subaqueous nearshore zone where one or more bars may be present.

Research on the morphodynamics of beaches examines the mutual interaction of morphology and hydrodynamics. Chief among these interactions is between the type of wave breaking (an indication of the degree of reflection or dissipation of wave energy) and morphology as a function of the textural properties of the sediment and slope of the bed. Wright and Short (1984), using field data from a number of beaches in Australia, classified beach systems in high-energy microtidal environments as one of six possible states based on the surf similarity parameter ($\varepsilon$) (Guza and Inman 1975):

$$\varepsilon = \frac{(a_b \omega^2)}{(g \tan^2 \beta)}$$

where $a_b$ = breaker amplitude, $\omega$ = incident wave radian frequency ($2\pi/T$ where $T$ = period),
COASTAL DEPOSITIONAL PROCESSES AND LANDFORMS

$g =$ acceleration of gravity, and $\beta =$ the gradient of the beach and surf zone. The two end members of the beach classification spectrum are reflective and dissipative beaches. Reflective beaches, $(\varepsilon < 2.5)$ are analogous to a swell or summer profile and characterized by a steep foreshore slope, the lack of an offshore bar or surf zone, and coarse sediment. The backshore is narrow and there is a pronounced step at the base of the foreshore. Waves surge up the steep foreshore and may reach 1 m in height. The beach foreshore is generally planar but cusps may form under higher wave energy. Dissipative beaches $(\varepsilon > 20)$ are analogous to the classic storm or winter profile. They are characterized by fine sediment and spilling waves (>2 m) that dissipate energy over a wide low gradient surf zone. There is large subaqueous sediment storage in the surf zone and generally at least one to three linear shore-parallel bars present. Between the reflective and dissipative limits are intermediate beaches that are distinguished by both reflective and dissipative conditions and the presence of bars and rip currents in the surf zone.

Over time, beaches will exhibit a modal state based on wave conditions and sediment characteristics. Using a modified dimensionless fall velocity parameter $(\Omega = H_{b}/W_{s} T)$, where $H_{b}$ is the wave height at breaking, $W_{s}$ is the sediment fall velocity, and $T$ is the wave period, Wright and Short (1984) showed that beaches were modally reflective when $\Omega < 1$ and modally dissipative when $\Omega > 6$. Masselink and Short (1993) extended the work of Wright and Short (1984) to include meso- and macro-tidal beaches within the morphodynamic classification system. They introduced a parameter called the relative tide range $(RTR = MSR/H_{b})$ where $MSR$ is the mean spring tide range and $H_{b}$ is the wave height at breaking. The RTR parameter reflects the importance of swash, surf zone, and shoaling wave processes on the beach profile over the tidal cycle. As the RTR increases, modally reflective beaches transition from low tide terrace beaches with rips to low tide terrace beaches without rips and modally dissipative beaches transition from nonbarred dissipative to ultra-dissipative beaches.

Coastal dunes

Coastal dunes are aeolian depositional landforms formed under winds capable of entraining available sediment on the beach and where there is an obstacle to reduce winds and allow deposition to occur. The obstacle is often vegetation or wrack accumulation on the backshore but on highly developed coasts, where vegetation or wrack is intentionally eliminated by human action, a sand fence with artificial plantings may be used to trap sediment. Vegetation traps sediment in transport creating shadow dunes. Growth of vegetation after burial by sediment deposition creates conditions for additional sediment deposition and growth of the dune form. Vegetation also may emerge landward of the toe of the dune and create new areas for sediment deposition.

Several models have been developed to predict aeolian sediment transport potential. Application of these models to coastal environments has yielded higher rates of transport compared to actual transport rates observed on beaches. One of the most frequently used equations to quantify the rate of transport $(q)$ is based on the work of Bagnold (1941) and relates the rate of transport to sediment size on the backshore and the shear stress imparted by the wind to the sand surface:

\[
q = C(\rho_{a}/g)(d/D)^{0.5}u_{*}^{3}
\]

where $q$ is the rate of sediment transport, $C$ is an empirical constant ranging from 1.5 to 2.8, $\rho_{a}$ is air density, $g$ is acceleration due to gravity, $d$ is grain diameter, $D$ is a reference grain diameter of 0.25, and $u_{*}$ is shear velocity.
The underlying assumptions of many aeolian transport equations, including the above, are that the wind is unidirectional, fully turbulent, uniform, and steady, that the sediment is uniform in size and dry, and that the bed is planar, flat, and unobstructed. Often one or more of these conditions are violated in coastal environments. For example, the presence of salt crusts, vegetation, and wrack accumulations on the backshore, surface sediment moisture, topographic variation across the backshore, and changing fetch distance as a function of beach width, can reduce sediment entrainment and transport potential for dune formation. Field studies of aeolian sediment transport on beaches have refined sediment transport models over the past two decades, providing insight to turbulence and unsteadiness of the wind, fetch distances required to achieve full transport potential, and spatial and temporal variability of transport rates due to the presence of surface sediment moisture, lag deposits, and microtopographic variability across the backshore (Davidson-Arnott 2010).

The interaction and sediment exchange between beach and dune are critical to understanding the size, shape, and persistence of dunes on the backshore. The likelihood for dune formation and growth has been explained using a morphodynamic approach over short time scales and a sediment budget approach over longer time scales. The morphodynamic state of a beach, driven by nearshore waves and currents, influences sediment characteristics, bed slope, and backshore width. These attributes, in turn, influence the potential rates of sediment transport for dune formation. The dune provides a source of sediment to the beach and nearshore system during storms and the net result is an exchange of sediment between the beach and dune system. Dunes will form on both reflective and dissipative beaches but dunes will be smaller and lower in height on reflective beaches due to the narrow backshore widths and steep slopes (Short and Hesp 1982). The sediment budget approach links sediment volume in the beach and dune and between beach and dune to the size of a dune with increasing dune size occurring under a slightly negative beach budget (Psuty 1988).

Saltmarshes

Saltmarshes and mangroves are found in estuaries and lagoons at the margins of rivers and on the landward side of barriers islands and spits. Saltmarshes are found in the mid- and upper latitudes and their location in the estuary or lagoon is a function of wave energy, tidal flow, sediment availability, and recent sea level rise history. In tropical areas the marsh will be vegetated by mangroves. The low wave energies in estuaries and lagoons promote growth of salt-tolerant vegetation that is capable of dissipating flow velocity, focusing fine sediment deposition, and increasing the surface elevation of the marsh. Sediment may be derived from the drainage basin, from the ocean via transport through the tidal inlets or via storm overwash of the barrier. Biomass production, influenced by subsurface processes such as groundwater flow and oxygen availability, is also an important contributor to marsh development (Townend et al. 2011). Tidal creeks within the marsh provide the transport network for the movement of sediment and organic matter. Saltmarshes occupy the upper intertidal zone and there is a zonation of vegetation based on surface elevation, and frequency and duration of inundation (hydroperiod). Less salt-tolerant species (i.e., *Spartina patens*) are found at the mid- and upper elevations of saltmarshes where tidal inundation occurs less frequently and over short durations (i.e., spring high tide). More salt-tolerant species (i.e., *Spartina alternafora*) occupy the lower elevations.
where tidal inundation occurs daily and for longer durations.

The elevation of a saltmarsh is a function of tidal range but the long-term stability of the system is a function of the marsh surface elevation relative to eustatic sea level rise or local subsidence. With an increase in sea level or local subsidence and no increase in surface elevation the marsh system will translate inland or drown in place if there is insufficient accommodation space for migration. Most influential in the loss of saltmarsh systems are the cumulative effects of human action. Diking to allow conversion for agricultural production, filling to provide a substrate for human development, and restricting the inland migration with human structures have reduced both the extent and function of these systems.

Salients, tombolos, and cuspate forelands

Salients are triangular, accretionary shoreline features that can form in the shadow zone of an offshore island or reef system. Shore protection structures such as detached breakwaters also result in the development of shoreline salients with the ratio of the length of the offshore obstacle and the distance of the obstacle to the initial shoreline influencing the morphology of the salient. Wave refraction and diffraction around the obstacle result in lower energy conditions and sediment deposition within the lee of the structure or obstacle. When the apex of a salient attaches to the offshore feature it is called a tombolo. A cuspate foreland is a large-scale, triangular, accretionary shoreline feature and may occur in isolation or in a series. Examples of these features include Dungeness, on the south coast of United Kingdom, and Cape Hatteras and Cape Canaveral on the southeast coast of United States. Several explanations for the formation of cuspate forelands have emerged, including changes in wave magnitude and direction, reworking of deltaic deposits, and wave refraction around offshore shoals (Davis and Fitzgerald 2004).

Coastal erosion processes and landforms

Alan S. Trenhaile
University of Windsor, Canada

Most types of coast experience occasional erosional events that can lead, for example, to the formation of scarps on beaches and fore-dunes, and low muddy cliffs along the seaward margins of salt marshes. Erosional features on primarily depositional landforms are generally quite ephemeral and quickly masked by renewed deposition. Conversely, erosion is irreversible and is the dominant mode of development of rock coasts. Rock coasts are found in all types of environment, in tropical regions where they are often cut into raised coral limestones, in cooler, frequently storm wave-dominated middle latitudes, and in high latitudes where they may have been eroded by glaciers in the past and are subjected to the effects of frost and shore ice today. Bare, rocky surfaces are generally dominant, but there are often small, stony pocket beaches between rocky headlands and sandy beaches over shore platform foundations. Rocky coasts can be an important source of sediment for adjacent coastal areas depending on: rock resistance and the strength of the erosional agents, which determines rates of erosion and sediment production; the grain size of the sediment, which reflects rock grain size, joint density, and weathering efficacy; and whether the potential sediment sinks are wave-dominated, which promotes deposition of coarse-grained sand and gravels in beaches, or tide-dominated which promotes deposition of fine-grained clays and silts in tidal flats, salt marshes and mangrove swamps, and deltas.

Erosional processes

Rock coasts experience a very wide range of erosional agents whose efficacy varies with the chemical and physical characteristics of the rock and the wave regime, climate, and other aspects of the morphogenic environment. Although the terms are poorly defined, the distinction has been made between “hard” and “soft” rock coasts. Soft rock coasts are generally considered to consist of fairly nonresistant materials such as cohesive clay, marl, shale, and highly weathered rock with low resistance to mechanical wave erosion, and cliff recession rates of more than 10 meters per century. Hard rock coasts (limestone, gneiss, granite, etc.) are much more resistant to wave erosion, with cliff recession rates generally ranging from almost nothing up to a few meters per century.

Mechanical wave erosion, including abrasion by sand and gravel and hydraulic quarrying by water hammer (impact), shock pressures from breaking waves, and air compression in rock discontinuities, is usually the dominant mechanism in the storm wave environments of the mid-latitudes and in other areas where there is strong wave action. Quarrying processes depend on alternations of air and water, and abrasion is most effective in shallow water where wave-generated bottom currents are strongest. As standing, breaking, and broken waves also generate the highest pressures at, or slightly above, the mean water surface, mechanical wave erosion must be most effective at or close to this
level, although wave-generated bottom currents are also effective on cohesive clay and other soft rock coasts. Only a few workers have measured wave transformation and energy dissipation on rocky foreshores. Recent studies have shown that infragravity energy is present on shore platforms, although it is unclear whether it plays any role in their erosion and evolutionary development.

Because of abundant moisture and saline solutions, coasts provide nearly optimum conditions for many weathering mechanisms, including chemical and salt weathering, frost, and wetting and drying. Most weathering, with the exception of frost which is important in cool coastal regions, is generally considered to be most effective in warm to hot environments. Weathering may be the dominant mechanism in such areas today, but by operating along joints it also facilitates hydraulic quarrying in temperate, wave-dominated environments.

Microflora and faunal borers and burrowers erode rock surfaces whereas vermetid gastropods, coralline algae, and other organisms produce hard crusts that protect the underlying rock. Bioerosion, bioconstruction, and bioprotection play important roles in the formation of deep notches, organic protrusions (corniche), and narrow shore platforms (trottoir, surf ledges) on coral, aeolianite, and other calcareous substrates in tropical and Mediterranean environments.

Bioerosion also occurs in cooler regions where its main role may be to promote limestone solution and karren formation through faunal respiration and carbon dioxide production in pools, which reduces the pH of the water at night when it cannot be extracted by algae.

Rockfalls, landslides, and other types of mass movement result from the undercutting and oversteepening of coastal slopes by waves and other marine processes. The type, size, and frequency of these slope failures are determined by rock structure, lithology, and other geological characteristics, and by the absolute and relative intensity of the subaerial and marine processes. Rock falls typically occur in well-fractured rocks, translational slides in seaward-dipping rocks, alternations of permeable and impermeable strata, and massive rocks overlying incompetent materials. Rotational slumps occur in thick, fairly homogeneous deposits of clay, shale, or marl. Human activities promote slope movements in some places because of the addition of water from septic systems, irrigation, and runoff disruption, and the depletion of protective beach material by the construction of coastal obstructions and the damming of rivers.

Rates of erosion

Much of the data on cliff recession rates, which range from virtually nothing up to 100 meters per year, is of questionable quality. Although there are erosional data for many parts of the world, it is impossible at present to identify any reliable relationships with rock type or wave and tidal conditions. Cliff retreat rates have been measured or estimated in a variety of ways, using sequential terrestrial and aerial photography, old maps, repeated surveys, cliff-top stakes or metal pins driven into the cliff face, morphological evidence, erosion of ancient and modern anthropogenic structures, and dated inscriptions. Unfortunately, whereas cliff recession is strongly episodic, with long intervals between large slope failures, the most precise techniques have been used usually only over short periods of time. Sequential air photographs and satellite images can be used to determine recession rates over half a century or more, although there may be too little change to hard rock coasts over this period, and too much change between consecutive images on soft rock coasts. Sequential airborne and terrestrial LiDAR is increasingly used to record cliff recession and other elements of rock
Coastal erosion processes and landforms

Coast evolution and, by scanning from the beach or shore platform, it can record the detachment of small rock fragments ranging from only a few centimeters in size up to large falls and slides. Microdrones may also provide an additional source of high-resolution airborne data in the future.

Micro-erosion meters have been used by many workers to measure rates of surface downwearing (erosion in the vertical plane) by weathering and abrasion in the intertidal and supratidal zones. These instruments cannot be used to record the dislodgement of larger rock fragments, however, or to measure backwearing (erosion in the horizontal plane) resulting from the retreat of rock scarps. Additionally, the responsible processes must be inferred from the erosional data. Mean rates of downwearing are usually from essentially 0 up to a few millimeters per year, with occasional rates of a few centimeters per year corresponding to the removal of thin slivers of weathered rock (Porter et al. 2010).

Climate change

The most important effect of climate change is likely to be from the rising sea level, which will allow waves to break closer to the coast and expend more energy at the shore, and possibly in some areas from increased storminess. Although all rock coasts will be affected, the greatest increases in erosion rates, and particularly in rates of cliff recession, will be on soft rock coasts, which will impact human settlements and infrastructure. Higher precipitation, more extreme rainfall events, coral reef mortality, and decreasing sea ice will also promote cliff failures. Rising sea level, changes in wave regimes, and other climate changes will trigger local adjustments to wave refraction patterns, longshore transport paths, and the production of sediment, causing rapid changes to beaches on and adjacent to rocky coasts. Many other climate-induced changes will only become apparent over longer periods, including the modification of weathering processes and efficacies, and the longitudinal and attitudinal migration of marine organisms with corresponding changes to their bioerosional and bioprotectional activities.

Geology

The geology of the substrate, including the structure, lithology, and mineralogy of the rock, usually controls the general morphology of the coast. Geological factors help to determine the intensity and efficacy of the erosional mechanisms; the amount, mobility, and size of the debris at the foot of the cliff; the degree of surface irregularity in the nearshore zone, which influences rates of wave attenuation and, in the intertidal zone, the degree of ponding and abrasional efficacy; and whether a coast is entirely contemporary or inherited in part from interglacial stages when the sea was at a similar level to today’s.

Rock hardness is frequently measured in the field with a Schmidt rock test hammer. Shore platform gradient and elevation and the height of the cliff foot (the cliff/platform junction) generally increase with rock hardness or resistance. Nevertheless, erosion usually occurs along joints, bedding planes, and other structural weaknesses, and the resistance of a rock, which depends on the processes to which it is being subjected, may have little to do with its physical strength or hardness. Rock resistance is also affected by the strike and dip of alternating beds of sedimentary rock, which determine rates of wave attenuation, and whether the weaker strata are sheltered from incoming waves behind more resistant, upstanding beds.
Landforms

Coastal scenery is the product of a unique combination of factors including the gradient, height, and other morphological characteristics of the hinterland; wave environment and tidal range; geological structure and lithology; and climate and sea level history. Although these variables provide infinite variety to rock coasts, their general morphology may reflect the regional geotectonic setting. Coasts are generally oriented along convergent plate boundaries where oceanic plates are subducted beneath continental plates. These coasts are characterized by narrow continental shelves; high, steep hinterlands, often with staircases of elevated marine terraces; and an abundance of beach sediment from steep stream courses. A much greater variety of rocks can be exposed along plate-embedded or trailing-edge coasts (passive margins) which may run at high angles to the structural grain. This produces indented coasts with bays and headlands; hilly, plateau, or low hinterlands; and wide continental shelves. Plate tectonics can therefore provide a partial explanation for differences in coastal characteristics, but rock coasts with high cliffs are widely distributed along both convergent and trailing or plate-embedded coasts.

Coastal plan shape

Variations in rock lithology and structure, often associated with folds, faults, and joints, create coasts consisting of alternating headlands and embayments. Whereas differences in the type of rock along a coast are usually fairly obvious, variations in rock structure can be quite subtle, involving changes in joint density and orientation, bed thickness, and the strike and dip of the rocks. Bays can also develop in more homogeneous rocks because of Holocene submergence and the more rapid retreat of the lower cliffs around the mouths of streams than of the higher cliffs on the adjacent interfluvies. Differences in the type and amount of beach material along a coast, and consequently in the degree of abrasion or protection afforded to the cliff and shore platform, may also produce crenulated coasts without marked variations in the resistance of the rocks to erosion.

Caves, arches, and related forms

Small coves, narrow inlets, blowholes, caves, arches, and stacks can form in rocks with closely spaced weaknesses, which could include a joint or fault system, or a particularly weak stratum, although their best development is in rocks that are strong enough to support high, near-vertical slopes and the roofs of caves, tunnels, and arches. The sea can also occupy and erode subterranean karstic systems and the mouths of lava tubes in igneous rocks, producing long tunnels, caves, and inlets.

Cliffs

Marine erosion undercuts coastal slopes creating steep cliff faces, whereas subaerial mechanisms — including weathering; runoff; and creep, slides, and other mass movements — produce more gentle, convex slopes. Consequently, steep and gentle cliffs predominate where, respectively, marine and subaerial erosion are dominant. Cliffs that are steep near the foot and sloping near the top develop where both process suites are effective. Steep cliffs are predominant in exposed sites in the stormy mid-latitudes and more gently sloping, vegetation-covered cliffs in sheltered, often coral-protected, humid tropical regions, although the collapse of deep notches commonly produces steep cliffs in tropical limestones. Geological factors are at least as important as climate and wave regime in determining the relative efficacy of marine and
subaerial processes. For example, weak rocks in the upper part of cliffs promote weathering and runoff gullying and the formation of sloping surfaces, whereas strong rocks inhibit weathering and allow steep, wave-cut slopes to extend to higher elevations, often to the top of the cliff. Rock structure is also important. Very steep cliffs tend to develop in horizontally or vertically bedded rocks and sloping cliffs along the joint or bedding planes of, respectively, landward- or seaward-dipping rocks.

Cliffs often have composite profiles composed of two or more major slope elements. These profiles may simply reflect elevational differences in rock resistance as, for example, when weaker rocks in the middle portion of a cliff face have a lower slope gradient than stronger rocks in the lower and upper parts of the cliff. Other types of high, composite cliff in resistant rocks are the result of reactivated marine erosion during interglacial periods of high sea level, and cliff abandonment and frost and other cold-climate weathering and slope reduction during periods of low glacial sea level. They include hog’s back (beveled, slope over wall) cliffs which have a steep, wave-cut face at the bottom and a convex or straight seaward-facing slope above, and multistoried cliffs consisting of two or more steep faces separated by more gentle slopes. Composite cliffs have been reported most frequently from northwestern Europe, and on other ancient, resistant massifs and many volcanic islands in the Southern Hemisphere. Resistant basaltic and other islands often have plunging cliffs which stand in deep water without any shore platforms or beaches at their foot. These cliffs experienced little erosion as sea level rose during the Holocene because the unbroken waves were reflected from the cliff face, and the lack of sediment prevented abrasion and reduction in the depth of the water at the cliff foot.

Shore platforms

The term “shore platform” is used in preference to older genetic alternatives, including wave-cut or abrasion platform, to refer to horizontal to gently sloping, intertidal rock surfaces. Shore platforms usually terminate landward in a sea cliff, although they may extend under sand or pebble beaches or colluvial deposits where the hinterland is low.

Much of the traditional debate was concerned with the relative contributions of wave and weathering processes to the formation of predominantly sloping shore platforms around the North Atlantic and subhorizontal platforms, terminating abruptly seaward in a low tide cliff, in Australasia. It is generally accepted today that mechanical wave erosion and weathering play important and often supportive roles in platform development. The contributions of these process suites vary through time, with changes in such factors as climate, sea level, and platform morphology, and in space with changes in elevation and distance from the cliff foot. Surface topography plays an important role in determining the efficacy of wave quarrying, which is highest where waves impact seaward-facing scarps in horizontally bedded rocks or the upstanding, more resistant beds in steeply dipping strata. Without abrasive material, mechanical wave erosion is much less effective on shore platforms with fairly smooth, even surfaces, especially if they have very low gradients and low tide cliffs that cause the waves to break at their seaward edge (Stephenson and Kirk 2000). Subhorizontal shore platforms are often dominated by weathering today. These platforms in much of the Southern Hemisphere and in areas affected by glacio-isostatic movements of the land may have been cut by waves during a period of higher sea level in the Holocene, and subsequently leveled and lowered to their present elevations by weathering.
COASTAL EROSION PROCESSES AND LANDFORMS

Traditional explanations for the occurrence of sloping and subhorizontal platforms were based on differences in climate and wave regime, and consequently in the efficacy of mechanical wave erosion and weathering. There is strong evidence, however, to suggest that regional mean platform gradient is determined by the tidal range, although gradients may increase within regions with rock hardness and possibly with the size and mobility of any beach deposits. Tidal range influences mechanical wave erosion by determining the degree to which wave energy is expended at particular elevations within the intertidal zone; and weathering and biological erosion and protection by controlling the frequency and duration of the wetting and drying cycles.

Inheritance

Cohesive clay and other soft rock coasts erode fairly easily and are contemporary features related to modern morphogenic conditions. Conversely, shore platforms and other elements of hard rock coasts may have been inherited in part from interglacial stages when sea level and climate were similar to today. Hard rock coasts may also retain vestiges of former conditions during the Quaternary, such as scree slopes and raised beaches that developed when morphogenic conditions were quite different from today.

The occurrence of wide terraces on tectonically uplifted coasts shows that shore platforms can develop during single interglacial stages, and presumably therefore over similar periods of time in the Holocene. Although dating is difficult, it has been opined that some shore platforms in very resistant rocks are too wide to have developed in the few thousand years since the sea reached its present level. These platforms are often backed by ancient composite cliffs covered in places by glacial or periglacial deposits, and by elevated erosional ledges and raised beaches. There is convincing evidence that some shore platforms were formed incrementally in the Holocene and over one or more interglacial stages. They include dated platforms in southern Australia, and in northwestern Spain where they extend under ancient cemented beach deposits and dated alluvial and colluvial slope deposits from the early and much of the middle portion of the last glacial stage (Blanco Chao et al. 2003). Cosmogenic beryllium-10 dating suggests that the seaward portions of shore platforms in Korea are up to about 150,000 years old, and that the modern platform is cutting into its interglacial predecessor (Choi et al. 2012). Modeling also suggests that inheritance has been important in the development of shore platforms on tectonically stable coasts.

Modeling

It is difficult to determine the long-term development of rock coasts because they change very slowly and usually lack any datable sediment. Many workers have modeled these coasts but it is difficult to represent the myriad interacting geological and morphogenic factors that play a role in their development. Nevertheless, models have been used to study the development on hard rock coasts of shore platforms, erosional terraces, and submarine shelves on stable, uplifting, and subsiding landmasses, with sea level either constant or changing over periods ranging from a century or so up to a million years or more. Erosion is more rapid on cohesive clay and other soft rock coasts, and the threat to human life and property has generated a need for predictive erosional models with constant and rising lake and sea levels, usually operating over much shorter timescales than those for hard rock coasts. Less
modeling has been conducted on the plan shape of rock coasts by incorporating the effects of wave refraction and integrating erosional changes in the vertical and horizontal planes.

Coastal zones

Randolph A. McBride
Christopher T. Seminack
George Mason University, USA

Definition

The coast is a dynamic environment because it involves the triple intersection of land, ocean, and air; thus it experiences terrestrial, oceanic, and atmospheric processes concurrently. Major sea level changes have caused the active coastal environment to migrate tens to hundreds of kilometers horizontally over geologic time. The most recent changes in sea level occurred during the Quaternary period (from 2.6 million years ago to the present) in response to the growth and decay of continental ice sheets (i.e., glaciations and deglaciations) driven by Milankovitch cycles. Consequently, global (eustatic) sea levels fluctuated up to 135 m vertically during intervals of climate cooling (i.e., glacial or sea level lowstands) and warming (i.e., interglacials or sea level highstands) during the Quaternary period, resulting in the coast migrating back and forth across the entire continental shelf repeatedly. In the light of the dynamic and migratory nature of the coast during the Quaternary, the specific spatial boundaries of the coastal zone are delineated in Figure 1 and follow the definitions of Inman and Nordstrom (1971), Inman and Brush (1973), and Masselink, Hughes, and Knight (2011).

Specifically, the upper and lower boundaries of the coastal zone correspond to the elevational range over which coastal processes have operated during the Quaternary period, and include the coastal plain (Quaternary deposits only), shoreface, continental shelf, and the waters that cover the shelf and shoreface, as well as waters filling coastal water bodies, such as estuaries, bays, lagoons, sounds, harbors, and inlets (Inman and Brush 1973; Masselink, Hughes, and Knight 2011). As such, the landward limit of the coastal zone includes the oldest Quaternary coastal plain deposits laid down during sea level highstands at or several meters above present-day levels, whereas the seaward limit extends out to the continental shelf break, typically lying between the 100 m and 200 m isobaths with an average depth of 135 m.

Primary types of coastal zones worldwide

Globally, the geology and morphology of continental margins are determined by the following factors: (i) plate tectonics; (ii) wind, waves, and wave-generated currents; (iii) tidal range and intensity of tide-generated currents; (iv) sediment supply to the coast and longshore sediment flux; (v) storm impacts (tropical and extratropical); and (vi) coastal climate. Based on a combination of these factors, Inman (1994) identified five primary types of coastal zones worldwide: (i) collision coasts; (ii) trailing-edge coasts; (iii) marginal sea coasts; (iv) cryogenic coasts; and (v) biogenic coasts.

Collision coasts face trenches (subduction zones) offshore and are predominantly erosional features. These coasts are tectonically active and are typically characterized by narrow continental
Coastal zones are characterized by three main regions: Quaternary coastal plain, shoreface, and continental shelf. The coastal plain is a low, net progradational plain with its seaward edge at the mean low-tide line along an oceanic shore, and its strata are either horizontal or gently dipping toward the ocean. The shoreface extends from the mean low-tide line to the depth of average wave base (depth varies depending on coastal setting but typically averages from 5 m to 10 m water depth), while the continental shelf occurs from average wave base to the shelf break. Source: Modified from Christian and Mazzilli (2007).

Collision or leading-edge coasts are common around the perimeter of the Pacific Ocean (i.e., Ring of Fire), where trenches and volcanoes dominate (e.g., Peru–Chile Trench, Cascadia Trench, Aleutian Trench, Kuril–Kamchatka Trench, Japan Trench, Mariana Trench, Tonga Trench), as well as in the eastern Indian Ocean (Java Trench), as documented by Inman and Nordstrom (1971). Trailing-edge coasts face mid-oceanic ridges (divergent boundaries) and are dominated by depositional features. These coasts are tectonically quiescent and are typically characterized by wide continental shelves; moderate wave energy; depositional features such as barrier islands, spits, and deltas; long rivers with large drainage basins and robust deltas (e.g., Amazon, Niger); and well-developed coastal plains. According to Inman and Nordstrom (1971), trailing-edge coasts are common around the perimeters of the Atlantic and Arctic oceans where few to no trenches are present, as well as around most of the perimeter of the Indian Ocean.

Marginal sea coasts face the backside (non-open ocean side) of volcanic island arcs (e.g., Aleutians, Kuril Islands, Japan, Philippines, New Zealand, and the Greater and Lesser Antilles) and are dominated by depositional features. Marginal sea coasts are fronted by shallow water bodies with more limited fetch than an open ocean, as observed in the Bering Sea, Sea of Okhotsk, Sea of Japan, East China Sea, South China Sea, Coral Sea, Tasman Sea, Gulf of Mexico, and Caribbean Sea. Marginal sea coasts are found along the...
entire eastern mainland shoreline of Asia (e.g., Russia, China, North Korea, South Korea, Vietnam, Cambodia, and Thailand), around most of the perimeter of the Gulf of Mexico, and the western Caribbean Sea shoreline of Central America (Inman and Nordstrom 1971). Marginal sea coasts can be similar to trailing-edge coasts in appearance. Their tectonically stable setting and general protection from open ocean waves and tidal processes afford fluvial processes the opportunity to dominate marine processes, thus enabling large fluvial deltas to develop (e.g., Yangtze, Yellow, Mekong, and Mississippi). Marginal sea coasts are variable but may be characterized by wide continental shelves and coastal plains (e.g., northern Gulf of Mexico coast).

The primary cryogenic coasts are found around the perimeter of the Arctic Ocean, specifically the northern shorelines of Alaska, Canada, Greenland, and Russia. Based on the tectonic coastal classification of Inman and Nordstrom (1971), these Arctic coasts are categorized as trailing-edge coasts because they face a mid-oceanic ridge (spreading center) located on the seafloor of the Arctic Ocean. These Arctic coasts are tectonically aseismic and are characterized by wide continental shelves, broad coastal plains built of fluvial and glacial deposits, low-profile depositional features (e.g., barrier islands, spits, and deltas), microtidal conditions, and extensive permafrost, including subsea permafrost. These Arctic coastlines experience two primary seasons: eight to nine months of winter when the sea ice expands to cover most open water and the coast is frozen solid, in contrast to a short summer when the sea ice retreats and open water returns, allowing normal coastal processes to operate ephemerally (i.e., wind-generated waves, longshore sediment transport). In winter, coastal processes are dominated by ice-push phenomena and other cryogenic processes (see Washburn 1979; Yershov 1998).

Biogenic coasts (coral reefs and associated carbonate environments) are found in tropical and subtropical latitudes, particularly between 30°N and 30°S. They are best developed across the Indian Ocean, and along the western margins of the Atlantic and Pacific Oceans, although biogenic coasts are generally excluded from the eastern margins of the latter two oceans by the upwelling of cold water (Woodroffe 2003, ch. 5). Globally, the most prolific reef development area is known as the Indo-Pacific province, in contrast to the less prolific area known as the Atlantic province. Coral reef growth and evolution are controlled by a complex interaction among plate tectonics, sea level changes, environmental conditions (i.e., water temperature, light, wave activity, water turbidity, salinity, nutrient levels, etc.), and biological activity, as discussed by Woodroffe (2003, ch. 5) and Masselink, Hughes, and Knight (2011, ch. 10).

History of definitions

The term “coastal zone” has been used extensively in scientific literature and, more recently, in legislation. Popular in the 1800s as a general expression, “coastal zone” lacked a scientific definition. Perhaps the first documented scientific definition of the coastal zone was based on Stephen (1934), who specified that the coastal zone extends seaward from the littoral zone to the neighborhood of the 40 m bathymetric line. “Coastal zone” is now an important term used in environmental legislation, as well as in the physical and biological sciences.

The US government has played a significant role in developing a political definition of the coastal zone through the passage of extensive legislation beginning in the late 1960s. During this time, the US government passed groundbreaking environmental legislation that set the
stage for present-day international policy. All environmental legislation in the United States ultimately stems from the National Environmental Policy Act (NEPA) of 1969. This piece of legislation forced the US government to review the environmental impact of all government and government-funded actions. NEPA represents the first step in creating a political definition of a coastal zone.

The Coastal Zone Management Act (CZMA) of 1972 provides federal funding for a state to meet a balance between development and the environment (Vernberg and Vernberg 2001). This act is the only piece of US legislation that addresses the definition of a coastal zone; the CZMA permits each state to develop its own definition because of each state’s unique coastal setting. However, the CZMA does supply a blanket guideline of a coastal zone as follows:

The term “coastal zone” means the coastal waters (including the lands therein and thereunder) and the adjacent shorelands (including the waters therein and thereunder), strongly influenced by each other and in proximity to the shorelines of the several coastal states, and includes islands, transitional and intertidal areas, salt marshes, wetlands, and beaches. The zone extends, in Great Lakes waters, to the international boundary between the United States and Canada and, in other areas, seaward to the outer limit of State title and ownership under the Submerged Lands Act (43 U.S.C. 1301 et seq.), the Act of March 2, 1917, (48 U.S.C. 749), the Covenant to Establish a Commonwealth of the Northern Mariana Islands in Political Union with the United States of America, as approved by the Act of March 24, 1976 (48 U.S.C. 1801 et seq.), or section 1 of the Act of November 20, 1963 (48 U.S.C. 1705), as applicable. The zone extends inland from the shorelines only to the extent necessary to control shorelands, the uses of which have a direct and significant impact on the coastal waters, and to control those geographical areas which are likely to be affected by or vulnerable to sea level rise. Excluded from the coastal zone are lands the use of which is by law subject solely to the discretion of or which is held in trust by the Federal Government, its officers or agents. (Coastal Zone Management Act 1972, 4)

The CZMA contains special programs within its legislation. The National Estuarine Research Reserve program created a system of natural laboratories in order to study ecosystems (Vernberg and Vernberg 2001). Another program created by the CZMA is the Special Area Management Plan. This program was created to address coastal environmental issues which affect multiple jurisdictions (e.g., federal, state, and local governments).

Many US legislative works involve the definition of a coastal zone or its subhabitats. The US Army Corps of Engineers regulate activities in navigable waters under the Rivers and Harbors Act of 1899. They also spearhead construction projects along the coast for hard structures (i.e., jetties, seawalls, etc.) and soft structures (i.e., beach replenishment; Vernberg and Vernberg 2001). The Clean Water Act of 1972 regulates discharges into water bodies, both terrestrial and coastal (Vernberg and Vernberg 2001). The Clean Air Act of 1972 aims to “Preserve, protect, and enhance the air quality in national parks, national wilderness areas, national monuments, national seashores, and other areas of special national or regional natural, recreational, scenic, or historic value” (section 160). This act primarily affects development along the coast (i.e., oil and gas industry; Vernberg and Vernberg 2001). The National Flood Insurance Act offers subsidized insurance for coastal flooding damage to property owners. Federal funding to recover from natural disasters is provided by the Federal Emergency Management Agency (FEMA). The agency will reimburse (up to 75% in most cases) public entities such as publicly renourished beaches, water and sewer systems, roads, bridges, recreational

facilities, and buildings (Vernberg and Vernberg 2001). Significant marine areas of historical, educational, research, ecological, recreational, or aesthetic value are protected under the National Marine Sanctuaries Act (Vernberg and Vernberg 2001). The National Coastal Barrier Resources Act put in place legislation to reduce the development of undeveloped barrier islands in hopes of reducing storm-related damage to people and property, as well as preserving coastal
COASTAL ZONES

habitats (Vernberg and Vernberg 2001). Finally, the Endangered Species Act of 1973 is one of the most powerful pieces of US legislation. The goal of this act is to conserve endangered and threatened species. Many of the species listed under this law reside in the coastal zone (Vernberg and Vernberg 2001).

Political definitions of the coastal zone extend to the international stage as well. Table 1 provides brief summaries of coastal zone definitions from various international bodies and conferences, as well as authors of scientific articles.

Conclusion

The future viability of coastal zones worldwide will depend on numerous factors and impacts. The most important factors and impacts include global climate change, rising sea levels, human population growth and disturbance in coastal areas, pollution, utilization of coastal resources (e.g., groundwater, aggregate, and energy extraction, e.g., oil and gas), and the implementation of sustainable coastal management (SCM) practices (see Vernberg and Vernberg 2001, ch. 9; Masselink, Hughes, and Knight 2011, ch. 12).

References

The coast is where the land meets the sea. Coasts attract people because of their beauty, abundant supply of natural resources, and their special appeal as a place to live, harvest resources, and recreate. Nearly half the global population and associated development is already concentrated at the coast, and this is likely to intensify in the future. Consequently, coasts are crucial for human wellbeing but they are subject to mounting pressures. Unsustainable practices are widespread and worsening in many localities in this narrow strip. Coasts are also impacted by distant activities, such as poor farming practices far inland or pollution at sea. Coastal ecosystems are now among the most threatened on the planet, jeopardizing the livelihoods, wellbeing, and future prospects of coastal communities, nations, and humanity. Therefore, one of the defining challenges for the twenty-first century is to overcome the failures of sustainability, both distant and local, that are concentrated at the coast. Increasing attention is being focused on how to manage the coast to promote sustainable coastal development. Coastal communities have managed coastal resources for millennia. Contemporary coastal management efforts involving coastal communities and their governing authorities developed rapidly from the early 1970s and are now underway in most coastal localities. There are notable success stories but they tend to be small-scale and coastal sustainability writ large is elusive despite dedicated efforts and a wide range of progressive coastal management practices. To compound matters, global environmental change is making many coasts less suitable for human habitation. Climate change, in particular, is compounding coastal hazard risks especially in areas already exposed to the impacts of coastal erosion and flooding. Future prospects are dismal unless the root causes and drivers of unsustainable practices are addressed and effective measures institutionalized that enable coastal communities to build adaptive capacity and resilience. Transformative change is needed to govern the coast sustainably. Such systemic change challenges the status quo and is likely to be resisted. Issues to address are how sustainability failures can be transformed into successes and what coastal management “best practices” need to be fostered to bring about sustainable coastal development. A starting point for addressing these issues is to understand the distinctive characteristics of the coast.

Defining the coast

The coast can be defined as the interface between land and sea. It is a relatively narrow transitional zone characterized by direct interactions between purely terrestrial and marine environments with indirect influences extending far inland and out to sea. For example, activities in remote catchments, such as damming of rivers or farming practices that cause soil erosion, nutrient enrichment, or other polluting activities, cause environmental impacts that negatively affect the health, productivity, and diversity of coastal waterways like estuaries and associated ecosystems. Activities in the marine
realm, such as an oil spill, can have significant impacts on coastal ecosystems and the people whose livelihoods depend on them.

Land–sea interactions involve multiple biogeochemical processes and gradients and a myriad of human–nature and human–human interactions, which vary greatly in geographic and temporal scale and duration (Crossland et al. 2005; Figure 1). Consequently, coasts are highly interconnected, diverse, and dynamic environments. These intensive land–sea interactions give rise to a variety of distinctive coastal ecosystems and human communities that are interdependent and constitute a coupled coastal socioecological system made up of the coastline or seashore, coastlands, and coastal waters.

The coastline is the area between the low- and high-water marks but extends land- and seawards depending on seasonal influences and longer-term changes in coastal biogeochemical processes. Coastlands are areas above the high-water mark extending inland that have an influence on or are influenced by the sea. The inland extent depends on the reach of these direct and indirect land–sea interactions. Rivers are a pivotal connector between inland areas and the marine realm and channel the influence and impacts of catchment activities that, for example, compound and abstract water, pollute rivers, and add or trap sediments. Coastal waters extend from the seashore into the ocean as far as terrestrial processes and activities have influence and impact. River discharge, for example, can have a powerful influence far out to sea. Land-based sources account for most marine pollution and include persistent, bioaccumulative, and toxic substances that can be magnified up the marine food chain and pose a severe threat to human health and marine ecosystems. Marine activities can negatively impact coastal ecosystems through, for example, pollution from passing ships and plastic debris that is carried via ocean currents far from their source to distant coasts.

The coastal socioecological system can thus be thought of as a meeting place – of land and sea, of people and cultures, and a plethora of activities from fishing to coastal development, recreation, farming, mining, and nature conservation (Figure 2). It is also a place where different societal institutions and administrative jurisdictions intersect. For example, local
COASTS

authorities typically use land-use planning provisions to regulate development and the use of coastal resources from the high-water mark landwards – typically under a regime of private property rights. In the marine realm, from the high-water mark seawards up to the boundary of the exclusive economic zone, by contrast, the allocation and exercise of user rights and responsibilities are shaped by national (e.g., fisheries legislation) and international (e.g., the UN Convention on the Law of the Sea) provisions that regulate user practices under a regime of state ownership and/or stewardship in the public interest. The terrestrial and marine legislative and property rights regimes are bifurcated by the high-water mark. They need to be aligned, coordinated, and integrated because the coastal socioecological system needs to be managed holistically to realize the system-wide benefits that coastal ecosystems provide to coastal communities, nations, and the global community at large.

Over time various definitions of the coastal zone have been used, including fixed and variable distance (and elevation/depth) options; definitions according to particular coastal issues, interests, activities, or uses; and definitions that combine elements of the foregoing. No one boundary definition for the coastal zone is suitable for all purposes because of the variable relevance and extent of direct and indirect land–sea interactions. Defining appropriate boundaries for the coastal zone therefore needs to be guided by the purpose at hand. For the Millennium Ecosystem Assessment, Agardy et al. (2005) defined the boundaries of the coastal zone to include land-based influences up to a maximum of 100 km from the seashore or 50 m elevation (whichever is closest to the sea), and the seaward extent as 50 m depth in the marine environment. On this basis, the coast comprises less than 5% of the terrestrial surface area of the Earth. Exploring further the “geography of the coast” reveals more about the distinctive characteristics of the coast and the particular challenges and opportunities it presents for coastal management and governance.

The geography of the coast

Physical geography of the coast

Coasts are characterized by intensive, often high–energy interactions, significant nutrient and material fluxes, and incessant change – from short-term changes driven by winds, waves, currents, and tides to changes across seasons, decades, and long-term climatological and biogeochemical changes (McLusky and Wolanski 2012). Coasts encompass an incredible range of features and habitats from cold, arid coasts like those fringing Antarctica to subtropical islands like those in the Pacific and a panoply of ecosystems – including estuaries, marshes, salt ponds, coastal aquifers, and lagoons; mangrove forests; intertidal habitats, deltas, beaches, and dunes; rocky shores; coral reefs and atolls; seagrass beds or meadows; kelp forests; other benthic communities, like rock and shell reefs, mudflats, coastal seamounts, and rises; near-shore islands; and semi-enclosed seas (Figure 3). Coastal ecosystems are among the most biologically productive systems on Earth (Agardy et al. 2005).

The dynamism, diversity, and productivity of coastal ecosystems stem from complex interacting biogeochemical processes and fluxes. These coastal ecosystems are resilient to change but they are finite and have thresholds beyond which degradation and even collapse occurs. These ecosystems perform a range of ecological functions, such as the role played by mangroves and estuaries in providing a safe and food–rich habitat for the growth and development of juvenile fish, crab, and prawn species. Coastal ecosystems and
the ecological functions they perform yield a wide range of ecosystem services that benefit people, such as subsistence, recreational, and commercial fishing. The physical and human geographies of the coastal socioecological system are thus interwoven.

**Human geography of the coast**

For millennia, people have flocked to the coast because of its beauty, diversity, productivity, and cultural and spiritual significance. Albeit a narrow strip comprising a fraction of the Earth’s habitable surface, about 40% of the world’s population live within 100 km of the seashore (Agardy et al. 2005; Martínez et al. 2007; Small and Nicholls 2003). Most people are concentrated in densely populated rural areas, and small and medium-sized cities, chiefly in the vicinity of estuaries, mangroves, and coral reefs. Average coastal population density is three times greater than the global average. More than 50% of coastal nations have 80–100% of their total population in this narrow strip. Wealth and wellbeing is concentrated at the coast with per capita income typically four times higher and lower infant...
mortality and higher life-expectancy than inland areas.

Many people live in coastal cities and megacities (Pelling and Blackburn 2013): 16 of the world’s 23 megacities with populations over 10 million people occur here. Large-scale urbanization is causing widespread transformation of coastal ecosystems. There is especially rapid urban sprawl, fragmentation, and agglomeration in less wealthy countries. Coastal cities play a crucial role in the search for sustainability pathways because they are focal points of consumption and social reproduction and are pivotal centers of global trade, innovation, and geopolitical leadership (Figure 4).

The coast is the locus of global economic and human development with immense aesthetic, cultural, spiritual, and educational value and an estimated 61% of global total gross national product sourced within 100 km of the seashore (Agardy et al. 2005; Patterson and Glavovic 2008). Coastal ecosystems provide a wealth
of provisioning services (e.g., fish for food, raw materials for construction and boat building, fresh water, and medicinal resources), regulating services (e.g., carbon sequestration and storage, local climate and air quality, moderation of extreme events, wastewater treatment, erosion prevention and soil fertility maintenance, pollination and biological control), habitat or supporting services (e.g., habitat for coastal species and maintenance of genetic diversity), and cultural services (e.g., recreation and mental and physical health, tourism, aesthetic appreciation and inspiration for culture, art, design, spiritual reflection, and sense of place). Coasts contribute proportionately more ecosystem services than most other systems, including those that cover vastly larger areas. A preliminary estimate by Costanza et al. (1997) indicated that the total value of coastal ecosystem services is about 43% of the total value of global ecosystem services. Estuaries and marshes are among the most fertile coastal environments and provide the widest range of ecosystem services. For example, if the natural capital of the Mississippi river delta were treated as an economic asset, it would provide annual benefits of US$13–47 billion and have a minimum asset value of US$330 billion–1.3 trillion (Batker et al. 2010).

Sustaining these benefits is already imperiled and the prognosis for the future is dismal (Agardy et al. 2005; Moser, Williams, and Boesch 2012). In recent decades, there has been a rapid increase in coastal population, urban sprawl, and development intensification, especially in parts of Africa and central Asia, driven by, among other things, migration to the coast, high fertility rates, and, in some regions, high visitation by tourists and those seeking recreation (Figure 5). Coasts are consequently undergoing more rapid and pervasive change due to human pressures and impacts than at any other time in human history despite long-standing pressures in some localities. These changes include direct physical (e.g., infilling of wetlands for urban development) and biological (e.g., overexploited fisheries) transformations. In addition, there are indirect changes due to, among other things, changes in water flow in rivers and sediment patterns that lead to altered deposition and erosion dynamics at the coast which are exacerbated by chronic degradation and chemical transformations due to land-based (e.g., eutrophication, and bioaccumulated persistent toxins) and marine-based pollution (e.g., plastic disposal) as well as the proliferation and spread of invasive non-native species.

The coastal population and associated drivers of change are not uniformly distributed. People are concentrated in close proximity to the most productive coastal ecosystems (Agardy et al. 2005) – over 70% of the coastal population lives within 50 km of estuaries. In tropical coastal regions, many communities are located within reach of mangroves and coral reefs (58% of the world’s coral reefs are within 50 km of urban centers of 100,000 people or more and 64% of mangrove forests and 62% of major estuaries are near such centers).

Furthermore, access to and distribution of ecosystem service benefits, and bearing the consequences of degraded or destroyed coastal ecosystems are also differentially distributed with some groups and communities faring much worse than others largely because of their sociopolitical and economic marginalization, for example, small-scale fishers and traditional communities. Gross inequity is common at the coast with marked economic disparities within and between rural and urban coastal areas; and poverty and inequity is pronounced and increasingly concentrated in urban coastal areas (Brown et al. 2008; Pelling and Blackburn 2013). Brown et al. (2008) estimate that there are over 250 million coastal poor, with 80% living in just 15 countries – 27% in India, 13% in Indonesia,
and 9% in Bangladesh. The coastal poor receive a disproportionately small share of benefits from coastal ecosystems and have had minimal impact on overall changes in coastal ecosystem services. However, in some locations, unsustainable practices by those with limited livelihood alternatives have caused major coastal degradation. There is a complex interrelationship between poverty, ecosystem health and service provision, and livelihood sustainability. Coastal poverty and inequity can fuel conflict and catalyze a vicious spiral of ecologically and socially unsustainable practices that increase vulnerability and risk and undermine already fragile livelihoods and future prospects, especially in the face of climate change.

Climate change is compounding and exacerbating coastal hazard risks in localities already prone to inundation, coastal erosion, and saltwater intrusion into groundwater, especially in areas with vulnerable populations (Glavovic et al. 2015; Nicholls et al. 2007; Wong et al. 2014). Coastal systems are particularly sensitive to increases in sea level, ocean temperature, and ocean acidity. Low-lying coastal areas will be exposed to erosion, flooding, and submergence due to inevitable sea level rise, albeit variable in different localities and regions. Coral reefs are

Figure 5  Qingdao, a major seaport, naval base, and industrial hub in Shandong Province, China. Photos by Bruce Glavovic.
the most vulnerable coastal-marine ecosystem to increasing ocean temperature and acidity and have little prospect for adaptation with inevitable coral bleaching and other changes, including altered ranges of coastal-marine species. Climate change will cause other coastal changes but they are difficult to distinguish from human-related drivers of unsustainable practices (e.g., transformation of coastal habitats and ecosystems through land-use changes, development expansion and intensification, resource exploitation, and pollution). Climate change will exacerbate socioeconomic and infrastructure impacts due to:

- unsustainable practices such as loss of coastal property and land;
- loss of and damage to assets, including safe housing, public services, and infrastructure;
- negative impacts on coast-dependent livelihoods and human health due to loss of coastal resources, food insecurity, exposure to extreme events, heat stress, vector- and water-borne diseases, and diminished access to potable water;
- increasing costs of insurance (and rising un-insurability) and protective works and diversion of resources for adaptation;
• increasing mortality
• unforeseen socioeconomic disruptions.

Social institutions, cultures, and ways of life will also be adversely affected by increasing uncertainty, dynamism, and unprecedented events that disrupt community routines and lifestyles (Figure 6). Extreme events may become more frequent and unpredictable. Displacement and migration of vulnerable people may become more commonplace. Some coast-dependent cultures and ways of life (e.g., those dependent on coral reefs) may be imperiled. There are likely to be adverse impacts on cultural identity, national prestige, and sovereignty (e.g., as a result of submergence of low-lying small island states like Kiribati). Sociopolitical instability, unrest, and conflict may escalate in localities adversely impacted by climate change. Climate change will, however, also open up new opportunities for some groups and communities. Prospects for realizing these opportunities and adapting to change vary significantly within and between developed and developing coastal nations, with low-lying regions (e.g., Mississippi delta), developing nations (e.g., Bangladesh and Vietnam), and small island states (e.g., Kiribati) expected to experience very high impacts and related loss and damage as well as adaptation costs.

It is unequivocal that coastal hazard risk is escalating due to rapid coastal population growth, urbanization and development intensification, and climate change (Wong et al. 2014). By 2100, without effective adaptation, hundreds of millions of people will be impacted by coastal flooding and displaced due to land loss, mostly in east, southeast, and south Asia. Many coastal cities face escalating flood risk due to population growth and urbanization compounded by subsidence and climate change. According to Hallegatte et al. (2013), average global flood losses in the 136 largest coastal cities were about US$6 billion per year in 2005 and are expected to increase to US$52 billion per year by 2050 based on projected socioeconomic changes alone. Taking into account subsidence and climate change, existing protective measures will need to be upgraded to avoid unacceptable losses of US$1 trillion or more per year.

Many coastal communities, nations, and regions are vulnerable to climate variability and shocks that will compound the impact of unsustainable practices. Understanding and addressing this predicament is, however, difficult because of the complex interrelationships between coastal community wellbeing, resource and urban development trajectories, sustainability, and climate and global environmental change. Many vulnerable coastal communities will experience additional stress, existing problems will intensify, new problems will emerge, and risk will escalate – especially for those who are poor, and socially and politically marginalized, and thus least likely to benefit from new opportunities created by a changing climate. Climate change therefore poses a formidable challenge, especially for those already adversely impacted by inequitable and environmentally unsustainable coastal development. It raises vexing questions about how to mobilize, integrate, and apply scientific and local knowledge in practical ways to promote coastal resilience and sustainability (Figure 7).

Coastal challenges and opportunities in the Anthropocene

Post-industrial human activities have caused environmental impacts that may transgress critical planetary boundaries and threaten human wellbeing and survival, leading Nobel laureate Paul Crutzen (2002) among others to say that we now live in the Age of the Anthropocene. The coast is the frontline of the sustainability crisis
arising from the dominant influence humans now have on the Earth’s biogeochemical and climatological processes (Glavovic 2013a).

Humanity faces a “quadruple coastal squeeze” in the Anthropocene: (i) population growth, resource exploitation, urban sprawl, and development intensification; (ii) coastal ecosystem degradation, conversion and loss; (iii) rising CO$_2$, climate change, and alteration of coastal-marine biogeochemistry and ecosystems; and (iv) ecosystem thresholds and tipping points being transgressed, resulting in rapid and irreversible changes in the coastal socioecological system and societal responses. Consequently, we face a dilemma at the coast because as the coastal population grows there is increasing dependence on coastal ecosystem services, but unsustainable practices are pernicious, pervasive, and intensifying, compounded by global environmental change and climate change in particular, accelerating coastal hazard risk and making the coast less suitable for human habitation (Agardy et al. 2005; Moser, Williams, and Boesch 2012; Glavovic 2013a; Glavovic et al. 2015).

There are no ready-made “fixes” for the challenges facing coastal communities in the Anthropocene. Communities will need to chart their own pathways in the face of the complexity of the coast, including inevitable change, systemic uncertainty, and surprise; nonlinear and emergent interactions with intricate feedback loops; and real socioecological limits and barriers. Opportunities to chart pathways that foster adaptive capacity, resilience, and sustainability
are constrained by prevailing institutional structures and processes that are ill-equipped to forge timely solutions and which incentivize unsustainable coastal development. Business as usual is therefore untenable. Incremental stepwise improvements may alleviate some impacts and reduce some risk, but there is a compelling and urgent need to comprehend and address the underlying drivers and root causes of unsustainable coastal development, climate change complacency, institutional inertia, and maladaptive policies and practices. Ultimately, transformational change is necessary to chart resilient and sustainable pathways at the coast.

Science does not offer a panacea, but it is foundational for understanding the nature of the coastal sustainability crisis. The coastal science–policy–practice interface needs to be bridged and research on priority issues carried out through co-design and coproduction of knowledge involving scientists and the policymakers, practitioners, and local coastal stakeholders and community members who play vital roles in real-world coastal management (Bremer and Glavovic 2013). Inevitably, potentially viable solutions will be contested because there are multiple legitimate views shaped by divergent values, perceptions, and interests about how to address coastal problems. Moreover, the capacity or “power” to chart new pathways is not spread evenly within and between coastal communities and nations. Coastal communities need to be enabled to reflect critically on the challenges and opportunities they face, learn from experience (while recognizing the limits of relying on past practices to confront novel challenges), and envision, investigate, and explore new pathways to reverse localized and distant unsustainable practices, reduce risk, adapt to change, and foster resilience. Innovations in coastal management offer the best prospect for charting such pathways.

From coastal zone management to coastal governance for sustainability

Five broad approaches to coastal management can be distinguished: traditional community-based coastal management; ad hoc sector-based coastal management; coastal zone management; integrated coastal management (ICM); and coastal governance.

Traditional community-based coastal management

For many centuries, coastal communities and cultures developed and implemented management regimes to benefit from and sustain a variety of coastal and marine resources and fisheries in particular. Some Pacific Island cultures, for example, used measures such as limited entry, closed seasons, closed areas, size limits, and even, on occasion, gear restrictions enforced through cultural taboos, incentives, and sanctions, to manage these resources. Many of these practices have been eroded by globalization and Westernization with the spread of cash economies, export markets, new technologies, and other socioeconomic, geopolitical, and cultural influences (Johannes 1978). However, there has been a resurgence of interest in and application of traditional practices over the last three to four decades in Oceania (Johannes 2002), and different forms of devolved co-management, involving traditional communities, governing authorities, scientists, and nongovernmental organizations, have been adopted around the world (Figure 8).

Ad hoc sector-based coastal management

Up to the early 1970s, in developed countries in particular, coastal management was typically carried out in an ad hoc and compartmentalized
manner with provisions tailored to address sector-based interests and issues, for example, coastal development including housing and public infrastructure, nature conservation, fishing, farming, and recreation. Little consideration was given to the impact of ad hoc sector-based decisions on the coastal socioecological system as a whole. Public engagement was limited, environmental concerns were given minimal attention, and management efforts were largely reactive. The shortcomings of this approach became increasingly apparent with growing environmental consciousness.

Coastal zone management

The sea and seashore have long been considered a public asset and have enjoyed special legal status since pre-Roman times as an asset that should not be owned but enjoyed by citizens or held as public property vested in the state as custodian on behalf of the public. Such provisions were, however, insufficient to ensure effective management of the coastal zone as a whole. One of the earliest nationwide comprehensive efforts to manage the coastal zone was instituted with the passage of the US Coastal Zone Management Act in 1972. This initiative recognized the compelling case for dedicated government attention to be focused on the coast through formulation of state-wide integrated coastal zone management plans that make explicit the need to bridge different spheres of government responsibility, enable integration across sectors and activities, and involve the public in planning and decision-making. This enabling legislation, which includes technical and financial supporting measures and a federal consistency provision that requires federal agencies to comply with approved state plans, incentivized states to develop and implement plans that support federal objectives and standards for coastal zone management.

Focused attention on environmental concerns and proactive efforts to manage the coastal zone better grew rapidly from the early 1970s, and by the time the UN Conference on Environment and Development (UNCED) took place in Rio de Janeiro in 1992, many nations had embarked on initiatives to institutionalize dedicated coastal zone management regimes. One of the difficulties encountered was to define the boundaries of the coastal zone in a way that enabled effective management of the coastal socioecological system as a whole, taking into account both direct and indirect drivers of change. As explained above, defining a single static set of boundaries for the coastal zone is problematic because of the variable extent of local and distant influences on the coastal socioecological system. The need to shift the focus from “the zone” to “integration” came to the fore at UNCED and the notion of ICM gained traction.

ICM

A dedicated chapter on ocean and coastal areas, with an emphasis on integration as the primary
means to foster sustainable coastal development, was included in Agenda 21 (ch. 17) – the action plan produced by UNCED. This emphasis was reinforced in Johannesburg at the 2002 World Summit on Sustainable Development and in many other international and regional initiatives (UNEP Regional Seas Programme, and EU initiatives on ICM and Marine Spatial Planning to complement framework directives on water and fisheries, among others) as well as national and more localized ICM practices (e.g., the passage of South Africa’s ICM Act in 2008).

Defining ICM

According to GESAMP (1996), ICM can be defined as a continuous and dynamic process that enables government, coastal communities, scientists, and coastal managers to work together to formulate and implement an integrated plan that sustains coastal ecosystems and reconciles sector-based, private, and public interests in the coast. The goal is to improve the quality of life of coastal communities who depend on healthy, productive, and diverse coastal ecosystems. Achieving this goal requires an integrated management regime that coastal communities consider legitimate, equitable, transparent, and adaptable in the face of change. In short, the goal of ICM is to promote sustainable coastal development.

Why ICM?

First, the coast is an interconnected socioecological system that presents distinctive challenges and opportunities compared to either the marine or terrestrial realm per se. Management practices cannot simply be transferred from the marine or terrestrial realm and applied at the coast. ICM needs to be founded on tailored and hybrid approaches that take into account the intersection of land and sea influences, processes, interests, activities, and governance regimes. Bridging these realms requires integration across a number of domains (see Table 1).

Second, the coast is a public asset that requires dedicated and integrated management to maintain and secure it as a public heritage, for example, by providing public access and right of way over private property to the seashore and sea and reconciling public and private as well as intergenerational interests.

Third, ad hoc sector- and interest-based management efforts result in a “tyranny of small decisions” that might be individually rational but fail to realize system-wide benefits and undermine the healthy functioning of the coastal socioecological system. The whole is greater than the sum of the parts. ICM is necessary to address the crucial issue of interconnected scales of interaction at the coast that extend from the local to global level.

By way of illustration, constructing a causeway that impedes river flow to the sea might be compelling to minimize road construction costs. But estuarine functions (e.g., as a nursery for fisheries) may then be disrupted, diminishing ecosystem services (e.g., lower fish catches) with dire consequences for those whose livelihoods are dependent on such services. Choices made that result in incremental degradation or irreversible impacts might yield short-term benefits for some stakeholders but cause long-term costs that are borne by others and the wider community. The environmental impacts (including ecological, social, cultural, and economic impacts), social costs and benefits, and risks associated with alternative sector- and interest-based decisions need to be considered in the context of the coastal socioecological system as a whole. Hence the ICM imperative.
<table>
<thead>
<tr>
<th>Table 1</th>
<th>Dimensions of integration.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Geographic/spatial integration</td>
<td>Connections extend across the land–sea interface, landwards and seawards, and up and down the coast. Water is a major connector at the coast. Geographic interconnections are not only physical but include important cultural, social, economic, trade, geopolitical, and institutional linkages that can reach worldwide.</td>
</tr>
<tr>
<td>Temporal integration</td>
<td>Short-term decisions can lead to impacts with cumulative (a seemingly trivial choice assumes greater import in the face of multiple such choices over time) and synergistic (the impact of two interacting factors that produces an impact greater than the sum of their individual impacts) effects with significant long-term consequences and hence the need to take into account the interaction between short- and long-term consequences and intergenerational interests and equity.</td>
</tr>
<tr>
<td>Sectoral integration</td>
<td>Integration between sectoral activities is vital to ensure that decisions made by those involved in coastal property development, public infrastructure, agriculture, conservation, recreation, and so on take into account sector-specific impacts on the wider socioecological system.</td>
</tr>
<tr>
<td>Political, administrative, and institutional integration</td>
<td>Jurisdictional boundaries typically define the geographic extent of administrative and institutional responsibility. Such boundaries seldom coincide with coastal ecosystem boundaries, let alone align with the coastal socioecological system, and hence the need to integrate across jurisdictional boundaries to ensure coherent decision-making. In addition, “vertical” integration is vital to ensure that spheres of government from local to national and even international levels adopt approaches consistent with ICM principles and best practices. There also needs to be coordination and integration between relevant laws, policies, and practices that impinge on the coast and in so doing enable integrated action by coastal stakeholders, including those in government, civil society, the private sector, and research community.</td>
</tr>
<tr>
<td>Disciplinary integration</td>
<td>Understanding the nature and dynamics of the coast and associated management challenges and opportunities necessitates research, education, and learning approaches that draw on disciplinary insights, but, where appropriate, integrate such insights to understand the coast holistically. The complexity, uncertainty, and dynamism that characterizes the coastal socioecological system reinforces the need to draw from and integrate a wide range of disciplinary perspectives, recognize the limits of our understanding, and explore ways to align scientific understanding with local, traditional, and tacit knowledge.</td>
</tr>
<tr>
<td>Science–policy–practice integration</td>
<td>Disciplinary, interdisciplinary, and transdisciplinary knowledge and learning are necessary but not sufficient. Such understanding needs to be framed by policy and practice imperatives. Addressing the challenges of the coast requires more effective bridging across the science–policy–practice interface – an undertaking that necessitates co-design and coproduction of applied research and social learning processes that enable community-wide awareness and application of context-relevant best practices.</td>
</tr>
</tbody>
</table>
What does ICM involve?

ICM encourages those involved in discrete coastal activities to think about the system-wide and long-term consequences of their decisions and actions. ICM is usually based on establishing institutional mechanisms that enable cooperation, coordination, and integration between spheres of government (vertical integration) and different actors, activities, sectors (horizontal integration), and other dimensions of integration (see Table 1). ICM promotes social learning and integrates scientific understanding with local, traditional, and tacit knowledge. ICM requires strategic planning that is applied in locally relevant and locally informed ways and adapted over time based on deliberate lesson-learning through monitoring, evaluation, and program adjustment. ICM involves a range of activities, including:

- engaging coastal stakeholders in formulating and implementing a plan to foster sustainable coastal development;
- maintaining ecosystem health, diversity, and productivity;
- sustaining the benefits of ecosystem services;
- enabling sustainable livelihood opportunities;
- resolving conflicting interests;
- facilitating awareness of and understanding about the coast;
- stimulating cooperation, coordination, and ultimately integration.

Resolving conflicting interests is central to ICM. Direct conflict can occur between and within coastal resource user groups especially when there is intense demand for limited space or resources, and/or where activities are incompatible. For example, shore angling, bathing, surfing, off-road vehicles, and dune mining are not feasible in the same locality without interests conflicting. Indirect conflict also occurs as in the example of the road causeway in which a road engineering decision can unintentionally undermine the interests of fishers and other stakeholders.

Deciding how to allocate and utilize the increasingly scarce resources of compromised coastal ecosystems presents a profound management challenge. It needs to be determined how tradeoffs should be made and conflicting interests resolved given the synergies and interconnections between coastal ecosystems, associated services, livelihoods, and the inequitable distribution of entitlements, benefits, costs, and risks that frame such choices.

ICM draws upon and seeks to integrate a range of disciplinary, sector-, and profession-based processes and practices to make such choices, including:

- land-use planning, development approval processes, and monitoring and evaluation protocols;
- strategic planning;
- provisions for housing and service delivery;
- infrastructure planning;
- transport planning;
- economic development planning;
- community development planning;
- emergency management;
- tourism and recreation;
- nature conservation;
- catchment management planning;
- integrated pollution control and waste management.

ICM does not replace these processes and practices but seeks to integrate them through a series of steps and successive cycles of policy and program formulation and implementation that include (i) identification and assessment of coastal issues, problems, and opportunities; (ii) negotiation and formulation of ICM policies and a course of action or program; (iii) formal
adoption by governing authorities of the ICM program or plan and provision of funding; (iv) implementation of agreed policies, provisions, and actions; and (v) ongoing monitoring, review, lesson-learning, and revision (GESAMP 1996). ICM is thus framed as an ongoing and iterative process of negotiated program- and plan-making, lesson-learning, and adaptation (Cicin-Sain and Knecht 1998; Kay and Alder 2005).

ICM in practice

ICM practices have varied significantly around the globe. The European Union (EU), for example, has outlined a general framework for ICM but it is merely advisory and non-binding on member states, and, unlike the US Coastal Zone Management Act, does not provide administrative, financial, and technical incentives for member states to adopt and implement ICM. ICM in developing countries has been mainly donor-funded and project-based. Billions of dollars have been invested in ICM by bilateral and multilateral agencies since the 1990s, aside from in-kind, financial, and nonfinancial contributions by international environmental and humanitarian organizations, national governments, and community-based and nongovernmental organizations. Upscaling and sustaining ICM initiatives has, however, proved challenging in practice despite significant progress made in places as diverse as the Philippines, Vietnam, Bangladesh, South Africa, Ecuador, the United States, and the EU (Kremer and Pinckney 2012; Krishnamurthy et al. 2008). Many ICM initiatives have been small-scale and limited in scope and influence and/or they have not been sustained over sufficiently long periods of time to secure systemic institutional change and sustainable outcomes. ICM is increasingly reframed as coastal governance, wherein divergent goals, understanding, and interests are negotiated in political interactions between coastal stakeholders (Figure 9).

Coastal governance

What is coastal governance?

Governance refers to the interactions of key actors from the state (government), civil society, and private sector, together with the scientific community and media, in seeking to address societal problems through power sharing, social coordination, and collective action. Coastal governance involves interactions between these actors to reconcile sectoral, private and public, and short- and long-term interests in pursuit of coastal resilience and sustainability. These interactions take place through a range of institutions that include both formal (e.g., law and government administration) and informal (e.g., sociocultural norms and “rules”) structures and processes to make social choices that shape community prospects at the coast.

Governance institutions invariably have two features that coexist in dynamic tension. On the one hand, they are authoritative, constraining, disciplining, and stabilizing; and, on the other hand, they are generative, enabling, empowering, and innovative. The art of coastal governance lies in mobilizing these dynamic and countervailing features in ways that foster individual, group, and community behaviors and interactions that are socially equitable, adaptive, resilient, and sustainable. Coastal governance institutions thus convey norms and confer rights, roles, routines, responsibilities, and the resultant culture of coastal management. The outcome of governance interactions and the extent to which the aspirations of different groups and communities are realized is dependent among other things on the power and entitlements
Managing coastal activities: scenes from Guanabara Bay between Rio de Janeiro and Niteroi, Brazil. Diverse and productive coastal ecosystems, especially mangroves, have been heavily impacted by urbanization, deforestation, and water pollution. Photos by Bruce Glavovic.

There has been a tendency to move away from reliance on centralized government authority through top-down prescription, regulation, and control toward more localized, bottom-up, and networked governance interactions. However, both top-down and bottom-up governance modalities are important. Government plays a crucial role in establishing the policy and legislative framework, enforcement, and providing enabling resources. Establishing credible and legitimate governance arrangements depend on the level of trust that communities have in their governing authorities. Civil society thus plays a crucial role in legitimizing government, building social capital, and realizing community aspirations. The private sector and market interactions play a crucial role in entrepreneurship, economic development, and enabling alternative coastal livelihoods.

The remarkable dynamism and diversity of the coast precludes a static “one-size-fits-all” approach to governance. Governance institutions,
processes, and practices need to be tailored according to the distinctive features of different coastal cultures, communities, and jurisdictions. Many coastal issues transcend the scale at which prevailing governance arrangements in coastal communities and even nations operate, for example, land-use planning provisions that stop at the high-water mark or bisect water catchments, or the peril of sea level rise facing low-lying coastal localities and even nations. Particular attention therefore needs to be focused on developing scale-appropriate governance arrangements and enabling integration across scales. Localized issues may need to be addressed through devolved, decentralized, and bottom-up provisions. However, such provisions invariably require higher-level enabling legislation, policies, and resourcing. Cross-scale governance interactions are crucial for addressing issues that transcend the local scale, for example, to address the distant indirect influences of activities in a remote catchment. Institutionalizing “bridging” arrangements may require novel initiatives such as creating forums for dialogue between coastal stakeholders and those who live far inland and who might not even think of themselves as playing a role in coastal governance.

In recent years, attention has been focused on the role of coastal governance in building adaptive capacity in the face of climate change. Any long-term plans or decisions (e.g., infrastructure provision) need to anticipate escalating risk, cope with a wider range of changing conditions, and deal with systemic uncertainty, turbulence, and surprise. This prognosis has significant implications for coastal governance and underscores the need to move beyond traditional linear, science-based decision-making processes that seek to predict future change and resultant impacts, and then prescribe solutions. Attention needs to be focused on how coastal governance can enable communities to deal with this deepening uncertainty, reduce risk, and enable adaptation in the Anthropocene by adopting “no or low regrets” strategies (that are beneficial independent of climate change); adopting redundancy provisions, and flexible, and reversible, policies and practices; maintaining safety margins in significant public investments; and keeping open options to pursue adaptive pathways in the face of inevitable but uncertain change (Moser, Williams, and Boesch 2012; Glavovic et al. 2015). Future prospects at the coast will be shaped by the extent to which governance practices address the root causes and drivers of unsustainable practices, reduce climate risk, and overcome the institutional inertia and maladaptive practices that prevail at the coast.

**Toward best practice coastal governance in the Anthropocene**

Coastal governance practices need to take into account the distinctive features of the coast and draw on lessons from coastal management experience.

**Distinctive features of the coast**

The following distinctive features of the coast need to inform coastal governance endeavors.

The first feature is that of interconnected systems. The coast is defined by powerful and dynamic linkages and direct and indirect interactions between the terrestrial and marine realms, and between coastal ecosystems, functions, services, and people’s livelihoods. Consequently, a single, static definition of the boundaries of the coastal zone is not appropriate for all governance purposes. The geographic extent of the coast needs to be defined in the light of these interconnections and influences relevant for different governance endeavors, including enabling
institutional innovations that resolve local and distant sustainability failures concentrated at the coast.

The second feature is the immense value of coastal ecosystems. These interconnections give rise to a system that is highly dynamic, diverse, and productive, founded on ecosystems that provide services that underpin coastal livelihoods and benefit coastal communities, nations, and humanity. The value of coastal ecosystem services far exceeds that of services derived from terrestrial and marine ecosystems alone. The coast is foundational for enabling and sustaining global human development because it is the primary habitat of humanity, with proportionally more people and economic development concentrated here than elsewhere, and this proportion is growing rapidly. The coast is also the locus for innovation in the Anthropocene.

Third is pervasive and intensifying unsustainable practices. Coastal ecosystems are among the most threatened on Earth, resulting in irreversible loss of ecosystem services that endangers coastal livelihoods, and human wellbeing and development prospects. The coastal sustainability crisis is thus more than an ecological crisis. Poverty and inequity are commonplace and coastal livelihoods are imperiled necessitating that the root causes and drivers of unsustainable practices be confronted.

The fourth feature is the concentration of complexity, change, and uncertainty at the coast. Addressing this crisis is challenging because of the complexity of the coastal socioecological system and the powerful and intricate linkages between natural and human-induced changes in inland, coastal, and marine ecosystems. Our understanding of this complexity is growing but remains far from complete. Uncertainty prevails about the precise nature of locality-specific change in the Anthropocene. Moreover, many coastal communities are likely to face challenges that are unprecedented in recent human history (e.g., rapid melting of arctic ice presents novel challenges for arctic communities and cultures). Coastal governance endeavors must be reframed to deal with the deep complexity, dynamism, uncertainty, and turbulence that characterize the coast in the Anthropocene.

Fifth, the coastal socioecological system is resilient but finite and subject to escalating vulnerability and coastal hazard risks. Accelerating global change, and climate change in particular, will have its most immediate and long-lasting impacts on ecosystems and human activities in coastal and near-shore marine areas due to the very strong linkages between catchments, the coast, and marine systems. The coast, and its constituent ecosystems and human communities, is resilient, but prevailing practices have transgressed critical system thresholds and tipping points and coastal hazard risks are increasing rapidly. Those already vulnerable to the adverse impacts of unsustainable practices, and especially those also exposed to flooding and coastal erosion, will have to contend with increasing sea level, ocean temperatures, and acidity, along with other climate change impacts. Coastal communities are therefore on the frontline of the sustainability crisis in the Anthropocene.

Finally, business as usual is untenable and transformative change is imperative. Traditional community-based coastal management efforts have not been able to withstand the impacts of globalization and Westernization. Over five decades of dedicated and widespread coastal management efforts have not stemmed unsustainable practices globally. Business as usual is fatally flawed for addressing the foregoing features of the coast and is indefensible given the reality of and prospects in the Anthropocene. A paradigm shift in coastal governance thinking and practice is necessary.
Coastal management has evolved rapidly in recent decades and builds on much longer standing efforts. There is growing recognition of the distinctive features of the coast and best practices in coastal governance (Burbridge, Glavovic, and Olsen 2012; Cicin-Sain and Knecht 1998; Glavovic et al. 2008; Glavovic 2013b; Kay and Alder 2005; Stojanovic, Ballinger, and Lalwani 2004). Despite this recognition by coastal scholars, and even rhetoric to this effect in coastal management provisions in diverse coastal settings from the international to local level, prevailing practices tend to prioritize private, short-term interests and economic considerations over longer-term concerns about public safety and the ecological, cultural, and social dimensions of coastal sustainability. Consequently, unsustainable practices prevail.

Best practices for transformative coastal governance

A transformative praxis of coastal governance for sustainability needs to be framed by and take account of the distinctive features of the coast, founded on the following best practices.

People-centered and empowering

Geared toward the needs and wellbeing of current and future generations, transformative coastal governance resolves conflicting interests and empowers coastal communities so that vulnerabilities are reduced and adaptive capacity, resilience, and sustainability fostered. It is framed as a capability building process for all governance actors. Particular attention is focused on sustaining coast-dependent livelihoods and distinctive coastal cultures and lifestyles. A people-centered approach recognizes that coastal communities are reliant on diverse, healthy, and productive coastal ecosystems. It secures the coast as a public heritage.

Ecosystem-based

Coastal governance best practice enables alignment of otherwise incongruent ecosystem and administrative jurisdictional boundaries through ecosystem-based approaches. Coastal ecosystems are managed to sustain ecological functions and ecosystem services. Biophysical limits, assimilative capacities, and ecosystem and resource constraints are understood and respected and ecosystem functions and services secured by, among other things, establishing marine protected areas, sustainable use of renewable coastal resources, avoiding irreversible impacts from nonrenewable resource use, integrated waste and pollution control, and taking into account the powerful physical processes (e.g., currents, tides, and waves) and fluxes that take place in the coastal zone.

Participatory and collaborative

No single coastal stakeholder or actor from government, civil society, or the private sector can secure sustainability outcomes on their own. Inclusive, meaningful opportunities for stakeholder and public engagement in governance processes and decision-making is key to building strategic and practical partnerships, sharing information, developing common understanding and a shared vision for the future, pooling resources and capabilities, and institutionalizing and adapting governance provisions and practices. Authentic participatory and collaborative processes resolve conflicting interests and enable effective partnerships that empower coastal communities and endure over the long term to facilitate coastal sustainability.
Holistic and integrative

Best practice coastal governance is holistic, recognizing the interconnectedness of the coastal socioecological system and the need to take into account powerful, dynamic, cumulative, and synergistic interactions across multiple scales. Integration is enabled iteratively and progressively. It does not replace the need for sector- and interest-based management but invokes institutional mechanisms that enable cooperation, coordination, and, ultimately, scale-relevant vertical and horizontal integration. Complementary bottom-up and top-down measures engage key actors from government, civil society, the private sector, science, and the media in a locally relevant and locally informed manner, recognizing cross-scalar interactions. Account is taken of the timescales relevant to ecosystem functioning and sustainability as well as the shorter timescales relevant to business, political, and project cycles. Attention is focused on meeting the needs of the current generation without foreclosing options for future generations to meet their own needs.

Visionary, strategic, and contingent

Business as usual is unsustainable. Visionary leadership and authentic community engagement enable the paradigm shift in thinking and practice required to chart new pathways in the Anthropocene. A strategic focus enables progress on pre-eminent community concerns and issues, taking into account institutional constraints and capabilities in agenda setting (i.e., be realistic and focus on a few issues that can be done well rather than being overambitious and do many things poorly). Coast-dependent activities and livelihoods (e.g., fishing, ports, and harbors) are prioritized. Coastal governance endeavors are tailored to account for locality specific ecological, cultural, and livelihood diversity at the coast.

Risk averse and precautionary

Risk avoidance and mitigation measures are proactively adopted to reduce vulnerability and build resilience in the face of escalating coastal hazard risks instead of relying on ad hoc postevent response and recovery measures. Particular attention is focused on reducing exposure and vulnerability to coastal hazards, especially those compounded by climate change. If the consequences of a decision are uncertain and potentially dangerous, preventive actions are undertaken even if there is scientific uncertainty about whether or not detrimental impacts will occur and, in the absence of scientific evidence, the burden of proof falls on those advocating the policy or action that may cause harm.

Deliberative and reflexive

Deliberation is a noncoercive process of information sharing, reflection, dialogue, and negotiation over societal values, preferences, and opinions. It is foundational for coastal governance in the Anthropocene. Albeit contested, time-consuming, and resource intensive, deliberative governance builds the community capabilities necessary to understand and address coastal challenges better. Reflexivity refers to critical self-reflection and self-correction which are crucial qualities to develop in the face of the adversity, uncertainty, surprise, and conflict that prevail at the coast. Deliberative and reflexive modalities of governance enable intentional community reflection on current circumstances as well as future prospects, the conscious charting of pathways that are attuned to changing circumstances over time, and the
local and distant drivers of sustainability failure that are concentrated at the coast (Figure 10).

In the long run, these coastal governance best practices need to be mainstreamed into day-to-day planning and decision-making. Hence, it is imperative to reframe and underpin livelihood choices and business practices, and technological development and application, with institutional innovations that facilitate transformation for coastal sustainability. Support and commitment by key governance actors from the highest level down are necessary to build and institutionalize a governance culture of innovation, compliance, and enforcement that fosters sustainable coastal development in the Anthropocene.

Charting pathways to coastal sustainability in the twenty-first century

Unsustainable practices are pervasive, many coastal livelihoods are already precarious, and coastal risk is escalating. Achieving the requisite paradigm shift in thinking and practice, however, poses a fundamental challenge to business as usual and is likely to be strongly resisted by those who benefit most from maintaining the status quo. It remains to be seen if coastal communities will chart new pathways toward sustainability or if seemingly unstoppable trajectories of cumulative demographic, development, and environmental change will be foisted on them. The social benefits of anticipatory strategies that chart new pathways are likely to far outweigh the costs of imposed change. Far-sighted leadership and governance innovations will be needed to transform myopic practices that undermine adaptive capacity, resilience, and sustainability.

Coastal communities need to reconcile the contending governance imperatives of stability and predictability on the one hand, which is prone to rigidity and path-dependent maladaptation, and, on the other hand, flexibility and nimbleness to anticipate and respond to changing circumstances. Maintaining the status quo is unsustainable in the long run, but radical change in the short term could be disruptive, socially unacceptable, and paradoxically impose an unfair burden on those most vulnerable to the adverse impacts of prevailing practices. “Windows of opportunity” to trigger transformative governance innovation can open up, for example, after coastal disasters, but waiting for such opportunities may be futile because experience shows that recovery efforts often re-entrench pre-event vulnerabilities.

Despite mounting evidence about the need to chart a new course, coastal communities find it difficult to build consensus on the need to depart from business as usual – what course ought to be charted and how best to implement it. Locally relevant anticipatory strategies need to be tailored for changing conditions and possible future scenarios. Choices in the short term can be geared toward “no or low regret” outcomes while retaining options for future generations. The relevance and feasibility of local adaptation pathways are likely to be increased when triggers for change have social impacts salient to local people and when pathways resonate with coastal stakeholders.

Transformative change challenges prevailing business and technology and underpinning societal values, institutions, and practices. Profound societal change has occurred in the past, for example, the abolition of slavery, but it invariably involves protracted struggle to overcome formidable obstacles. Deliberate exploration of alternative coastal sustainability pathways is urgently needed. New markets need to be created and alternative governance strategies mobilized. Safe arenas need to be created for communities to experiment with
alternative ways to implement the coastal governance best practices outlined above. In so doing, coastal communities can build shared understanding about the limits of prevailing practices and the opportunities created by alternative pathways. Institutional support, including government support, will be needed to facilitate the diffusion and mainstreaming of emerging innovations. Ultimately, coastal governance practices that build adaptive capacity, resilience, and sustainability need to become progressively more people-centered and empowering; ecosystem-based; participatory and collaborative; holistic and integrative; visionary, strategic, and contingent; risk averse and precautionary; and deliberative and reflexive.

Cognition and spatial behavior

Daniel R. Montello
University of California, Santa Barbara, USA

A core goal for geographers is to describe, predict, and explain human activity on the Earth. The concept of spatial behavior highlights the geographer's focus on the spatial and temporal aspects of this activity – where people go to carry out particular activities at particular times, and how they travel there. Because the smallest cohesive unit of human spatial activity may be one trip carried out by one person at one time, some geographers study human activity at the level of single trips by individual people rather than groups of trips or the activity of groups of people. In contrast, most studies by human geographers traditionally take a group approach, analyzing activity at the level of neighborhoods, cities, institutions, cultures, and so on. In the 1960s and 1970s, what was then the new individualistic approach to understanding human geography came to be known as behavioral geography.

Historically, this turn toward understanding human activity at the disaggregate level that was at the heart of behavioral geography led relatively directly to the further idea that human activity should be understood in terms of human beliefs and reasoning. From the inception of behavioral geography, scholars realized that individual people are not passive agents in the world but active decision-makers who reason about behavioral choices. This reasoning, it was assumed, would not be based upon actual properties of the world and the individuals, but upon people's beliefs about properties of the world and themselves. That is, behavior is based on the subjective or perceived world. The subjective world consists of beliefs about spatial properties, such as location, distance, direction, connectivity, and containment. It also consists of beliefs about nonspatial properties, including temporal properties and thematic properties, such as what objects and events are in the world, what their positive or negative hedonic qualities are (i.e., their potential as resource or hazard), what preferences and abilities a person has, and so on.

Human beliefs and reasoning are part of the study of cognition, and behavioral geographers focusing on cognition are sometimes said to be doing cognitive geography. (Other behavioral work is not specifically cognitive but does focus on the behavior of individuals.) Cognitive geographers participate in a multi- and interdisciplinary scholarly endeavor, in terms of theories, concepts, and methods. Besides connecting with the work of other geographers, such as those in economic geography, human–environment relations, and cartography and geographic information science, they connect directly with the work of psychologists, including those in cognitive, environmental, perceptual, social, and developmental subfields. They also connect with the work of other cognitive scientists, including those in computer science, philosophy, linguistics, and neuroscience, and other social-behavioral scientists and scholars, including those in sociology, economics, anthropology, animal behavior, and planning and architecture.
Several concepts are basic to understanding cognition and spatial behavior. **Sensation** is the first response of the nervous system to stimulation from the world. Sensory receptors transduce patterned world energy, such as light or chemical, into patterned nervous system energy, which is electrochemical. A widespread misconception is that humans have but five sensory modalities; depending on how one slices it, the correct number is at least eight or nine, and includes vision, hearing, smelling, tasting, pressure and texture sensing, temperature sensing, kinesthesia (limb position and movement), and vestibular sensing (linear and angular acceleration). Pain is sometimes considered a sense. To (sighted) humans, vision is probably most important for sensing the spatiality of the world, but hearing, kinesthetic sensing, and vestibular sensing all play important roles. Senses like smell and texture and temperature sensing are important for place or feature identification, but play a limited role in humans for sensing spatiality. One can detect the direction of the wind or the sun on one’s face, which sometimes provides a useful cue to heading or travel direction.

The organization of sensory input into meaningful impressions of oneself and of the world, as influenced by prior beliefs, is **perception**. In commonsense experiential terms, the environment as perceived is three-dimensional with oneself in the center, and detachable objects and events against a stable background. The perceived world has varied sensory qualities, such as colors, tones, and so on; presents information redundantly (e.g., different depth cues typically coincide); is incompletely apprehended from a point of view and point in time; demonstrates constancies; and tends to be perceived in terms of meaningful and familiar objects, events, and settings. **Constancies** are the phenomena wherein entities appear to stay the same even as the sensory information they offer changes radically. A long-standing puzzle for perception theorists has been to explain constancies in the face of our locational perspective from a single place and time. How does a swinging door appear to remain rectangular even as its outline on the retina changes shape?

Perception is considered to be part of the larger topic of **cognition**, which is about knowing and knowledge (believing and beliefs), and also includes thinking, learning, memory, concepts, imagery, language, and reasoning. The focusing or directing of cognition is **attention**. Attention is controlled internally, as when you intentionally retrieve a certain belief from memory or try to listen to a particular speaker, or externally, as when a loud sound or colorful building captures your attention (the degree to which stimuli attract attention is called **salience**). Some types of cognitive processing require explicit attentional resources – they are said to have **capacity limitation** and are readily subject to **interference** by distracting tasks. Attempting to find your way in an unfamiliar environment is an example. But at the same time, other cognitive tasks require little or no attentional resources. Following your typical route to work each day is an example. Walking around without running into walls is another.

Cognition clearly influences and is influenced by **emotion** (affect), as when certain mental images lead to emotional states or certain emotional states motivate one to focus attention on certain aspects of the world. Although human emotions can be complex and nuanced, at their core is the central component of **evaluation** or hedonic tone – a positive or negative response to beliefs about the world. The results of coupling beliefs with affective states, possibly leading to behavioral intentions, are known as **attitudes**.

As we described earlier, geographers are interested in cognition primarily because of its links to behavior. **Behavior** is potentially observable,
goal-directed body movement; it is sometimes called action or activity. Behavior is goal-directed in that its purpose is to achieve some end, such as getting to a place, obtaining a resource, or avoiding a hazard. It is not an internal mental state, such as thoughts or moods, although it is profoundly interrelated to them, as we have noted. In fact, the relationship of behavior to cognition (and emotion) provides a large and complex set of issues for ongoing research and theoretical debate in several fields. That said, behavior is clearly influenced by cognition, if not entirely determined by it. Sometimes overlooked is that cognition is also influenced by behavior, as when people travel about in order to gather information about their surroundings.

Just as behavior is not equivalent to internal mental states, it is not equivalent to neurological states of the brain or the rest of the nervous system. The relationship of the mind and brain is the profound and very old mind–body question in philosophy. Briefly, this asks, what is the nature of mind (experience, awareness, soul, spirit), the nature of body (brain, body, physical world), and their relationship? There are many highly developed philosophical views on this question over the centuries. Many behavioral and cognitive scientists believe the mind emerges from the action of a brain in a body, living in a physical and sociocultural world. Thus, the mind requires a brain but is not reducible just to the brain. Still, without committing to the strong reductionism that equates mind and brain, it is evident that we learn more about the mind (and behavior) by better understanding the brain. In the past two or three decades, there has been a great increase in research on the neuroscience of cognition, much of it fueled by advances in brain imaging technologies, especially fMRI (functional magnetic resonance imaging). Such research attempts to relate patterns of activity in various regions of the brain to particular cognitive states, such as certain reasoning styles or content. Cognitive neuroscience has made substantial contributions to our understanding of the cognition of space and place over the last couple decades, and such studies are just now beginning to appear in geographic literature. We can expect to see the influence of neuroscience grow in the discipline of geography, as it is doing in nearly every other field that studies human mind and behavior.

**Empirical methods for studying cognition and spatial behavior**

As in other problem domains within geography, researchers who study cognition and spatial behavior need methods to observe and measure their phenomena of interest. The major approach to such methods in the study of cognition and behavior has been observing and recording the behaviors of research participants, individually or in groups. Other useful methods include examining secondary archives, including data mining of the Internet and social media. Physical traces can support inferences about where behaviors occurred and what people believed about something; these physical traces may have been intentionally or unintentionally created. Computational modeling, including robotics and other forms of artificial intelligence, continue to shed light on cognition and spatial behavior. During the late twentieth century, neuroscience methods became available for studying brain activity during ongoing thought in conscious, nonclinical respondents. Finally, a truly geographic approach to studying cognition and behavior should involve thorough analysis of the environment, whether natural or built, and any informational material involved in cognition and behavior (such as cartographic maps, photos, texts, etc.).
Recognizing this methodological diversity, it can still be noted that behavioral methods are the dominant way geographers study cognition and spatial behavior. These can be based on verbal or nonverbal behaviors, and include where people travel and along which routes, where and at what they look or point, what they draw, and what they say or write. Some behavioral geographers focus on the observed behaviors themselves as their phenomena of interest. For instance, some geographers record daily commuting trips without considering what people believe about their trips or why they think they make them. Other geographers with more cognitive interests typically make inferences about thoughts and beliefs from the observed behaviors. Either way, one can broadly distinguish behavioral methods involving the nonmanipulated observation of ongoing behavior from those that ask people to explicitly express their beliefs. The latter are called explicit reports: whether written, drawn, or spoken, these expressions are behaviors. Explicit reports are used to study people’s beliefs about themselves or others, about places or events, about objects or activities; any of these beliefs can include beliefs about spatial properties or attributes. When providing data via explicit reports, research participants know they are supplying information about their beliefs to a researcher, and these beliefs must be consciously accessible to the participants. Explicit reports can be further distinguished as tests, which generate responses that are evaluated for accuracy, or surveys (polls, interviews), responses to which cannot readily be judged in terms of accuracy or whose degree of accuracy is not of central interest to researchers (although truthfulness is). That is, surveys generally assess opinions, preferences, or personal experiences rather than knowledge. Of course, the explicit reports used to study spatial cognition are more often tests than surveys, but other cognitive geographers use surveys frequently.

Sketch mapping

A widely used method to obtain data for the study of cognition and spatial behavior is having research participants sketch maps (or construct physical models, etc.) of places or regions. Sketch mapping is one of the most straightforward ways to find out what people believe about spatial layouts at any scale, and perhaps hundreds of studies and thousands of informal demonstrations have collected sketch maps. But as with other open-ended methods, the ease and simplicity of collecting sketch maps is not matched by easy and simple coding and analysis. In the end, the questions you want answered by the sketch maps should determine how you code and analyze them – there is no omnirelevant approach. Types or specific instances of features such as paths or landmarks can be counted. Spatial properties such as distance or direction can be measured. The orientation of the sketches can be coded, as can their drawing style, or the presence or absence of particular verbal labels. The challenge of unambiguously identifying map features and making comparisons across individuals or groups can be made easier if the sketching task starts with more structure than just a blank sheet of paper or blank computer screen. Cardinal directions, distance scales, road networks, or mountains and water bodies can be present at the start. A list of features to be located on the map can be provided, allowing the researcher to focus on the location of placed features rather than whether they are included at all.

Scaling

A diverse set of explicit-report techniques used to study spatial cognition is known as scaling.
When scaling, research participants directly express their beliefs about quantitative properties, meaning properties that are not just classified but rated or estimated at a metric level of measurement – interval or ratio. Scaling derives from two methodological traditions within the history of research psychology: psychophysics and psychometrics. Psychophysical scaling originated during the nineteenth century. It requires participants to estimate quantities of a property that researchers relate to values of objectively measured quantities. For instance, participants can estimate distances, directions, or sizes. A specific example would be asking someone to estimate the distance between two cities in miles. Psychometric scaling, in contrast, originated during the early twentieth century. It requires participants to estimate quantities of a property that cannot be compared directly to objectively measurable quantities. For instance, participants can quantitatively express attitudes, abilities, preferences, or moods. A specific example would be asking someone to rate how much they like different cities on a scale from 1 to 10. Both psychophysics and psychometrics demonstrate persuasively that subjective mental states in humans can be scientifically studied.

Values generated using scaling techniques can be statistically interpreted as individual variables describing individual entities, such as the area of a city, or relational variables describing pairs of entities, such as the distance between two cities. A sophisticated way to analyze scaling data, called multidimensional scaling (MDS), however, provides a way to analyze and interpret values concurrently across an entire set of entities of interest. To understand this technique intuitively, imagine using a ruler to measure distances on a map between pairs of points representing cities in order to create a traditional mileage chart: a matrix of distances between pairs of the cities. MDS effectively reverses this procedure (computationally) to create a configuration of points given only the matrix of pairwise distances between cities in a given set. In fact, MDS algorithms can generate metric configurations from nonmetric input, such as ranks of distances, instead of metric distances, and other spatial properties such as directions can provide a basis for MDS. Importantly, when the separations between points represent dissimilarities between the entities rather than literal distances, so-called semantic spaces can be created that use space metaphorically to represent meaning with any types of entities as a spatial configuration.

Cognitive maps and mapping

The concept most central to the study of cognition and spatial behavior is the cognitive map. Downs and Stea (1973, 9), in the introductory chapter to their influential edited collection, defined cognitive mapping as “a process composed of a series of psychological transformations by which an individual acquires, codes, stores, recalls, and decodes information about the relative locations and attributes of phenomena in his [or her] everyday spatial environment”; the stored information is the cognitive map. Cognitive maps are fundamentally idiosyncratic to individuals but are partially shared among groups of people. The notion that mental representations of the environment guide behavior may be found in the academic literature at least as long ago as the early twentieth century, but the specific term “cognitive map” is attributed to the animal behaviorist Tolman (1948) to explain the behavior of his rats in a tabletop maze.

The concept of the cognitive map is a metaphor, suggesting that mental representations of the environment are like cartographic maps in the mind. Many other metaphors for this
Cognition and Spatial Behavior

Concept are possible and have been suggested by various scholars, such as imaginary map, mental model, or cognitive collage. But like any metaphor, the source domain of cartographic maps may not capture the target domain of environmental knowledge perfectly; research literature has discussed this issue at length. Both cartographic and cognitive maps are representations that contain spatial and nonspatial information, both are selective, both distort properties of the world, both encode from different spatial perspectives, both represent features on a continuum of abstractness (from relatively iconic to relatively arbitrary), and both serve various functions beyond just guiding navigation. The metaphor can be quite misleading, however. The cognitive map is not a unitary and uniform representation, contrary to the idea of a “mental picture” in the mind. It is a collection of pieces (separate representations) that are not continuously integrated with a constant or continuously varying scale. The cognitive map derives from multiple sources and is mentally represented in various formats and perspectives. The pieces that make up the cognitive map are not mutually coordinated, at least not completely, and they may express spatial beliefs that do not follow a Euclidean metric or any metric geometry at all. While cartographic maps can certainly stimulate emotional responses in map users, cognitive maps themselves incorporate emotionality, such as attitudes of fondness or fear toward places.

In the end, aspects of evolution and learning shape beliefs and decision-making to generally support adaptive behavior, leading people to be spatially oriented, travel efficiently, make rewarding choices and avoid harmful ones, and communicate effectively. In this regard, the idea that internal mental states and processes mediate observed spatial behavior leads us to see geographic beliefs and reasoning as functioning to organize, direct, and enrich experience. But early in the scholarly history of this domain, behavioral researchers also recognized that the subjective world may deviate greatly from the objective world and that beliefs can be mal-adaptive. Spatial knowledge includes beliefs that are in error relative to objective reality. These errors have both systematic (consistent) and random components. Researchers study errors as a way to understand several aspects of spatial knowledge, including its content, its resolution, how it is structured and processed in the mind, and how it relates to emotion and behavior.

Landmarks

An important component of people's knowledge of the environment is the landmark, which in general terms is a feature or object in the environment that is relatively distinct and can be noticed and remembered. People use landmarks to recognize places and orient themselves, and to communicate this with other people. In more sophisticated terms, landmarks can express a symbolic meaning for a place, serve as cues for actions, or function as reference points around which place knowledge more broadly is mentally organized. Although we usually think of landmarks as providing a key to location, in many cases, it is our knowledge of a landmark's location that provides the context to disambiguate its identity as a landmark in the first place. And even though landmarks are often caricaturized as prominent point-like features (the Eiffel Tower!), they are often extended features that are line-like or areal, especially at particular spatial scales. Even acknowledging how common it is that people orient themselves by visually (or via other senses) recognizing the environment, it is important to realize they often do it by recognizing entire scenes within the visual field, perhaps without being consciously aware they are doing it. Such “landmarks” are not useful as
part of verbal route directions the way landmarks as distinct and discretely labeled features are.

**Regions**

Another important structural component of spatial knowledge of the environment at any scale is the areal (two-dimensional) concept of *regions*. Long studied by geographers and used by them to organize their understanding of the Earth’s surface, regions are central to the spatial thinking of laypeople as well. Regions break a continuous Earth surface into discrete pieces, essentially spatial categories. They are bounded, and the boundaries vary in their precision or vagueness, and in their permeability to matter, energy, and information. Furthermore, regions are often organized hierarchically, with regions at different levels of status (such as size or power) connected to each other in relations of containment. This allows hierarchical reasoning, wherein spatial relations between places are inferred from relations between the regions to which they belong, rather than stored directly (Stevens and Coupe 1978). More subtle models of hierarchical reasoning suggest that locations are inferred by weighting combinations of coarse regional membership and precise metric location.

There are various types of regions in geography. *Cognitive regions* (also called perceptual regions) are informal regions in the mind, socially/culturally shared to varying degrees. A diverse set of behavioral phenomena has been offered as evidence for regional organization and hierarchical reasoning, including systematic errors in direction or distance judgments, particular patterns of response latencies to answer questions about spatial relationships, systematic ordering of sequences of recalled places or features, and more. Friedman and Brown (2000) collected estimates of cities’ latitudes to show that people organize their knowledge of spatial relations at the continental scale in terms of regions (they termed them *cognitive plates*) that compress spatial relations within the regions but exaggerate them between regions. Furthermore, the separate regions can be mentally shifted independently of each other, producing distinct patterns of distorted knowledge (see Figure 1).

**Environmental spatial learning and development**

Any process of systematic change over time may be called *development* or *evolution*. Processes of change are of interest across the discipline of geography. They occur at any temporal and spatial scale and for entities at many levels of analysis, including individuals, cultures, institutions, ecosystems, species, and landforms. Cognitive researchers in geography are most interested in *ontogenesis* (ontogeny), the development of cognition from an individual’s conception to his/her death (also called child or lifespan development), and *microgenesis* (microgeny), the development of cognition over shorter time periods from initial exposure to new information or new situations to later states of familiarity.

An important distinction for those studying ontogenesis and microgenesis is that between *learning* and *maturation*. Learning refers to relatively permanent change in the content, structure, or processing of knowledge due to specific cognitive experiences such as those involving new information or semiotic representations, not physical experiences such as those involving illness, injury, or exercise. Maturation is the unfolding of innate change processes over time, which do not require specific environmental experiences (but usually require general experiences, such as adequate nutrition). Of course, while learning occurs as part of both developmental processes, maturation typically
Figure 1  Estimated latitudes of cities in North America, Europe, and North Africa, ordered left to right from cities judged most northerly to cities judged most southerly, and plotted against actual latitudes. The pattern reveals subjective latitude compression within regions, exaggeration between regions, and north- or southward shiftings of cities in certain regions. Source: Friedman and Brown (2000), Fig. 2. Copyright American Psychological Association. Reprinted with permission.

does not take place within the limited time periods of microgenesis, which often occur within as little as seconds or minutes. Nonetheless, the nature of an individual’s learning is strongly linked to his or her maturational development, as when older children can learn more complex spatial layouts than younger children can in the same exploration period.

Commonly, theorists studying change of any type in any system contrast stage and continuous models of development. Stage models propose that change occurs in qualitatively distinct episodes or periods, each stage having a coherent theme of interrelated events or abilities, with relatively abrupt transitions between stages, and an invariant sequencing of stages (although the timing of transition may vary). Continuous models oppose this idea, suggesting that change occurs relatively continuously rather than in discrete stages, and is more accurately described
as quantitative rather than qualitative in nature. Although the contrast between stage and continuous models is intellectually fruitful, it is typically ambiguous to choose between them definitively, in part because processes that appear discontinuous at one scale of analysis appear continuous at another.

Scholars study a host of specific aspects of cognitive change, but central to those studying geographic spatial cognition is the issue of how children and adults organize their understanding of location on the Earth’s surface, both in thought and in communication. This is the topic of reference systems (sometimes called frames of reference). As geographers know well, all locational information is relative; reference systems are the ways that locational statements are defined or anchored. These include the precise and quantitative systems familiar to surveyors and geographic information scientists, known as coordinate systems. Cognitive geographers are usually more interested in the approximate and qualitative systems mostly employed by laypeople. A variety of typologies of cognitive and linguistic reference systems have been proposed over the years. Such typologies usually distinguish egocentric systems based on one’s body (“front-back,” “left-right”) from allocentric systems based on something external to the body. The latter is sometimes further distinguished as being based on nearby features or landmarks that define location only very locally (“near the tree,” “at the gas station”) versus distant or global features that define location over large areas (“head toward the ocean,” “go north”); those based on global features are also known as absolute reference systems. The topic of reference systems is a rich one. Individuals of different ages clearly tend to use different reference systems, as do people differing in their level of familiarity with places. Different cultural or linguistic groups use reference systems somewhat differently; even people of the same cultural group apparently use them differently as a function of their residential environment (for instance, whether they live in flat or mountainous terrain). And a single person can use multiple reference systems in thought and language, either as a result of subtle changes in context or even with the same chain of reasoning or expression.

Ontogenesis of environmental cognition

A great deal of research for over half a century has looked at the spatial cognitive development of infants and children. Early in their life, infants develop various aspects of spatial perception, including the perception of shape, depth, size constancy, and perspective changes. Important to perceptual and cognitive changes are changes in motor behaviors, whether lifting one’s head, crawling, or walking. As infants become toddlers and young children (variously up to age 6 or so), they are typically able to travel much further in their environment and acquire richer, more extensive cognitive maps. Other research has looked at the acquisition of spatial concepts at different levels of geometric sophistication, including metric and topological properties. As young children become middle children (up to adolescence) and teenagers, they further develop their ability to plan and choose routes, and conduct organized spatial searches. Their ability to give and interpret verbal directions improves, and their understanding and use of cartographic maps increases in accuracy and complexity.

During the mid-twentieth century, the theories of the Swiss psychologist Jean Piaget and his colleagues were widely explored to explain cognitive development in children, including spatial and environmental cognition. His stage theory
of cognitive ontogenesis saw development as a biologically evolved process of adaptation to the complex, uncertain environments that children encounter. For Piaget, knowing involves actively selecting, interpreting, and constructing. Action upon the world and its effects on the surroundings is critical to knowledge development. The nature and modification of knowledge structures (schemas) can be characterized in terms of four major stages, typically taking place during certain characteristic age spans: sensorimotor (ages 0–2 years), preoperational (2–7), concrete operational (7–11), and formal operational (11+). The theory is rich and rather complicated, but in brief, changes through these stages can be summarized as cognition going from simple to complex, prelogical to logical, concrete to abstract, and perceptual/action-based to conceptual/reasoning-based. Besides his elaborate theoretical framework, Piaget’s work also provided a series of influential empirical tasks and concepts for later scholars, including object permanence, spatial egocentrism and perspective-taking, conservation, and nonmetric spatial thought.

Substantial problems have been identified with Piaget’s large body of work, including doubts about the timing of his stages, his tendency to underestimate the abilities of infants and young children, and his tendency to overestimate the abilities of teenagers and adults. Various theoretical alternatives have cast doubt upon the existence of coherent general stages of cognitive development and criticized Piaget’s relative ignoring of the roles of language, culture, and social interaction, including formal and informal schooling. Some of these alternative theories include information-processing theory, situated cognition, linguistic relativity, and conceptual nativism (see Newcombe and Huttenlocher 2000).

Microgenesis of environmental cognition

By analogy to stage theories of ontogenesis, an influential framework for understanding the microgenesis of environmental spatial knowledge arose during the 1960s and 1970s. This “dominant framework” was most eloquently expressed by Siegel and White, as described by Ishikawa and Montello (2006). It proposed that spatial knowledge in a new environment, such as when a person moves to a new city, develops over time in an invariant sequence of three stages. The first is landmark knowledge, which is not explicitly spatial at all, but merely implies recognition of distinctive features or objects. The second stage is route knowledge, which refers to locomotor routines connecting sequences of landmarks. Knowledge at this stage, at least initially, is nonmetric and organized only egocentrically or with reference to local landmarks. The third and most mature level of knowledge is survey knowledge (or configurational knowledge). This is two-dimensional layout knowledge, simultaneously representing spatial interrelations of landmarks and routes. It contains metrically scaled distances and directions, and integrates stored landmarks and routes into a unified, coordinated representation organized according to a global allocentric reference system. Taking inspiration from Tolman’s (1948) rats, the behavioral sign of survey knowledge is the ability to create novel shortcuts and detours — in short, to navigate creatively. Although presentations of this framework have never specified how much time passed between stages, they implied that the time periods would be substantial, perhaps in the order of months or years.

Some researchers have questioned this dominant stage theory of spatial microgenesis. Ishikawa and Montello (2006) describe an alternative framework, published earlier by Montello, that proposes that development is relatively continuous and quantitative, not stage-like. That is,
spatial knowledge acquisition starts immediately upon arrival at a new place, and the extent, accuracy, and completeness of knowledge continue to grow indefinitely (the exact time-course and ultimate limit of knowledge development were recognized as important research questions). This spatial knowledge includes some approximate metric knowledge right away; there is no period of pure nonmetric landmark or route knowledge. This framework does include the relatively abrupt step that separately learned knowledge of routes and regions acquired during unitary travel episodes can relatively suddenly be integrated into more complex, hierarchically organized structures in what might be considered a form of spatial insight.

Ishikawa and Montello (2006) presented a longitudinal study designed to compare these two frameworks for microgenesis. Participants rode individually with the researcher on automobile trips through a local neighborhood they were not previously familiar with, taking one ride per week for 10 weeks. Their distance and directional knowledge about the relationships between landmarks on two test routes was tested each week, and participants drew sketch maps of the routes every other week. Unexpectedly, the results, shown in Figure 2, indicated that different participants showed

![Figure 2](image_url)
very different patterns of knowledge acquisition over time, which neither framework implies. Contrary to the dominant framework, some participants acquired accurate and surprisingly precise metric knowledge after their first trip, and continued to demonstrate very good spatial knowledge throughout the 10 weeks. Contrary to both frameworks, other participants acquired little or no metric knowledge after their first trip, and even 10 weeks of visiting the site resulted in little or no metric spatial knowledge. Only a subset of participants showed marked improvement over 10 weeks, and this improvement appeared more continuous than stage-like.

Navigation and orientation

All human geographers are interested in people’s activities in space and place, and perhaps the most central example of such activity is travel between places, whether temporary, as in a shopping trip, or more permanent, as in migration (residential relocation). Perhaps the most salient aspect of travel for cognitive geographers is that people so often do it in a coordinated and efficient manner. Such coordinated and goal-directed movement of oneself through the environment is navigation. Navigation includes not just the specialized activity of professionals on ships and airplanes, but something almost everyone does many times every day, when they walk to class, drive to work, and so on. Because the literal navigation referred to here – actual body movement over the Earth’s surface – provides such a concrete and universal case of problem-solving within a complex situation, laypeople and scholars alike often speak of other problem-solving contexts metaphorically as navigation. For example, we may navigate through a math problem, a difficult text, a website, or an emotionally vexing relationship crisis.

One can distinguish two components of navigation: locomotion and wayfinding. Locomotion is the coordination of the body to the local surrounds during movement, serving to avoid obstacles and barriers, move toward perceptible landmarks, and so on. It involves processing information about the surrounding environment that is directly accessible to sensory and motor systems, and thus does not typically require internal (memory) or external (cartographic maps, etc.) representations of the environment. Locomotion takes place via various modes, whether strictly body-based or involving technologies, like automobiles or airplanes. People locomote at various speeds, facing various headings, and following various courses. Active locomotion is often distinguished from passive, usually referring to whether the movement is self-directed or not. Navigation also involves wayfinding, the goal-directed planning and decision-making part of travel. The goal of navigation is getting to a destination efficiently. Wayfinding is the set of processes by which a person strives to achieve this in the common situation where the goal is not perceptible from the person’s current location. That is, wayfinding is coordinated to the distal environment not directly accessible to sensory and motor systems. Thus, wayfinding does require either an internal or an external representation of the environment, although it may be very schematic or incomplete. Typical wayfinding tasks include choosing routes, scheduling trips, and maintaining orientation to the environment beyond the immediate surrounds.

Maintaining geographic orientation – a sense or knowledge of where you or where your destination is on the Earth’s surface – involves some combination of knowledge about location, distance, and direction. Of course, a significant wayfinding problem, unfortunately common for some individuals, is that people are not always oriented. You are oriented when you think you
know where you are or where to go, and you are correct. If you are not oriented, you may be either disoriented or misoriented. Disorientation is subjective, occurring when you think you don’t know where you are or which way to go, or aren’t sure; it is what people usually mean by saying they are lost. Misorientation is objective, occurring when you are actually not where you think you are or are actually going the wrong way. Each state often happens without the other, especially being misoriented without being disoriented. This is unfortunate, as people do not attempt to reorient if they are misoriented without being disoriented.

There are two types of processes people use to update their orientation as they move about: landmark-based updating and dead reckoning. Landmark-based updating, also known as pilotage, position fixing, or taking a fix, is based on recognizing external features or objects. Sometimes a visible (or audible, etc.) landmark is available at a person’s destination location, and the person can simply locomote toward it, a process called beacon-following. This is actually fairly rare as a case of landmark-based updating. Much more commonly, people pilot by recognizing visible landmarks in the surrounds, which in turn allows them to identify their location and heading within their cognitive or cartographic map, which then allows them to relate their current position to the locations of distal features and places. In contrast to landmark-based updating, dead reckoning, also known as path integration or inertial navigation, does not involve recognizing external features. Instead, given knowledge of one’s initial location, information about the direction and speed of one’s travel can be used to infer one’s final destination, after travel. Without specialized technology, people can sense movement direction and speed with the help of idiothetic (internal) or allothetic (external) signals. An important example of idiothetic information is the information one gets about linear and angular acceleration from vestibular sensing. An important example of allothetic information is the information one gets from optic flow, the movement of textural elements through the visual field, without recognizing specific features. Of course, dead reckoning is useful in completely unfamiliar areas, but it has some important limitations. It requires that you know the location where you started for full orientation on the Earth’s surface. And it suffers from the accumulation of error over time, which must be corrected by position fixing.

When cartographic maps are used to maintain orientation during ongoing travel, the navigator must coordinate his or her current location and heading on the map with his or her location and heading in the surrounding environment. Examples are “you-are-here” (YAH) maps or road maps used while riding as a passenger in a car. Such navigation maps exhibit orientation specificity: They are perceived and interpreted best in a single orientation. That orientation is generally “forward-up,” with the navigator’s forward heading in the surrounds represented as up on the map (assuming a vertically held map, facing the navigator). Any other relationship between the map’s orientation and the navigator’s heading tends strongly to produce misalignment effects (usually called “alignment effects” in the literature). This is the extra time, error, effort, and/or displeasure that results when using misaligned navigation maps. Travelers typically rotate detached navigation maps to keep them forward-up aligned as they change headings; digital navigation systems usually have the option of automatically reorienting in this way. Fixed YAH maps cannot be rotated in this way, and it is surprisingly common to find such misaligned maps mounted in public places. Various cognitive strategies have been identified for reasoning effectively with misaligned navigation.
maps, but the map user must recognize these strategies are called for, they must know how to use them correctly, and they must have the cognitive ability to do so. Interestingly, while the automatic forward-up realignment of maps in digital navigation systems helps most people stay oriented, it may not support the acquisition of cognitive maps of an area as well as a fixed orientation, such as north-up, does.

Distance and direction knowledge

Being oriented often requires knowing something about distances and/or directions in the environment, and effective spatial planning and decision-making more broadly typically require some knowledge of distances and directions. From a cognitive perspective, the concept of an environment implies a space that is so large and otherwise obscured by features that one can directly apprehend its spatial layout only by locomoting around and mentally integrating separate sensorimotor experiences over time. It cannot be viewed entirely from a single point, as a cartographic map allows. Thus, beliefs about distances in directly experienced environments are beliefs about distances along traveled routes. Research has suggested a variety of types of information that can provide a basis for beliefs about environmental distances, or at least that can influence judgments of distances if they do not entirely determine them. Evidence indicates that the presence of environmental features such as path intersections and segments, turns, barriers, and landmarks will typically increase subjective distances. The cognitive mechanism for this is not entirely clear. People might just mentally equate distance traveled with the number of features noticed and remembered. It appears more likely that they use prominent features to subjectively segment routes into pieces, which in turn leads to longer subjective distances on more segmented routes because of category or psychophysical scaling effects in estimation.

The presence of environmental features can also affect one’s sense of travel time, which in turn can influence one’s sense of traveled distance. Geographers often treat travel time as distance itself, insofar as they consider distance abstractly to mean any measure of the cost of overcoming the separation between places. In many cases, people undoubtedly use travel time as the relevant cost to consider when they spatially plan. This does not mean that people cognitively equate time and distance, however, only that in some situations they use time instead of physical distance to make decisions. Limiting cases show that people do cognitively distinguish time and distance, as when they realize they have not gone far when sitting in a traffic jam, or they know they have gone far while sitting for a couple of hours on a plane. But it is still quite likely, especially when people have poor access to information about their movement speed, that travel time influences judgments of traveled distance. Evidence does not suggest this relationship is very robust, however, whatever intuition suggests. And basic psychological research indicates that the relationship of events (such as the presence of features) to subjective time is not simple. Events can expand estimates of past time intervals when the events are recalled retrospectively as part of judging the interval. But events can shrink estimates of time intervals if they are the focus of attention prospectively, during travel – they can distract one from focusing on time or distance. Finally, physical effort has also been proposed to influence judgments of traveled distances, at least over relatively short extents, but demonstrations of the influence of effort are also not robust and invite severe
criticisms about the possible role of participant expectations on observed judgments (known as demand characteristics).

Knowledge of directions in the environment is also important to spatial planning, and especially central to being oriented. Given that localizing entities on the Earth’s surface is mostly a two-dimensional problem, the focus of cognitive research has almost entirely been on azimuths rather than elevations or slopes. Many studies ask research participants to point to features (with their hand or a tool) from their current location and heading, or from an imagined location and heading (“point to the grocery store as if you were at the courthouse steps, facing west”); these are often called judgments of relative direction. When exploring theoretical questions about the resolution or vagueness of spatial knowledge, researchers are most interested in random or unsystematic errors in direction estimates. It is generally correct to calculate variable errors in this case. At other times, researchers want to explore theoretical questions about bias or distortion in spatial knowledge; they are most interested in systematic tendencies to estimate directions either clockwise or counterclockwise of the correct direction. It is generally correct to calculate constant errors in this case. At still other times, researchers want to explore theoretical questions about how people differ from each other in their abilities to estimate directions; they are interested here in analyses that combine the two types of error, calculating absolute errors to do so. Properly calculating absolute errors is just a matter of taking the absolute value of the difference between estimates and correct directions. Properly calculating variable and constant errors is more involved and requires using circular (directional) statistics.

Cognition of cartographic maps and other geographic information displays

People experience the Earth and acquire geographic information, including spatial, temporal, and thematic information, from directly interacting with the world via sensorimotor systems or from interacting with some type of symbolic medium. The nature of people’s experience and the information they acquire varies as a function of the nature of this interaction. If one directly interacts with the world, they can be stationary or locomoting. If locomoting, they can be crawling, walking, or running. Their locomotion may be mechanically aided, with a bicycle, car, boat, or plane. If one interacts indirectly with the world via symbolic media, they may do so with static pictorial representations, such as graphs, maps, drawings, or photos. Or they may do so with dynamic pictorial representations, such as animations or movies. They may experience the world through natural language like English or Mandarin Chinese, whether spoken, written, sung, or signed, or formal language like mathematics, symbolic logic, or a computer programming language. Virtual reality systems may be more like dynamic pictorial representations or more like direct experience, depending on the nature of the system. Of course, people commonly experience the world through more than one of these, either simultaneously or sequentially over time. Ongoing research addresses how information from multiple sources is combined, or even whether it is.

These different ways of interacting with the world present the world and its properties differently, and likely influence the beliefs one acquires about the world. They involve different sensory and motor systems; for instance, some involve body locomotion and some do not.
COGNITION AND SPATIAL BEHAVIOR

Some present static information about the world and some present dynamic; furthermore, some present their information statically and some present it dynamically (for example, a map with arrows statically presents dynamic information). Some ways provide nearly simultaneous access to the world and others provide it sequentially, perhaps over long time periods. Indirect interaction requires the interpretation of symbol systems. The semiotic abstractness of symbols varies, ranging from very iconic (resembling what they represent) to very arbitrary (not at all resembling what they represent). Some symbols require scale translation for interpreting spatial or temporal scale, and some are more flexible in showing different scales. Different ways give different viewing perspectives on the world, ranging from horizontal to oblique to vertical. They vary in the precision with which they depict spatial properties, as well as the detail they provide.

Map symbols represent spatial, temporal, and thematic entities and properties of the Earth’s surface. That is, they express meaning (semantics) by referring (corresponding) to a portion of the Earth’s surface and the events and features found there. Cognitive map research asks questions such as how information is perceived from maps, how it is interpreted and stored in memory, how it is used to reason and solve problems, how it is used to guide behavior, and so on. An ongoing academic debate explores the degree to which map skills (interpreting, using, making maps) have an innate basis, and how maps should be incorporated into early education. But there is no question that the sophistication of different map skills develops over childhood, and in fact, that many adults struggle with various map skills. The meaning of largely arbitrary symbols, such as contour lines, can be obtuse to children and adults; iconic symbols, such as green for vegetation or blue for water, can readily mislead children and adults to over-interpretation.

Understanding spatial scale and translations between scales confuses many people, as does the proper interpretation of symbol generalizations and perspective transformations (e.g., overhead to terrain-level perspectives). The appropriate interpretation of size, distance, and direction as depicted on various projections may even vex quite a few professional geographers.

Cognitive aspects of geographic information science

Almost from its beginning in the 1980s, basic research on geographic information science (GIScience) included concerns with human beliefs, communication, reasoning, and decision-making about and with geographic and environmental information. A distinct area of study within this focus on cognitive GIScience looks at cognitive and computational geo-ontologies. The traditional philosophical study of ontology concerns the ultimate nature of what exists in reality. During the 1980s and 1990s, it became widely recognized that geographic databases and information systems are essentially computational models of reality, and at the same time, mental and linguistic representations are conceptual models of reality. Cognitive GIScientists address the possibility and desirability of increasing the congruence of these computational and cognitive ontologies.

Another central cognitive research program within GIScience continued the tradition of research on map perception and cognition, but no longer dealt only with traditional flat and static pictorial maps. Digital technologies allowed a host of new forms of geographic information displays, often referred to as geovisualizations (notwithstanding the unintended limitation this implies to the visual modality). Images need not be flat but could incorporate stereopsis (three-dimensional vision); they could include
nested images and textual annotations revealed only with interaction; they could include dynamic animations; and they need not be only visual, but could incorporate sound, touch, even smell and taste! Critically, the traditional passive consumption of maps designed by others and inflexible in appearance could be replaced by interactive user control, including variable or theme selection, slider bars, brushes, zooming, panning, and more. Spatial displays of nonspatial information that resemble familiar spaces like landscapes were dubbed spatializations. This fit in with the explicit recognition that the appearance of computer interfaces functioned metaphorically, by suggesting particular familiar domains for users. Ongoing cognitive research looks at various digital interface-design issues, whether maps on the Internet, on cell phones, on eyeglass screens, or as part of location-based services.

Natural language and space

Another symbolic medium for mentally and externally representing spatial properties is natural language. The relationship of language to thought is an old question for philosophers and social scientists. It is relevant to geographers insofar as it suggests something about cultural (linguistic) variation in spatial thought, which in turn has important implications, for instance, for the design of geographic information systems (GIS) outside a monolingual context.

Linguistic expressions often include spatial content. The spatial properties of the characters, objects, places, and events that make up narratives are often described, whether size, shape, or location; changes to spatial properties, especially location, often figure centrally in the story. Other common examples of linguistic expressions containing spatiality include instruction manuals, road signs, and giving verbal route directions. GIScientists are quite interested in entering, storing, processing, and outputting verbal geographic information in systems like general-purpose GIS, navigation systems, digital libraries, tourist systems, and more.

A variety of intriguing issues concern how language expresses spatiality. Spatial terms sometimes involve a spatial scale for their interpretation, and this scale is often provided implicitly by context. We can be “near the mailbox” or “near Mumbai.” “Near” likely refers to very different extents in these two cases. Language expresses mostly nonmetric or very imprecise metric information, such as in terms like “near” and “right” (although it can express precise information). Does this reflect something fundamental about the imprecision and nonmetric nature of spatial thought, or does it simply mean that language avoids encoding our more quantitative thoughts because communication typically doesn’t need it, perhaps because metric precision is so often perceptually available in the surrounding environment? Spatiality is expressed in nearly all grammatical classes, including nouns (“top”), verbs (“approach”), adjectives (“far”), and adverbs (“nearby”). Prepositions are an especially important and interesting case, as most deal with spatial relations, and yet they are difficult to translate – even native speakers often struggle with them. We get “on a bus” but “in a car”; we refer to “the house on the lake” as well as “the boat on the lake.” Linguistic scholars study the expression of spatial relations in prepositions in different languages and the nature of constraints on preposition use. For example, it has been shown that larger, more stable objects usually serve as reference objects for figural objects; we say the “book is on the table” not the “table is under the book.”

Probably the greatest amount of cognitive research on spatiality in language of interest to geographers has been on verbal route directions (navigational instructions). In a prototypical
COGNITION AND SPATIAL BEHAVIOR

route direction exchange between two people, the direction-giver (person G) has a series of cognitive and social tasks to accomplish as part of providing directions to the asker (person A). G must identify the identities and locations of A's start and destination. In many cases, the start is the location where the direction-giving exchange is occurring, but even then, G must become cognizant of where the two of them are, and how it relates to other locations in a cognitive map that includes the start, destination, and intervening route. (In rare situations, such as at an information help desk, a person may have “canned” directions in their mind that can be expressed without accessing a cognitive map.) After G has determined the spatial relationship of the start and destination from the cognitive map, he or she must plan a route for A; this may be presented in whole or piece by piece. G must select the information advisable to communicate to A, including which turns, street names, landmarks, and so on. G must monitor A for ongoing comprehension, repeating and/or revising instructions as necessary. To complete the interaction, G and A must achieve consensus that the directions have been understood and make sense. In live situations, gestures are critical, although they are absent from navigation systems (arrows have been described as “graphical gestures”).

Cognitive geographers have carried out descriptive analyses of how people actually give and interpret route directions. Does G choose the shortest, simplest, safest, or most aesthetic route? G must judge A's ability to handle routes with particular characteristics. How many landmarks does G include, and which landmarks are those? How much metric information about distances and directions is included, if any? How do people use gestures when giving directions? Does G show sensitivity to aspects of routes that are potentially more ambiguous? What does G mean by the common expression “you can’t miss it” and what makes G say this?

Researchers have also carried out prescriptive analyses aimed at determining how directions can optimally be generated and interpreted. Researchers have suggested many ideas as to what constitutes “good” or “best” directions, but more empirical evaluation is needed. Every question that can be asked about what people say or write when giving directions can be turned into a question about whether they should say or write those things – whether they help or hinder the traveler’s thoughts, emotions, and behaviors. Substantial research suggests that directions work better when they contain explicit reference to landmarks, especially salient landmarks at critical decision points along routes, but also along routes for course maintenance, and off or beyond routes for error correction. How much metric information should be given? How valuable are corrective or overshoot statements, considering that they require extra time and effort? How much redundancy is good? Efforts to automate direction-giving, as in digital navigation systems, struggle with two considerable complexities. First is the substantial difference among individuals and groups of individuals as to what is optimum. A prominent example of such differences that has received considerable empirical support is the distinction between route thinkers and survey thinkers. As in the theories of spatial microgenesis discussed earlier in this entry, route thinkers reason about the environment in terms of linear sequences of places and simple turns, such as right or left; their thought is one-dimensional and largely nonmetric. Survey thinkers reason about the environment in terms of a two-dimensional layout of places that supports spatial inferences directly between places, even if the thinker has not previously traveled directly between those places; their thought requires more metric distance and direction.
knowledge. As well as this and many other potentially relevant individual and group differences, a second complexity in determining optimal route directions is the large difference between particular places and routes as to what directions will work best there. This depends on a variety of factors, such as spatial scale, street geometry, street signage, architectural style, and topography.

COGNITION AND SPATIAL BEHAVIOR

Cognitive geoengineering

Martin Raubal
ETH Zurich, Switzerland

Cognitive engineering

Donald Norman (1986) invented the term “cognitive engineering” in an effort to integrate cognitive and computer science approaches to the design and construction of machines. More broadly, cognitive engineering is referred to as an interdisciplinary approach to the analysis, modeling, and design of engineered systems or workplaces where humans and technologies operate together to achieve system goals (Lee and Kirlik 2013).

According to Norman, cognitive engineering is a type of applied cognitive science. When people interact with different everyday things, such as telephones or doors, one often notices a discrepancy between psychological user variables and physical system variables. The psychological user variables include goals, intentions, concepts, and spatial and cognitive abilities. The physical system variables describe the state of the system. During task performance users must interpret the physical system variables in the context of their psychological goals and translate their psychological intentions into physical actions upon the system. The goal of cognitive engineering is to bridge the so-called gulf of execution and evaluation (Figure 1), which results from the differences between user and system states in terms of form and content. This gulf can be bridged from two sides: either the system designer moves the system closer to the user by finding better matches to his/her psychological needs, or the user bridges the gap by approximating the description of his/her goals and intentions to the system’s language. In his account of cognitive engineering as a new discipline, Norman focused on computer design in general and on the design of user interfaces in particular. A major viewpoint in the analysis was that different users may require different interfaces, even when performing the same tasks and working with the same system. Norman therefore advocated a user-centered system design, which starts with the user’s needs regarding a particular problem.

Cognitively engineered geoservices

The goal of cognitive geoengineering is to design geographic information systems and services (such as location-based services) based on the principles of spatial cognition, human communication, and reasoning (Raubal, Mark, and Frank 2013). It is an extension of the cognitive engineering approach into the domain of geographic information. Cognitive geoengineering is an interdisciplinary endeavor, involving the disciplines of geographic information science, cognitive science, computer science, and engineering. A special focus lies in human–computer interaction based on the integration and processing of the spatial and temporal aspects of phenomena. The field of cognitive geoengineering is motivated by the belief that useful and usable solutions to people’s geospatial problems can only be found by considering the cognitive abilities and strategies people bring to the spatiotemporal problem-solving process.
Geoservices are unique in the way they use data, which are related to locations in space and time, and the potential ways of processing the data with respect to spatial locations. This leads to increased complexity during reasoning with and analysis of data. Resolving the discrepancy between psychological user variables and physical system variables in the geodomain goes beyond the user interface level, because space and time are integral elements of reasoning processes, such as when people need to agree on spatiotemporal concepts or perform various kinds of spatiotemporal reasoning. People use different conceptualizations of space and time depending on the context, and these conceptualizations need to be matched between users and systems. For example, in transportation, the semantics of the term “road” can be depicted as an open way of travel whereas, in a wildlife habitat, “road” may represent a potentially dangerous border for various species. Semantic heterogeneity, that is, two contexts that lead to different interpretations of the same information (Wache et al. 2001), can lead to erroneous decisions when geoservices are used. Results of a spatiotemporal analysis can be correct for the data model of the dataset, but may not meet the user’s expectations and can therefore lead to wrong outcomes. An example using topographic data for noise abatement planning (Lutz, Riedemann, and Probst 2003) is shown in Figure 2. When determining the noise effect of roads on residential areas, those roads touching or crossing these areas must be identified. A user may have the concepts of roads and residential areas as illustrated on the left in Figure 2, whereas the system uses the representations as shown on the right. If the user is not aware of the system designer’s conceptualization she might assume that roads overlap residential areas and will thus use the dataset as input for an intersect operation to find roads crossing residential areas. Based on the system’s representation though, the user will not find any roads by doing so.

Spatial reasoning and decision-making in a spatiotemporal context include characteristics which must be accounted for during human–computer interaction. Spatial reasoning is about topology, distance, orientation, and shape with regard to objects and configurations of objects in space and time. Instead of doing exact calculations, people apply qualitative methods of spatial reasoning (Cohn and Hazarika 2001) that rely on magnitudes and relative values. The differences between wayfinding instructions as given by humans and those given by machines serve as an example in this respect. When people perceive space through different channels, they arrive at various kinds of information, which are usually qualitative in nature. Well-designed cognitively engineered geoservices will take these qualitative aspects into account in order to move closer to users.

Although also applicable to and useful for the design of static desktop environments, cognitive geoengineering has recently gained importance due to the ongoing evolution of
personalized (mobile) geoservices. Nowadays, different providers offer such services for geospatial problem-solving and by that means sell geographic information to many individual users in small quantities. Location-based services (LBS), that is, information services that are sensitive to the location of a (mobile) user, are prominent examples (Raper et al. 2007). They support users of transportation systems, inform them about the locations of nearby points of interest and friends, or help people find a new apartment or house. In the optimal case, such services are personalized, that is, they emphasize individual persons or personal details. From the perspective of cognitive geoengineering this translates into the customization and adaptation of geoservices to their users, who vary in cognitive styles, abilities, and preferences. Cognitive research helps to understand how individuals and groups of people differ in their cognition of geographic information, and its results can be used to improve the usability and efficiency of geoservices (Montello and Raubal 2012). Based on work done in the areas of psychology, spatial cognition, and user interface design, one can distinguish between three categories of cognitive user parameters: generic, group, and individual (Raubal 2009). Designing cognitively engineered geoservices also means accounting for the consequences of age and gender differences, or the effects of different background and culture. Further explanatory variables for differences in spatial cognition as part of a comprehensive (but non-exhaustive) list are genetic constitution, physiology and anatomy, sex, education, expertise, socioeconomic status, family membership, and residential environment (Montello 1995).

Examples of cognitively engineered geoservices can be found in various domains, such as navigation, tourism (mobile guides), emergency response, geosocial networking, or location-based health. Specific techniques and methods that follow such an approach include the following:

- Implementing natural-language query interfaces to allow for a more natural human–computer interaction.
Cognitive Geoengineering

- Spatializing user interfaces to account for people’s spatial experiences.
- Designing geoservices that consider user preferences for the performance of spatiotemporal tasks.
- Applying cognitive design principles to cartographic maps and geographic visualizations to facilitate people’s understanding and knowledge acquisition.
- Personalizing wayfinding services that offer customized directions based on landmarks.
- Designing geoservices for disabled people, such as for the visually impaired.

Future research directions

The further development of cognitive geoengineering requires future research along various avenues. As mobile geoservices will continue to gain importance it will be necessary to address questions regarding mobile decision-making: How do people operate in dynamic and often complex situations? What kinds of information do they need? How can such information be communicated effectively? Studies within different domains will shed light on how people actually make decisions while on the move and how these decisions are impacted by technology and its current limitations. Researchers must not only investigate and specify spatiotemporal constraints for different environments but also consider people’s interaction with mobile devices, and perceptual, cognitive, and social processes. Bridging the gap between psychological user variables and physical system variables requires further insights into the formalization of human conceptual representations. Such representations need to be integrated into computer systems so that system views will come closer to user views. This will enhance the likelihood of facilitating human–computer interaction and delivering cognitively adequate answers to the users’ spatiotemporal problems. Novel mobile sensors, as can be found nowadays in mobile phones and personal digital assistants, will help in acquiring real-time values for context parameters, such as velocity or visibility. This data feed from sensors to mobile device will support decision-making processes. Important questions relate to filtering context data for a particular user and making this filtering process adaptive to the user’s spatial and cognitive capabilities. Emerging technologies such as mobile eye-trackers can be employed for novel interaction methods based on gaze. For example, a user’s gaze history can be utilized to enhance human–computer interaction on small display maps (Giannopoulos, Kiefer, and Raubal 2012). Finally, an important research topic concerns spatial learning: it has been argued that the use of mobile navigation services may result in users losing concentration (Parush, Ahuvia, and Erev 2007). A key aim must therefore be to ascertain how the functionality of such services can be adapted so that users achieve immediate and longer-term objectives.

Collaborative resource management

Thomas Gunton
Simon Fraser University, Canada

Collaborative resource management is the delegation of responsibility for resource planning to a group of stakeholders who engage in a face-to-face dialogue to reach consensus agreement on planning and management decisions (Gunton and Day 2003). Although it can be structured in many ways, it normally commences by government appointment of a group of stakeholders to a planning committee that is given responsibility for a specified task such as preparing a land and resource management plan for a specific geographical area. The stakeholders typically develop their own terms of reference and operating principles consistent with the general direction provided from government. The process is managed by a facilitator and supported by professional experts who work under the direction of stakeholders to undertake joint fact finding and analysis to support stakeholder deliberations. The plans generated by collaborative processes are, in most instances, submitted as recommendations to be ratified by governments who retain their legislative and fiduciary obligation for final decision-making.

Collaborative resource management is emerging as the preferred model of planning in many jurisdictions in North America, Europe, and Australia by agencies such as the US Forest Service, the US Environmental Protection Agency, and many state and local planning agencies (Gunton and Day 2003; Sabatier et al. 2005). The most comprehensive application of collaborative planning to date has been in British Columbia, Canada, where collaborative planning was successfully used commencing in 1992 to develop land and resource management plans for the entire provincial land base (Gunton and Day 2003; Morton, Gunton, and Day 2012).

The collaborative model arose in response to growing opposition to the scientific model of resource management, which has been the dominant paradigm for much of the twentieth century (Yaffee and Wondolleck 2003; Susskind, Van der Wansom, and Ciccarelli 2003). The scientific paradigm relies on experts working for independent government agencies such as the US Forest Service to make decisions based on scientific principles such as sustained yield. Opposition to the scientific model is rooted in fundamental disagreements over values and goals of resource management, such as preservation versus development, that have no right or wrong answers and are beyond the capacity of the scientific management paradigm to resolve. The scientific paradigm is useful for assessing impacts of different management options but is unable to assess the validity of competing goals and values or to resolve differences among stakeholders.

Resource managers have recognized the limits of the scientific paradigm and the importance of engaging the public in resource management processes for some time. Many tools for engaging the public have been developed and tested including: notifying the public, seeking public comments, holding public meetings and open houses, appointing public advisory committees, funding stakeholders to prepare alternative plans, and using formal public hearing processes such as quasi-judicial hearings (Beierle and Cayford...
These varieties of public engagement can be divided into three basic categories: information sharing, consultation, and collaboration (Gunton, Rutherford, and Dickinson 2010). Information sharing fulfills resource managers’ statutory obligation to inform stakeholders about resource management without formally seeking stakeholder input. Consultation formally seeks stakeholder input without any obligation to incorporate the input into decision-making. Collaboration fully engages stakeholders in decision-making by an interactive process of dialogue among stakeholders to seek consensus agreement.

Advocates of collaboration conclude that the collaborative model is superior to other models of resource planning for the following reasons (Gunton and Day 2003; Innes and Booher 2010; Yaffee and Wondolleck 2003; Susskind, Van der Wansem, and Ciccarelli 2003). First, collaborative planning is more likely to produce a better plan in the public interest because it meets the diverse interests and objectives of all stakeholders by relying on consensus agreement and development of more creative options developed through interactive dialogue. Second, collaborative planning is more likely to lead to effective implementation of plans because stakeholders actively support implementation of a plan that they developed and that benefits all stakeholders. Third, collaborative planning generates additional “social capital” benefits, such as improved knowledge and skills of participants and improved stakeholder relationships that help reduce conflict and improve public decision-making.

Collaborative planning also faces challenges (Gunton and Day 2003; Frame, Gunton, and Day 2004). Collaboration requires those in control of resource management to give up their power by delegating management responsibility to other stakeholders. In many instances, resource managers may resist this change and therefore prevent a collaborative process from being created. If a collaborative process is allowed to occur, its success is contingent on participation of well-organized stakeholders representing the spectrum of society’s interests. In many cases this broad spectrum of capable and willing stakeholders may not exist. A third challenge is that the consensus rule for decision-making is difficult to achieve and may result in vague or second best solutions in order to reach agreement. The likelihood of achieving consensus is further reduced the more challenging the planning problem is and the larger the differences in values of stakeholders. Collaborative management may increase the time and cost of planning by engaging stakeholders in a complex, lengthy process.

Empirical evaluations of collaborative resource management generally confirm that the benefits outweigh the challenges (Cullen et al. 2010; Frame, Gunton, and Day 2004; McKinney and Field 2008; Morton, Gunton, and Day 2012; Scholz and Stiftel 2010; Susskind, Van der Wansem, and Ciccarelli 2003; Susskind, Camacho, and Schenk 2012; Wieble and Sabatier 2009). Evaluation studies show that consensus plans are achieved and successfully implemented in the majority of applications, collaborative planning generates social capital benefits including improved stakeholder relations, reduced conflict, and improvement of societal skills and knowledge, and collaboratively developed plans are also more likely to meet the public interest because they meet the interests of all stakeholders, are approved by democratically accountable governments, and are based on sound scientific information developed by participation of experts in joint fact finding. Overall, stakeholders who have been engaged in collaborative resource management rate the collaborative models as superior to other models of planning.
The evaluation research on collaborative resource management emphasizes that realizing these benefits is contingent on using the following best practice design and management principles (Gunton and Day 2003; Margerum 2011). First, all interests need to be represented in the planning process. To ensure that the number of participants is manageable, organizations with similar interests can be presented by one party at the main planning table. A second subsidiary planning table can be used by the common interest organizations to ensure that their delegate at the main table adequately represents their interests. Collaborative planning processes also need clear objectives, clear delineation of roles and accountability, adequate support staff, and training and financial support for stakeholders. It is particularly important for stakeholders to be supported by experts to provide sound scientific information for stakeholder deliberations through joint fact finding. Collaborative planning processes require sufficient time to reach decisions, sometimes over four years for complex management problems. Attempts to expedite the process may undermine its success. Collaborative planning requires a good facilitator and consultation through more traditional mechanisms such as open houses and public meetings with the general public, who may not be represented at the stakeholder table. Governments also need to retain their final statutory decision-making authority over planning proposals recommended by collaborative processes to provide a final review and ensure democratic accountability.

Collaborative resource management is an innovative model that shows considerable promise. Although evaluation of performance of collaborative planning is still in its early stages, the evidence to date confirms its many benefits relative to other models of resource management based on the more traditional scientific paradigm. Given the increasing popularity of collaborative planning, continued evaluation and development of best practice guidelines will be important to ascertain its strengths and weaknesses.

Collaborative Resource Management

Description and purpose

ACOGE is a private, nonprofit organization with four membership types: patrons (former chairmen of the association or individuals who have contributed one-time sizeable donation to the Geographer’s Home project), regular members (individual geographers or scholars from related fields keenly interested in geography), student members (undergraduates in geography), and institutional members. The promotion of geography as a science as well as a professional career is central to ACOGE’s undertakings. One of its practical purposes is to provide a friendly setting for intellectual interaction where geographers can introduce their research and discuss ideas concerning developments in geographical theory and practice.

Journals or major publication series

*Semestre geográfico*
*E-Boletín-ACOGE. http://www.acoge.net/e-Boletín.html*

Current activities or projects

The association’s principal activities concentrate on organizing the Colombian Congress of Geography, a biannual meeting that has been held twenty times during the past four decades (in one occasion, in 1977, this meeting was held in conjunction with the Conference of Latin Americanist Geographers (CLAG), an USA-based international organization). Since 2012, all activities of the association have been concentrated in a five-year plan designed to commemorate its semi-centennial, which takes place in 2017. Several initiatives are underway including the Geographer’s Home project; research and writing about the history of modern geography in Colombia; a comprehensive geographic treatise of the country and other books; and the Convention on Geographical Education, among others activities. But the main project is the organization of the first international convention of Spanish and Hispanic-American geography, Congreso Panhispánico de Geografía, which will be held in mid-2017 in Tunja, the city where ACOGE was founded. This project has earned the endorsement of the Spanish, Mexican, and other geographical communities, aiming at bringing interested scholars together to explore and set forth strategies to further develop geography in the Spanish-speaking world.

Brief history

Three scholars represent the phase of pre-modern geography in Colombia: Francisco José de Caldas (1768–1816), Agustin Codazzi (1793–1859), and Francisco Javier Vergara y Velasco (1860–1914). Caldas, a self-educated geographer of the cosmographic school, is generally regarded as a scholar par excellence.
COLOMBIA

and the “father” of Colombian geography. He became personally acquainted with Humboldt in Quito in 1801. The land surveys of Codazzi in the mid-nineteenth century confirmed a trend which led to the founding of the Colombian Geographical Society (1903) and the Geographic Institute Agustin Codazzi (IGAC) (1935) as government-sponsored agencies.

Academic geography at university level, however, was a late development. Since the mid-1960s, the Colombian Pedagogic and Technological University (UPTC) collaborated with the IGAC to achieve this goal. This process started in Tunja in 1967 when the UPTC hosted a small gathering of would-be geographers, conveyed there by Dieter Brunnschweiler, a Fulbright visiting scholar from Michigan State University, and Hector F. Rucinque, his Colombian liaison. The outcome of that meeting was the creation of the Association of Colombian Geographers (ACOGE).

For over four decades, ACOGE has provided leadership to build a geographic profession and to promote geography as a modern scientific discipline. Graduate seminars were taught in the 1970s by American geographers led by C.W. Minkel, a Michigan State University professor. Minkel helped students of those seminars to continue their graduate training in the USA; one of them, Hector F. Rucinque, already holding a Master’s degree from Wisconsin-Madison, would become the first Colombian ever to earn a PhD in geography (1977).

The UPTC and IGAC founded a highly qualified Master’s program in Bogotá (1983), staffed with six geographers holding doctoral degrees. Later on, but not under Rucinque’s leadership, a doctoral program was established within the UPTC-IGAC project. In general, the UPTC-IGAC formed the geographers that have built a thriving geographical career in this country, through subsequent individual projects started in the 1990s in Bogotá, Pasto, Popayán, Montería, and Cali. There are schools of geography in three private colleges as well.

Submitted by Hector F. Rucinque
Colonialism, decolonization, and modern imperialism

In her account of imperialism and the rise of totalitarianism in Europe, Hannah Arendt (1951) saw the three decades from 1884 to 1914 as the period in which the bourgeoisie became “politically emancipated.” It was an era in which the bourgeois ruling class, hitherto contained within the nation-state – “it had left all political decisions to the state” (Arendt 1951, 3) – realized that the nation-state itself proved unfit for the further growth of the capitalist economy. Expansion is everything, said the great nineteenth century imperialist Cecil Rhodes. It was precisely expansion as a permanent and all-encompassing aim of politics that, says Arendt, “is the central idea of imperialism” (Arendt 1951, 5). Imperialism, or rather modern imperialism, was born at the moment when capitalist production and an expansionary capitalism system ran up against national limits to its growth. As Arendt put it, “the process of the never ending accumulation of power necessary for the protection of never ending accumulation of capital determined the ‘progressive’ ideology ... that foreshadowed the rise of imperialism” (Arendt 1951, 23).

The original sin of primitive accumulation required by capitalism demanded other sins, and imperialism bore its name. Unlike true imperial structures, where the imperial power integrates conquered territories, the late nineteenth century imperium involved a sort of trusteeship for conquered peoples in which national metropolitan and colonial administrations were separate though bound together by relations of control and power. This classical age of empire, as it is often called, in which one-third of the globe was colonized by the competitive drives among expansionary nation-states of Europe (and Japan), stood awkwardly in relation to nationalism. On the one hand colonization reflected new nationalist aspirations of imperial powers reflected in new forms of class alliance (what Arendt called an alliance between capital and the mob); on the other hand when the nation-state appeared as an imperial conqueror it “aroused national consciousness and desire for sovereignty among the conquered people” (Arendt 1951, 7).

Politically, an empire is a geographically extensive group of states and peoples (ethnic groups) united and ruled either by a monarch or by a political oligarchy. In geopolitical terms, empire has denoted very different political and institutional forms of territorial rule: at the strong end is the extensive British Empire of the nineteenth century and at the weaker end the Holy Roman Empire, which began in the eighth century but at the time of its final dissolution in 1806 was more a city-state than a territorial empire. Somewhere in between is the Spanish empire of New Spain of the sixteenth century. These imperial forms reflect different expressions of globalization that vary in their extensivity of reach, their intensivity of interaction, their velocity of exchange and communications, and
the potential impact of geographical integration. Imperialism and empires, whether of sixteenth or nineteenth century provenance, express transcontinental flows and networks of activity, interaction, and exercise of power. Arendt is, of course, describing a distinctively modern form of empire, namely the creation and maintenance of an unequal economic, cultural, political, and territorial relationship between states and their dispersed colonies based on domination and subordination. Colonialism refers to the establishment and maintenance of rule for an extended period by a sovereign power over a subordinate and alien people that is separate from the ruling power. The colony is a territory under the immediate political control of a metropolitan-state and its emissary, so to speak, the colonial state. Colonialism is one form of, and also a consequence of, imperialism: it is defined by the means by which disparate parts of the world are subordinated to the typically national interests, drives, and dictates of a separate and distant imperial center (often in competition with other imperial centers over markets, resources, and territory). For colonies in antiquity, city-states would often found their own colonies. Some colonies were historically countries, while others were territories without definite statehood from their inception. In modern forms of empire, the metropolitan-state is the state that possesses the colony and over which it extends its sovereign power.

Colonialism

Modern colonialism in its various norms and forms extended over the period from the fifteenth to the twentieth centuries. In the New World, which had been subjected to Spanish, French, Portuguese, and Dutch colonial rule in the First Age of Colonialism, the first wave of decolonization occurred in the eighteenth century. In this regard, the so-called Classical Age of Imperialism in the last quarter of the nineteenth century was short, the first decolonizations of the second wave being achieved after the end of World War II. The two cycles of imperialism both concluded with a limited phase of decolonization followed by the rapid collapse of empires and an irresistible push to political independence. What neocolonialism as an analytical category offered was a critical sense of how this process occurred and whether it was in any sense complete.

These phases of colonization and decolonization constituted not only the making of the “West and the Rest” (Hall 1992) but also of a distinctively new and different modern world system. The new world economy that arose in the sixteenth century and thereafter differed from earlier empire systems because it was not a single political unit. Empires depended upon a system of government which, through commercial monopolies combined with the use of force, directed the flow of economic goods from the periphery to the center. Empires maintained specific political boundaries, within which they maintained control through an extensive bureaucracy and a standing army. Only the techniques of modern capitalism enabled the modern world economy, unlike earlier attempts, to extend beyond the political boundaries of any one empire. The definition of a modern world system by Immanuel Wallerstein (1977) is intended to combine the developments of the different societies since the sixteenth century in different regions into one collective development. The main characteristic of Wallerstein’s definition is the development of a global division of labor, including the existence of independent political units (in this case, states) at the same time. It is divided into core, semi-periphery, and periphery and is ruled by the capitalist mode of production.
and in normative terms a free market. There is no political center, compared to global empires like the Roman Empire; instead, the capitalist world system is identified with the global market economy.

If colonialism is an enduring relationship of domination it entails both forms of dispossession (the sovereignty of a colonized people and their indigenous political structures is compromised, typically violently, and in ways which may involve enslavement, forced removal, and subjugation) and the exercise of power by a colonizing minority that is not only convinced of its own racial and cultural superiority but also deploys forms of rule that simultaneously include coercion, persuasion, collaboration, and compromise through colonial state apparatuses. The term colonization refers to the raft of strategies and projects – from exploration, mapping, to violent conquest, pacification, occupation, state building, forms of rule, settlement, market building, mobilization of labor – entailed by typically quite different colonial enterprises in different regions in various historical epochs. Colonization, in sum, entails the constructions of cores and peripheries within a global totality, what Franz Fanon described as a world cut in two and a colonial world divided into compartments (Fanon 1963).

A useful way to think about the variety of forms of modern colonialism is by understanding the conditions of possibility for the existence and reproduction of a colony (Bernstein 1990): namely, the colonies have to be acquired territorially (often as part of a competitive inter-imperial rivalry), they have to be financed (there is always the question of cost, whether through standing armies or administrators), they have to be governed (“stabilized” through forms of direct, indirect, or autocratic rule), and they have to be made profitable (sources of accumulation and resource acquisition, and forms of labor mobilization). These conditions can be met, of course, in a variety of ways – a fact that highlights the considerable diversity of forms of colonial political economy (even within contiguous regional or continental territory). The British–ruled settler economy of Kenya in 1930, for example, looks rather different from King Leopold’s Congo in 1900.

The differing structures of colonial political economy can be mapped by using the tripartite structure developed by Samir Amin (1978) in relation to African colonies. He distinguished settler, peasant trade, and concessionary colonies. In colonies in which European settlers were central to the political economy (Kenya, for example), colonial states typically ruled directly in order to protect white interests while African cultivators were displaced and dispossessed (typically shunted into native reserves). Labor was mobilized through a combination of wage, smallholder, and tenant (squatter) labor forms, and landholding inequality along racial lines was its hallmark. The peasant colonies (Nigeria, for example) were distinguished by indirect rule (local African elites were converted into colonial bureaucrats) in which African cultivators (peasants) were effectively left intact and presided over by their own indigenous elites (so-called customary rule and law). African and European traders and intermediaries used taxes and the cash nexus to acquire the resources (cotton, cocoa, groundnuts) they needed for European markets and industries. Labor was for the most part drawn from the household. The concessionary or mine economy (South Africa) was dominated by the extractive sector in which foreign capital and migrant and coercive labor systems were distinguishing features. White and capitalist industrial interests were combined in a racialized form of accumulation, called apartheid in the case of South Africa, but the broad elements of the political economy can be
found in other colonial mine economies such as the Belgian Congo. Each of these differing colonial political economies possessed differing sorts of political dynamics and trajectories, and each left rather different postcolonial legacies.

Analyses of the reasons behind colonialism in its modern forms is, of course, a source of considerable intellectual debate and contention. The vast literature on theories of imperialism dating back to the nineteenth century (Karl Marx, J.H. Hobson, Lenin, Luxemburg, Weber, Schumpeter, and so on; see Brewer 1990 for a review) and continuing up to contemporary accounts of the post-9/11 American imperium and the war on terror, all address the complex social and political forces, all operating within a global political economy, that are in play in various colonial and imperial projects (Harvey 2005). To take, for example, the case of the late nineteenth century scramble for Africa, a raft of “driving forces” of vastly different theoretical persuasions has been identified by scholars: commercial competition and inter-imperialist rivalry, the impact of global economic recession, the demands of the so-called “second industrial revolution,” the limits of informal empire, intraregional class antagonisms, social atavism, the expanding role of finance capital (“over accumulation”), the civilizing mission, the spillover effects of the South African mineral boom, the drive of expansionary capitalists such as Cecil Rhodes, and the “political emancipation of the bourgeoisies.” All have been invoked as key to the rise of the late-nineteenth-century African partition embodied in the Treaty of Berlin in 1884 (Hobsbawm 1989). What is clear is that there are multiple imperial or colonial trajectories in which the relations between colonizer and colonized — between metropole and periphery — were complex, unstable, and to a certain degree open. That is to say, colonialism — and the operations of colonial states — was a dialectical engagement: colonial powers were in some cases weak and unable to obtain what they wanted; in others the very fact of colonization gave birth to anti-colonial nationalism; for some countries the trajectory was relatively short (in world time) punctuated by serial crises; and in others trajectories were long and relatively stable. The key themes of the quite different colonial projects have been well articulated by Jane Burbank and Fred Cooper (2010) in their book *Empires*, which describes differing colonial “trajectories.” They focus on the politics of difference, imperial intermediaries, and local compradors, the intersections among and between empires and colonies, imperial imaginaries, and repertoires of power and contention.

The danger is then to see colonialism as monolithic, in reducing the experience to vapid generalization (for example, seeing Indians or Kenyans as simply colonial subjects or as national or proto-nationalist actors). An alternative approach pursued by the so-called Subaltern School (Guha and Spivak 1988) sees colonialism as a hegemonic project fragmented as colonial rule attached itself to local idioms of power. From this experience characterized by hybrid forms of identity, of blurred boundaries, and contradictory practices, the process of colonization must necessarily look more complex than imperial domination and peripheral subordination. The colony is a particular sort of space in which, to quote Edward Said, the struggles are not only about soldiers and canons but “about forms, images and imaginings” (Said 1993, 7). Place and identities — class, ethnic, racial, gender — were all inscribed and contested in the colonial crucible, producing unstable forms of hybridity, intermixing, and dialectical self-definition. All colonial projects had their forms of “orientalism” (i.e., cultural discourses), their own cultural technologies of rule, and their
own forms of discourse, practice, and investigative modalities (Cohn 1996). These imaginative geographies (Gregory 1994) of the colonial world have produced a vast and often contested scholarship – much operating under the sign of postcolonial theory – that attempts to understand not only the complex ways in which culture is generative under conditions of colonial oppression, but also how other colonial histories can be told that depart from the totalizing vision associated with the inexorable march of capital and the advancing frontiers of western domination. Under its most robust analyses (Goswami 2004), the very nature of the colonial project takes on not simply a contingent form but exposes the contradictory ways in which colonial state space is produced and reproduced.

Decolonization

Decolonization refers to the process, often long, tortuous, and violent, by which colonies achieve their national aspirations for political independence from the colonial metropolitan power. Decolonization can be understood as the period of later colonialism but implicit in the notion of neocolonialism is the idea that decolonization was incomplete or perhaps aborted to perpetuate a form of metropolitan or imperial hegemony. The first challenge to the first wave of colonization came in 1776, as British North American colonies declared independence and subsequently the French were overthrown in the Haitian Revolution (1791–1804). While Britain maintained its Caribbean and Canadian colonies, the Napoleonic upheavals in Europe so weakened Spain and Portugal that European settlers from Mexico to Chile expelled their imperial masters. By 1825 the Spanish and Portuguese empires were dead. In the subsequent 115 years up to World War II, decolonization was limited to Cuba in 1898 and two groups of British colonies: the white settler colonies (Canada, Australia, New Zealand, and South Africa) granted internal autonomy and finally full sovereignty in 1931 (although full constitutional powers came later), and Egypt and Iraq after World War I. World War II marked the death knell for European colonization: India’s separation from the British, Indonesia’s from the Dutch, the remaining Arab mandated territories and Indo–China from the French. The independence of Ghana in 1957 marked an avalanche of liberations in Africa, although the process was not complete until 1990 (Namibia). Between 1945 and 1989, over one hundred new independent states were created.

Decolonization is a process marked by the achievement of political independence but the duration, depth, and character of decolonization movements vary substantially. In some African colonies, colonization was barely accomplished and resistance movements of varying degrees of organization and institutionalization attended the entire colonial project. In other cases, an organized anti-colonial and nationalist movement came late, accompanied by a rapid and hastily assembled set of political negotiations in which it is clear that the metropolitan power wished to hand over the reins of power with utmost expedience (Nigeria). In others it took a war of liberation, a bloody armed struggle by leftist guerillas or nationalist agitators pitted against white settlers or intransigent colonial states (as in Laos, Vietnam, and Zimbabwe).

One of the problems with analyzing decolonization, as Fred Cooper (1997, 6) notes is that the story “lends itself to be read backwards and to privilege the process of ending colonial rule over anything else that was happening in those years.” It should also be said that any account of decolonization – or for that matter neocolonialism – presumes an account, or a theory,
of colonialism itself: top-down interpretations take colonial projects at face value whereas the nationalist account denies any reality to the goal of modernization that the colonial state purported to bring. In general, decolonization is seen as either: (i) self-government as an outcome of negotiated preparation and vision from above by a colonial state apparatus; or (ii) as a nationalist triumph from below in which power is wrested (violently or otherwise) from recalcitrant colonizers (Burbank and Cooper 2010). In practice, decolonization was an enormously complex process involving something of each, shaped both by the peculiarities of colonialism itself and by the particular setting in world time in which the nationalist drive began.

There are two forms of decolonization that rest on what one might call nationalist triumph. The first is built upon social mobilization, in which a patchwork of anti-colonial resistances and movements (many of which are synonymous with colonial conquest itself) are sown together into a unified nationalist movement by a western-educated elite (Malaysia, Ghana, or Aden). Mobilization occurs across a wide and eclectic range of organizations – trade unions, professional groups, ethnic associations – bringing them into political parties and propelled by a leadership focused on racism, on liberation, and on the sense of national identity of the colony given its own history and culture. The second is revolutionary – Franz Fanon was its most powerful and articulate spokesman – in which the vanguard is not western-educated elites or indeed workers, but the peasants and lumpenproletariat. It rested upon violence and rejection of any semblance of neocolonialism. Decolonization rejected bourgeois nationalism (of the first sort); rather, as Fanon put it, “the last shall be first and the first last. Decolonization is the putting into practice of this sentence” (Fanon 1963, 30).

Both views depict nationalism as subsuming all other struggles and, hence, obscure and miss much history; both posit a true cause, as Cooper (1997, 7) puts it, in which there is little truck with opposition. Mamdani’s (1995) enormously influential book on Africa makes the important point that decolonization posed the possibility of breaking with traditional European colonial indirect rule (what he called “decentralized despotism”), in which African custom granted enormous powers to local systems of traditional (and therefore cultural) authority, to develop instead a sort of civic nationalism, in which cultural politics did not play a key role. Most African states continued the colonial model in which African colonial subjects were granted a racial equality and citizenship rights, but in which “indigenes” were simultaneously a sort of bonus. In much historiography, the nationalist road to self-government tends to take for granted the depth and appeal of a national identity. It is precisely the shallowness of such nationalisms in the postcolonial period that reveals how limited the simple nationalist account of decolonization itself is. In practice, decolonization occurred in the context of all manner of contradictions and tensions between the national question and other social questions.

There is another narrative of decolonization, which has a singular vision but from the side of the colonial state. It was the colonial bureaucracy, long before nationalist parties arose, that shaped self-government on a calculus of interest and power derived from an older conception of colonial rule (New Zealand and Canada) as a stepping stone to independence. In this view Africa, by 1947, had already been set on the road to decolonization in spite of the fact that the Colonial Offices typically saw early African leaders as schoolboys or demagogues (Cooper 1997).
Another version of the dirigiste theory is rendered through the cold calculation of money and cost. It was the decision-making rationale of accountants estimating costs and gains against the backdrop of weakened metropolitan economies after World War II that sealed the fate of the colonies.

Neocolonialism

A critical understanding of decolonization and the political forces that are assumed all point to the knotty problems surrounding political independence and neocolonialism. Kwame Nkrumah, the anti-colonial leader and first president of Ghana, defined the neocolonial condition as: “modern attempts to perpetuate colonialism while at the same time talking about ‘freedom’” (Nkrumah 1965, 41). In his formulation it was the “last stage” of imperialism because it emerged in the context of the Cold War (in which the third world became the site of proxy anti-communist struggles) and the deepening militancy of ex-colonial territories. This was no longer “naked colonialism” but rather more invisible modalities – economic, ideological, political, and cultural – in which colonial exploitation was perpetuated. For Nkrumah, control by imperial powers over nominally independent states was achieved through new forms of corporate and, especially, financial forms of capital, by a psychological dependency among third world elites, by the effects of what he called “limited wars,” and by the capitulation of African, Latin American, and Asian leadership to the hegemonic forces of the former colonial states.

While Nkrumah first gave voice to the concept of neocolonialism as an analytical device, the substance of the term was an integral part of African anti-imperialist theorizing. Leopold Senghor, Alioune Diop, and Albert Memmi all articulated similar sorts of ideas in the 1950s and 1960s. It was Franz Fanon, in particular in his searing account of Algeria and what he called “the pitfalls of nationalist consciousness,” who laid out a profound map of the forms and norms of the neocolonial condition. The Algerian war of liberation played an absolutely indispensable role in the formation of neocolonialism as a category of thought, and French intellectuals – most obviously Jean Paul Sartre – also contributed to the theorization of, in his case, French neocolonial rule and the deployment of violence (the assassination of Patrice Lumumba in particular) as its particular instrumentality.

The term neocolonialism has fallen out of fashion since the 1970s. It is quite true, however, that the broad thrust of critical development work from the late 1960s onwards – dependency theory emerging from Latin America, the calls for a new international economic order, unequal exchange theory, and the French Marxisant modes of production debate, and world systems theory (Wallerstein 1977) to take a handful of the most prominent trends in development discourse – all spoke of relations of exploitation between former colonial states and the advanced capitalist core. Indeed, any theory of imperialism, almost by definition, presumes the exercise of powerful forms of dependency among first and third world states, and to this extent the analytic core of neocolonialism identified by Nkrumah has been central to any critical account of global political economy.

More recently in the so-called anti-globalization protests – the movement of movements – the critique of corporate power, of the expanded role of finance capital in the impoverishment of the Global South, and the imperialist role of multilateral development institutions such as the IMF and World Bank, is entirely consistent in substance with Nkrumah’s account. The
revivication of neocolonialism is especially clear in the World Social Forum. First convened in January 2001 in Porto Alegre, Brazil, the World Social Forum (WSF) is an annual meeting held by members of the so-called anti-globalization movements – sometimes dubbed the “movement of movements” – to provide a setting in which global and national campaigns can be coordinated, shared, and refined. It is not an organization or a united front but “an open meeting place for reflective thinking, democratic debate … by groups and movements of civil society that are opposed to neoliberalism and to domination of the world by any capital or any form of imperialism” (http://www.worldsocialforum.info/). The WSF has grown substantially from its first meeting in Brazil.

Neocolonialism more than anything was a key marker of a certain sort of 1960s third world nationalism. Neocolonialism was a by-product of its largely African and Marxist origins, of the Bandung moment, and of the contradictions of decolonization as it unfolded in the wake of World War II and in the heart of the Cold War. For a while it was central to thinking of the theories of imperialism within a Marxist frame but it fell out of intellectual fashion. The so-called neoliberal counterrevolution and the devastating consequences of structural adjustment and economic reforms on a large part of the Global South (and Africa in particular) have given neocolonialism a shot in the arm, seen in the various forms of anti- or alternative globalization movements. There are also close affinities between neocolonialism in the Nkrumah sense and postcolonial theory, but the latter always distanced itself from the sort of determinism and historical telos that accompanied so much of Leninist and orthodox Marxist accounts of empire.

Color theory

Amy L. Griffin
UNSW Canberra, Australia

Color theory includes several sets of ideas about how colors can or should relate to each other. Mirroring the cartographic design tradition more broadly, these ideas draw from both scientific and artistic investigations of color. Today, the use of color in maps is commonplace, a result of the increasing ease and economy with which map production technologies can create it. As a type of map symbol that easily draws the attention of map-readers, its use by map-makers can greatly affect the legibility of the map as well as map-readers’ reactions to and engagement with the map. Although it is easier than ever to include color on maps, this technological ease can be counterproductive when there is a lack of understanding among map-makers of the effects of their color symbol choices on how map-readers interpret the map.

Color serves many roles on maps, ranging from the decorative to the functional, though in practice it is often difficult to separate these roles neatly. Furthermore, some cartographic treatments of aesthetics have been normative rather than discriminating, such as Arthur Robinson’s (1952) contention in The Look of Maps that the art in maps has a single purpose: to heighten the efficiency of the map’s communication. Yet, part of the “art” in cartography lies in the map-maker’s capacity to develop his or her own expressive style for effectively conveying information (i.e., a house style), and color plays an outsized role in this process. The challenges of choosing colors that are both aesthetically pleasing and effective for communication of spatial relationships are heightened by the many uses to which maps may be put and the tasks they may be asked to support. Some of the major functions of color in map design include its use to differentiate different map features or feature types; provide emphasis to particular map features; indicate all map features of a particular type; make an association with a real-world feature or another map element; signify a change in trend or condition; and capture the map-reader’s attention and improve his or her memory of the information contained within the map.

Human perception of color

What is colloquially known as “color” is produced by the interaction of the human visual system and electromagnetic energy. Electromagnetic energy can be scientifically described using several objectively measurable spectral dimensions. These spectral dimensions include hue, which refers to the wavelength of the energy; lightness, the quantity of energy; and saturation, the range of wavelengths of light, also sometimes referred to as chroma (see Figure 1). However, human perception of color cannot be perfectly summarized with these three spectral dimensions, as light with the same spectral characteristics can be experienced differently by different people and under different conditions (e.g., levels of light).

Fundamentally, the effective use of color in maps relies on a solid understanding of the human visual system and its particularities. Human color vision relies on a combination of
COLOR THEORY

Figure 1 Differences in the spectral reflectance characteristics of electromagnetic energy that correspond to different spectral dimensions of color, including approximate red, green, and blue (RGB) color values for each color swatch. Spectral simulations were generated using Nan Schaller’s Spectrum Applet (http://www.cs.rit.edu/~ncs/color/a_spectr.html).

a light source that emits light with wavelengths in the visible portion of the electromagnetic spectrum (ca. 400–700 nm); the eye and its sensory cells; and the part of the brain devoted to visual processing, the visual cortex. These sensory cells, two types of neurons known as rods and cones, respond differently depending on both the quantity and wavelength of light.
Rods respond to very low levels of stimulus, as little as one photon of light. Cone cells, on the other hand, require much brighter light to fire. This is the reason that it is not possible to see in color in very dim light. Cone cells come in three variants, short (S), medium (M), and long (L), which differ in the wavelengths of light to which they are most sensitive, though all of them respond to some degree to a range of wavelengths. Individually, they do not produce perception of the color of wavelength of light to which they are most sensitive. Rather, the perception of color is derived from the brain comparing the relative strengths of the signal from the different kinds of cones. So, for example, strong absorption by the S cones but weak absorption by the M and L cones will result in perception of the color blue. Strong levels of absorption across all three cone types, on the other hand, results in the perception of the color white. This account of color vision is known as the trichromatic theory.

Understanding that color perception is a function of the relative levels of absorption of multiple cone types leads naturally to diagnosis of the cause of color vision impairment: defective function or the absence from the eye of one or more types of cone. In other words, if the “accurate” perception of a color requires a comparison of the relative strength of signal between all three cone types, then a diminished or missing signal for one of the three cone types will lead to the map-reader perceiving a color “inaccurately.” Color vision impairment is a reasonably common disability. Though its prevalence is geographically variable, up to 8% of males and about 1% of females experience some form of the condition. It can be caused by a variety of factors, some congenital, others acquired as a result of one of several chronic illnesses, accidents, exposure to industrial chemicals, or physiological changes that the eye experiences as it ages. Therefore, it is important for map-makers to be aware of how color vision impairments may change the ways in which map-readers can see colors in their maps, and to choose colors carefully so that their maps are legible for their end users. Color confusion diagrams, which identify color hues that are likely to be confused with each other, can be used to avoid color hue pairs that may be problematic for map-readers with particular types of color vision impairments (see Figure 2). Researchers have developed a variety of software tools, such as Color Oracle or Vischeck, to assist map-makers with identifying map symbols that are likely to be confused by map-readers with different kinds of color vision impairments.

It is not just the types of functional sensory cells that a person has that influence whether he or she can see colors accurately. The spatial arrangement of cones on the retina is also important for color vision. The highest densities of cones are found in the fovea, the area directly behind the lens. While cones are present across the retina, they are greatly reduced in number outside the fovea. Rods, on the other hand, are found in most areas of the retina except the fovea. The implications of these spatial distributions for color vision are that (i) it is best in the fovea (the center of your vision where your eyes are focused), and (ii) the ability to differentiate between different colors for objects of a given size decreases as the objects move further into peripheral vision. So, if it is important that map-readers can discriminate between different colors, and the map features are small, the colors need to be more distinctly different than if the map features are large. Otherwise, the map-reader will need to move his or her eyes much more to foveate (focus on) each map feature to differentiate it from the others. In many instances, particularly for areas, because map features are tied to a geographical extent and location, it is simply not possible to make the symbols larger at the periphery than at
Figure 2  Example of confusing and accommodating renditions of qualitative color schemes, where the confusing scheme falls along a color confusion line, while the accommodating scheme crosses color confusion lines (top). The image pair at the bottom simulates what a person with deuteranopia (red–green color vision impairment) would see when looking at the confusing and accommodating schemes. The color vision impairment simulation was created using Color Oracle. Adapted from Olson and Brewer (1997, 131).
The background that surrounds a color can influence how the color is perceived. The central figures in both examples at the top are spectrally identical: a square of 30% black. However, the square on the left is perceived as being darker than the square on the right due to the tendency of a color to induce its opposite hue. Hence, the white background induces its opposite and makes the central figure appear darker. The same effect can be observed for the spectral dimensions of saturation (middle) and hue (bottom).

**Figure 3** The background that surrounds a color can influence how the color is perceived. The central figures in both examples at the top are spectrally identical: a square of 30% black. However, the square on the left is perceived as being darker than the square on the right due to the tendency of a color to induce its opposite hue. Hence, the white background induces its opposite and makes the central figure appear darker. The same effect can be observed for the spectral dimensions of saturation (middle) and hue (bottom).

A second account of color vision explains what happens to the neural signals after they leave the photoreceptors (i.e., the cones and rods) and are integrated in the opponent neurons. This theory explains the experience of a phenomenon known as simultaneous contrast, in which the surround of a color affects how it is perceived (see Figure 3). The opponent process model explains color vision as comprising the action of opposing color pairs: red/green, blue/yellow, and black/white. When one member of each of these pairs is activated, the other is inhibited, preventing, for example, the perception of a yellowish blue or a reddish green. Simultaneous contrast effects can be found in all three spectral dimensions of color: hue, lightness, and saturation. Because map symbols are rarely viewed in isolation, map-makers need to account for the effects of simultaneous contrast to reduce the likelihood that different map symbols will be confused with each other. The ColorBrewer tool (http://colorbrewer2.org) can be used to evaluate the effects of simultaneous contrast for the color schemes presented there (see Figure 4). While it is probably not possible to “control for” this effect in maps (i.e., adjust each symbol to account for its background), it is possible to select color sets in which all elements are discriminable across the range of surrounding symbols that appear in the map. The difficulty, however, of achieving this increases with increasingly small visual differences between symbols. Therefore, to ensure that all symbols are discriminable in a choropleth map, a good rule of thumb is to use no more than six or seven different classes.

**Methods for describing color: color models**

The complexities of the human experience of color notwithstanding, scientists have been
searching for ways to systematize and organize the description of color for centuries. Color models, as these organizing systems are called, are abstract systems that can be used to describe a color precisely. The complete set of colors that a given color model can produce is known as a color space, or gamut. Different color models have arisen because different methods of producing color create different gamuts – different subsets of the set of all possible colors that human vision can perceive. The CIE color model represents the complete set of colors that a standard observer can perceive under particular illumination conditions, called a standard illuminant.

One early color model with which most people will be familiar is the hue circle, which was first described by the physicist Sir Isaac Newton. The idea for organizing colors as a circle of hues had its origins in his observations during optical experiments with prisms that white light was composed of a mixture of lights of different wavelengths. A modern color model founded on similar principles of adding together light produced at particular wavelengths in different proportions, whose increments typically range in value from 0 to 255, is the RGB (red, green, blue) color model employed in many electronic devices, such as computer monitors, televisions, and scanners (see Figure 5). Because the specific hues and saturations of red, green, and blue light produced by the particular phosphors or dyes used by a device manufacturer may vary, the appearance of a color defined by a given location in the RGB color space may differ from one device to the next, giving rise to the need for color matching when colors need to be specified and seen precisely.

Another early color model that anticipated a modern color space was the hue circle described by Goethe in 1809. While Newton’s hue circle was developed by his observations of the
COLOR THEORY

properties of light, Goethe’s was derived from observations of the eye’s experiences of color, that is, human perception. In particular, Goethe was interested in the perception of the color of pigments on paper and in paintings, rather than of light emitted from a light source. Thus, his focus was the perception of reflected rather than emitted light. His model also presaged the concept of opposing colors, by developing a symmetrical hue circle in which each hue opposed another. There are two prominent modern color models that share some similarity with Goethe’s hue circle: the Munsell color space and the CMYK (cyan, magenta, yellow, black) color space. Both color spaces are based on how we perceive color from pigments rather than from emitted light.

The Munsell color space is based on perceptually uniform and independent dimensions of color: hue, lightness, and chroma (saturation). In particular, the Munsell scheme was the first to identify perceptually equal steps in these different dimensions. Of particular note is the fact that human visual perception of the change in color dimensions is not linear: a point that is perceived to be halfway on the continuum between white and black would actually have a luminance of 20% (on a scale of 0%, black, to 100%, pure white). However, because Munsell’s system is perceptually uniform, a value of 5 in his space is one that is perceived to be in the middle of white and black (his lightness scale ranges from 0 to 10). Inspection of his space reveals that human perception of color is not symmetric across the three dimensions. That is, humans can perceive more steps of some hues at a particular lightness or chroma level than at others. A major drawback of Munsell’s system in the context of making maps is that the Munsell color gamut is not necessarily the same as the gamut of the map production system that is used to produce a map. For example, while there are translators that produce approximate RGB values for a particular Munsell color, the RGB gamut is restricted (as demonstrated in Figure 5), so not all Munsell colors can be produced in the RGB color space.

The CMYK color space, like RGB, is a production-oriented color space that is also sometimes called process color, and is used in offset printing. This color model produces different colors by mixing together different amounts of pigments (inks) using the three hues and black. Because the inks are typically applied to a white background, it is called subtractive, as the color that is perceived is based on the wavelengths of light that are not absorbed by the pigments that are laid down on the paper (i.e., those that are “subtracted” from white). Depending on the particular printing device (e.g., inkjet printer, color laser printer, or offset printer), the color gamut may be slightly different. When maps are printed, particularly in large volumes on offset printers, the color gamut may be expanded by also adding one or more spot colors (a non-CYMK offset ink) to the printing process.

While the RGB and CMYK color spaces are most commonly used for specifying colors when map-makers create maps for digital and printed maps, respectively, the Munsell color space most closely matches the way that cartographers have conceptualized how color can be employed as a visual variable or as a building block for making meaning with maps. In his seminal description of visual variables, Jacques Bertin (1983) identified hue, which he called “color,” and lightness, which he called “value,” as fundamental visual variables. While Bertin discussed saturation, he merged it with hue, and did not treat it as a separate dimension or variable. Of particular note is the distinction that Bertin made about the use to which “color” and “value” could be put when constructing a map. His syntax (set of rules for matching visual variables to
data characteristics) identified “value” as being appropriate for ordinal information with the basic logic of “darker means more,” and “color” as appropriate for nominal information. Other cartographers have since described saturation as a third color variable, but its use as a visual variable in its own right is uncommon.

Color schemes for maps: logical relations between colors

Reference maps and thematic maps commonly use slightly different strategies for developing color schemes. While reference maps often use hue to represent differences in kind or qualitative differences (e.g., blue lines for water features such as rivers and brown lines for contours), the assignment of particular hues to particular feature types often draws on conventional associations that have been built up over centuries of mapping. So, for example, while the Amazon River may often appear brown when one looks at it owing to the suspended sediment load it contains, it is usually represented using a blue line or area on maps, depending on the map’s scale. Similar conventions have been developed for other types of features, though these may vary from one country to the next. For example, while most countries’ topographic maps represent vegetation using a green symbol, Finnish topographic maps use orange and white symbols for vegetation. This decision is driven perhaps by a desire to save ink, given that forests cover about 75% of Finland’s land mass. Lightness is sometimes used in reference maps to give an indication of the relative size of features. For example, minor tributaries of major rivers may not only vary in the width of the line used to represent them, but also be represented using a lighter shade of blue.

A typical symbolization challenge in reference maps, which commonly depict many different types of map features and many layers of information, is to place particular map features at the desired place in the map’s visual hierarchy. The use of a high-contrast color, such as a saturated red or yellow, often moves the feature up the visual hierarchy. This is one reason that major roads may be represented using a red or yellow line rather than a thick black line (see Figure 6).

By contrast, fewer conventional color associations exist for thematic maps, though there are a few well-known exceptions, such as maps of voting in elections, where a political party in a given country is often associated with a particular hue (e.g., blue for Democrats and red for Republicans in the United States). A map of unemployment rates, for example, could use any hue and communicate the spatial distribution effectively. What is particularly important with thematic maps is that the logical relationships in the data are matched to logical relationships in the colors used, and that this logic is based on what is understood about how map-readers perceive color. The ColorBrewer tool summarizes a body of research undertaken by Cynthia Brewer and colleagues on how to match the logical relationships in data with the logical relationships in a color scheme. It presents three types of color schemes that are commonly used in thematic maps: qualitative, sequential, and diverging (see Figure 7).

Qualitative schemes are those whose symbols vary in hue, while holding lightness relatively constant. This type of scheme might typically be used to map nominal data such as land-use types or majority race/ethnicity within an area. Within qualitative color schemes it is also possible to associate pairings or relationships between classes by using similar colors. So, for example, if a land-use map included coniferous forest and deciduous forest, both feature types might be represented with different and differentiable green hues. A particular challenge with designing
qualitative schemes is choosing colors that will not be confusing for readers with impaired color vision, as qualitative schemes by definition avoid the use of lightness, which may help such readers correctly infer ordinal or quantitative relationships in the data even when hues are confusing.

Sequential schemes are best used to represent data with ordinal or quantitative characteristics, where a goal of the map is to indicate how much of something is present in a given location. The classical sequential scheme is one that uses only lightness, with a gradient from white to black, but often sequential schemes use one hue in combination with lightness, for example, using a gradient from light orange to dark orange. Because a simple gradient, linearly interpolating between 0% of a hue and 100% of a hue, does not produce perceptually equal lightness steps, as illustrated by Munsell’s work, it is useful to begin by specifying a color scheme in the Munsell system, and then translating it to the production specification that is needed for the production environment the map will be made within, noting that the mismatch between the gamuts of the two specification systems may limit which colors within the Munsell space can be used in

**Figure 6** The use of color contrast to move a map feature up the visual hierarchy. Lightening and increasing the saturation of the blue used to represent the river features increases the contrast and lifts them above other linear features, such as roads or contours.
Figure 7  Examples of maps using (a) qualitative, (b) sequential, and (c) diverging color schemes. Sources: City of Ithaca, NY; UN Population Division, UNEP.
practical application. Because most hues are not highly saturated when they are very light or very dark, the saturation within a sequential scheme is often not constant, with mid-range lightness values having a higher saturation level than the end points (see Figure 8).

Many visualization software packages that can be used to create maps include what is known as a spectral scheme as a default symbolization option. While there is a logical ordering of hues in a spectral scheme (i.e., they are ordered by decreasing wavelength of light), there is not a logical ordering of lightness in the symbol set. This can prove problematic in maps of quantitative information, as it can lead readers to incorrect inferences about the nature of the spatial distribution of the mapped quantity. Researchers who work with other types of scientific visualization have also noted this problem, yet, unfortunately, it persists as a default symbol set in many applications. Despite the problems of spectral schemes, it is possible to use a subset of the spectral order to increase the information-carrying capacity of sequential schemes. A sequential hue–lightness transition that begins with light yellow and progresses either through orange to red or through green to blue can provide map-makers with a larger number of clearly differentiable classes, while preserving the “darker means more” logic of schemes based solely on lightness.

A final type of commonly employed color scheme is the diverging scheme. This scheme comprises two sequential schemes that diverge in opposite directions from a critical value, such as zero, a mean, or the eligibility threshold for a government program. The central value in a diverging scheme is light (e.g., white, light gray, or yellow), while the end points of the scheme are dark. These schemes may or may not be symmetrical (i.e., use the same number of classes on each side of the critical value).

Figure 8  Comparison of color schemes derived from the Munsell space that do (left) or do not (right) employ saturation transitions.
COLOR THEORY

Figure 9 Examples of bivariate color schemes: (clockwise from top left) qualitative/sequential, sequential/sequential, diverging/diverging, diverging/sequential.

These different types of color schemes may be combined when mapping multiple variables, to represent relationships between variables. Useful combinations might include qualitative/sequential schemes, sequential/sequential schemes, diverging/sequential schemes, and diverging/diverging schemes (see Figure 9). Great care must be taken to ensure that the visual logic of individual variables is appropriately represented in the final symbol set, and this may require fine-tuning of saturation levels to ensure that all symbols are clearly differentiable.

Color can also be employed persuasively, in order to amplify the memory of a map’s overt or less overt message. For example, colors can be chosen to deliberately emphasize particular elements on the map. High contrast color choices (large areas of black, red, etc.) draw the reader’s attention to particular areas of the map, often at the expense of others, and moreover create emotional associations with the map’s content.

While red symbolizes joy or good fortune in Chinese culture, in many Western cultures it is associated with danger. When cultural meanings of color are combined with high levels of contrast, they are particularly likely to evoke a high level of arousal and a strong emotional response. There is a reason that both saturated reds and black feature strongly in propaganda maps: it’s hard to feel threatened by a pastel country (see Figure 10).

COLOR THEORY

Commodification of nature

Ryan Gunderson  
*Miami University, USA*

The commodification of nature refers to the process of incorporating biophysical entities and/or information about them into economic systems for the purpose of exchanging the good or service for a profit. The notion is most commonly employed in political ecology, human geography, environmental sociology, and environmental and sociocultural anthropology. When the term “commodification of nature” is used to denote a frame for investigation or a process mediating human–nature relations, the work is typically in the Marxist tradition, whether classical, revisionist, or simply borrowing conceptual categories from the Marxian catalog. There is a direct effort in this work to denaturalize capitalism’s historically unique relationship with nature based on generalized and specialized commodity production. Emphasizing the historical character of nature commodification shows that the biophysical world has existed and can exist free from the commodity form. While all human societies have employed labor to work up nature to produce things for use and survival, nature commodification literature takes great pains to show that the current mode of production, which appropriates nature primarily to exchange for a profit, is a relatively recent social formation and, because nature commodification is historical, it is also mutable. This historical and critical approach is a unifying theme in nature commodification literature that distinguishes it from ahistorical and uncritical work on economics–nature relations. Nature commodification literature is typically directly or indirectly critical of the further expansion of the market into natural domains on environmental and/or social grounds.

The most recent integration of literature on the commodification of nature is over a decade old (Castree 2003), though it has excellent organization and typologies that are employed here in revised and updated form. This entry first highlights the theoretical origins of this area of inquiry and then outlines the basic elements and structures that comprise nature commodification. It then explores three research emphases in nature commodification literature: (i) the way commodification processes function and adapt in different domains of nature; (ii) the socioecological consequences of, and barriers to, nature’s commodification; and, more recently, (iii) the limitations of neoclassical environmental economic valuation models and their applications. It goes on to argue that there should be a scholarly effort to conceptually and theoretically link future case studies in order to achieve some level of generalizability and connect the area of inquiry.

Classical theoretical background: Marx, Polanyi, and three modern classics

Although the theoretical underpinnings of nature commodification research vary, many can be traced back to two classical frameworks put forth by Karl Marx and Karl Polanyi and/or expansions...
of these two classical frameworks, especially elaborations offered by Neil Smith, Allan Schnaiberg, and James O’Connor. Marxist-oriented social scientific research exploring the causes and outcomes of nature commodification go back as far as Marx himself. As Foster (2000) has shown, Marx has numerous applications for studying the relationships between capital and nature. Most importantly, Foster retraced a formerly underappreciated development in Marx’s analysis of agriculture. Marx incorporated insights from Justus von Liebig, a German chemist, to theorize capitalism’s role in soil fertility loss in his investigations of the town–country divide. Following England’s removal of peasants from the soil through the enclosure of common lands, rural populations were forced to flock to cities for work, leading to a lack of human waste for fertilizer and long-distance trade of food and fiber to urban centers. Marx argued that this movement, combined with the early intensification of agricultural methods, created a “metabolic rift,” or a disruption of energy and material flows, which ultimately undermined soil fertility in the long term at one end and caused an accumulation of waste in cities at the other (e.g., Marx 1977, Chapter 15; 1981, Chapter 47). Additionally, as Ricoveri (2013) has detailed, Marx’s (1977, Part 8) analysis of the early land enclosures – not only a prerequisite for the development of capitalism, but also one of the earliest movements to commodify nature on a massive scale – has contemporary applications for understanding the commodification of commonly owned environments in the Global South. Harvey (2004) too emphasizes the continuation of what Marx called “primitive accumulation” as a persistent feature of global capitalism today, and describes many of the processes detailed below as “accumulation by dispossession.” More generally, Marx’s theories of how capitalism operates and the nature of the commodity form provide the conceptual building blocks for contemporary work on the commodification of nature, whether or not this is made explicit.

A second important classical influence on contemporary research on the commodification of nature is the work of Hungarian economist Karl Polanyi, specifically his notion of “fictitious commodities.” In The Great Transformation (1944), Polanyi described “land” (which denotes commodified nature) as a make-believe commodity, meaning that the natural environment, a prerequisite for production, is treated as if it were produced for the market through labor, even though it is not (though this deserves some nuance today due to biotechnologies, see “Commodification of internal nature,” below). Land exists within and outside the production process. Polanyi (1944, 178) asserted that liberal capitalism could only develop and function because the fiction of nature as a commodity, “perhaps the weirdest of all undertakings of our ancestors,” is sustained. His argument has been influential in nature commodification literature because it is helpful for conceptualizing the utopian nature of treating nature as if it were a commodity, whether to criticize an environmental economist who attaches exchange values to biodiversity, to understand why a logging company assumes that a forest acts – or should be made to act – in accordance with market forces, or to explain why nature presents “barriers” to commodification in the first place. Further, scholars studying the commodification of nature are confirming Polanyi’s (1944, 73) assertion that allowing “the market mechanism to be sole director of the fate of human beings and their natural environment … would result in the demolition of society. … Nature would be reduced to its elements … landscapes defiled, rivers polluted … the power to produce food and raw materials destroyed.” Additionally,
Polanyi has influenced some attempts in the environmental social sciences to formulate alternatives to wholly commodified human–nature relations. Following Polanyi’s assertion that capitalism “dismembeds” the economy from society and nature (i.e., social relations and nature are subjected to economic activity), some environmental social scientists have argued that economic systems must be re-embedded in both domains for economic activity to meet human needs and operate in accordance with natural laws.

As noted in the introduction, exploring the processes and consequences of nature commodification is common in human geography and environmental sociology. Three “modern classics” from these subfields are worth noting as they have stimulated a great deal of increased inquiry into nature commodification in the last few decades (though Mann and Dickinson 1978, Kloppenburg 1988, and Cronon 1991, explored below, could certainly be placed under this “modern classics” label as well). Perhaps the most influential work on nature commodification in political ecology and human geography is Smith’s *Uneven Development* (1984). In attempting to break down the notion of nature as detached from society, Smith argued human labor, especially as organized under capitalism, clearly “defies” this dualism. Economic production is, at bottom, the “production of nature.” What makes capitalism’s production of nature unique is its global scale and “exchange value relation” to nature (see below). For Smith, capitalism is a system that reaches across the globe to commodify nature to the extent that the distinction between “first” and “second” nature becomes problematic. Likewise, Schnaiberg’s *The Environment* (1980) is the foundation of a great deal of (neo-)Marxist work on the relationship between commodity production and nature in environmental sociology. His “treadmill of production” theory maintains that the market’s further encroachment into nature is inherently unsustainable because capitalism is growth dependent, requiring more material and energy throughput. This means the overuse of resources and unchecked pollution are inevitable features of capitalist societies. A third notable recent classic is James O’Connor’s (1998) second contradiction of capitalism thesis, first developed in the late 1980s, which has inspired a good deal of research on nature commodification in both political ecology and environmental sociology.

Pulling together Polanyi and Marx, O’Connor has maintained that capital may undercut the natural prerequisites (“land” in Polanyi and a “condition of production” in Marx) necessary for further production because noncommodified environments have no immediate economic value to individual capitals. The ideas of Smith, Schnaiberg, and O’Connor are explored in more detail below after an outline of the constellation of features that characterize nature commodification.

### Aspects of nature commodification

Along with highlighting the theoretical underpinnings of nature commodification research, it is helpful to outline the basic elements and structures of nature commodification before exploring contemporary work and themes. Castree (2003) has presented a helpful typology for analytically distinguishing six “aspects” of commodification commonly used or assumed, though rarely together, in work on nature commodification: (i) privatization, (ii) alienability, (iii) individuation, (iv) abstraction, (v) valuation, and (vi) displacement. In combination, these six aspects are meant to describe the chief characteristics of nature commodification in capitalist societies.
COMMODIFICATION OF NATURE

1 **Privatization** refers to a legal title being assigned to a private entity (usually an individual or corporation) for exclusive, or nearly exclusive, use. Private ownership and use can be clearly contrasted with public, collective, or common ownership and use. Because commodity production depends on the private ownership and operation of goods and resources, privatization of a natural entity or class of natural entities is a precondition of nature commodification.

2 Much of the work on nature commodification has emphasized the role of privatization in the commodification process due to neoliberal environmental policies.

3 As commodities are produced to be sold, they must be **alienable**. This means that for a natural entity to be commodified, it must be able to be separated from its sellers to go to new owners.

4 **Individuation** is the process of partitioning the world with material and/or legal boundaries in a way that makes possible commodity production and distribution. In relation to nature commodification, this means separating a class of biophysical things from ecological contexts.

5 **Abstraction** is a process whereby distinct, individualized natural entities are grouped into categories based on similarities (functional abstraction) and/or a distinct, individualized natural entity in one place is used as if it belonged to the same category in another place (spatial abstraction).

6 Another unique aspect of nature commodification involves the leveling and reduction of qualitative differences between individualized natural entities and between categories of natural entities to quantity, specifically in the form of money (**valuation**). In theory, this makes qualitatively distinct objects commensurable for the market. All ways of valuing objects are subsumed and/or replaced by price values.

6 The last aspect of nature commodification identified by Castree (2003) is **displacement**. Displacement refers to the way in which the commodity form masks the social and material relations that brought the commodity into being (termed “fetishism” by Marx (1977, Chapter 1)), though work on nature commodification focuses on what happens to the environment behind the commodity (i.e., the ecological effects at the site of production that are hidden by the commodity).

An analytically distinct and especially important aspect of commodification, subsumed under “valuation” in Castree (2003), can be teased out when examining the (vii) **purpose** or **logic** of market-oriented production regimes. This is also stressed by Smith (1984) and Schnaiberg (1980). Marx (1977, Chapter 4) outlined this purpose in a straightforward way in his “general formula” for capital: $M \rightarrow C \rightarrow M'$ (money-commodities-more money). As elaborated in the second volume of *Capital*, Figure 1 represents the basic processes of capitalist production and exchange.

Money–capital (M) is used to buy labor power (LP) and the means of production (MP) (machinery, tools, inputs, etc.), which are...

![Figure 1](image-url)
commodities (C) in the form of productive capital. LP and MP are utilized in the production process (P) to create a commodity of greater value, or “commodity-capital” (C'). C' must be sold in the marketplace for M plus a profit (Δ). Money-capital is reinvested, reproducing the circuit. Capitalism is unique in that the purpose of economic production is to amass private wealth for further investment and that it universalizes this form of production. This is the essential distinction Marx placed between commodities (as the term is used here) and the products of labor in pre-capitalist societies. The commodity is a good produced with the sole aim of exchanging it for a profit in the marketplace. Without question, economic products in pre-capitalist societies were often exchanged, but, unlike today, the general purpose for production in pre-capitalist societies was to create goods for personal use or for a local community. Exchange was “subordinate,” as Polanyi put it. Today, with some exceptions, the reason goods are produced is to accumulate capital for the owners of the means of production for further investment. Capitalism is concerned with accumulating capital “for the sake of accumulation” and “production for the sake of production” (Marx 1977, 742), not with meeting human, animal, or ecological needs. In Marxist terminology, the purpose for production in pre-capitalist societies was to produce use values, while capitalist societies are structured around the production of exchange values. This distinction is central for understanding what is meant by the commodification of nature. When nature is incorporated into economic systems in order to be sold on the market for a profit, it has been commodified. Although these basic elements and structures of nature commodification are rarely discussed in their entirety in studies on nature commodification, they provide conceptual groundwork for understanding how commodification processes work in the varying “domains” of nature.

Domains of nature commodification

Thus far, this entry has explained the theoretical origins of nature commodification research (Marx, Polanyi, and contemporary elaborations) and the basic elements and structures that comprise nature commodification (privatization, alienability, individuation, abstraction, valuation, displacement, and the logic of capitalist production). This section will explain the way commodification processes function and adapt in different domains of nature. Although all commodities have origins in the biophysical world and/or the human body, it is important to analytically distinguish specific categories of natural entities because (i) certain entities have particular environmental and/or social consequences that deserve special attention and (ii) focusing on the material makeup of these specific entities, common in nature commodification literature, casts a stronger light on the material processes of nature commodification (Castree 2003). There are four broad and often overlapping domains of nature focused upon in work on the commodification of nature: external nature (i.e., the nonhuman, biophysical environment), internal nature, the human body, and information about nature (Castree 2003). This typology is retained here, though a fifth domain is added: the commodification of animals, an area of inquiry that has increased since Benton’s (1993) work. In the following subsections, each domain of nature is delimited and defined (external, internal, animals, the human body, and informational) along with examples from principle works or recent case studies to show how commodification processes function and adapt in these different domains.
Commodification of external nature

One domain of nature examined in nature commodification literature is “external” nature. External nature here simply refers to what is commonly called the biophysical world, the natural environment, or nonhuman nature. The commodification of external nature refers to the extension of the commodity form into formerly noncommodified natural arenas. Even if not explicitly stated, every modern study of extractive and agricultural industries engages in an analysis of an “exchange value relation” to natural entities, excluding studies of commonly held or publically owned natural resources. Yet studies of agricultural and extractive industries that draw on the commodification of nature as a frame for analysis usually stress the historical and socioeconomic forces that led to and shape the particular industry. Cronon’s (1991) now famous account of the ecological roots and consequences of Chicago’s industrial growth in the nineteenth century is representative of this approach.

*Nature’s Metropolis* shows in great detail that the expansion of a metropolitan economy (Chicago’s) played a central role in linking city and country and shaping the landscape of the frontier. Made possible by the railroad, new markets opened up for grain (Chapter 3), timber (Chapter 4), and meat (Chapter 5). These markets radically transformed the ecosystems of the Great West: a few farm plants replaced the dozens that formerly made up the prairie ecosystem, northern forests were clear-cut, and the bison of the Great Plains were almost exterminated to be replaced by pasture and, later, early feedlots. In short, the commodification of nature “had transformed prairies into wheat, forests into lumber, livestock into meat,” a harbinger for “many of the environmental problems we face today: large-sale deforestation, threats of species extinction, unsustainable exploitation of natural resources, widespread destruction of habitat” (Cronon 1991, 149, xiii).

Employing similar terminology to that used by Smith (1984), the theoretical and conceptual significance of Cronon’s work is that capitalism, via the commodification of nature, problematizes the separation of a pristine “first nature” and the artificial “second nature” created by humans. The expansion of capitalist markets transforms first nature in its own image, thereby “merging” first and second nature. “What had once been a diverse prairie landscape produced fewer and fewer species. Although the local ecological conditions of first nature continued to influence which species grew where, the economic imperatives of second nature – distance from the city, cost of transportation, supply and demand, price – played an ever more important role in determining the shape of the landscape. As the human inhabitants of Chicago’s hinterland responded to the siren song of its markets, they simplified local ecosystems in the direction of monocultures. … The merging of first and second nature was thus a shift from local ecosystem to regional hinterland and global economy” (Cronon 1991, 266, 267).

While it would be brash to level a critique of Cronon’s masterful work in this short summary, it is important to note that other scholars argue that *Nature’s Metropolis* fails to explain the underlying mechanism for Chicago’s commodification of “first nature,” as if trade itself were such a mechanism (see Walker 1994, special issue of *Antipode*). Thus, for future researchers drawing from Cronon (1991), it is helpful to supplement this drawback with some of the conceptual insights summarized above, especially the Marxian account of capital accumulation.

Commodification of internal nature

A second domain of nature explored in nature commodification literature is “internal” nature.
Castree (2003) uses the term the commodification of “internal” nature to refer to the process of strategically altering natural entities in a way that overcomes their “resistance” to complete commodification in order to become “pure” or “real” commodities. Thus, “internal” refers to a smoother “internalization” of nature into the market system through biophysical modifications via technological means (genetic modification, growth hormones, hybridization, etc.). The function of the commodification of internal nature is to change the biophysical makeup of a given natural entity for more efficient incorporation into the market to overcome natural barriers and increase productivity (see “Physical and ecological barriers to nature commodification,” below). A helpful way to conceptualize the different processes of, or rather, opportunities presented in the commodification of external nature described above and the commodification of internal nature is to distinguish the “formal” and “real” subsumption of nature. Analogizing Marx’s (1977, Appendix) distinction between real and formal subsumption of labor, Boyd, Prudham, and Schurman (2001) argue that, in contrast to the formal subsumption of nature – where extractive, nonbiologically based industries cannot manipulate the given resource to increase productivity (e.g., the diamond industry) – the real subsumption of nature, the transformation of nature into a productive force itself, is becoming the norm in biologically based industries (e.g., plant and animal cultivation) through biotechnologies.

Today, there are many examples of how the very nature of nature is altered for the market through biotechnologies. Perhaps the most famous text that provided groundwork for examining the internal commodification of nature is Kloppenburg’s First the Seed (1988). Addressing the theoretical side of the Marxist “agrarian question” (how does/will capital deal with and transform agriculture), Kloppenburg (1988) focused on how enduring pre-capitalist social relations are broken down by “binding” farmers to inputs – particularly, to commodified, hybridized seeds. He argued that the seed had “resisted” commodification for a long time, but through privatization laws, the barring of public agricultural scientists from providing cheap or free new seed varieties, and hybridization by private research labs, the seed has fully “submitted” to the commodity form. Castree (2001) has depicted Kloppenburg’s argument within Marx’s basic model of capital accumulation (see Figure 2).

![Figure 2](image_url)

**Figure 2** Seed firms, farmers, and capitalist accumulation. Source: reproduced with permission from Castree 2001. Malden: Blackwell Publishers, p. 200.
Hybrid seeds are produced by seed companies with the help of scientific research into nature (SRN) and sold to farmers as an MP. These hybrid seeds are sterile and, thus, must be purchased each growing season with part of the given farmer’s profits (Δ*).

In relation to nature commodification research, Kloppenburg’s classic shows how science and capital interact to fundamentally transform the makeup of natural entities, as well as global social relations, for the accumulation of private wealth for reinvestment. More examples of internal commodification can be found in the genetic engineering of foods and industrial animal agribusiness “husbandry” practices, described shortly. However, as Castree (2003) notes, technical attempts to overcome “incomplete commodification” through internalization can produce risks (see “Physical and ecological barriers to nature commodification,” below).

**Commodification of animals**

The commodification of animals is a third domain of nature studied in nature commodification literature. Although animal commodification falls under the categories of “external” and “internal” nature commodification, there are two immediate reasons to distinguish animal commodification from the former two categories. First, the unique physical and social features of animals compared to the rest of nature, not to mention the differences between animal species, demand analytical division, especially when examining the unique “barriers” animals pose to full commodification. Second, the commodification of sentient beings presents unique moral concerns. Ted Benton’s *Natural Relations* (1993) provided much of the neo-Marxist groundwork for this area. In Benton’s typology of human–animal relationships, he specifies animals as sources of profit as a distinct category. He justifies this distinction by arguing that the requirements of capital can dramatically transform the form and organization of human relations with animals. Factory farmed animals are designated as the clearest representative of this category. The lives of food animals have been fundamentally altered by the demands of capital. By drawing on a revised early Marx, Benton argues that factory farmed animals are “alienated” beings. The social and technological transformation of animal agriculture has led to a contradiction: intensive animal agriculture is attempting to maximize output through an array of technical means (and animals are treated accordingly) yet, to be “productive,” there are constraints posed by the social, organic, and psychological requirements of farm animals that are undercut in the process of instrumentalizing animals (animals become ill, cannot reproduce, etc.). Benton predicts that attempts to overcome these barriers through antibiotics, growth hormones, and other technical means will lead to unintended consequences (see “Physical and ecological barriers to nature commodification,” below).

In addition to factory farmed animals, Benton (1993) argues that there are animals commodified as a “direct consequence” of capital, namely those animals that are subjected to safety experiments for cosmetics, new foods, and medicine. Of course, the commodification of animals precedes factory farming and advanced animal experimentation. For example, Van Sittert (2005) has retraced a 100-year history (1850–1950) of wild animal commodification in Cape Colony/Province (now part of South Africa, hereafter the Cape). Inverting the usual colonial narrative of game conservation in southern Africa (i.e., urban elite sportsmen saved select wild animals from the market in state reserves), Van Sittert shows, in the Cape, it was actually a rural gentry who used conservation as a step toward the privatization and commodification...
of various game species. Public game reserves were uncommon. In fact, in this colonial period, some of the only wild animals deemed “public property” were “vermin” (mostly jackals and hyraxes) who were slaughtered in large numbers for a bounty with proof of slaughter. Game stocks were enclosed by the rural gentry for incorporation into their market (as “trophies” and meat for consumers and spectacles for zoos). The ostrich and eland were privatized, domesticated, and commodified as agricultural animals during this period. Van Sittert (2005) shows how studying the commodification of nature can challenge taken-for-granted narratives.

Commodification of the human body

A fourth domain of nature in nature commodification literature is the human body. While human bodies as physical things are not empirically detachable from social influence, it is helpful to theoretically separate the somatic from other realms of the human, as well as from other natural entities, because of the body’s unique makeup (Castree 2003). Further, it is clear that the increased “fungibility” and alterability of the human body through technological innovation has increased the opportunities for its commodification. A great deal of work on the causes, consequences, nuances, and domains of human body commodification has occurred in sociocultural anthropology, a line of inquiry spanning back to early studies of slavery and prostitution (Sharp 2000). Drawing from Marcel Mauss and Marx, sociocultural anthropologists explore the “social lives” of bodies and body parts as commodified things. Recent work has emphasized the commodification of reproductive capabilities, organ transplant markets, “elective” surgeries (cosmetic and gender reassignment), genetic material, and the fusion of human, animal, and technological parts (as “cyborgs”). They have asserted that the Cartesian mind–body dualism (in which the mind encompasses the extent of the self) in concert with scientific reductionism has helped legitimize the commodification of the body and its parts.

In a similar vein, Dickens (2000) argues that the human genome project (and its implications in capitalist societies) is another good reason for linking the social and natural sciences. Dickens discusses the commodification of the human body on two levels. The first entails the genetic implications of the basic processes of capitalism. He makes clear that the commodification of the body shapes intergenerational genetic makeup. For instance, social stratification—currently based on the commodification of labor power for amassing private wealth for elite groups—predisposes certain populations to various diseases and developmental outcomes even before birth due to poor prenatal environments. In other words, Dickens argues that the commodification of the body alters the very makeup of human genetics even without biotechnologies. The second level is based on the potential and various routes biotechnologies have for altering human beings in capital’s “own image.” Like sociocultural anthropologists, he stresses the revolutionary role genetic modification could play in body commodification. More specifically, upper classes may soon have the ability to manufacture ideal offspring through commercial means, further magnifying existing inequalities. Both Dickens (2000) and Sharp (2000) demonstrate that the human body shares a similar fate to that faced by the rest of nature under capital.

Commodification of informational nature

The fifth domain of nature explored in nature commodification research is information about nature (“informational” nature). Informational nature, while clearly “materially different” from
COMMODIFICATION OF NATURE

The other natures outlined above, is not only still tangible and physical, but can be, and is, commodified (Castree 2003). Further, privatized informational nature, whether a genetic database or indigenous knowledge about the medicinal and agricultural utility of plants, is often easier to alienate, individuate, and abstract than biophysical entities. The commodification of genetics is perhaps the quintessential example of informational nature commodification. Directly related to the discussion of human body commodification above, Everett’s (2003) argument is that the genetic privacy movement is a direct reaction to the commodification, or potential commodification, of one’s genes for employers, pharmaceutical companies, and insurance companies. However, she clearly shows this countermovement is inadvertently perpetuating genetic commodification by utilizing the same logic as biotechnology companies. Genetic privacy supporters argue that individuals should be able to sell their own genetic information; they support private property laws if applied to one’s own body, and adopt a similar genetic determinist framework (i.e., one’s self is reducible to one’s genes). In short, property discourse becomes the only discourse available for supporters and critics, illuminating the completeness of our “exchange value relation” to nature and the body.

Another emphasis in the work on the commodification of informational nature involves the selling of local, traditional, communal, or indigenous knowledge about natural entities to Western pharmaceutical and agricultural corporations. “Bioprospecting” involves pharmaceutical or agricultural corporations actively searching for local knowledge about, and genetic samples of, natural entities, usually plants, in order to patent and use this local knowledge and genetic material for a profit. Because multinational corporations profit from seizing local knowledge and genetic material, usually from developing countries, without offering financial compensation, the term “biopiracy” directly calls into question the legality and morality of this process, perhaps most famously and forcefully by Shiva (1997). One of the most publicized examples is the patenting of genetic material taken from the seed of the Indian neem tree as a pesticide property by WR Grace & Company. Although the neem tree had been used in India as an insecticide safe for humans for years (as well as for medicinal purposes for thousands of years), neither India nor Indian farmers were compensated, raising a wealth of moral, legal, and political questions related to the commodification of informational nature (Marden 1999).

The socioecological effects of, and barriers to, nature commodification

Along with exploring the way commodification processes function and adapt in different domains of nature (external, internal, animals, the human body, and informational), explaining the socioecological consequences of, and barriers to, nature’s commodification is a research emphasis in nature commodification literature. The explanatory thrust of contemporary work on the commodification of nature can be roughly divided into two broad and interrelated arguments. Both arguments counter apolitical explanations for environmental degradation as well as dominant market-oriented and technical approaches to normative environmental research. First, the process and/or outcomes of nature commodification are ecologically harmful because (i) commodified entities have material impacts on noncommodified environments that are systematically linked to and/or near the former and (ii) nature commodification brings more natural entities into an inherently unsustainable economic system. Second, there are natural
“barriers” to “real” commodification. More specifically, (iii) internal and external obstacles arise during the commodification process that can create unintended socioecological side effects (risks) if “overcome” through technological means that can potentially further complicate the commodification process. Castree (2003) has helpfully labeled (i) “commodification effects” and (iii) “incomplete commodification.” Here, (ii) is included with (i) under “commodification effects.” (iii) is labeled “incomplete commodification effects,” and broken down into physical/ecological, social, and economic barriers to commodification. First, this section summarizes the two subtypes of commodification effects (impacts on noncommodified environments and the expansion of the “treadmill of production”). Then it summarizes the three subtypes of incomplete commodification effects, or the barriers to nature commodification (physical/ecological, social, and economic).

Commodification effects

The first subtype of commodification effects asserts that the production and consumption of commodities have negative ecological impacts on proximate or related noncommodified environments. The basic claim is that spaces of the natural environment that are noncommodified, because they are not immediately economically valuable for individual capitals, are harmed by the production of other commodities. For instance, vehicle production and consumption pollutes the atmosphere and, for an example more relevant in this case, commodifying a single tree species in the Amazon harms surrounding forest and fauna (Castree 2003). O’Connor (1998) has explained this process well. Because degrading the natural environment does not immediately negatively impact a given firm’s balance sheet (in fact, it can increase profits), individual capitals do not have any short-term, instrumentally rational motivation to sustain production conditions (for the unintended economic dilemmas created by this process, see “Economic barriers to nature commodification,” below).

The second subtype of commodification effects is the claim that nature commodification is ecologically harmful because it brings more natural entities into an inherently unsustainable economic system. Capitalism is a mode of production that operates and reproduces itself largely through intensification and geographical expansion. It is growth dependent: it must continuously accumulate capital on an ever-increasing and ever-expanding scale. A number of (neo-)Marxist environmental scholars have argued that the inbuilt expansionary mechanisms of capitalism make it fundamentally unsustainable. The most representative theory that expresses this view is Schnaiberg’s (1980) notion of a “treadmill of production” (ToP). The expansion of production in capitalist economies creates a production cycle (“treadmill”) that inevitably increases “withdrawals” from the environment (natural resource extraction) and “additions” into the environment (pollution) (thus, ToP theory also includes many of the claims of the first commodification effects subtype above). Businesses must reinvest surplus profits in production to create more commodities to be sold for a profit. ToP theorists argue that this treadmill is the system at the core of ecological degradation. In relation to the commodification of nature, the encroachment of the market into natural spaces and increase in material and energy throughput is not only inherently unsustainable, but possibly unstoppable within the constraints of capital. Unlike a great deal of works on nature commodification that rely on the case study method, studies drawing from ToP theory frequently provide national- and international-level data that show the ecological
Incomplete commodification effects: barriers to nature commodification

Here, “incomplete commodification effects” refers to (i) the immediate barriers to nature commodification and the consequences of these barriers as well as (ii) the side effects (risks) created when attempting to overcome these barriers that can further complicate commodification processes. Barriers to nature commodification sit on both sides and in between the society–nature interface. Thus, it is helpful to analytically separate three barriers to commodification: physical and ecological barriers, social barriers, and economic barriers.

1 Physical and ecological barriers to nature commodification. A first barrier to nature commodification results from the nature of nature. Physical and ecological barriers to nature commodification refer to material obstacles natural entities exhibit in the process of commodification as well as the socioecological risks produced by attempting to overcome these barriers through technological means. Bakker’s (2003) examination of the difficulties encountered in the privatization of water in England and Wales is an excellent example of physico-ecological barriers to nature commodification. For Bakker, water is the quintessential “uncooperative commodity.” Arising from neoliberal criticisms of the welfare state’s failure to efficiently manage public services, water was reassigned the status of a tradable good, as opposed to a public one. On the one hand, the socially created and defined (“second-order”) scarcity of water presented an opportunity for capital as a justification for the privatization and commodification of water. On the other hand, Bakker (2003, 28–29) asserts that the “materiality” (biophysical properties) of water erects barriers to commodification: it is (i) a “flow resource” and (ii) heavy. Flow resources are “not easily bound” (Bakker 2003, 32). This makes it difficult to create property rights boundaries (see “individuation” above), and “negative externalities” (undesired environmental harms) can easily flow from user to user. The heaviness of water, although cheap to store, makes its transport expensive “relative to value per unit volume, requiring large-scale capital investments in infrastructure networks which acts as an effective barrier to market entry” (Bakker 2003, 33). In short, the materiality of water presents obstacles to commodification.

Many examples of physical and ecological barriers to nature commodification can be found in modern agricultural practices. In Mann and Dickinson’s (1978) classic article, they argue that there is a “lag” in agricultural production between “labor time” and “production time” due to biophysical processes (e.g., photosynthesis, gestation) that pose natural barriers to capital accumulation. Thus, capital is unable to completely subsume agricultural spheres, a thesis that continues to influence a great deal of critical work on agriculture. Yet capital attempts to overcome these natural barriers through various technological means (see “Commodification of internal nature,” above). In this case, overcoming natural barriers often means an attempt to accelerate natural processes. These attempts can bring about manufactured socioecological risks. For example, as Benton (1993) predicted (see above), there are consequences of submitting animal bodies...
commodification of nature to the imperatives of capital, such as BSE (bovine spongiform encephalopathy) and avian flu (Castree 2003). These risks, what one could call incomplete commodification side effects, present further barriers to the commodification process.

2 Social barriers to nature commodification. A second barrier to nature commodification results from social movements. Social barriers to nature commodification refer to social movements that organize explicitly to oppose the further encroachment of markets into nature or social movements whose interests overlap with this goal. Although all environmentalist groups oppose environmental degradation, not all oppose capitalist expansion and growth. Similarly, although all social justice movements support human flourishing, not all link social injustice to environmental degradation. Despite this, there has been a more clear and active overlap between traditional leftist politics and environmentalism since the 1980s. Red-green political coalitions and permanent parties, environmental justice groups, Third World movements against the privatization of commonly held resources, and farmer opposition to buying seeds are all movements that attempt to strengthen the barrier between nature and the commodity form. Social barriers to nature commodification present unique obstacles as they are the only impediment to commodification with the potential of formulating and implementing alternative economics–nature arrangements.

While physico-ecological and economic barriers interrupt, divert, and restructure the ways nature is commodified, social barriers can potentially improve society–nature relations. For example, following the neoliberal structural adjustments required by the IMF and World Bank, a number of indebted countries in the Global South privatized and commodified water services, especially throughout the 1990s. However, there was a sharp and extended backlash from social justice movements, especially in Latin America. In concert with the difficulty of making large profits in poor countries through tap water commodification, these movements have pushed many multinational water firms out. Yet capital also challenges and overcomes social barriers to nature commodification. For instance, bottled water, a more profitable and portable route to water commodification, has increased steadily despite resistance from social movements at the sites of production and consumption (Jaffee and Newman 2013).

3 Economic barriers to nature commodification. A third barrier to nature commodification is economic. Usually, nature commodification literature focuses on how economic forces are antithetical to ecosystem health. However, some have gone further and claimed that capitalism may undermine its ability to accumulate capital due to the antithesis between capital and nature. This view is typified by O’Connor’s (1998) second contradiction of capitalism thesis. For O’Connor, the environment is a condition of production that does not operate in accordance with the “laws” of the market and value. Because the natural environment is a “fictitious commodity” (see above), it is neglected (degraded) by individual capitals. Over time, this impairs the environment’s productive powers for future capital accumulation. In Marxist terminology, the reproductive demands of the conditions of production are not met, creating economic crises. While Marx (1981) theorized a demand-side crisis
COMMODIFICATION OF NATURE

of overaccumulation/underconsumption, O’Connor’s “second” contradiction of capitalism leads to a cost-side crisis, which can come about in two ways. First, individual capitals maintain or increase profit margins through means that damage or diminish the natural conditions necessary for production. Second, the social movements described above can put pressure on capital to sustain or repair natural environments. Although individual capitals maximize profits by degrading the natural environment in the short term, this negatively affects capital as a whole and can undercut long-term productivity of given industries. Thus, according to O’Connor, only the state can effectively regulate access to and use of natural resources, but O’Connor maintains there is no reason to believe it necessarily will under current conditions. Indeed, in mainstream economic theory and international environmental policy, markets are often put forth as a solution instead.

“Proxy” nature commodification: criticisms of neoclassical environmental economics

Together with exploring the way commodification processes function and adapt in different domains of nature and explaining the socio-ecological consequences of, and barriers to, nature’s commodification, critiquing neoclassical environmental economics is a third research emphasis in nature commodification literature. Unlike the commodification processes described above, “proxy” commodification, as Castree (2003) calls it, refers to the process of placing price values on noncommodified or not-yet-commodified natural entities. This section (i) briefly summarizes the logic behind proxy nature commodification; (ii) explains how proxy nature commodification is used to further real nature commodification; (iii) provides two critical examples of the latter (emissions trading and wetland offsets); and (iv) abridges four general criticisms of neoclassical environmental economics leveled by (neo-)Marxists and institutional ecological economists.

1 Neoclassical environmental economic valuation schemes assume environmental degradation is a result of market failure and, thus, are designed to make up for “missing markets” (i.e., when an “unmet demand” exists without a market). The claim is that when property rights are nonexistent or vague, natural resources are overused. According to neoclassical environmental economic theory, without markets for noncommodified environmental goods and services people fail to recognize that environmental goods and services have “value,” which is synonymous with “positive prices” in neoclassical environmental economic theory (Adaman and Özkaynak 2002). Similarly, pollution occurs because the “social costs” of economic processes are not represented in the “private costs.” This means that environmental harms (conceptualized as “negative externalities”) are not accounted for either in the market price of the product or in the product’s production costs. This occurs when neither producers nor consumers are liable for the costs of environmental harms. Despite the fundamental differences between the neoclassical environmental economic and (neo-)Marxist positions detailed below, both camps agree that noncommodified environments are harmed because they are not considered economically valuable. For (neo-)Marxists, this is only one feature of the environmental
COMMODIFICATION OF NATURE

harms caused by commodification (see the first subtype of “commodification effects” above) and these destructive circumstances further solidify the need for a qualitatively different social formation. However, for neoclassical environmental economists, the solution to this problem is to internalize these negative externalities. Thus, in opposition to (neo-)Marxists, who argue that further nature commodification will increase environmental degradation, neoclassical environmental economists argue that further nature commodification via economic valuation models is the solution to environmental degradation.

2 Foster (2002) explains how neoclassical environmental economic valuation schemes operate in three stages. The first two stages depict what is meant by proxy commodification while the third stage depicts the use of proxy commodification models for the real commodification of nature. The first stage is to analytically split up the non-commodified environments into particular categories of goods and services (see individuation above). Second, price values based on manufactured supply and demand curves are assigned to these goods and services. Demand curves are often created through willingness to pay (WTP) and willingness to accept (WTA) methods. WTP refers to the highest amount a consumer is willing to pay for a good or service (e.g., clean air) or to prevent a negative externality (e.g., algal blooms), a method used when this amount is unknown. WTA refers to the amount a consumer is willing accept for a good or service lost (e.g., compensation for a flooded homeland due to a dam project) when this amount is unknown. Third, new markets are created based on these valuation schemes or, if markets already exist, policies, regulations, and new mechanisms are implemented to alter existing markets. This third step should make clear that proxy commodification is not simply an abstract way of monetarily depicting nature’s value for economic productivity. It is also used as a platform for furthering real commodification. There are several ways to put valuation schemes into practice (Adaman and Özkaynak 2002; Foster 2002), the results of which often appear under the heading “payments for ecosystem services” (PES). The first step is introducing clearly defined property rights of environmental goods and services when none exist or they are not explicit (see privatization above). This will ensure that, in theory, compensations for use and/or pollution of natural resources are appropriately allocated. Second, regulations are imposed. The simple option is to impose taxes for environmental impacts and subsidies for environmental improvements. More abstract and complex options, which are preferred by neoclassical environmental economists (Foster 2002), involve the creation of new markets with incentive systems via state intervention and policy. Although there are a number of proxy commodification schemes put into practice (e.g., tradable harvest rights in the fisheries industry, wildlife enhancement schemes, biodiversity credit schemes, and debt for nature swaps), the Kyoto Protocol’s emissions trading scheme and the creation of wetland mitigation banks are used as examples here.

3 The idea of emissions trading, born in the United States (who did not ratify the treaty), is to make carbon sources economically scarce through imposed emission limits and, subsequently, assigning tradable legal rights to emit. The prices created through bargaining would, in theory, represent how
much society “valued” the resource. The United Nations distributed rights to emit to the Northern countries that ratified the treaty. These rights were then usually distributed to leading industrial polluters. These polluters could sell unused permits to heavier polluters. Alternatively, those who wanted to avoid caps were given two more options: build or invest in new carbon dumps (offsets) or, invest in business ventures and infrastructure abroad, usually in developing countries, if the results can be shown to emit less than if they had not invested (Lohmann 2005). Usually framed as a “first step” to climate change mitigation, the Protocol has not only failed to reduce total emissions but has other social and ecological implications. Lohmann (2005) has argued that the emissions trading scheme has successfully redirected intellectual and financial resources from innovations and social changes that have the potential to actually reduce emissions. Additionally, alternative social futures that lie outside “national allowances” and the like are effectively marginalized. Indeed, Lohmann details how environmental criticisms of the Protocol were scorned as a “do-nothing” stance. Lastly, the treaty is thoroughly technocratic and corporatist, which excludes input and solutions from nonprofessional and noncorporate groups.

Wetland offsets via mitigation banking is another (in)famous example of applied proxy nature commodification (Robertson’s work is especially notable here, e.g., 2004). Due to failures to enforce the compensatory mitigation provision in the Clean Water Act (i.e., if a firm fills a wetland it must restore or set aside a set acreage of wetland in compensation), President George H.W. Bush’s administration devised a “No Net Loss to Wetlands” policy goal whereby developers who fill a wetland for development can buy “wetland mitigation credits” from owners of a wetland who agree not to develop in the future or companies who restore degraded wetlands (“wetland mitigation banks”) (Robertson 2004; Smith 2007). The intention is for wetland acreage in the United States, at a minimum, to remain constant. For example, a developer who fills a wetland to build apartments can buy wetland credits from an off-site mitigation bank instead of conserving or restoring wetlands on the same parcel of land his/her company is developing. However, the attempt to make commensurate the value lost at the development site and the value gained at the mitigation banking site creates problems. The value gained at the banking site is often conceptualized as “bundles” of ecological functions and measured through algorithms known as “rapid assessment methods,” while at the development site acreage is often used as a proxy measure of these bundles of ecological functions. A contradiction emerges when mitigation banks begin to “bank” on the different minute and opportunistically conceptualized ecological functions between the development site and the mitigation banking site in order to take advantage of their mitigation bank’s unique ecological characteristics. This search for additional fabricated markets clashes with the mitigation permit market’s need for quantitative abstraction (Robertson 2004).

In addition to the specific criticisms of emissions trading and wetland banking, (neo-)Marxist and institutional ecological economic literature levels a number of criticisms at economic valuation schemes and their applications (e.g., O’Neill 2001; Foster 2002; Smith 2007; Kosoy and Corbera...
The first two of the following four lines of criticism are in response to the valuation schemes of neoclassical environmental economics. The second two are in response to their application.

Neoclassical economic valuation models reduce human beings to the utility maximizing, instrumentally rational, fully informed, and egoistic *homo economicus* of liberalism. This model of humanity is distilled in neoclassical economic theory and is presupposed in their environmental economic valuation schemes. Economic man, as a one-sided and empirically imprecise depiction of humanity, implicitly omits other forms of relationships real humans have with nature that stand outside the limits of *homo economicus*.

Nature has no other value than exchange value in neoclassical environmental economic models. Or, more specifically, any value nature has can be quantified and expressed in monetary terms. This assumption carries two problems. First, qualitatively distinct natural entities may not be comparable in quantitative ways, or, they are incommensurable to begin with. Second, this assumption excludes the possibility that natural entities have intrinsic worth irrespective of human thought and action. Even if one assumes only humans can assign value to objects, neoclassical environmental economic models are incapable of accurately taking account of noneconomic values. However, this does not stop WTP technicians from asking “consumers” how much a view of a landscape – a “cultural service” – is “worth” to them in monetary terms, for example. That is, neoclassical environmental economic models assume all values can be reduced to, and successfully translated into, dollars and cents. (Neo-)Marxist nature commodification literature firmly disavows this assumption, as do other schools of thought, such as institutional ecological economics (Adaman and Özkaynak 2002). This is not only seen in left-leaning scholarly critiques of greened neoclassicism, but also in the refusals of some study participants to price environmental goods and services in accordance with WTP and WTA surveys, interpreting the questions as corrupt and an answer as a betrayal of personal values (O’Neill 2001).

Another line of criticism asserts that some of these valuation schemes, when put into practice, may reproduce or intensify global inequality and poverty. For instance, a Third World farmer who is compensated for preserving a forest will not likely experience any long-term increase in life quality, an opportunity that could have come about if that forest had been developed. The belief that there is voluntary cooperation among those who provide “carbon sequestration services” in the Third World may hide the fact that participation exists due to structural poverty. Similarly, it is not clear how WTP and WTA methods should practically deal with wealth stratification among its “consumers.” The question is whether demand curve calculations should be hierarchized by magnifying the preferences of those with more disposable wealth and minimizing or excluding those with little or no disposable wealth. On the other end of the social pyramid, mitigation permit banks are making a good deal of money and there is already a speculative “environmental derivatives” market. On top of this, there is concern about how property rights are implemented, contested, and negotiated. Those in power assign property rights and, often, negotiations are structured by extant power inequalities.

When put into practice, economic valuation schemes only serve to further the socioecological consequences associated with nature commodification described above. Many acknowledge there may be short-term environmental gains, but, in the long term, capitalism is the problem, not the
solution, or “the [proposed market] solution is the problem,” as the subtitle of O’Neill’s (2001) essay puts it. This is the fundamental critique of neoclassical environmental economics and PES schemes put forth in nature commodification literature. In particular, PES schemes are criticized for severing natural entities from their ecological contexts as “functions” (see individuation and abstraction above). This undermines the wealth of data that depict the interdependent, relational, and interactive nature of nature.

In summary, Marxian-rooted nature commodification literature and institutional ecological economists level a series of criticisms that undercut the conceptual and empirical core of the market-based environmentalism common today: (i) “rational economic man,” the agent presupposed in nearly all neoclassical economic models, is not an accurate characterization of real human beings and the diverse relations they have with nature; (ii) the totality of nature’s value cannot be expressed in monetary terms; (iii) applications of valuation schemes may reproduce social inequality; and (iv) increasing the scope of capital’s penetration of nature will only serve to perpetuate the structural causes of environmental problems.

Future directions

Before discussing future directions work on nature commodification can take, it is important to clarify what is already present in current studies that is valuable and should be sustained. First, studies of nature’s commodification should continue to stress the historical and contingent character of nature commodification. As stated in the introduction, past social formations have traded economic products derived from the biophysical world, but capitalism is unique in that the primary purpose of “producing nature,” as Smith puts it, is to amass private wealth, not to meet human and ecological needs. Historicizing and denaturalizing these relations is a defining feature of nature commodification literature that ought to be preserved. Second, studies of nature’s commodification should continue employing critical perspectives. While there is a diverse range of lenses available for exploring the commodification of nature, from classical Marxism to feminist political ecology, these perspectives are unified by a normative stance that the further penetration of nature by capital is problematic and the relationship between economic and natural forces ought to be restructured. Castree (2003) has argued that researchers should make their normative critiques explicit. Third, studies should continue to study the commodification of nature in its diverse domains, geographical areas, and historical periods. One lesson gained from studies of nature’s commodification is that the natural entity in question alters the way commodification proceeds and operates. Thus, case studies from a wide range of natures, areas, and times are necessary for advancing the area of inquiry. Fourth, studies should continue elaborating the effects nature commodification has on the natural entity in question, surrounding ecosystems, social relations, and the commodification process itself. Relatedly, to further the generalizability of one’s study, it may be helpful to conceptually align the results to critical and general explanations for environmental degradation, such as Schnaiberg’s treadmill of production theory or O’Connor’s second contradiction of capitalism thesis. Fifth, studies of nature’s commodification should continue to illuminate barriers that arise in the commodification process as well as resulting manufactured risks when industries attempt to overcome these barriers, if applicable. Lastly, scholars should continue critically evaluating neoclassical environmental
economic valuation schemes and their applications. Neoclassical valuation schemes have a great deal of influence in regional, national, and international environmental policy today, limiting the scope of alternative solutions.

Despite the strengths of nature commodification literature, there are openings for new directions and improvements. Most glaringly, there should be a scholarly effort to conceptually and theoretically link future case studies in order to achieve some level of generalizability as well as to connect the field. There are two openings that could help meet this goal. The first is to draw from a similar stock of conceptual categories. It seems difficult to envision something that looks like a general theory of nature commodification due to the diverse ways the commodification process adapts to the given natural entities and vice versa. Thus, as stated above, case studies will continue to be an important feature of nature commodification literature in order to understand and explain these nuances. Because abstraction and generalization are made more difficult, nature commodification scholars should be more attentive about employing similar concepts in order to approximate generalized explanations and predictions. Castree’s (2003) integrative typologies, which were retained here with some modifications, seem especially applicable. This is not a call to limit the perspectives utilized to theorize nature commodification, but a proposed means to help unify the area of study. A second way to help unify the area of inquiry is to increase communication and collaboration between disciplines. Because the topic/problem sits in-between fields, the diversity in disciplinary backgrounds studying the commodification of nature appears necessary. Further, one of the reasons nature commodification literature is innovative and exciting seems to emerge from this amalgamation of traditions. However, this diversity also carries difficulties, namely an abundance of sometimes unfamiliar perspectives and their accompanying jargon. Increasing explicit collaboration and communication across fields (interdisciplinarity) could benefit future studies.

COMMODIFICATION OF NATURE

Community

Briavel Holcomb
Rutgers University, USA

The word community, derived from the Latin communitas, has variable meanings but all imply relationships, whether among people, plants, or animals. Until relatively recently, and still to a large extent today, community had spatial implications. A common usage refers to the relationships among people in a particular place and indicates a sense of belonging both to place and to the social group(s) within it. Attention to the notion of community followed from Ferdinand Tonnies’s 1887 groundbreaking distinction between gemeinschaft (communal society) and gesellschaft (associational society). The former references traditional, personal, face-to-face relationships typical of rural life at that time. The latter identifies less personal relationships following from individuals interacting with businesses and bureaucracies. Gemeinschaft was romanticized as providing deeper senses of belonging and mutual aid, while industrialization weakened traditional bonds of family, religion, and kinship. The writings of Karl Marx center on conception of community. For Marx, community is a democratic form of association which replaces the state. Humans are communal animals and can only achieve their highest form of existence in a community. The individual develops in association with others but Marx saw traditional village community as stifling, enclosed, and not conducive to the true freedom and individualism to which all should aspire. While the cities of the Industrial Revolution provided the antithesis of community, they could eventually, in Marx’s view, provide the possibility of evolving to an environment in which the individual contributes according to his ability and receives according to his need. That perfect community is democratic and free. It could be, but is not necessarily, place-based. For Marx, democracy is of the nature of community. The ideal communist society is one in which the freedom of the individual is obtained through their free association with others in which all productive activity is a matter of individual or collective choice.

The famous “Chicago School” in sociology also offered a distinctive notion of community. In the first half of the twentieth century, this School focused on ecological ideas of urban form and stressed the importance of place and location in ideas of community formation, while reinforcing the notion that the modernization of urban life was reducing traditional values of community belonging. Louis Wirth’s classic article on urbanism, published in 1938, argued that people living in cities depended on more daily interactions than their rural predecessors, but that those interactions were impersonal, superficial, and transitory. In a heterogeneous society, people belonged to more groups, but their needs and preferences were subsumed into those of the majority. People join groups in order to pool resources which are directed to serve the average constituent. Communities, then, are rational or functional rather than emotional. Another member of the Chicago School, Robert Park, applied ideas of ecology developed for plant and animal communities to observations of urban life. The notions of competition, invasion, dominance, and segregation which were current in ecology were used to study human behavior and Park...
COMMUNITY

emphasized the importance of communication in the formation of community. Park saw the city as a series of “cells” in the urban organism with spatial contiguity of neighborhoods, immigrant groups, and functional districts providing bases for community. Nonetheless, although he stressed place and locality, Park also was open to the possibilities of nonspatially determined forms of human association. He noted that various urban institutions from schools, to churches, to street gangs, aided by communications including newspapers, could create communities of interest not reliant on spatial contiguity. The place-based idea of community so redolent in the Chicago School has remained a strong theme in both geographical theory and praxis, particularly in urban areas. However, the Chicago sociologists assumed the urban societies were characterized by impersonality, social disorganization, alienation, and anomie. Urban places were essentially anti-community in the conventional sense. Marx’s optimistic predictions made in nineteenth-century Manchester about the (r)evolution of industrial cities were not evident in twentieth-century Chicago.

While ideas of community historically have not been exclusively place-based or spatial, the second half of the twentieth century saw growing recognition of the existence of aspatial or at least not place-based communities. An early contribution was Melvin Webber’s 1963 “Order in Diversity: Community without Propinquity” in which he argued that the sociologists’ lament that community was dead/dying was short-sighted, and that people were continuing to form communities based on common interests, professional identities, and other nonspatial associations. This focus on time–space distantiation was a relatively fresh idea in 1963, but was a precursor to subsequent thought which has, of course, “exploded” with the Internet. Webber likewise noted that traditional distinctions between rural and urban were diminishing as people of all occupations could participate in national urban life.

Around the same period, Herbert Gans and others argued that the Chicago School was too pessimistic in its view that industrial cities destroyed the real sense of community which had characterized rural village life. Gans’s 1962 classic study of the West End of Boston found that the cohesive social networks and sense of identity associated with rural life were replicated in “urban villages” often based on either ethnicity (Italians in Boston’s case) or class (working class in London or Chicago). Some reinforced this view, pointing to the strong ties formed by shared experience, kinship, friendships, and attachment to place. But others pointed out that working-class neighborhoods were frequently characterized by economic insecurity, social stress, conflict, and crime. High density, sometimes combined with ethnic diversity, was not conducive to mutual support and community enhancement. Some considered Gans a romanticist. But few found a sense of community in suburbia. Mid-twentieth-century critics, such as Lynds, Mumford, and Whyte (*The Organization Man*), saw suburbia as a place of nuclear families enjoying privacy and individuality rather than strong community ties. Nevertheless, Gans’s (1967) study of suburban Levittown found evidence of communities in which residents chose to participate in relatively loose association for purposes ranging from parent–teacher associations to country clubs, gardening, and the like. It seemed that urban versus suburban communities were similar in purpose but different in execution.

Whether or not community was dead, it was resurrected by activists and government in the 1960s and 1970s. Faced with “the urban crisis,” civil disturbances, and cries for a war
on poverty, various federal programs based on
the presumption of community were initiated,
and in many cases have survived well into
the twenty-first century. The Community
Development Block Grant (CDBG) program
was enacted in 1974 under President Gerald
Ford with bipartisan support. Cities and states
received federal grants and were required to
submit allocation reports showing where and
how the money was spent. The amount of
the grant was determined by such measures
as poverty rate, overcrowding, and amount of
deteriorated housing, and a rural “set aside” sent
a third of monies to rural areas. The idea behind
CDBG was that it would be a “bottom-up”
approach with local people setting priorities
and being involved in deciding where and how
monies would be spent. It was also a reaction to
the Johnson administration’s “war on poverty”
which had spawned a large federal bureaucracy
inappropriate for Republican administrations.
However, perhaps ironically, proponents of
CDBG included such organizations as ACORN
(Association of Community Organizations for
Reform Now), begun in 1970, which grew to
the largest community organization for low and
moderate income people before disbanding in
2010. ACORN and other activist community
organizations of the period were inspired by
the ideas of community organizer Saul Alinsky
(who had studied with Robert Park at Chicago).
Alinsky’s book Rules for Radicals (1971) was based
on his experience organizing with the Industrial
Areas Foundation. He recommended working
with the “have nots,” the poorest segment of
society, and stressed the need to communicate
in organizing. Alinsky was both idealistic and
pragmatic. Among his rules were: Make the enemy
live up to its own book of rules. Ridicule is man’s
most potent weapon. Never go outside the expertise of
your people. A good tactic is one your people enjoy.
ACORN survived until 2010 but other less
radical alternatives, such as the Industrial Area
Foundation, continue today to carry on similar
community organizing.
CDBG has, of course, had its critics, who
argued that its priorities and execution were
flawed. Critics noted that some projects on
which funds were spent were frivolous and did
not target the most needy, and the amount
of money allocated had declined (from US$2.7
billion in 1975 to $1.7 billion in 2014). Although
the program was conceived with an antipoverty
agenda, much of the money now is widely
distributed to middle and even upper income
places, while that going to lower income com-
munities may be spent on infrastructure which
makes places more attractive to middle income
residents. CDBG monies have paid for tennis
courts, recreation centers, and senior citizen
centers in well-off communities, sugarcane mills
in Hawaii, and, reportedly, psychic readings for
a mayor in Texas. Yet CDBG remains a viable
program as local people receive federal funds
for locally determined needs. In the United
States, the Community Development Society,
an organization formed several decades ago with
a mostly US-based membership, is devoted to
helping professionals engage with community
members to improve the sustainability and well-
being of communities. Among their principles
is that members should disengage from support
of any effort that is likely to adversely affect the
disadvantaged members of a community. The
society holds annual conferences for practitioners
of community development and publishes Com-
munity Development quarterly. The articles include
both theoretical and case-based contributions,
focused primarily on North America.
A considerably more international perspective
is that of the Community Development Jour-
nal, a quarterly that claims to be the leading
international journal in the field and seeks
to publish articles that challenge conventional
wisdom, suggest innovations, and relate to issues of social justice, diversity, and environmental sustainability. Published by Oxford University Press, a recent (July 2013) issue included articles about communities in Columbia’s mining region, fishing versus oil production in Ghana, and the role of anthropology in New Guinea’s extractive industries. While providing provocative reading, the journal complicates the task of defining community development and challenges the conventional wisdom that community is local by showing the many ways communities are linked to outside, sometimes distant, forces. The adage “think globally, act locally” (a saying attributed to various people) might be thought of as a theme of the journal.

Cities throughout the world have recently seen the growth of “specialized” communities often catering to particular interest groups such as the elderly or the affluent. Ironically, perhaps, the first retirement community established was Youngstown, Florida, and was followed by hundreds of others in warmer states like Arizona, California, and other parts of the world. Such communities may provide a continuum of housing from independent living to assisted living or even nursing homes. They typically cater to middle income residents and have services which build community among them, such as shared club houses and sports facilities. Not surprisingly, they have both advocates and critics of segregating older people into physically discrete locations, most of which ban younger residents and children, except as visitors. But proponents praise the social capital built by shared spaces and activities.

Gated communities, now proliferating in many countries, range in size from small developments to larger villages. They typically have limited and guarded entrances and may be surrounded by fences. It is assumed (possibly wrongly) that this reduces crime, but it also increases the number of rules and regulations residents must obey, many to do with the appearance of property. Gated communities are popular, with over 11 million residents in the United States. They offer shared amenities and, presumably, an enhanced sense of community. They are, however, criticized as exclusionary and catering to the affluent. In some Latin American countries, Saudi Arabia, India, and South Africa, gated communities are desired for their assumed increased security as well as their prestige. Critics of gated communities are many, but so are their proponents. In possible contrast, “intentional communities” are part of a movement which has its roots in utopianism and blossomed in the 1960s in the United States, but continues to be a lifestyle of choice for a small but significant segment of the population. Intentional communities are those in which residents live together with a common purpose, often working cooperatively to create a lifestyle that is typically eco-friendly, and based on shared values. They include rural villages, residential land trusts, and urban housing co-ops, as well as communities for particular groups such as Christians or gays. The movement publishes a magazine, Communities, which gives advice on establishing and maintaining intentional communities.

In a perceptive book Lyn Lofland (1973) discussed how in preindustrial societies most people knew most of the people with whom they came in contact on a daily basis. Strangers were few and far between; however, in the industrial city, we know very few people we see in the course of a day with whom we are acquainted. Most people we see are strangers. Thus, while we may feel we live in a “community,” we have evolved ways of interacting with unknown people by assuming commonalities with them. Subsequent critics have argued that in fact current city dwellers no longer assume or rely on community, but instead go “bowling alone,” as Putnam (2001) warned. Putnam
described the decline of participation in civic and other social groups during the period after about 1970 in the United States. He notes that voter turnout and membership in voluntary associations, including churches, all declined. Americans and other “Westerners” started to spend more time on individual leisure pursuits (movies, watching—not playing—sports) and less on eating meals together, playing on teams, and other communal activities. Americans gave less to charities proportionately, and while the rate of volunteering grew from 1970 to 1990, most of the increase was due to people over sixty years old. Trust in strangers decreased and hitchhiking died. While community thrived among some specialized groups (e.g., evangelical Christians, self-help groups), overall people felt much less connection to community, and what Putnam (and others) call social capital declined. Putnam attributes this decline in community to such things as suburban sprawl and the replacement of local shops with regional malls, the increase in commuting to work alone by car, and the increase in TV viewing. But, according to Putnam, if we can rebuild social capital we will be more prosperous, healthier, and happier. We might do so by involving young people in meaningful civic projects, making workplaces more family-friendly, reducing commuting times, using mixed-use zoning and pedestrian-friendly streets. While Putnam’s arguments were not wholly new, his book was influential in calling attention to what may be a decline in feelings of place-based community commitment in some parts of the world in this century. Other advanced industrialized and suburbanizing countries (e.g., United Kingdom, Japan, Australia) experienced similar trends. In China the rapid growth of cities caused by rural in-migration has disrupted traditional rural communes, but new forms of urban communities have evolved. Putnam’s work generated considerable response, many people pointing out that while local neighborhood participation may have declined, membership in larger groups has grown. DeFilippis (2001) is among Putnam’s critics, pointing out that social capital without financial capital has limited utility in community development.

Technology, at first the telephone, now the Internet, has greatly facilitated the emergence and maintenance of a great diversity of communities, some place-based but many essentially aspatial. The idea of geographically dispersed community was central to Anderson’s (1983) *Imagined Communities* in which he describes ways in which people of a nation feel a sense of belonging to a group which never meets in person, but which is assumed to have certain interests in common. While such communities have territorial limits, they are imaginary in the sense that the members of a nation may have little in common and few mutual interests. Ironically, perhaps, while Putnam and many others attribute a major reason for the decline of community to media (such as TV), Anderson attributed the imagined communities of nations of early modern Europe to the ability of entrepreneurs to print books in the vernacular rather than Latin. Early European states were thus able to find and distribute ideas of nation in their own language, leading to a decline in the belief of divine rights and the beginning of modernity.

Ideas about community have been revolutionized by the Internet. Today, it is probable (at least in the United States) that citizens feel more connected to online, virtual communities than to their place-based community. An early discussion of some implications of this was Rheingold’s (1994) *The Virtual Community: Homesteading on the Electronic Frontier*. Rheingold’s involvement followed from an online discussion group (the WELL—Whole Earth ’Lectronic Link) in 1985. The group had grown to over 8000 members by 1993 and while some
met in the “real world” (San Francisco, naturally!), most communicated online. By 1994 Rheingold noted that the Internet enabled many communities, and allowed people to find a date, sell a lawnmower, publish a book, and conduct a meeting. He was largely optimistic about the community-building potential of the Internet, noting that it encourages the sharing of interaction, interests, and passions. He argued such interaction could challenge the monopoly of mass media and invigorate democracy. But he also presciently warned of the danger of corporate monopolies in cyberspace and the role of government in monitoring web content. He understood the challenges to privacy that the then new technology provoked, and which remain today.

Since Rheingold’s initial book on virtual communities, much scholarly work has been devoted to understanding these new iterations of community, with both praise and criticism of their effects. While critics point out the loss of in-person socializing (the many hours spent in front of person-avoiding screens and the stultifying tedium of much content), others note the ability to connect with others with similar interests (or problems) who are geographically distant, the ability of invalids and other “shut ins” to make meaningful contact, and even the emotional benefits to being part of a network of people coping with similar adversities such as disease or disability. Similarly, while in-person attendance at local community meetings may have declined, civic engagement among especially the young has been encouraged by online media. Online chat rooms provide possibilities for interaction with others with similar interests and concerns. Emotional support can be accessed quickly and cheaply, though not always reliably. Renninger and Shumer (2002) praise the opportunities for building diverse communities – from young girls to math teachers and other learning groups – which online communication facilitates.

While there are thousands of online communities, virtual worlds are probably the most interactive. Second Life, a virtual world run by Linden Labs, has millions of members, although most are inactive and regular “residents” number about a million. Nevertheless, Second Life is a “place” which emphasizes community and enforces community standards (such as forbidding intolerance, harassment, and “assault” – you may not shoot or shove virtually when the resident is in a safe area). Although teenagers may join Second Life, much of its content is inappropriate for children and a rating system is used to designate “adult” areas of the virtual world. As its website claims, in Second Life there is always someone to talk to, dance with, and learn from. You can meet people from all over the world without leaving your home. A children’s equivalent is the game Minecraft in which players manipulate digital landscapes to build desired terrains either individually or in teams. Minecraft has been downloaded 20 million times and is quite addictive.

Changes in meanings of the word “community” from place/neighborhood to interest group, often facilitated by online communication, are evidenced by data from Google’s Ngram viewer. The single word “community” appeared in books infrequently until the twentieth century, but increased rapidly after 1950, with double peaks in the 1970s and 1990s. (In Chinese the word “community” peaked in 1920 and 1970. In French and German there were marked increases after 1940.) However, the term “Urban Community” in English had a major peak in the early 1970s (correlating with the passage of US federal legislation related to community), while the term “gay community” rose rapidly in the 1980s to the end of the century (and probably continues to the present, though the Ngram
viewer does not cover the period after 2000). Google Scholar shows over a million entries under “gay community” while there are 1.5 million for “women’s community,” 3.2 million for “black community” (and 2 million for “African American community”) and 3 million for “white community.” Obviously, none of these “communities” are constituted of people who know each other, though they may (or may not) have interests in common. Clearly, the meaning of community has migrated from primarily place-based association, or geographical community, toward that of mutual interest or characteristic, while still often maintaining its original territorial connotation. As Collins (2010) argued, this shift from territory to interest group has important political implications as communities of various kinds now constitute sites of political engagement and contestation.

The spatial or geographical meaning of community continues to be prevalent in the fields of community mental health and community policing. The former are services which substituted for care provided in mental hospitals, many of which were closed in the mid-twentieth century in a movement to deinstitutionalize mental patients. Community mental health centers were established to provide outpatient psychiatric treatment to lessen the social exclusion of the mentally ill. Though it has its critics and is habitually underfunded, it remains the model for mental health provision in both the United States and United Kingdom, and assumes that people are better off staying “in the community” where social relations can be maintained. Similarly, the notion of community policing, which emerged in the late 1970s, encourages police to develop good relationships with citizens and key stakeholders in neighborhoods, to establish neighborhood substations, conduct foot patrols, and attend community meetings.

The largest online “community” is probably Facebook, with over a billion members. While Facebook publishes community standards (relevant to terrorist threats, nudity, hate speech, and the like), it also has “communities” within it devoted to cooking or celebrities or whatever generates interest. Facebook nurtures off-line communities as it provides a way for friends and neighbors to keep up with each others’ lives. It has been shown to enhance social capital (among college students) and to build political support for candidates. For geographers, the location-based social networking site Foursquare is of interest since it uses global positioning technology to locate members, enhance commercial enterprises, and enable the meeting of friends in real time/space. The rapid growth of online communities and the geographical implications of location-based networking is a fertile field for further research (Erickson 2010).

If the meaning of community is stretched to include online communication between people who are gathering in a virtual space for political change, one can argue that the various Facebook/Twitter “revolutions” are bringing people together both online and in the material world to create sometimes radical social change. The first such occasion was in Moldova in 2009 when the Communist Party was overthrown for a coalition government. Although public demonstrations had been planned prior to the election, the role of social media (especially Twitter) in effecting the mass mobilization which happened in the streets of Chisinau was partly responsible for the political movement. The following year (2010), Iranian “dissidents” hoping to foster change used Facebook to rally support for the candidacy of an opposition leader, Mir-Hossein Mousavi. The Facebook page was administered from outside Iran, due to government censorship, but nevertheless was able to organize defiant nightly “Allahu Akbar” chants from rooftops in Tehran.
as well as various street protests. Ultimately, this has not led to the change desired by government opponents. It could be said that the Jasmine Revolution (in Tunisia) was enabled by the community-building potential of online social networking.

In conclusion, as the notion of community has expanded from place-based localities to international connectivity, the geography of community still matters, and Smith (1999) urges us to consider the implications of community for ethics and morality. Geographers are among those who contribute to the development and strengthening of real-world communities. In New York State, the Syracuse Community Geography group provides geographical assistance to help build a more just society, and geographers in many parts of the world are offering their expertise and energy to encourage ecologically and socially beneficial communities.

Community-based natural resource management

Chasca Twyman
University of Sheffield, UK

Community-based natural resource management (CBNRM) encompasses both a broad approach to the management of natural resources as well as a defined project format or program that is implemented through specific policies and practices. At the heart of CBNRM is community control over decision-making about the local environment. CBNRM emerged in the 1980s as both approach and practical project closely aligned with developments in participatory approaches and farming systems research of that time. Its reach was significant with its principles underpinning a range of projects around the globe, such as community forestry projects in Nepal and Bolivia, wildlife conservation in Namibia and Zimbabwe, and marine conservation in Madagascar and the Caribbean. It was seen as the panacea of community conservation and heralded as a transformative form of local development and environmental management. However, CBNRM has come under fire in recent decades for departing from its central ethos and even contradicting some of its core principles of social justice and socioecological sustainability.

This entry explores CBNRM with a particular focus on the Global South. The history of CBNRM provides an important account of how a revolutionary approach evolved and changed over time. The typology of CBNRM explains its current diversity based around resource type, operational mode and level of devolved control. CBNRM was appropriated by different parties in different regions, and arrives today at a fundamental crisis of purpose. The entry examines these contemporary crises focusing on the politics of control, the role of conservation science, the marketization of the environment, and the everyday challenges of living in poverty before examining the opportunities for CBNRM in the future.

First, however, it is important to review what we mean by some of the key terms in CBNRM. It is easy to use the term community without adequate precision and definition. It needs to be recognized that not all communities are alike and membership of communities is often negotiated, contested, highly heterogeneous, and exceedingly political. For the purposes of CBNRM we tend to assume a neat village easily identifiable on a map, but in reality communities involved in CBNRM can be extremely diverse, disparate, and even ephemeral. They may encompass subcommunities of self-selected participants within urban areas, they may include (or exclude) mobile pastoralists or hunters, and communities may struggle over definitions of who counts as a resident when the stakes involved are high. For an approach or project to be community-based it assumes a commonality in purpose among a group and a willingness and ability to work together toward a common goal. Ostrom (1990) provided influential work on how common resources (i.e., those owned or held in trust communally, not individually) could be managed by a set of rules that defined key parameters within a community that would lead to successful outcomes. Inherent within these notions of community and...
community-based are issues of power and representation that are explored later in this entry. Lastly, natural resources within CBNRM refer to specific resources (water, marine resources, land, wildlife, forests, and so on) but also to the environmental services they provide (mitigation of soil erosion, enhancement of range quality or landscape aesthetics, sequestration of carbon, and so on). Projects are often defined around specific resources, though more general everyday forms of CBNRM often encompass a more holistic recognition of the environment.

The emergence of CBNRM

History suggests that in the past, rules and regulations regarding access to natural resources were organized and precise, though rarely written down, and were enforced through traditional institutional structures and moral codes of conduct within societies. Thus everyday forms of CBNRM, rooted in these histories and traditions, have been structuring the day-to-day management of natural resource in most societies around the globe for centuries. CBNRM was a phrase coined to capture the formalization of an approach to natural resource management particularly through policy and prescribed practices. CBNRM initiatives were greatly influenced by theories around common pool resource management heralded by Elinor Ostrom. Ostrom (1990) produced seminal scholarship around the role of public choice in decision-making about the production of public goods and services and on how human interactions with ecosystems could maintain long-term sustainable resource yields. Her guiding principles for common pool resource management are still widely used today.

CBNRM initiatives came into vogue in the 1980s, following a wider move within development discourse away from prescriptive top-down policies and practices toward grassroots community development and local management of natural resources. These approaches aimed to involve and integrate communities in management processes within a structured policy framework (i.e., not wholly top-down or bottom-up), with the ultimate aim of achieving social justice alongside environmental sustainability. Much of the initial influential research and practice in this area was in Africa (particularly for wildlife and rangelands) and Nepal (noted for its social forestry).

One well-known and influential project was the Community Areas Management Programme for Indigenous Resources, better known as CAMPFIRE, in Zimbabwe (Taylor 2009). This pioneering program emerged in the late 1980s and aimed to return land and resource rights to poor communal farmers to promote environmental and economic welfare. The CAMPFIRE association was formed to represent the interests of district councils who had been granted authority to take the leading role in the coordination of CAMPFIRE activities and the representation of CAMPFIRE within national, regional, and international fora. Its success spread and in 1992 Zimbabwean ecologists helped to establish a similar scheme in the Luangwa Valley of Zambia called Administrative Management Design (ADMAKE). In Zimbabwe, the CAMPFIRE program was implemented widely. By 2003, the population of elephants on communal lands, under CAMPFIRE management, had doubled, even though human population had also doubled. Other wildlife numbers were reported to have increased by 50%. The greatly increased revenues meant that land that would have been settled or cultivated was protected at the local level for wildlife. The success has not been without difficulty. The politics of decentralization have been complex with accusations of elite capture, missed beneficiaries, and
COMMUNITY-BASED NATURAL RESOURCE MANAGEMENT

Corruption. However, it is still heralded as one of the pioneering CBNRM programs to date.

Another notable example of CBNRM is community or social forestry in Nepal. Community forestry is a branch of forestry that deals with the communal management of forests for generating income from timber and nontimber forest products while also regulating and ensuring sustainable ecosystem services. The evolution of community forestry in Nepal dates back to the late 1970s and was first devised as an attempt to improve the management of forest resources and address environmental issues that were of great concern given the country’s failing centralized forest policy. In recognition of these problems, in 1976, the government introduced innovative and farsighted legislation whereby the Forest Department could hand over forest land to the panchayat (the local administrative unit, usually comprising several villages). A completely new level of land tenure was thus introduced, aimed at encouraging public participation in forestry activities by giving ownership of the resource, as well as responsibility for its management, to local communities. Further decentralization was promoted in 1982 to provide more local control, and the 1993 New Forest Act allowed handover of the national forest to the adjoining forest users for accountable management. The legislation of CBNRM in this case provides a powerful structure through which control over natural resources can be handed over to village councils for fully devolved management. However, though the policies are far-reaching on paper, in reality elite capture of benefits and the inability of the poorest (often the most dependent on forest resources) to have a voice in the decision-making processes means that the principles of social justice have not always been upheld in CBNRM in Nepal.

Although this entry focuses on CBNRM in the Global South, the movement has not been confined solely to this region. CBNRM projects can be found all over the world, from North America and Europe to Australia and Russia. Not all go under the name of CBNRM and various terms such as co-management and participatory management may be used alongside other terms referred to in this entry. Given the great variation in CBNRM projects it is useful to think about how they might be categorized to better understand how these differences might influence the success, or not, of different projects.

A typology of CBNRM

CBNRM is diverse and manifests itself differently across the globe, so it is useful to think about a typology for categorizing CBNRM. Taking a resource or sector-based approach is one of the most common ways of thinking about CBNRM. Community-based conservation or community-based wildlife management has one of the strongest identities in this category. These projects may revolve around single species (e.g., pheasants in Nepal) or may focus on collections of resources such as habitat preservation incorporating a range of flora and fauna conservation. Community-based conservation may be driven by a strong conservation science approach with the community element added in, or it may be more socially driven to enable the achievement of the dual goals of livelihood enhancement alongside conservation. Both approaches are not without difficulty, and sometimes controversy, and outcomes can be highly variable. For example, in many countries ownership over wildlife is vested in the state and the state may grant rights to hunt or cull wildlife through licensing schemes or permits; however, governments often retain control over the revenues generated. Community-based wildlife management schemes often involve the devolution of control and decision-making about wildlife within a designated area, though the real
extent of this devolution is sometimes debatable. Good examples in this category include the CAMPFIRE program in Zimbabwe (Taylor 2009) and Rema-Laenga Wildlife Sanctuary in Bangladesh (Chowdhury et al. 2013).

Community-based management of pasture and rangelands is an often under-recognized form of CBNRM despite, for example, arid and semiarid grasslands occupying 40% of the world's land area with 100–200 million people deriving a living from pastoralism. Commonly, pastoralists have been highly mobile, exploiting the variability of the rangelands over space and time. These grasslands may be managed through formal or informal rules governing who has access and use rights. When external pressures such as population growth, agricultural expansion, climate change, and policy shifts come into play, then these rules governing rights are often disrupted and the outcomes are complex for all stakeholders and for the rangeland ecosystem itself. Good examples in this category include community-based grassland management in western China (Banks et al. 2003) and Du Toit, Kock, and Deutsch's (2010) comprehensive work on Wild Rangelands.

Community-based forestry management is another well-known resource sector approach to CBNRM. It is estimated that most of the world's forests are publically owned (by the state) with the rest held by municipalities, communities, and individuals. Communities in many countries retain access and use rights over these public forest resources. The case of Nepal showed that while success can be well recognized, the exclusion of some households can be highly problematic. A further challenge and opportunity is coming from the United Nations' scheme to reduce emissions from deforestation and degradation (REDD+). Under this scheme, community forest management can be an opportunity for communities depending on how it is negotiated. Community involvement in REDD+ schemes is reshaping how states, the private sector, and communities interact to manage forest resources. A good example from this category can be found in Cronkleton, Barton Bray, and Medina (2011).

Community-based marine management encapsulates a wide range of different resources such as fish (through fisheries and fishing), plants (aquaculture), and reef and coastal environments (including mangroves and coral reefs). Many of these resources may be located within marine protected areas (MPAs) and increasingly it is being recognized that the poor performance overall of MPAs can be traced to a failure to effectively include local communities in the design and implementation of conservation practices. Recent efforts to incorporate community-based management systems into this sector have struggled as conservation of marine resources is often constrained by a lack of adequate policy frameworks, insufficient customary management in the face of economic or social-ecological changes, incompatibility with MPA design and policy, the risk of elite capture, or a lack of coordination and integration beyond the local level. A good example is a coastal ecosystem management project in the Gulf of Mannar in India (Samarakoon 2011).

Community-based water management is perhaps one of the least prominent but most widespread forms of CBNRM. Rural water supply programs have striven to build and strengthen community management of local water resources either at the water point scale or local catchment scale. As with other forms of CBNRM, there are complex issues governing rights of use and access over water. More recently some countries have begun to privatize the management of water supply which further changes the complex governance of this resource. Good contrasting examples of the successful and problematic
COMMUNITY-BASED NATURAL RESOURCE MANAGEMENT

outcomes of community-based water supply are Crow’s (2012) research in Kenya and Mandara, Butijn, and Niehof’s (2013) work in rural Tanzania.

Another way of categorizing CBNRM is to think about an operational distinction. In this categorization, distinction is made between “everyday” general CBNRM institutions and practices, and the more project-based “focused” CBNRM activity. “Everyday” CBNRM refers to what is happening anyway, that is, the everyday ways in which people and communities organize themselves to use and manage the natural resources around them aside from “focused” implemented schemes and activities. These “focused” activities are often initiatives funded by governments, donors, and other conservation and development agencies. These types of projects often receive the most funding and prominence but actually involve far fewer people overall than the everyday CBNRM that structures most people’s rural (and sometimes urban) lives. External CBNRM initiatives that address the landscape as a whole are not common, yet many communities are managing multiple resources, often through different initiatives and structures. Communities may have quite complex institutional configurations with village development committees, water point committees, forestry groups, and wildlife committees, and so on. Thus recognizing the difference, and interactions, between everyday practices and implemented projects is important.

Last, CBNRM can be categorized according to the power that is devolved from the state to communities. CBNRM is fundamentally based on the devolution of responsibilities, rights, and authority from central government to local communities and the bodies or committees they designate for management. The transition from centralized natural resource management to CBNRM can be measured by the level of local control over socioeconomic benefits and revenue flows from natural resource management. Globally, the term CBNRM is applied to a wide range of situations along a transitional axis from full state control toward full community control, where local people make management decisions and benefit fully from the resources. In centralized states, CBNRM is often used to describe situations where local people are mobilized as labor for government programs under state control, particularly in situations where the resource has high monetary value. Toward the middle of the CBNRM transitional axis, decision-making authority remains with central government, but certain services and administrative activities are decentralized from central government to regional and district level government and co-management provides some benefits to local people. At its most advanced, CBNRM refers to community control over resources, implemented with technical and conflict resolution support from national government agencies and district level administration. CBNRM at that point is integrated into the overall land use and income generation and livelihood strategies used by communities. Under fully devolved CBNRM, rural communities are able to evaluate local ecological conditions and decide how to manage the harvest of their fish, wildlife, and forests with technical advice (not control) from government agencies.

Table 1 summarizes the CBNRM typology discussed above, grouping the approaches according to resource/sector-based, operation distinctions, and power relationships, but does not draw comparisons between them.

CBNRM in crisis?

While CBNRM has been on the ascendancy for several decades and plays a leading role in conservation strategies worldwide, Dressler et al. (2010) argue that CBNRM is currently experiencing a

Crisis of identity and purpose. These discontents can be grouped as follows: the dominant role of conservation science, the controversial politics of control, the marketization of the environment and the everyday challenges of living in poverty.

**Conservation science** occupies a powerful role in community-based conservation and CBNRM. There is a current resurgence of the “protectionist paradigm” in conservation that aims to separate conservation and development and this is having impacts on the success of CBNRM projects. This backlash upholds that an excessive emphasis on development can lead to a de-emphasis of conservation goals to the extent that they are no longer seriously addressed. The surge in protectionist conservation has sidelined some forms of CBNRM and in some instances ensured that preservation has taken precedence over indigenous people’s demands and rights over natural resources. This move “back to barriers” (see Hutton, Adams, and Murombedzi 2005) is worrying as it is antithetical to the core values of CBNRM, that of shared conservation and development outcomes. Protectionists have also worked to align devolved conservation with market-oriented solutions, a further complexity that may cloud the successful outcomes of CBNRM projects.

The politics of control is central to any contemporary analysis of CBNRM. While community-based natural resource management frameworks have at times been seen as solely conservation projects (or vice versa), they have rarely been critically evaluated in terms of development theory, which acknowledges the power and positionality of the different stakeholders. There is a critical need to examine these programs in terms of local understandings and opinions of CBNRM initiatives and local relationships with the environment. The extent to which CBNRM programs have been shaped by local priorities or government agendas will reflect the power relationships involved and the balance between conservation and development objectives within the programs. Central to the ethos of community-based natural resource management is the “participation” of local people and their “empowerment” through the development process. Yet we have seen that there is great variety in the real amount of devolved control to communities and even in so-called successful projects, the poorest are sometimes still excluded from the benefits of such schemes.

CBNRM has been used by some communities to levy new political control and openings and is heralded as a success in securing true empowerment to manage the natural resource base. However, in most cases the politics of who is in control, who trusts whom, and who has the power to make decisions and enforce actions
is highly variable and hotly contested. The differential access to resources inside local communities is often mirrored in community-based management approaches. People who use fewer resources might not depend less on them, but simply lack the entitlement for access. A broadening of the involvement of local communities via established leadership structures will not necessarily lead to the integration of everybody’s interests. Situations may occur where only particular members of a community attend meetings, while others avoid them as they perceive they have nothing to gain from participation. At a higher level, the complex administrative and policy structures have been hybridized with wider neoliberal restructuring to make the relationships between local communities, the state, and nonstate actors mired in complexity. For example, Botswana was praised for its CBNRM approach in the 1990s and the devolution of control and facilitation of joint-management activities. However, the government is now considering re-centralizing the management of natural resources away from local communities in key areas, arguing that wildlife is a state resource and the whole country should benefit. This goes against the very principles of CBNRM that suggest local communities (in close proximity to the natural resources) have a vested interest in managing them.

One of the ways that CBNRM has been molded in the twenty-first century is through the *market-based solutions* to the perceived environmental problems. The view is that if communities can see a monetary return on their investment in natural resource management, then more and better conservation outcomes are likely. Therefore joint-ventures and co-management regimes have proliferated (with the sharing of safari and tourism revenues) and more recently through global financial mechanisms, such as REDD+, for the payment of ecosystem services, such as carbon sequestration. A key driver here is that strengthening the role of the market in conservation actually moves conservation from a concern to *protect nature from the market* to a concern to *achieve conservation through the market*. This neoliberal approach is not necessarily compatible with achieving the goals of community controlled conservation and development in all cases. In the process of integrating market-based approaches with CBNRM the tendency for devolved conservation to become hybridized and bureaucratized has grown considerably. In some cases, where CBNRM is aligned with market-based solutions, it has strengthened the hegemonic position of the state rather than weakened it (e.g., Botswana).

The individuals and communities involved in CBNRM projects are facing the *everyday challenges of living in poverty*. They have to secure livelihoods, negotiate benefits, and participate in projects to manage their natural resources. Dressler *et al.* (2010) argue that CBNRM has been so reconfigured and standardized over the years that it is often misaligned with local realities. The bureaucracy of CBNRM, led by the state and NGOs, has rendered livelihood problems as concrete, with pre-assigned solutions that involve greater market-integration and intensification. Those charged with community-based design and practice have begun simplifying community problems in order to offer clear solutions already aligned with expected outcomes. Thus the process has become a technical exercise rather than an engagement in empowerment through conservation. As such, projects often become divorced from the everyday challenges of living in poverty in many of these environments.

**The future of CBNRM**

Community-based natural resource management programs were based on the premise that local
COMMUNITY-BASED NATURAL RESOURCE MANAGEMENT

populations have a greater interest in the sustainable use of natural resources around them than that of more centralized or distant government or private management institutions. These local communities were credited with having a greater understanding of, as well as vested interest in, their local environment and were thus seen as more able to effectively manage natural resources through local or traditional practices. This move in global and local development discourse was part of a wider reassessment of the goals of conservation by international bodies such as the UN (for example, the Convention to Combat Desertification and the Biodiversity Convention both advocate community-based approaches), national governments north and south (for example, indicated by the number of countries signed up to the sustainable development goals of Agenda 21 and the Millennium Development Goals), and NGOs and “community-based” organizations across the world. Several decades into CBNRM policies, there is now increasing recognition that natural resource management must be effectively linked with issues of equitable access to natural resources, the promotion of sustainable livelihoods, and the alleviation of poverty through participatory and empowering processes of development.

CBNRM arose as a powerful ideal with promise to become a near universal strategy for actors to use for rendering otherwise complex problems into manageable solutions. In the process of moving from small-scale diverse grassroots projects, where funds were low but perspective was clear, it has been scaled up as a global prepackaged solution to local problems. CBNRM’s universality may be leading to its demise. Its bureaucratic intricacies and convoluted layers of governance are making being poor more complicated. Ultimately, CBNRM needs to re-privilege social and environmental justice (such as individual and communal rights) over neoliberal logic and return to its core principles.

Adams (2008) sets out a series of points to pave the way for CBNRM to return to its core principles of community control over decision-making about the local environment to ensure social justice and socioecological sustainability of the local natural resource base. He argues that conservation-based poverty reduction should provide the focus with “pro-poor conservation” providing conservation-based natural resource management strategies that are used as a tool for poverty reduction and social justice. These strategies of sustainable use of natural resources should allow optimization of economic return and/or impacts on poorest people, not just in terms of accrued revenues. There should also be a focus on livelihood-linked conservation such that conservation can and should contribute directly to local livelihoods and generate positive benefits for local communities. Although conservation should still be the overall objective, programs should be designed to generate maximum benefits for poor people. This might include resource-sharing (or revenue-sharing) in protected areas or their “buffer zones” (e.g., wildlife tourism). Poverty neutral conservation is another principle that would ensure the net impact of conservation on the poor is neutral. Conservation can have negative impacts on the poor and should compensate fully for local opportunity costs of protected areas or laws that constrain resource use. Poverty can be a constraint on conservation success and therefore poverty needs to be addressed in order to deliver on conservation objectives. Addressing the poverty of neighbors and others who have the power to disrupt conservation programs (e.g., those who might poach or encroach on parks) can also ensure long-term sustainable success of many activities.

Ultimately, for CBNRM to be effective, policy and practice must facilitate devolved community
control over natural resources and protect the interests of the very poor to ensure social justice is rooted within socioecological sustainability. CBNRM has much still to offer to communities and to the world as both approach and practical project.

Community/continuum in biogeography

Christopher R. Hakkenberg
Dennis D. Tarasi
Robert K. Peet
University of North Carolina at Chapel Hill, USA

An ecological community refers to the association or assemblage of living organisms that coexist within a given space–time context. The dual concept of “community/continuum” refers to two complementary approaches to characterizing communities: as a community-unit or as a continuum of compositional variation. The community-unit hypothesis describes ecological communities as distinct and repeatable entities across the landscape. By contrast, the continuum hypothesis represents communities as idiosyncratic assemblages, conceptually represented as a region within a multidimensional continuum of independently distributed species that track environmental gradients and reflect chance events of dispersal and disturbance.

The community-unit concept came to prominence at the turn of the twentieth century through the concurrent work of continental European phytosociologists such as Josias Braun-Blanquet and North American and British plant ecologists such as Frederic Clements and Arthur Tansley. Clements argued that a biotic community is analogous to a “superorganism,” consisting of interdependent parts that together constitute a coherent whole. Envisioned as such, communities were asserted to express a significant degree of cohesion by means of positive interactions as well as similar adaptions to competition, disturbance, and environmental change. In the Clementsian view, the developmental development of communities through time is best characterized by the deterministic replacement of individuals (and species), eventually resulting in a stable “climax” community.

The Clementsian community-unit concept was challenged by Henry Gleason and colleagues, who observed that while biotic interactions affect species presence, the abiotic environment ultimately assumes the most significant role in constraining species distributions. In Gleason’s individualistic approach to species assemblages, the composition of communities is the product of overlapping yet independent species distributions, rather than discrete repeatable community units. In addition to environmental factors, the composition of any one stand is constrained by stochastic disturbance events and historical contingencies affecting dispersal and recruitment from the local species pool. While Gleason’s individualistic hypothesis was initially met with resistance, by the mid-twentieth century empirical evidence increasingly supported his view.

Skepticism regarding the concept of the Clementsian superorganism and the discreteness of the community-unit hypothesis reached a turning point in the 1950s with the simultaneous, independent development of the community-continuum hypothesis by ecologists John Curtis and Robert Whittaker. The community-continuum hypothesis describes variation in floristic composition and structure as the product of species’ individualistic responses to continuous environmental gradients. In this view, communities can be characterized as regions within multidimensional compositional space where spatiotemporal variation in community

composition is driven by site-level environmental variables as well as biotic interactions such as competition, pathogens, and herbivory. While Curtis and Whittaker described the principle of community continuity in space and time using a Gleasonian framework (as individual species, rather than entire communities, replacing each other over time), it was their focus on community-level assemblages that distinguished their community-continuum concept from Gleason’s species-scale individualistic hypothesis.

John Curtis and his students proposed a continuum approach and developed quantitative methods to identify continuous gradients of compositional variation between forest stands, independent of environment or history (Curtis 1959). This use of numerical similarity to order vegetation samples is referred to as indirect gradient analysis, or ordination, and remains in wide use today. Recognizing that abiotic factors can strongly influence establishment and dominance, Curtis applied known environmental values such as pH and soil texture to describe and differentiate compositionally dissimilar groups. This post hoc inclusion of abiotic drivers to describe differences among communities provided an initial framework for Curtis and colleagues to examine compositional variation in vegetation as well as other groups of co-occurring organisms ranging from birds to lichens.

Concurrently and independently, Whittaker advanced the continuum hypothesis through his innovation of direct gradient analysis, an analytical method to describe and explain spatial patterns in community composition (Whittaker 1967). Whittaker contextualized compositional variation in relation to measureable aspects of the physical setting using either direct environmental gradients or complex gradients such as elevation and topographic position. Gradients were graphically depicted as orthogonal axes where one could visually distinguish distinct regions, and upon which community mosaics could be overlaid. Viewed in ordination space, the $n$-dimensional environmental gradients described by Curtis and Whittaker define species’ fundamental niche space and the stage on which biotic forces such as competition constrain species to their realized niche space. While Curtis and Whittaker represented species distributions as unimodal response curves to multidimensional environmental factors, the gradient analysis approach has since been broadened through the application of a broad array of ordination techniques, including those which incorporate polymodal response curves (see Austin 2013).

Whittaker recognized the need to categorize community types in a standard framework for community classification. Although Gleason correctly noted that no two communities are exactly alike, modern community classification efforts are predicated on the idea that one can designate community types while still recognizing compositional variation and the idiosyncrasy of individual stands. From this dualistic perspective, the community-unit and continuum concepts are concurrent and compatible models of great utility in describing complex biological phenomena, much like the morphological species concept is useful despite sometimes large amounts of intraspecific genetic variation. From this perspective, community units exist as nominal entities such that the classification of vegetation into discrete types is feasible, provided the arbitrary character of their delineation is recognized.

Terrestrial community types are most commonly, though not exclusively, characterized by dominant or diagnostic flora. Variation among communities can be quantified by the degree of compositional similarity/dissimilarity between them, and used as the basis of a synthetic community classification system whose typological structure is determined by statistical relationships and expert opinion. Communities can
be classified as belonging to a single, exclusive “crisp” type, or assigned to a set of “fuzzy” types ranked according to relative membership probability. These classification efforts recognize that species associations are empirically observable and that broadly defined community types exist in replicate over landscapes, while still acknowledging that individual assemblages are fluid and dynamic in composition. Though some disagreement remains between national schools regarding the best methods for organizing community types into a coherent classification structure, recent efforts have aimed to globally standardize classification protocols for consistent standards across geographic regions (see De Cáceres et al. 2015 for a review).

Although most ecologists today recognize the utility of the Gleasonian concept of individualistic species assemblages and the continuum model underlying community classification, debate continues regarding the relative merits of these models for use in different contexts. Part of this debate may be attributed to different methodological approaches or scales of reference, with no one perspective inherently correct. Where the community unit is an abstraction based on geographical space, the community continuum reflects an abstract environmental space in the context of biological–environmental relationships (Austin 2013). For land managers and policymakers, envisioning communities as convex volumes in environmental hyperspace may not be as useful as characterizing them as discrete units upon which management plans can be effectively implemented. On the other hand, recent trends in landscape ecology emphasize communities as continuously intergrading over larger spatial extents. Species distribution models increasingly reflect abiotic proxies and likelihoods for species presence as a wall-to-wall raster grid, rather than a patch mosaic of discrete community polygons (see Evans and Cushman 2009).

Land cover maps based on remotely sensed imagery provide another arena to highlight the distinction between the two approaches. While remote sensors detect energy from the Earth’s surface and convert these measurements to a continuous range of integer values, the land cover maps produced from these pixel arrays are the result of the classification of continuous data that partially reflect the subjectivity inherent in the choice of sensor design and classification algorithm. For example, the US National Gap Analysis Program (GAP) uses remotely sensed imagery to produce wall-to-wall land cover maps that depict vegetation as discrete polygons representing plant community types. Ultimately, both the community-unit and the individualistic-continuum perspectives possess their own distinct advantages in describing the nature of ecological communities. With climate change and other global environmental trends demanding disparate responses from scientists, policymakers, and land managers, the practical imperative to classify community types into discrete classes will remain, even as projections for how biotic assemblages will respond to global change will be conducted within a framework of continuous compositional variation.

COMMUNITY/CONTINUUM IN BIOGEOGRAPHY

Comparative advantage

Godfrey Yeung
National University of Singapore

Comparative advantage is defined as the capacity of an agent, a region, or a country to produce a specific commodity or provide a service at a lower opportunity cost (the value that one has to forgo) over another agent, region, or country. This concept is based on the relative cost ratio for one agent to produce a commodity compared to the cost ratio of another agent. It is one of the fundamental concepts in international economics and is normally used to support free trade and pertinent policy agendas in the Washington Consensus. The original concept of comparative advantage and the neoclassical international trade model are explained before a brief overview on the propositions outlined by heterodox economists and neo-Marxist social scientists.

Ricardian comparative advantage

The concept of comparative advantage was first mentioned in Adam Smith’s seminal book (1904/1776) *An Inquiry into the Nature and Causes of the Wealth of Nations* and this brilliant idea is elucidated in David Ricardo’s (1973/1817) classic *On the Principles of Political Economy and Taxation*. Under the scenario of a barter economy with a fixed exchange rate of 1:1, he illustrated the concepts of absolute and comparative advantages with the opportunity costs of producing wine and cloth in Portugal and England. In Portugal, the cost of producing one unit (gallon) of wine was 80 labor hours and one unit (yard) of cloth took 90 labor hours (Table 1). In England, the corresponding opportunity costs were 120 and 100 labor hours, respectively. Portugal clearly had the absolute cost advantage over England (i.e., it used fewer labor hours) to produce both commodities: their cost ratios are 80:120 (0.66; Portugal utilizes 66% of England’s labor hours to produce the same output) in wine and 90:100 (0.9) in cloth. Naturally, this suggested Portugal should produce both types of commodities and England should just buy (import) them from Portugal.

Instead of focusing on the cost ratios or absolute cost advantages between Portugal and England alone, Ricardo (1817) argued that the cost ratios of producing both commodities within each country needed to be considered. Portugal then had a comparative advantage in wine production while England had a comparative advantage in cloth production. The opportunity costs of Portugal to produce one yard of cloth was equivalent to 1.125 gallons of wine, that is, $1 + [(90 - 80)/80]$, while the opportunity costs of England to produce one gallon of wine was 1.2 yards of cloth, that is, $1 + [(120 - 100)/100]$. Therefore, both countries should specialize in producing the commodity that gave them a comparative advantage and trade with each other. In other words, the best course of action was for Portugal to produce wine instead of utilizing 90 labor hours to produce one yard of cloth because it could get 0.125 yards more cloth by trading with England (at the 1:1 barter exchange rate), that is, better to use 90 labor hours to produce 1.125 gallons of wine and exchange it for 1.125 yards of cloth from England (so the 90 labor

hours yielded one yard of cloth directly and another 0.125 yards of cloth indirectly). By the same token, it was better for England to produce cloth rather than utilize 120 labor hours to produce one gallon of wine because a further 0.2 gallons of wine are available by trading with Portugal, that is, the 120 labor hours to produce 1.2 yards of cloth could have been exchanged for 1.2 gallons of wine from Portugal. Rather than each country trying to produce all the commodities they need, Ricardo further argued that countries can gain from trade if they produce commodities for which they have the comparative advantage and then trade them for commodities from other countries.

The neoclassical Heckscher–Ohlin–Samuelson trade model

In the original two-country and two-commodity model, Ricardo showed that even if one country had the absolute advantage in producing both commodities, both countries could benefit from trade if they specialized in producing the commodity where they had comparative advantage, that is, the opportunity costs of producing that commodity would be lower than those of their trading partner. In Ricardo’s example, both England and Portugal would have gained from trading, even though Portugal had a cost advantage for producing both wine and cloth. In the Ricardian version of comparative advantage, differences in the technologies employed by labor in different countries determine costs and comparative advantages.

However, Ricardo’s extraordinarily influential conceptualization of comparative advantage is based on three highly restrictive assumptions. First, his illustration is based on a two-country and two-commodity barter economy with a fixed exchange rate of 1:1; no currency and exchange rates are considered (see Dunford et al. 2014 for the importance of wage costs and exchange rates for international trade). Second, labor, one of the factors of production (labor, capital, and land are the three main factors of production), is immobile. Third, there are no transaction costs (costs incurred in the collection of information and the processing of exchanges, including transportation) in international trade.

The Ricardian conceptualization of comparative advantage was further developed by Eli Heckscher and Bertil Ohlin, and later enhanced by Paul Samuelson into the canonical neoclassical Heckscher–Ohlin–Samuelson (H–O–S) model of international trade. To address concerns about the restrictive assumptions of Ricardian comparative advantage, Ohlin (1967/1933) relaxed the single factor assumption in the two-country, two-commodity, and two-factor (labor and capital) model and argued that comparative advantage, geographical specialization, and trade are driven by regional factor endowments in his book Interregional and International Trade. According to the Heckscher–Ohlin theorem (H–O theorem), countries export products that make intensive use of production factors (labor and capital) and natural resources that are relatively abundant and relatively inexpensive. In other words, a capital-abundant country exports capital-intensive goods to
labor-abundant countries while importing labor-intensive commodities in return.

Neoclassical economists therefore argue that the international division of labor (specialization of production on a national basis) is a natural consequence of the spatial differentiation of labor productivity (Ricardian comparative advantage) and (Heckscher–Ohlin) factor endowment. As the production factors (labor and capital) are mobile within countries but immobile between countries (as stipulated in the H–O theorem), and markets are perfectly competitive, factor prices will be equalized across countries as a result of international trade, according to Samuelson’s factor price equalization theorem (see also Barro, Mankiw, and Sala–i–Martin 1995; Mankiw, Romer, and Weil 1992). Therefore, the neoclassical theory of international trade hypothesizes that incomes across countries will converge and development will not be uneven. In other words, free trade promotes economic growth and reduces regional disparity across space.

It is unquestionable that the H–O–S model of international trade is a brilliant extension of Ricardian comparative advantage. However, it is unable to reconcile the uneven economic growth observed between developed and developing countries since World War II. The H–O–S model still suffers from a set of, although much less restrictive, unrealistic assumptions: the production function has constant returns to scale (i.e., no accounting for technological advancement), production factors are immobile across space (countries), and markets are perfectly competitive.

To address the lack of solid empirical evidence for the convergence of income across countries hypothesized by the H–O–S theorem, international trade economists, notably Paul Krugman, relax the constant returns to scale assumption and argue that the divergence of income between developed and developing countries is due to the increasing returns to scale of investment among the former in the new trade theory.

The new international division of labor and the neo-Marxists’ interpretation

Instead of the “win-win” scenario portrayed by neoclassical international trade theory in general and W.W. Rostow’s type of modernization theory in particular, heterodox economists and neo-Marxist social scientists argue that there is limited empirical evidence to support the H–O–S theorem. As there is increasing divergence of income across countries, especially between developed and developing countries since World War II, heterodox economists argue for the protection of infant industries in developing countries. Newly established industries in developing countries are unable to compete with the established giants in developed countries, hence, they need to be sheltered by import tariffs and quotas until they become competitive internationally. Hans Singer and Raúl Prebisch have similar policy recommendations based on their Singer–Prebisch thesis: developing countries are under unfavorable and deteriorating terms of trade (the relative price of exports compared to imports) and suffer from trade deficits due to the low export prices of raw materials and minerals relative to the higher import prices of machinery and manufactured goods.

The increasing dominance of transnational corporations (TNCs) in foreign direct investment (FDI) in developing countries, an important phenomenon of the new international division of labor due to the relocation of labor-intensive manufacturing activities from developed countries to Asian developing countries since the 1970s, fuels further debates about the effects of international trade on development. In his book, *Kicking Away the Ladder: Development*
Comparative Advantage

Strategy in Historical Perspective, Ha-Joon Chang (2002) highlighted the historical paradox that advanced economies (like the United States and the United Kingdom) used interventionist and protectionist economic policies to accumulate capital during their early stages of economic development yet bar developing countries from following similar pathways today.

Neo-Marxist social scientists go further by highlighting the exploratory nature of free trade and the subsequent dependent relationships between developed and (newly independent, especially former colonies) developing countries. Dependency theorists, notably Andre Gunder Frank, argued that the existing model of capitalist development promoted the “development of underdevelopment” in developing countries. He illustrated his argument by referring to the postcolonial (under)development experience in Latin America in his book Capitalism and Underdevelopment in Latin America (1967). By tracing the history of development in sixteenth-century Western Europe and America, in The Modern World System (1974) Immanuel Wallerstein articulated similar arguments in his world systems theory. Despite the fictitious nature of capital and the endless accumulation of capital by competing agents (see below), Wallerstein argues that the world economy is sustained by a dominant capitalist core (developed countries), which extracts surplus value (resources and capital) from the periphery (developing countries, especially former colonies, and to a lesser extent, semiperipheral countries at the developmental stage between the core and periphery) through a complex network of economic exchanges (including unfavorable terms of trade) and their control over the economic and political institutions. In an edited volume, The World System: Five Hundred Years or Five Thousand (1993), Andre Gunder Frank and Barry Gills further contributed to the debate by pointing out that the global and economic power of a nation is largely determined by its historical circumstances and geography.

Instead of lack of integration into the international trade, as normally argued by neoliberal trade economists, dependency theorists argue that developing countries are perpetually locked into a world system of core–periphery dependency where the core (developed) countries dominate the advanced technologies and global political and economic institutions while the developing countries are locked into unfavorable terms of trade and remain exploited.

Neo-Marxist geographers have typically highlighted the fictitious nature of capital in the debates. In his seminal work The Limits to Capital (1982, 2006), David Harvey pointed out that the relocation of manufacturing sectors from developed to developing countries is a spatial fix of TNCs due to the overaccumulation of fictitious capital and the intrinsic crisis nature of capitalism rather than the results of FDI and free trade.

Harvey’s geography of capitalism developed from the theoretical foundation of Karl Marx’s classical work on “fictitious capital” about the speculative quality of credit money that results in excessive accumulation. In Capital (1906/1867), Marx argued that capital has a dual role. As productive capital, it lubricates circulation and exchange by allowing the purchase of commodities in production and the exchange of transformed commodities back into money before being reinvested in production (through the financial system) and thus maintains the circulation of capital and the operation of capitalism. As commercial capital, it is an expression of value. Under the guidance of “miserly thinking” (see Doel 2009) where “scarcity” (the world is unable to fulfill insatiable consumption demands) and market prices control allocation, capitalists maintain the operation of neoliberal
capitalism by accumulating the surplus value produced by the working classes through primitive accumulation, such as privatization and financialization (Harvey 1982, 2006). (According to Karl Marx, surplus value is the difference between the value of money as capital used to purchase commodities and the value contained in the commodities transformed by labor.)

Should an investment involve some form of credit, financial capital remains a form of speculative holding (i.e., the value of commodities is “fictitious” and does not materialize until they are sold) in the circulation of capital and could be devalued. Financial institutions then act as intermediaries to facilitate the market for fictitious capital in the circulation of surplus value by offering interest payment to capital owners and charging interest premiums to capital borrowers. Once the expansion of production capacity goes beyond market demand, however, capitalists compete for limited opportunities to deploy their capital profitably, for example too much machinery and materials competing for too little labor power results in a reduction in surplus value. Subsequently, financial institutions may not be able to pay interest to capital owners due to the diminished surplus value generated from production, and hence the devaluation of the fictitious capital. The owners of capital thus withdraw it from circulation by liquidating their fictitious capital holdings and hoarding them as commercial capital, and this overaccumulation of capital leads to its further devaluation. Marxists believe this withdrawal of productive capital from the system happens from time to time, and the economic system is thus inevitably prone to cyclical and systematic crises as state intervention is unable to correct the intrinsically destructive force of the excessive and unsustainable accumulation of capital and the devaluation of surplus value through the circulation of capital (Harvey 1982, 2003, 2006).

Comparative advantage versus competitive advantage

Instead of comparative advantage, official policy papers prepared for governmental and nongovernmental institutes these days normally use the term “competitive advantage.” Competitive advantage was coined by Harvard Business School guru Michael Porter. In his seminal work Competitive Advantage: Creating and Sustaining Superior Performance (1985), he argued that countries have a competitive advantages either by producing commodities at lower costs or at different specifications or forms where consumers are willing to pay higher prices. In a major departure from the utilization of existing comparative advantages and factor endowments outlined by the H–O–S theorem, he emphasized productivity growth should be the focus of national strategies as countries cannot depend on nonsustainable low labor costs and the exploitation of natural resources alone.

Interestingly, Project Socrates was commissioned by the Reagan administration in the United States to establish the foundation for a technology-based competitive strategy development system that could be used to guide international trade policy while the Washington Consensus was germinating in the 1980s.

Competitiveness

Luis Rubalcaba  
*University of Alcalá, Spain*  
*World Bank, USA*

Competitiveness is about the ability and effort required to grow and to improve the living standards of citizens, organizations, social communities, cities, regions, and countries within the international global arena. In economic terms, it is usually defined as the performance of firms, regions, and countries in the global economy.

The concept of competitiveness

The term “competitiveness” is a rather vague, fuzzy word that can mean different things. Synonyms explaining what it means to be competitive are numerous: productive, good, best, cheap, efficient, effective, and so on. “Competitive” is defined by Oxford Dictionaries online as “relating to or characterized by competition” (synonyms given are ruthless, merciful, aggressive, fierce), “having or displaying a strong desire to be more successful than others” (synonyms are ambitious, driven, vying, combative, contentious, aggressive; insistent, driving, pushing, zealous, keen), and “as good as or better than others of a comparable nature.” Therefore, competitiveness is about success and improvement when judged against others. In economic terms, this is not necessarily the case, with concepts ranging from the competitive capabilities of workers, the market position of companies, the ability of a region, a country, or a group of countries to face global competition and to export more than they import, to the ability to steadily increase their participation in global supply, support, and raising income levels. All these alternatives assume the continued growth of productivity and hence the incorporation of technical progress in production processes.

The notion of competitiveness usually involves taking a position in relation to two factors. Firstly, it is a comparative term that requires comparisons to be made between countries, regions, companies, or individuals. Second, it is a term that presupposes a capacity for countries and other entities to modify their position in such a comparative context. The diversity of meanings has not prevented competitiveness from being used as a tool for analysis in economic geography, since it is basically about how organizations and countries are acting in new, global, interrelated spaces (regions, cities, etc.).

The construction of economic activity requires, at a given time, that distinctive features are present. These are the differentiators relative to the current state of things. These differentiators may be based on price, quality, reputation, or any other attributes that help to create comparative advantage. The success of economic development involves competing against the previous situation and with or against others. In its etymological sense, “competitiveness” is the result of a tension within a competitive jurisdiction; it is the action of “competing with.”

The term “competing with” involves three aspects. First, there must be a plurality of agents (at least two). Second, there must be a common aspiration (something shared, an objective). Third, some effort must be exercised (to make an attempt, a strategy, and a deliberate engagement).
COMPETITIVENESS

Following from this, competitiveness implies an ontological dimension (e.g., what a company, a region, or a country is in relation to others, or what a country is able to do) and a behavioral dimension (what a company, region, or country does and how it affects others). To understand this distinction, an analogy can be drawn with human behavior. What defines a person’s social dimension is “being with,” or what it means to “be with and to others,” rather than specific behaviors “with or against others.” A person is a social being by nature but can suffer antisocial deviations or enjoy high levels of sociability. The ontological significance of competitiveness, first of all, implies an improvement of an agent’s position in an environment in which others try to do the same. The individual who improves significantly against himself/herself, regardless of the impacts on others, is the competitive one. Competitiveness is more than an action; it also requires the ability to compete. In this sense, economic competitiveness at an international level must be defined as the economic fitness of two or more countries or regions to improve their economic welfare. They compete, for instance, to achieve higher levels of employment, income, or quality of life.

According to this concept, competitiveness is about the ability and effort required to improve the living standards of citizens, organizations, social communities, and countries, not only or even primarily to increase market shares abroad (this would be a behavioral meaning of competitiveness, “compete against”). In economic terms, it is usually defined as the performance of firms, regions, and countries in the global economy. To the extent that international trade is part of the economy of a country or a region, competitiveness concerns international trade, among other things.

If the ontological dimension of competitiveness is not taken into account, policy actions would be understood in the context of conflict behaviors and zero-sum games in which one country or region, for example, wins and another one loses. Collaboration with the competitors should be avoided in this approach. However, the world’s economies are not mostly zero-sum games and everybody can win from international trade; this makes collaboration highly positive for the competitiveness of everybody.

Definitions of competitiveness

There are many definitions of competitiveness. BusinessDictionary.com defines it as the “Ability of a firm or a nation to offer products and services that meet the quality standards of the local and world markets at prices that are competitive and provide adequate returns on the resources employed or consumed in producing them.” This definition clearly relates to business success. In relation to regions and countries, productivity appears to be the key determinant of competitiveness. According to Michael Porter (2004, 50) competitiveness is defined by the productivity with which a nation utilizes its human, capital, and natural resources; the starting point must be a nation’s underlying sources of prosperity. Productivity is at the center of a country’s standard of living and the way to measure competitiveness. For Porter, what matters most is not exports per se or whether firms are domestic or foreign-owned but the nature and productivity of the business activities taking place in a particular country. This also applies to individual regions, cities, and productive regional clusters.

There are two institutions in Switzerland that publish the key international reports on competitiveness, including definitions. In the World Competitiveness Report (WCR) Sala-i-Martín et al. define competitiveness
as the set of institutions, policies, and factors that determine the level of productivity of a country. The level of productivity, in turn, sets the level of prosperity that can be reached by an economy … a more competitive economy is one that is likely to grow faster over time. (2014, 4; emphasis original)

For Sala-i-Martín et al. there are two components of competitiveness: static and dynamic. The former refers to the ability to sustain a high level of income while the latter is related to growth potential. A rather different approach is employed in the IMD World Competitiveness Yearbook (ICY), where Bris and Caballero (2015, 2) state that competitiveness is “the ability of a country to facilitate an environment in which enterprises can generate sustainable value.” Thus, the WCR focuses on factors behind productivity growth while the ICY mainly focuses on factors behind value creation, mainly at firm level.

Based on the previously defined ontological dimension of competitiveness, a more general definition is provided that is not only about the productivity capacity or value creation in countries. In this instance competitiveness can be defined as the capacity (ability and effort) of people, organizations, cities, regions, and countries to create growth in living standards within the global arena. In economic terms, at country level, this growth can mainly be measured by productivity and value creation but welfare gains are also included. Under this overall umbrella, there are different types of competitiveness: trade competitiveness (the most used connotation in international economics), business competitiveness (at firm level), industrial competitiveness (at sector level), regional competitiveness (highly relevant for studies of cities and regions), social competitiveness (performance in terms of social indicators such as poverty and shared prosperity), and global competitiveness (the holistic approach followed in the WCR and ICY).

Each of these specific concepts requires specific indicators and measures, such as the regional profiles compiled using the EU Regional Competitiveness Index (Annoni and Dijkra 2013) or the sectoral approach for service industries based on comparative measures in productivity, internationalization, innovation, regulations, and competition (Rubalcaba 2007).

The social context

The notion of competitiveness has important social as well as economic implications. The ongoing wave of globalization largely explains the interest in this topic since the 1990s, beginning with the international expansion of trade in the 1960s. Large global flows enabled by a revolution in information and communications technology (ICT) emphasized the deepening economic relations between peoples, markets, cities, and countries. The first great wave of modern globalization between 1870 and 1914 was linked to the political and industrial strength of the colonial powers and it was relatively easy for politicians to lead the process. The European Union emerged after World War II with the objective of political peace and reconciliation, in which the economy served as a cornerstone. In today’s globalization, it is no longer so evident who leads the processes; economic power has often proved stronger than political power.

In this new context, to be competitive has more than ever become a priority in a more interconnected world. The welfare of workers, employers, shareholders, and citizens is increasingly linked to their relative position in the hierarchy. Workers therefore seek to improve their educational levels, language abilities, and technical skills in order to be able to compete for better jobs and a higher degree of employability. Employers must be alert to increasing
COMPETITIVENESS

competition in a world offering a higher level of opportunities but also with certain vulnerabilities. Shareholders and investors are increasingly dependent on the evolution of the major exchanges in the leading global financial centers (such as London, New York, Sydney, Shanghai), where they must compete to identify and acquire the best information. Citizens struggle to improve their living standards and compete for the best services in schools, housing, utilities, and all kinds of other public and private goods and services. Cities and regions are looking for ways to become more competitive in order to attract trade, investment, and economic activity that will enhance their economic and social welfare. Being competitive has become an unavoidable action for achieving improvements in welfare.

Competitiveness has reinforced the value of dynamism and flexibility. Not only is the competitiveness of a company defined by its income and profit, but it must also be able to continuously adapt to new requirements and to keep rethinking its goals and strategies. A sector is competitive when new firms generate new value, creating comparative advantage. A city or a region is competitive when it achieves sustainable levels of local development. A country is competitive when it is able to attract income and wealth over and above that arising from short-term economic development. In essence, competitiveness is an evolutionary concept.

The academic debate

Krugman (1994; 1996) argued that there are dangers associated with the careless application of the term “competitiveness”; its use should be restricted to well-defined cases. At best, it should be used synonymously with “productivity.” This is based on the assumption that, on the one hand, competitiveness mainly refers to international trade and, on the other hand, the economics of countries does not work in the same way as for businesses or firms. At a business level, there are zero-sum games, whereas this is not the case at international level where there are plenty of win–win transactions. Krugman later wrote on his New York Times blog (2011):

It’s OK to talk about competitiveness when you’re specifically asking whether a country’s exports and import-competing industries have low enough costs to sell stuff in competition with rivals in other countries; measures of relative costs and prices are, in fact, commonly – and unobjectionably – referred to as competitiveness indicators. But the idea that broader economic performance is about being better than other countries at something or other – that a country is like a corporation – is just wrong.

This position is useful in that it alerts us to a mistake often made by some policymakers when they blame external conditions in order to cover up internal problems, for example, when they set up protectionist measures instead of making domestic reforms to improve competition and productivity. However, Thurow (1994) and Cohen (1994), among others, did not concur with Krugman’s view of the role of external trade in domestic economy, while the IMD World Competitiveness Center (2014) notes that “Some scholars claim that nations themselves do not compete, rather their enterprises do. Nations compete because world markets are open.” To what extent do nations compete or not compete? These questions underpin disagreements between scholars’ views on competitiveness.

The aforementioned ontological dimension seems to support the Krugman side of the debate, since it is not restricted to international trade and closer to the win–win games view proposed by neoclassical theories. However, there is also room for behaviors such as zero-sum games. Following previous findings (Rubalcaba 2002),
what is right and wrong depends mainly on three factors: the geographical units and their sizes, the performance of these geographical units, and the dynamics of economic systems. The more that small and micro(geographical) spaces are considered, the more likely it is that a zero-sum game may exist. On the other hand, the bigger the units (large countries, large regions), the more likely it is that nonzero games exist. However, size is only one factor; it is also the case that not all geographical units have the same institutional and productive endowments. Nor do they have the same settings and capacity to change specialization patterns, mobilize resources to shift to more competitive sectors, and adapt to the advantages of international trade. Geographies evolve over time in such a way that the balances between win–win and zero-sum games will depend on system dynamics and evolutionary efficiency. Therefore, the scale, the flexibility, the quality, and the dynamics of each geographical space matter.

The drivers of competitiveness

The drivers of competitiveness will vary, depending on which concept of competitiveness is adopted. If it just involves international trade, division of labor in international markets, and market share, then factors related to business trade performance, such as costs, prices, and product differentiation will be very important. This is also true for some institutional and macroeconomic factors affecting trade, such as exchange rates, inflation rates, and the business climate for trading and investment. The relative importance of each driver can be classified and rated, depending on the theoretical model. Some examples include the classical absolute advantage theory (Adam Smith) which is based on intrasectoral advantages; the neoclassical thinking model (David Ricardo) which is based on relative comparative and intersectorial advantages; and the Heckscher–Ohlin–Samuelson (O–H–S) model which is based on general equilibrium and different factor endowments. If trade competitiveness is not substantially determined by price or cost factors, which is very often the case in both goods and services markets, it is referred to as the Kaldor (1978) paradox, whereby the market shares of sectors abroad are driven by factors not related to prices and costs; due to quality and differentiation, industries and countries may have more exports and better market shares in the context of higher prices and costs.

When competitiveness is approached from a more macro and holistic angle, all the factors that influence productivity, value creation and growth play a role. Productivity and growth are determined, in particular, by institutions, policies, markets, agents, and geography at the macro, meso, and micro levels. Michael Porter (1998/1990) proposed a “diamond” framework to help to understand what determines competitiveness at various local, regional, and country levels. The diamond comprises four pillars: (i) factor conditions (relative factor endowments, new factor dynamics, and intra- and interfactor dynamics); (ii) demand conditions, referring to the composition of domestic demand, size and patterns of demand growth, internationalization of domestic and demand dynamics; (iii) support-related sectors, for which a nation may have a competitive advantage in supplying sectors or related services around a particular industry; (iv) strategies, structure, and rivalries of companies, referring to the role of corporate competitiveness strategies (strategy and structure of domestic firms, goals and objectives, etc.). Within this diamond framework there is also room for the effects of chance and for public intervention.
COMPETITIVENESS

Recently, a more comprehensive approach has been proposed. The World Economic Forum (WEF) uses 12 pillars of competitiveness: institutions, infrastructure, macroeconomic environment, health and primary education, higher education and training, goods market efficiency, labor market efficiency, financial market development, technological readiness, market size, business sophistication, and innovation. Using these factors in combination, countries are placed along a continuum ranging from factor-driven economies to economies driven by efficiency and innovation. Innovation is the ultimate stage of development and is closely related to both economic and institutional factors. Technology change (Fagerberg 1996) and national systems of innovation (Lundvall 1992; Nelson 1993) are also highly relevant in this context. The World Competitiveness Center utilizes a similar set of factors but in a different way. Four pillars are proposed: (i) economic performance; (ii) business efficiency; (iii) government efficiency; and (iv) infrastructure. Four other dimensions are then analyzed for these pillars: attractiveness versus aggressiveness, proximity versus globalization, assets versus processes, and individual risk-taking versus social cohesiveness. Such approaches to global competitiveness rely on a comprehensive multidimensional view, with each having the potential to highlight important implications for policymaking.

Competitiveness policies

Whether competitiveness is understood in a narrow sense as a position on the international trade market (with other countries or regions) or in its traditional sense as improvement and superiority in key variables of economic growth and welfare (employment, income, etc.), identifying and utilizing appropriate policies is an important task. First, policies designed to improve the competitive position of a country or region relate primarily to foreign trade, although with obvious interrelationships to other policies. Second, specific competitiveness policy and economic policy in general largely overlap: policies that improve economic and welfare performance do establish the full range of possible policies, namely stabilization, structural, macro- and microeconomic policies. A competitiveness policy is, in this sense, a comparative economic policy in that the purpose is to analyze the factors that influence the relative positions of countries or regions. However, since the relative differences between countries and regions are related to structural factors and long-term policies, competitiveness policy tends to privilege the structural features that are linked to factors of production. Short-term stabilization policies thus remain at the level of macroeconomic policy formulation for a country as a whole, even though this may influence national or regional competitiveness.

From the perspective of regional or urban economic policy, six types of policy can shape competitiveness and competitive wellbeing.

- **Trade policy**, understood as directed toward the growth of international trade in the region and attracting investment; this is a policy of actual trade competitiveness.
- **Productive factors policy**, comprising natural resources and infrastructure, labor market and human capital, physical capital and financial capital. All affect competitiveness in general, and trade competitiveness in particular. The human capital factor is a central element in this set of policies.
- **Market and industrial policies** relate to the environment and markets in which industries are operating, and include state intervention in the markets for goods and services (regulation, competition policy, business climate)
and industrial policy in the traditional sense (clusters policy and industrial development).

- **Innovation policy** as a competitiveness element: here, incentives are used to encourage innovation in goods and services provided by the market, especially if market or system failures are detected. Innovation policy may be incorporated into technology and research and development policy as well as programs directly aimed at innovation and adoption and absorption of technology and knowledge, including labor market and employment policies (active and passive), social benefits (social security, pensions, disability), environmental policy, and income redistribution;

- **Urban planning policy**: the organization of space in cities and regions is a key factor rendering the city or region attractive to trade and investment. Also fundamental is support for the functional needs of the markets, such as logistics or the production of high-quality residential environments for workers. This is especially challenging when devising policies aimed at enhancing the availability of skilled professionals in knowledge-intensive services.

### Concluding remarks

Competitiveness is important, but studies of it are still at an early stage of development. Most date from the 1990s onward, even though Adam Smith and others mooted theories of competitiveness as far back as the early eighteenth century. A future research agenda may include further development of conceptual frameworks; addressing measurement issues; the new factors emerging as competitiveness drivers; the role of new global value chains and policy design. Competitiveness is a complicated multidimensional phenomenon; a multi- and pluridisciplinary approach will be important for further research. Geographers, economists, sociologists, urban planners, marketing and business researchers, and practitioners should work together more to deepen understanding of a process that ultimately has an impact on the economic and social wellbeing of us all.

Complexity in biogeography

Daehyun Kim
University of Kentucky, USA

Complexity is generally defined as a property of a system that results from the interactions between many basic components according to fundamental rules, with a potential to generate unexpected order (Levin 1998). In this broad definition, how such system components interact with one another is not stated explicitly due to differing views among geographers on the relationships between nonlinearity and complexity. Malanson (1999) considered that multiple variables per se do not constitute complexity; complexity exists when these variables are dynamically intertwined over space and time in a nonlinear way. This perspective is in accordance with the notion that feedbacks that lead to nonlinearity and, eventually (if not always or inevitably), to self-organized criticality characterize nonequilibrium systems, which are the building blocks of the science of complexity (Holland 1995).

However, Phillips proposed that “not all nonlinear dynamics are complex; not all complexity is nonlinear” (Phillips 2003, 4). To him, nonlinear dynamics and complexity have their own conceptual territory, although they share a commonality, termed complex nonlinear dynamics (CND), which represents the complexity that arises from intrinsic nonlinearities within a system. Put another way, CND simultaneously implies a subset of nonlinear system behaviors that lead to complex behavior and a subset of complexity that arises from nonlinearities. This entry will not evaluate which of these two perspectives is more relevant to the contemporary literature of biogeography; in either case, nonlinearity is an important part of the conceptual background of the complexity theory.

The complexity theory resulted from recognizing the inability of the traditional reductionist approach to explain how higher-level patterns of physical and biological systems across space and time emerge from and control localized interactive processes occurring at lower levels. Simply put, in biogeography, the detailed study of individual trees with regard to their physiology and anatomy (i.e., reductionism) provides limited insight into how they compete with and/or facilitate one another to develop a population. The systems in which such feedbacks occur between higher and lower levels are regarded as typical examples of complex adaptive systems (CAS) (Holland 1995).

The limitations of reductionism arise from several related properties of CAS, including nonlinearity and emergence. Nonlinearity is one of the cores in the behavior of CAS, and it makes a whole larger (or smaller) than the sum of its parts. A CAS cannot be investigated fully by viewing each of these parts in isolation because they continuously interact within positive or negative feedback loops. Salt marshes provide a biogeomorphic example: pioneer plants begin to colonize the uppermost portion of tidal flats, and they increase sedimentation rates by reducing the energy of tidal flows and by trapping suspended fine particles during submergence. As a result, the surface elevation of the flat increases (i.e., decreases in waterlogging frequency and...
duration). Moreover, the early-successional plants gradually ameliorate the salinity levels of sediments. This, in turn, facilitates the growth of plants and augments the height and density of vegetation cover, further enhancing the sedimentation process. This positive feedback mechanism explains how the marsh surface constantly readjusts itself toward equilibrium as sea level changes. In such a CAS, nonlinear dynamics may lead to chaotic behavior such that minor variations in the initial conditions across the marsh surface are magnified over time. In the example above, salt marsh plants are considered ecosystem engineers that modify their surrounding physical conditions and modulate the availability of resources to other species and/or themselves.

Another important concept in CAS, emergence (or emergent properties), is a feature or order that generates spontaneously without any definable rule during the process of self-organization. Although emergence is an unexpected property, it still constitutes coherent and integrated structures in CAS. In the biogeographical literature, emergence has often been associated with spatially divergent self-organization in the evolution of landscapes, or spatial differentiation of landscapes from a homogeneous to a heterogeneous pattern (Phillips 1999). This divergence can be characterized by entropy, which is an appropriate measure of the organization as in the following model:

$$\bar{\delta}(t) = A e^{\lambda t}$$

where $\delta(t)$ is a perturbation event at time $t$, $A$ is a constant (or initial variation) at $t = 0$, and the arrows represent vector quantities. $\lambda$ is a Lyapunov exponent. The number of Lyapunov exponents in a system indicates the number of system components. Therefore, when there is at least one positive Lyapunov exponent (i.e., $\lambda > 0$), the associated system should experience an exponential increase of variation, that is, unstable and divergent landscape evolution. Overall, such a situation is defined as deterministic chaos. The concept of Lyapunov exponents is also related to the Kolmogorov (K-) entropy, which is calculated by summing up all positive Lyapunov exponents. A positive K-entropy implies a magnification of the initial spatial variation of, for instance, soil nutrients over time. This nonlinear chaotic behavior of soil resources may in turn induce a differentiation of vegetation cover into diverse spatial units.

In salt marshes, environmental controls, such as elevation and/or salinity, greatly influence early-successional vegetation patterning and dynamics over space. Over time, as biological interactions between plant species proceed and organic/inorganic matter accumulates, patterns of vegetation dynamics become stochastic and complex on the increasingly mature marsh surface. Therefore, researchers have often proposed that distinct plant species composition may be found even at locations having the same surface elevation. Such an unexpected compositional variability produced by internal marsh processes (i.e., self-organization) can be considered an emergent property. These discussions imply that vegetation patterns and dynamics in salt marshes cannot be fully understood or explained by elevation only; thus, the traditional elevation-centered perspective may be an oversimplification of the complexity of tidal marshes. Similar ideas of augmented complexity and stochasticity in vegetation patterning and dynamics through time have been reported in other contexts such as old-field succession, post-fire succession in boreal forest, and Mid-Holocene mangrove succession.

Within the framework of complexity theory, Stallins (2006) has attempted to integrate ecological and geomorphic components to conceptualize four unifying themes in biogeomorphology: (i) multiple causality; (ii) the
function of ecosystem engineers; (iii) the expression of ecological topology; and (iv) ecological memory. Multiple causality recognizes the importance of reciprocal interactions between form and process. For example, disturbance by fire, via its impact on vegetation, can influence surface erosion and slope stability (i.e., process affects form). Conversely, topography, through its variations in slope angle and aspect, determines the rate and pathway of fire spread (i.e., form affects process). Stallins emphasized the need to investigate how these form–process interactions play out across time and space, and to what extent this multiple causality becomes self-organizing. Adopting the concept of domains of scale, he demarcated different stability domains in which distinct form–process feedback mechanisms are observed. The regions bridging these domains are characterized as transient states. Overall, the stability domains and transient regions are combined to comprise ecological topology. Within this framework of ecological topology, a shallow lake can flip over time between nutrient-rich and nutrient-poor states. It should be noted that this switch is often mediated by ecosystem engineers that directly or indirectly modify flows of matter and energy, and even disturbance regimes. Depending on the type of ecosystem engineers, a system may dynamically switch between several different stability domains or remain persistent with a certain domain. Finally, ecological memory suggests that disturbance becomes encoded and reinforced in both vegetation and topography across a landscape. In barrier island dune systems, for example, the frequency and spatial extent of overwash events driven by storm surges are dynamically encoded in plant species abundances and dune morphologies. These plants, as ecosystem engineers, actively construct and reinforce their topographic niches in light of the historic disturbance regimes. A specific vegetation–landform complex can potentially perpetuate through this developmentally intertwined feedback.

Confidentiality

Matt Duckham  
*RMIT University, Australia*

Confidentiality is concerned with protecting the privacy of information about an individual. Information privacy itself is defined as the “claim of individuals, groups, or institutions to determine for themselves when, how, and to what extent information about them is communicated to others” (Westin 1967, 7). Thus, the topic of confidentiality covers more specifically what types of information have privacy implications, and how that information can be protected from invasions of privacy.

Information privacy

Information privacy is one of several types of privacy. Other types of privacy include bodily privacy (e.g., freedom from physically invasive medical procedures) and territorial privacy (e.g., freedom from intrusion into homes). Privacy in its broadest sense is recognized as a human right in the United Nations Universal Declaration of Human Rights.

A lack of information privacy is associated with a range of negative effects on individuals and society. Specifically, a lack of information privacy can lead to misuse of personal information about an individual in several ways.

- **Unsolicited marketing**: Personal information can be used by unscrupulous companies for unsolicited marketing, such as sending “spam” (inappropriate and indiscriminate) mail and emails to individuals. The inconvenience caused by these activities has direct and negative economic and personal consequences for the individuals, and for society more broadly.

- **Identity crime**: Personal information about an individual can be used by a hostile agent to assume another individual’s identity (termed “identity fraud” or “identity theft”). In 2013, identity crime affected more than 10 million people in the United States of America alone, and it can lead to significant financial and personal distress.

- **Reduction in personal safety**: Detailed information about an individual’s circumstances (e.g., home address, medical history, place of work) can potentially be used by a hostile agent to endanger that individual’s personal safety.

- **Intrusive inferences**: Personal information can be used to make unfair or unwarranted inferences about other areas of an individual’s life. Such inferences can be particularly damaging when made by companies or government institutions. For example, personal medical coverage might be adversely affected by information about a person’s web searches for “cancer” and related terms, or his or her visits to an oncology ward.

- **Inhibiting technological advances**: A perceived or actual lack of privacy can in turn inhibit the development or uptake of potentially beneficial technological advances. For example, if privacy concerns had prevented the acceptance of Internet applications, such as email, social networking, and cloud computing, society would at the same time have forgone the substantial benefits associated with those technologies.
CONFIDENTIALITY

As a result of these negative impacts of breaching information privacy, mechanisms for protecting information privacy, and so ensuring confidentiality, are important in order to avoid or at least mitigate these negative effects.

Privacy protection

In general, there are two distinct approaches to information privacy protection: those that aim to proscribe unfair use of private information, and those that aim to prevent the release of private information in the first place.

There exists around the world a wide range of regulations for dealing with private information. For example, more than 80 countries around the world have comprehensive laws that explicitly recognize information privacy rights (Greenleaf 2012). While privacy regulations vary in their details, in general they all adhere to five fundamental principles of fair information practices (FIPs, also termed “information privacy principles,” IPPs). These five principles can be traced back to a 1974 US Department of Health, Education, and Welfare report (on “Records, Computers, and the Rights of Citizens”).

1 Notice and transparency: Individuals must be made aware of when personal information about them is collected, by whom, and for what purpose.
2 Consent and use limitation: An individual’s consent is required in order to collect personal information about them. Personal information can only be collected for specified purposes, and the subsequent use of that information is limited to those purposes.
3 Access and participation: Individuals have the right to access personal data that refers to them. In case that stored data contains any inaccuracies, individuals may also require that errors be corrected.
4 Integrity and security: Collectors of personal information must make reasonable efforts to ensure data is accurate and up to date. They must also protect against unauthorized access, disclosure, or use.
5 Enforcement and accountability: The collectors of personal information must be accountable for any failures to comply with principles 1–4.

There are, however, two main drawbacks associated with information privacy regulations. First, striking a balance between allowing innovation and precisely defining fair use is difficult or impossible to achieve in all cases. Regulations that are too specific may inadvertently stifle unanticipated and potentially beneficial technological innovations. Regulations that are too unspecific risk exploitation of loopholes, resulting in inadequate privacy protection. Second, irrespective of the balance struck, privacy regulations can only hope to deter information privacy infringements, and penalize those who remain undeterred. However, once a privacy infringement has occurred, it is typically difficult or impossible to undo. Once private information has been publically disclosed, for example, it can never be undisclosed.

As a result, a second approach to information privacy protection aims to protect the personal information itself, preventing its release in the first place. One approach is to use technologies and standards that support privacy policies specifying the acceptable use of information collected or released. For example, P3P (the Platform for Privacy Preferences Project, Cranor 2002) enables websites to declare in a machine-readable format what information is collected by the service provider about visitors to that site, and how that information is used. Like privacy regulations, privacy policies have their drawbacks.
P3P, for example, has been widely criticized for its high levels of complexity and lack of enforcement mechanisms (EPIC 2000), and is today only rarely used in practice.

Other, complementary technologies for preventing the release of personal information center on the use of cryptography to ensure information can be transmitted securely. The PGP encryption system, for example, can be used to ensure only trusted entities are able to decrypt encrypted information. It is important to note that despite the name (PGP, pretty good privacy), information privacy and information security are distinct concepts. Security is concerned with protecting information from unauthorized access; privacy is concerned with the control of personal information. It is possible to secure information that is not in any way private (e.g., encryption of a nonpersonal data file using PGP); and it is possible to preserve privacy without using any security (e.g., reject a website’s P3P policy, and not transmit any information to that service). Although they are distinct concepts, privacy and security are clearly complementary. Confidentiality is best supported by a system that both is secure and respects information privacy principles.

Location privacy

Location privacy is a special type of information privacy with particular relevance to geography and geographic information systems (GIS). Location privacy concerns the right of an individual to control information about his or her location. Location information is potentially highly sensitive. All of the potentially negative effects of a lack of privacy discussed above (unsolicited marketing, identity crime, threats to personal safety, intrusive inferences, and inhibiting technological advances) can also accrue from a lack of location privacy specifically. However, a lack of location privacy is associated with particular risks in three areas. First, location-based spam is unsolicited marketing based on a person’s current location or past patterns of movement. Shoppers, for example, could be bombarded with adverts and special offers for nearby retailers on their mobile phones if they are unable to protect their location information. Second, knowing someone’s current location or past patterns of movement can present particular risks to personal safety, for example through stalking. Third, a person’s location strongly influences the activities they are likely to be engaged in. Intrusive government agencies, organizations, or individuals can potentially use a person’s location to infer information about that person’s state of health (e.g., located at a specific hospital ward or clinic), political views (e.g., located at a political rally or demonstration), sexual orientation, religion, profession, hobbies, interests, and so forth.

In addition to presenting particular privacy risks, location information also presents particular challenges when applying IPPs. The IPP of notice and transparency, for example, is increasingly difficult to maintain because there is an ever-wider range of circumstances in which an individual’s location information may be captured as an incidental, secondary by-product of another function. A cell phone network, for example, must maintain information about the locations of mobile phones (in terms of the cell in which that phone is located) whenever a phone is switched on, in order to route calls to that phone. Making a credit or debit card purchase at a shop or ATM (automatic teller machine) implicitly locates the owner of that card (a feature widely used by banks to combat card fraud). Speed and safety cameras on roads track the movements of personal vehicles, and implicitly locate the registered owner of the
CONFIDENTIALITY

vehicle. Public transport smartcards (travel passes on an integrated circuit card) allow the movements of individuals to be tracked around the transport network.

Even in cases where location information is clearly understood to be the focus of a function, such as when using a personal navigation system or “what’s nearby” location-based service, notice and transparency may be impractical to maintain. Because location is likely to be continually tracked for those services (e.g., in order for a navigation service to provide turn-by-turn routing instructions), it is usually impractical to notify users every time their location is communicated to the service provider (possibly every few seconds or even more frequently). Alternatively, when users are notified about privacy issues at periodic intervals (such as reminders every month while they continue to use a service) they may forget and inadvertently reveal private information at specific, sensitive locations or times. Finally, in addition to common location-aware technologies, such as personal navigation systems, mobile phones, and smartcards, new technologies are continually emerging for identifying individuals at locations. For example, gait recognition of individuals using CCTV camera surveillance is continually improving, with recent advances making its widespread use a realistic possibility in the near future.

Location privacy protection

Given the potential sensitivity of location information, it is perhaps surprising that specific capabilities for location privacy protection have lagged behind the increasing use of location-aware technologies.

One problem facing legal avenues for location privacy protection is ambiguity over whether location information should even be regarded as “personal” information. Relatively few laws explicitly address protection of information about location. Instead, privacy protection usually focuses on “personal information” more broadly, usually defined as information “about an individual whose identity is apparent, or can reasonably be ascertained, from the information” (Australian Government 1988).

For many types of personal information, such as medical or banking records, privacy protection can be achieved relatively simply, by deleting any information about the identity of the person to whom that record refers. The process of removing an individual’s identity from information about that individual is termed “anonymization.” A special case of anonymization replaces an individual’s actual identity (e.g., their name) with a system-generated persistent identity (e.g., a student number), termed “pseudonymization.”

However, for location information, anonymization and pseudonymization alone may not be enough to guarantee a person’s privacy. Location information is special in that identity can frequently be inferred from location, especially from a history of locations over time. A person’s precise location recorded, say, over the course of a few days would often be enough to identify that person. For example, patterns of movements between a home, a workplace, a child’s school, and other locations over the course of a week would easily allow a resourceful hostile agent to identify a person, cross-referencing locations with other publically available data sources, like maps and telephone listings. Several studies have demonstrated the surprisingly small amount of anonymized location information that is needed to infer the identity of the individual tracked at those locations (e.g., Krumm 2007; de Montjoye et al. 2013).

Turning to privacy policies, technologies for specifically protecting location information
have been considered. For example, the IETF (Internet Engineering Task Force, an international open organization of networking experts) GeoPriv working group has developed PIDF-LO (Presence Information Data Format–Location Object). The proposed standard sets out mechanisms by which users can automatically annotate location information with privacy policies that specify acceptable uses of that location information. By allowing users to specify acceptable usage, PIDF-LO represents an example of a user-oriented privacy policy (in contrast to P3P, a service-oriented approach to privacy policies). Users may specify features such as how long location information may be retained, whether that information may be retransmitted, and usage notification requirements. Interestingly, PIDF-LO also provides explicitly spatial mechanisms to protect location privacy by restricting the level of precision of location information. The information that I am located “in Melbourne,” for example, is both less precise and more private, than revealing my (precise) latitude and longitude as $-37.7999253, 144.9610477$. The process of deliberately reducing the precision or accuracy of a person’s location information is termed “obfuscation” (Duckham and Kulik 2005). In order to provide differing levels of privacy, the level of precision may also be adapted depending on the number of other people in an individual’s vicinity. For example, to achieve the same level of privacy, a larger obfuscated region might be desired by a person when hiking on an isolated mountain than when walking around a busy city-center shopping mall.

Census data

While the growth in use of location-aware technologies, like smartphones and personal navigation systems, has brought location-privacy issues into sharp focus, confidentiality and privacy issues in geography are not new. Indeed, geographers have a long history of working with sensitive information with a range of privacy implications in the form of census datasets. Census data contains a wealth of detailed personal information, typically including ages, income, education, health, and religion, as well as home locations of citizens. Census data, then, provides a helpful illustration of the combination of many of the approaches to confidentiality discussed above.

First, when collecting or using census data information privacy principles are scrupulously adhered to, to ensure personal information is protected. For example, strict controls are placed on the capture and storage of census data to ensure information is secure. Those who deliberately or inadvertently disclose an individual’s private data from the census can incur severe penalties. Census data is also frequently anonymized, removing from the data the identities of the individuals to whom specific census records refer. Further, census data is usually only made publically available in an aggregated form, with records from many individuals combined together across defined geographical areas called census tracts. In some cases, random errors with known distributions may also be added to smaller units. Deliberately aggregating data and introducing errors to census data effectively reduces the precision and accuracy of data to a level that makes it much harder for a hostile agent to infer information about specific individuals, much as obfuscation aims to do for an individual’s location information.

The future of confidentiality

Sun Microsystems Chief Executive Officer Scott McNealy famously exclaimed: “You have zero privacy anyway. Get over it!” (Sprenger 1999). In a digital age, with exponentially increasing
volumes of information captured and communicated, attempting to safeguard information privacy can appear a futile endeavor. Indeed, personal information about us is not simply harvested by agencies who value this information, from search engines to state-sponsored surveillance; many individuals freely disseminate their own personal information through a range of channels, from retail store cards to social networks.

In this context, it is hard for anyone to predict what forms of confidentiality and levels of privacy protection will be common in the future. If the apparent trajectory of increasing disclosure continues, it is conceivable that societies may ultimately arrive at a new, stable equilibrium, such as the “transparent society” envisioned by Brin (1999), where everyone knows what everyone else is doing. It seems, however, equally plausible that changing attitudes to confidentiality apparent in digital societies may be a temporary phenomenon, yet to be checked as the negative impacts of a lack of privacy, discussed above, become more common and more widely understood.

Conservation and capitalism

Dan Brockington
University of Sheffield, UK

Capitalism has transformed the material world: think of all the mines sunk, land cleared, fish harvested, or air polluted in the name of making money. Capitalism also dominates our symbolic lives: think of the television, radio, and billboard adverts that daily sell various commodities to us, like mobile phones and automobiles. Conservation is normally seen as the antithesis of, and sometimes as an antidote to, all of this. Conservation is manifest in the form of parks and protected areas, maps of endangered species habitats and rare ecosystems, and exhortations to rethink our engagement with the environmentally destructive system that is capitalism.

Historically, this basic incompatibility has intensified as both spheres of influence have expanded in geographical terms. In its starkest form, and using now outdated language, “nature” is commonly seen as retreating before human despoliation. For many conservationists it is traditional to define the solution as the opposite to development, industry, and the use of natural resources. Some of the defining historical moments of the movement have been integrally linked to the protecting of landscapes from human use and depredation. Examples include the early establishment of protected areas in Europe and Africa (and the continued fight to keep them pristine, as manifest in Africa’s Serengeti recently), the failure to protect Hetchy in the United States, the success in protecting Australia’s Jervis Bay, and the fights over the Franklin River in Tasmania.

However, despite these iconic moments in conservation’s history, and ongoing disputes that bring human interests into conflict with particular forms of nature, the relationship between conservation and capitalism is changing. Many varieties of conservation and corporate capitalism now work closely together. This is not merely a case of opposing interests that have become adept at satisfying each other’s demands. It is more intimate than that. Nowadays it is hard to distinguish between the ways in which conservation reshapes the world using capitalism as its instrument from capitalism doing the same through conservation. The presence of this entry in this encyclopedia is testimony to the importance of this trend. Its purpose is to explore the ways in which conservation and capitalism are intertwining, and the consequences of the fact both practically and for research purposes.

The entry will first examine certain writings about conservation and neoliberalism, in which much current research on the interactions between conservation and capitalism is grounded. It will then explore manifestations of this relationship in important conservation practices, first with respect to the work of conservation NGOs, and second with respect to the marketization of conservation policies, especially the proliferation of new commodities associated with ecosystem services. Finally the entry explores the sorts of politics that are associated with capitalist conservation, and particularly the problems associated with postdemocracy and environmental change.

CONSERVATION AND CAPITALISM

Neoliberal conservation

Writings on neoliberal conservation have an interesting history. They stem from encounters with geographer Noel Castree’s seminal reviews of writings on neoliberal nature and a group of researchers who were exploring the impacts of market-based conservation policy (Castree 2007a; 2007b). Castree’s writings provided the framework to explain what was happening within conservation policy, to understand how these developments were interconnected, and to communicate them to a broader academic and activist community. He argued that neoliberalism is one particular form that capitalism has taken in recent decades. It is characterized by the following processes.

- **Privatization**: the assignment of clear private property rights to social or environmental phenomena that were previously state-owned, unowned, or communally owned. New owners of hitherto unprivatized phenomena can potentially come from anywhere across the globe.

- **Marketization**: the assignment of prices to phenomena that were previously shielded from market exchange or for various reasons unpriced. These prices are set by markets that are potentially global in scale, which is why neoliberalism is often equated with geographically unbounded free trade.

- **Deregulation**: the rollback of state interference in numerous areas of social and environmental life so that (i) state regulation is light touch and (ii) more and more actors become self-governing within centrally prescribed frameworks and rules.

- **Reregulation**: the deployment of state policies to facilitate privatization and marketization of ever-wider spheres of social and environmental life.

- **Market proxies in the residual public sector**: the state-led attempt to run remaining public services along private sector lines as efficient and competitive businesses.

- **The construction of flanking mechanisms in civil society**: the state-led encouragement of civil society groups (charities, NGOs, communities, etc.) to provide services that interventionist states did, or could potentially, provide for citizens. These civil society groups are also seen as being able to offer compensatory mechanisms that can tackle any problems citizens suffer as a result of the previous five things listed.

Castree argued that neoliberalism is consistent with attempts both to exploit and protect the physical environment, noting the growing use of neoliberal measures in the field of environmental policy worldwide. This is what is meant by the phrase “neoliberalization of nature.” For instance, individual transferable quotas issued to fisherman have become a favored way of protecting fish stocks, a form of state-led reregulation of human behavior that has privatization and marketization of environmental assets at its core.

There followed a series of landmark publications and international meetings which have explored different aspects of what neoliberal conservation on land and at sea entails (Igoe and Brockington 2007; Brockington, Duffy, and Igoe 2008; Brockington and Duffy 2011; Büscher et al. 2012). A fascinating commentary and appraisal of the epistemic community formed thus has been, appropriately enough, recently published by Castree and Henderson (2014).

It is notable how interdisciplinary this work is. It brings together geographers, environmental anthropologists, development studies, media studies, and politics and international relations. Yet, despite this disciplinary diversity, through these activities of meeting, writing, and sharing research ideas, methods, and successes, an
Conservation and Capitalism

An epistemic community has been forged which has come to tackle a series of similar problems in method, conceptual frameworks, epistemologies, and by contests over the same. Critical analysis of neoliberal conservation, and explorations of the interactions between conservation and capitalism, are a recognized subdiscipline.

What are the main tenets of writings on neoliberal conservation? At their core there is a suspicion of the role of markets in conservation policy. Markets come in many forms, but in this case the reference is to ones where commodities are exchanged for money between buyers and sellers. Opponents of neoliberalism observe that giving over things that people value to market control can result in the commodification of ecological and social relationships. Indeed, it can require impossible feats of quantification as attempts are made to reduce these relationships somehow to commensurable (that is, comparable or equivalent) forms. More than that, neoliberalism is associated with greater levels of inequality, with the withdrawal of social and state support for the disadvantaged and with forms of political decision-making that favor the rich and powerful. As Warren Buffet, one of the world’s richest people, said repeatedly, there is a class war, and it is his class, the rich, that is waging it, and they are winning.

Opposing neoliberal economics and politics is difficult. It has yet to result in a particularly satisfying alternative. In the academy, opposition entails documenting and exploring what these policies actually entail for nature and for society as they are implemented. Researchers explore the tensions and contradictions that develop around them, and the ways in which market-led governance can change levels of inequality, political forms, scientific discourse, and so on.

Igoe and Brockington’s 2007 paper in Conservation and Society provides a useful starting point for this literature. These authors observed that there had been a growing literature concerned with the neoliberalization of nature, and flourishing in particular among radical geographers. They also observed that these critiques did not mention changes in conservation policy. Yet, they argued, the key processes that were part of the neoliberalization of nature could also be observed within new conservation initiatives, particularly in Africa where their own empirical research has been situated.

These processes included all those summarized by Castree: deregulation, reregulation, privatization, marketization, and so on. These are visible in the new forms of conservation estate that is set aside outside protected areas to make space for new corporate ventures, including hunting and photography safaris in alliance with the rural owners of the lands. They include a proliferation of conservation NGOs working with companies and local groups. They include new markets for new forms of tourist activity such as green hunting (in which trophy animals are merely darted, not shot dead; the more daring versions are reputed to include elephant paintball), as well as markets for carbon in village forest reserves and other ecosystem services. But this deregulation, privatization, and marketization, all of which hand domains traditionally controlled by the state to other actors, is also accompanied by reregulation and new areas of state activity. Traditional protected areas have continued to expand, and indeed expand most during neoliberal times. And new forms of conservation estate remain governed and overseen by state actors, even where they are oriented toward catering to free-spending international tourists.

These developments are also accompanied by further changes which allow alliances of capital and conservation to become more profitable. There are new forms of territorialization which, following Vandergeest and Peluso (1995), refer
to “the demarcation of territories within states for the purposes of controlling people and resources.” Protected areas are one such form of territorialization. Another development is the rise of new attempts to manage and use resources more effectively. This is done by altering the ways rules control who can use resources, when, and how, or, in other words, how resource use is governed. Under neoliberal policies, governance is meant to be achieved by the market, meaning that who gets to use resources, and the ways in which they are to be used, are determined by who is willing to pay for their use. But to usher in and to make markets work, new networks of actors are required that include nongovernmental organizations (NGOs), companies, philanthropists, in various alliances with states. So powerful are these alliances that they can be described as a form of privatized, if sometimes spatially restricted, sovereignty.

In 2012 Büscher et al. (2012) wrote an assessment and critique of neoliberal conservation. Their contribution, they argued, was partly necessary because critiques of the neoliberalization of nature were still not recognizing the importance of conservation. The emphasis in writings about neoliberal nature was all about how nature and natural resources were used in the transformation of neoliberalization. The demands of capitalism were the main drivers of change, and conservation was somehow regarded as separate from all of that. Indeed, in Harvey’s work they found a tendency to treat environmentalism as a bastion against capitalism (Harvey 2005). Protest against capitalism, which Harvey lauded, was often environmental protest, and the complicity of NGOs in the neoliberal project that he critiqued did not include the conservation NGOs. Yet Büscher and colleagues (2012) had repeatedly shown that conservation NGOs have been at the forefront of bringing in new forms of neoliberal conservation, sometimes to the detriment of local groups.

Büscher and colleagues argued that this thinking missed the point that capitalism can expand even if it is not using and exploiting resources. Capitalism can expand through finding profitable ways to conserve resources. Thus they argued that “neoliberal conservation shifts the focus from how nature is used in and through the expansion of capitalism, to how nature is conserved in and through the expansion of capitalism” (Büscher et al. 2012, 5).

They suggested that there were three main arenas of activity within neoliberal conservation that required attention from academics and researchers. They first noted a basic contradiction in the thinking that promoted much neoliberal conservation. Current ecological crises are driven by economic growth and the hunger of market-based capitalism for profit, yet neoliberal conservation policies see markets as the solution to these problems. “Economic growth,” Büscher and his colleagues argued, “becomes, paradoxically, the prerequisite for healthy ecosystems, whose conservation in turn becomes the basis for further economic growth” (2012, 14).

And yet, Büscher and his colleagues observed that the potential contradictions and pitfalls of this policy are concealed by the ideology and the win–win rhetoric that inevitably accompany it. The objections and difficulties that arise from this project become reduced to technical problems. When considering problems associated with community forestry, for example, the problems include how one measures growth in carbon and how one pays for it. More fundamental questions of who decides which bits of the forest should be conserved, what forms of use and users are excluded, and whether poorer people (pastoralists and charcoal burners) suffer as a result are simply not part of the discussion. Another way of saying this is that what are actually intensely
political projects involving contests over how resources should be used, and by whom, are portrayed as apolitical issues, with the conflict and tensions driven from them.

Büscher and his colleagues (2012) go on to observe that neoliberal conservation achieves this smooth and happy facade through the clever use of image and spectacle (see Environment and celebrity). This is the second arena of activity they mention in their article. Spectacle in this instance refers to images that mediate relationships between people. Examples include dramatic images of tsunamis or earthquakes, tragic pictures of starving children or drowned toddlers, or heartwarming images of animals seeking adoption. These images mediate relationships between people because of the way that viewers act on them, and because of the attitudes to the places and issues portrayed that they cultivate. What we do and how we think as a result of these images affects the way we relate to other people.

Spectacle is integral to the establishment of an appearance of harmony and productive peace between the previously opposing spheres of the economy and the environment. Spectacle can be staged in public and experienced in person. It can occur in major showpiece events and global conservation meetings, when the new alliances between conservation and capital are celebrated. It encourages audiences to welcome and accept the new developments. More often spectacles are not experienced directly but are mediated, through websites, television broadcasts, and Internet videos which help forge the idea that, for example, carbon produced in the North can be interchangeable with carbon sequestered in forests in the South.

It is through such spectacular work that nature can come to generate value and profit for capital as conservation organizations raise finance and support for their ventures in the world’s metropoles. Elizabeth Garland’s (2008) work shows how images of wild nature are produced and cultivated by conservation NGOs and then turned into money by presenting them to audiences in fundraising events and campaigns. They can also be turned into social and political capital, changing the mindsets and decisions of key politicians and corporate leaders (Garland 2008).

The final arena of activity Buscher et al. (2012) observed was the disciplining of dissent. Mainstream neoliberal conservation is characterized by a broad (if somewhat superficial) consensus. It has been the unfortunate experience of many of those opposing its core tenets that objections are not often countenanced. Anyone speaking out against the smooth and comfortable visions of neoliberal conservation can expect a sharp reaction. Maintaining the happy vision is essential for the financial models and political influence of important conservation organizations. They take disagreement seriously.

At the same time as the criticisms of neoliberal environmentalism have consolidated, the criticisms themselves have come under closer scrutiny. On the one hand, there is concern that the word “neoliberal” is used too liberally. It is often too loosely defined, or it refers only to a general set of activities. A second pertains to the unbalanced agenda of neoliberalism’s critics. Their outcries against power have yet to produce a viable and well-defined alternative to neoliberal conservation. They focus too much on critique and not enough on what could feasibly replace neoliberal policies. For instance, the practical implications of their objections should be considered. For example, should an objection to the alliance of extractive industries with conservation be extended to an objection to the presence of metal in society more generally? Or perhaps we should object to the pulping mills and learn to live without paper?
Conservation and Capitalism

The challenge becomes not to resist any alliance with, for example, the extractive industries, but rather to forge alliances that are inclusive and egalitarian, even while maintaining a principled stance against unsustainable production practices, which are all too often “greenwashed,” that is, represented as being environmentally friendly by the corporations that engage in them.

The Marketization of Conservation Policies

At the core of neoliberal thinking on environmental and conservation issues is the idea that inefficiencies and failures in the allocation of resources can be solved by more efficient and effective markets. Or, in other words, if conservation problems cannot raise the resources to bring about the required solutions, then markets need to be created to allocate those resources according to conservation priorities. The key problem, argue the protagonists, is that many conservation values do not have a financial value that can be exchanged or realized through markets. It is impossible for consumers or citizens to express their choices financially, and therefore difficult for conservation programs to raise the revenues they require. Conservation’s problem is that it sells itself cheaply; nature’s problem is that it gives away its bounties free. If they could be costed and paid for, there would be less degradation.

For example, forest cover on hilltops is thought to provide enduring, regular water supplies to rivers draining hill catchments, and so to urban and industrial users downstream. The cost of that service however, is not recognized or paid for. If it were to be included in water bills, this would create and generate funds for conservation policies. More generally, this issue is part of the debate about payment for ecosystem (or environmental) services (PES), which is proposed for a broad range of benefits including carbon sequestration, pollination, amenity values (see Ecosystem services). Sven Wunder’s (2007, 50) widely cited definition insists that PES requires:

1. a voluntary transaction in which
2. a well defined environmental service (or a land use likely to secure that service) (3) is “bought” by a (minimum of one) buyer (4) from a (minimum of one) provider (5) if and only if the provider continuously secures the provision of the service (conditionality).

The idea that conservationists should realize the value of the goods and services that they are conserving has become extremely popular. The mantra is that nature has to be worth something in order to be valued by decision-makers, and that it would be much easier to convince politicians of the value of conservation if we could show how much conservation is worth. This logic is driving the work of organizations like the Economics of Ecosystems and Biodiversity (TEEB), which is collating and synthesizing numerous reviews to determine what value to place on different ecosystem services.

The move is interesting in a number of ways. First, it has been met with enthusiasm by the conservation community, particularly the research community. This is clearly visible in official conservation conferences where selling ecosystem services is widely promoted. Second, while providing valuations of goods for which no market yet exists is an uncertain science, this does not dampen the enthusiasm of economists, who have many ways of tackling the problem. The results of these analyses, however, can vary unpredictably.

Beyond the theoretical problems of valuation there is also a series of difficulties in implementing related policies of resource use, which derive from the difficulty of creating the new commodities of ecosystem services that could be traded on markets and of establishing the new markets themselves. It is not easy to delineate or measure...
carbon (for example), or to fix it permanently in trees in ways that can be paid for in advance. There is a lack of case studies, but those that are available underline the fact that the creation of markets requires more regulation and state governance, notwithstanding their stated ideologies. This does not mean that PES are all problematic and likely to fail, just that it requires particular conditions in order for them to work – such as clearly defined property rights or effective commodification of the service in question. Another crucial element is a culture of recognizing the legitimacy of payments. If people are not used to paying for forest cover to protect water supplies, or even paying for water, it will be difficult to persuade them to start doing so.

PES are more of a prospect and mood than an active and effective policy; the idea is more vaunted than it has been put into practice. Nonetheless, the philosophy and implications of them are already alarming critics. Nicolás Kosoy and Esteve Corbera (2010) argue that the commodities on which PES hinge are characterized by three simplifications which conceal important aspects of the services the PES schemes are trying to promote. First, ecologically, the commodities cannot capture all that is valuable in nature, only that which the markets try to value. Carbon forestry, for example, is not necessarily the same thing as preserving a biodiverse or watershed-preserving forest. One could promote a forest that maximizes carbon storage, but it may be full of fast-growing exotic species that are bad hosts of other biodiversity.

Second, reducing nature to commodities will simplify the social relations that pertain to natural resources, ecosystems, and environments. What one group might value, for example wildlife for hunting, another might detest as dangerous pests (in this example). Setting up a market for hunting wildlife requires healthy populations of those animals. Once again political disputes over how landscapes ought to be used become reduced to technical problems of how to set up markets that govern already determined uses. Moreover, markets cannot easily capture spiritual or aesthetic values.

Finally markets conceal the power inequalities that structure and shape them. Allowing those with money to purchase ecosystem services depends on a just distribution of money in the first place. And, for all the talk about efficient and free markets, in practice markets are structured by political pressures in a myriad ways even as their rhetoric denies that influence.

Redford and Adams (2009) list further issues which, in part, derive from the nature of conservation as a movement. Specifically, they argue that conservation is prone to fads, that is, wholeheartedly chasing the latest idea, sometimes before the evidence exists to show that it is robust. Furthermore Redford and Adams note that ecosystem services can include natural processes which are harmful to people (flood, fire); harmful to nature (when provided by alien species); and prone to being radically altered by climate change, which is reconstituting ecosystems under our feet. They welcome the possibility that the scheme offers, but call for more skepticism in testing and developing it. The difficulty, then, is not with PES as an idea or theory, but rather with the marketization of nature as a movement.

Conservation NGOs

One of the hallmarks of neoliberalism is its distrust of government. One of the characteristics of the rolling out of neoliberal policies is the growth in NGOs that have arisen to address the demand for services left by declining states. Conservation is part and parcel of this trend,
and for this reason conservation NGOs deserve special consideration.

The influence of conservation NGOs predates neoliberalism and derives from their concentration of research and policymaking skills. NGOs and NGO-based researchers have been at the forefront of numerous debates in conservation, whether these be concerned with identifying conservation priority areas, maximizing return on conservation investment, or the discussion of new neoliberal policies. Conservation NGOs do not speak with one voice here – far from it. Many cannot speak with one voice in themselves. They are large, diverse, and eclectic organizations. But the point is that they are a vital source of ideas and experimenters in new policies, particularly in poorer parts of the world where government policies are weaker because they have fewer resources and less capacity.

Yet, despite their diversity, there are some common trends among NGOs, particularly the more powerful organizations. Conservation NGOs have been the subject of several stinging critiques which have accused them of becoming too close to government and corporate power and of not doing enough to promote conservation interests where this risked upsetting the powerful. Mac Chapin’s (2004) critique is perhaps the most severe. It was published in 2004 in the popular magazine *Worldwatch*, complete with choice cartoons that compared conservation NGOs to imperial conquistadors. Chapin alleged that large conservation NGOs, in their pursuit of corporate funding and in trying to negotiate with powerful governments, had become identical to the capitalist and industrial interests they were meant to be opposing. This led to tragic and farcical situations where local environmental protestors and indigenous groups might find themselves opposing alliances of mainstream conservation NGOs, corporate power, and governments. Surely, Chapin, insisted, any conservation NGO worth the name would be found on the other side of the barriers.

Chapin’s polemic highlighted some stark contradictions within the conservation movement, but it is probably fair to say that the most egregious errors are not typical. It is rare to fund conservation organizations allying with mining companies against the interests of indigenous forest dwellers. A far more common alliance is NGOs embroiled in new policies that neoliberal conservation entail, for they often serve to help implement new forms of commodification and market governance, such as carbon credits, or new safari packages on community-owned lands. They are, in some ways, at the vanguard of neoliberal conservation, serving as entrepreneurs and restless innovators. In this respect they behave very like the capitalists described by Karl Marx who are endlessly and energetically seeking new opportunities to create profit.

In some respects, it must also be noted that the changes NGOs bring are welcome – the money provided by new commodities can be a valuable source of income to poor people’s livelihoods, as can the changes in governance. However, in other respects NGOs can be part of a deeper problem. Jesse Ribot’s studies of governance and devolution in the forestry sector have found that many potentially empowering incidences of devolution have been stymied and incomplete. They could have brought welcome change to impoverished places, but they have not done so because power has been devolved to institutions and entities, including NGOs, which are not downwardly accountable (Ribot 2004). NGOs are not elected by local groups. They cannot be dismissed. They are funded by outside agencies, donors, or rich foreigners and nationals. This means that, while they should exist to serve their local demographics, they may fail to do so and may be more closely oriented to serving their
funders. In this sense NGOs obstruct participatory local governance of natural resources. Their skills and competence may make them good at working with local people and with natural resource management. But their mandate is self-derived and their authority ultimately arbitrary.

At the same time, from the point of view of researchers, working with conservation NGOs can be rich and rewarding. For these are intelligent, reflective communities, passionate about their calling and thoroughly engaged in the practices researchers are trying to understand. (The same is true of the conservation filmmaking community.) The communities are also immensely diverse, for the nature and purpose of conservation organizations differs, and within larger organizations there will be many different views at work. Thus, while it is important to understand the nature and role of conservation NGOs, it is also important to realize that much understanding about them is coproduced with the NGOs themselves. There are interesting revolving doors between communities of natural scientists, who work on conservation issues, and conservation NGOs. Careers can switch between the two. These reciprocal relations are yet to develop properly between social scientists who study conservation and conservation NGOs.

The politics of capitalist conservation

One of the most interesting things about the close relationship being forged between conservation and contemporary capitalism is the politics of the decision-making and the sort of democracies in which this relationship has come to thrive. It is useful here to turn to writings on postdemocracy, particularly as described by Colin Crouch (2004). Postdemocracy, for Crouch, describes situations where the ruling elites have learned how to manipulate and control the voting public, and in which the voting public appears not to mind the development that much. Crouch notes that enthusiasm and participation in democracy tend to be uneven, with particular historical moments when it is strong followed by less activity. When voter turnout and participation in political decision-making decline, government becomes dominated by elite-level lobbies which are much less accountable to publics.

Crouch’s objection is to the form that liberal democracies take, particularly in unequal societies. Liberal democracies are founded on the belief that any form of political expression (within some limits) should be allowed and that everyone should be free to politically support the interests that matter to them. This becomes an issue in unequal societies when liberal democracies inevitably become dominated by the interests of the most powerful, who have the most money and resources to devote to supporting their interests. In postdemocratic situations, without a vigilant public to restrict the actions of politicians, liberal democracies will not be healthy democracies. The key issue for Crouch in this state of affairs is that it produces politics where decision-making can be dominated by elites, and that must inevitably tend toward unequal societies. Such elites tend not to be egalitarian or to benefit from egalitarian policies, yet they are able to prosecute their interests far more effectively than other groups in the politics of elite-dominated lobbies. The public interest can become subsumed beneath the pressures from well-funded, and often corporate-funded, interest groups.

It should be clear why this state of affairs matters for analyses of conservation and capitalism. The decision-making and politics that determine conservation policy directly, and issues of resource use and exploitation (and so,
indirectly, conservation issues) will be determined in elite-level forums. Conservationists who wish to prosecute their policies and interests successfully have to become adept at walking in these powerful corridors and lobbies. Viewed thus, the celebrity-filled, industry-sponsored events of the International Conservation Caucus in the United States are simply the necessary response of the conservation movement to the political dictates of the age (Corson 2010). So too are the business councils and corporate sponsorship programs that large organizations have pursued. As Crouch (2004) observes, organizations hoping to make a difference in postdemocratic politics have no alternative but to engage in elite-lobbying.

Nonetheless the common accusation is that the process of becoming so close to power has resulted in conservation organizations losing their critical edge (as can be seen in Chapin’s (2004) critique). Corporate capitalism is not afraid of conservation NGOs any more. Conservation organizations pose little threat to corporate brands or public opinion. More than that, there are times when corporate interests and conservation activists seem so closely aligned as to be indistinguishable. CEOs of major conservation groups sit on the same boards of major industries; they work closely together to build brand and income. A postdemocratic politics appears, of necessity, to be about consensus, and without the oppositional agonism that will make contentious decision-making more transparent.

It is in the realm of image and spectacle that so much postpolitical and postdemocratic conservation debates become visible. The lack of agonistic politics, the melding of elite leaders and rulers, and the coincidence of corporate and conservation agendas all become particularly clearly visible, and are actively enforced and maintained in the advertising campaigns, media events, and staged interactions that characterize protest and environmental debate in media-saturated societies. One of the reasons why Büscher and his colleagues (2012) identified spectacle as being so important for neoliberal conservation is because of its role in postdemocratic politics.

Summary

The study of conservation and capitalism provides important insights into the way conservation and environmental issues function in capitalist societies, and how each is being incorporated into the other. They help us to understand the sorts of relations between society and nature that are being constructed, and the hybrid socio-natures that result. This is illuminating both for what it tells us about contemporary societies and political economy and for what it tells us about nature. This is an exciting time to be involved in the social science of conservation, and in particular the relationships between conservation and capitalism. The field has expanded enormously, and there is now a strong theoretical framework guiding current inquiry and tying it to more general concerns about neoliberal environmental policies and critical geographical inquiry in the field.

Constructing 3-D GIS

Keiji Yano
Ritsumeikan University, Japan

We live in a three-dimensional (3-D) world and throughout human history the 3-D world has been represented through pictures and photographs presented in bird’s-eye view. Until now, geographers and GIS scientists have basically sought to graphically express their understanding of 3-D spatial aspects in reality through two-dimensional (2-D) maps. With a 2-D map it is possible to turn the surface of the round Earth into a planar graphic form via map projection and using contour lines to represent the various elevations. This allows us to imagine the 3-D world and create 3-D models. Using 3-D GIS, it is possible to view the entire 3-D space from various viewpoints.

Many types of 3-D GIS data structures have been developed and many related software applications have been created. In addition, methods for data acquisition in real life designed for these data structures have also been developed. This entry provides an overview of 3-D GIS data structure and 3-D GIS data acquisition, while introducing the latest technologies and several 3-D city models.

3-D GIS data structure

There are two kinds of 3-D spatial object representations: surface-based and volume-based. A surface-based representation is where an object is represented by surface primitives, whereas a volume-based one is where the interior of the object is described using solid information (Abdul-Rahman and Pilouk 2008). Surface-based representations include grid models, shape models, facet models, and boundary representations (b-rep); volume-based representations include 3-D arrays, octree, constructive solid geometry (CSG), and 3-D TIN (or TEN). Some of these representations are common in computer-aided design (CAD) systems but not in GIS.

Here, grid models and facet models (TIN) are outlined as surface-based models, and 3-D arrays, octrees, and 3-D TINs are outlined as volume-based models defined according to Abdul-Rahman and Pilouk (2008).

Grid model

A grid is a method for surface representation in GIS and digital terrain modeling (DTM). It is a structure that specifies the height value at regular locations and it is simple to generate. The topology of grid points can easily be determined, since each grid point is relative to other points. The grid structure is considered as an array structure in computer programming. Each array element represents the x and y locations of the grid, and the value of the element is z, which indicates the height. The positions of the grid points are easily defined, and their layout may be regular or irregular (Figure 1). The terrain surface model can be derived from this structure. However, this structure has disadvantages in the case where surfaces have multi heights such as vertical walls and overhangs.
CONSTRUCTING 3-D GIS

Figure 1  Grid model.

Figure 2  Facet model (TIN).

Facet model (TIN)

A facet model describes an object’s surface using planar surface cells that can be of different shapes and sizes. One of the most popular facet models using triangle facets is known as a triangle irregular network (TIN). A TIN is a vector-based representation of the physical land surface or sea bottom made up of irregularly distributed nodes and lines with 3-D coordinates (x, y, and z) that are arranged in a network of nonoverlapping triangles (Figure 2). TINs are often derived from the elevation data of a rasterized digital elevation model (DEM). An advantage of using a TIN over a raster DEM in mapping and analysis is that the points of a TIN are distributed variably based on an algorithm that determines which points are most necessary for an accurate representation of the terrain. Data input in this case is, therefore, flexible and requires fewer points to be stored than in a raster DEM with regularly distributed points. However, a TIN may be less suited than a raster DEM for certain kinds of GIS applications, such as analysis of a surface’s slope and aspect.

3-D array and octree

3-D array is the simplest structure in the 3-D domain, being easy to understand and implement. In the 3-D array (Figure 3), the size of the array elements is equal and each occupies the same amount of computer space. However, as a result, a 3-D array model requires large computing power to render. A much better way of representing 3-D objects is by varying the size of the voxel, known as the octree technique. Octree is one of the hierarchical data structures.
CONSTRUCTING 3-D GIS

3-D GIS data acquisition

3-D GIS data acquisition and reconstruction is the generation of 3-D or spatiotemporal models from sensor data. The techniques and theories, generally speaking, work with most or all sensor types, including optical, acoustic, laser scanning, radar, thermal, and seismic sensors. Acquisition can occur from a multitude of methods, including 2-D images and acquired sensor data.

Acquisition from 2-D images

Photogrammetry or stereo photogrammetry is the technology used for creating 3-D data \((x, y, z)\) of object features using stereo image pairs. Stereo photogrammetry is broadly divided into two types: aerial photogrammetry from an airplane and close-range photogrammetry on land. In the former case, serial images are taken using one camera with the same parts overlaid. In the latter case, the image of an object is taken by moving one or two cameras, so that parts of the captured images overlap with each other. Both methods can be used to acquire topologically structured 3-D data from 2-D aerial stereo images.

In both Figure 5a and Figure 5b, point P within the ground coordinate is recorded on the projection planes as p1 and p2 using cameras with projection centers O1 and O2. However, there is no difference in data processing between aerial photogrammetry and close-range photogrammetry without the distance between the camera and the object, and the parallel photographing with high accuracy. In the case of aerial photogrammetry, parallel photographing is easy, but in the case of close-range photogrammetry it is rather difficult to achieve (Susaki and Hatayama 2013).
Acquisition from acquired sensor data
LiDAR

Currently, laser scanners are fast and powerful enough to generate airborne-scans of large areas. Laser measurement using LiDAR (light detection and ranging, laser imaging detection and ranging) is one of the optical remote sensing methods where laser is used to obtain high-density sampling points to generate highly accurate 3-D data. Using GIS software, ArcGIS, it is possible to manage, handle, visualize, and share a cluster of many points in a 3-D space. LiDAR is used for airborne laser mapping instead of conventional photogrammetric methods for its cost–benefit performance (Figure 6). The main hardware of the LiDAR system consists of on-board equipment (attached to an airplane, helicopter, or car), tripod stand, laser scanner system, GPS (global positioning system), and INS (inertial navigation system). The INS system is used to determine the role and gauge the pitch and direction of the LiDAR system.

It is also possible to obtain semi-automatic building extractions from LiDAR data and high-resolution images. This approach allows modeling without the need to physically move towards the location or object in question. From airborne LiDAR data, a digital surface
model (DSM) can be generated and objects higher than the ground are then automatically detected using the DSM. Based on general data on buildings, information pertaining to geometric characteristics – such as size, height, and shape – is then used to separate the buildings from other objects. For instance, using ArcGIS in LiDAR Analyst it is possible to automate the extraction of 3-D terrain data, and other information such as buildings, trees, and forest areas from the LiDAR data obtained through aerial laser survey.

Around the year 2000 there were some semi-automatic methods available for creating 3-D GIS data from LiDAR data, such as Virtual London by UCL (Evans, Hudson-Smith, and Batty 2005) and Virtual Kyoto using MapCube by Tokyo CadCenter Corporation (Yano, Nakaya, Isoda 2007).

Virtual London has been utilized as a platform for communication, and Virtual Kyoto as 4-D GIS with a time dimension has provided a virtual time-space into which the digital contents in the historical city of Kyoto can be put.

MapCube, consists of prismatic 3-D building block models based on building footprints and heights of an entire city. The 3-D models are created by extruding building footprint data with airborne laser-profiler data that obtains height values at the interval of 2.5 meters within an error margin of ±15 centimeters (Figure 7).

In 2005 the extremely popular Google Earth was launched. It is a free web application that provides 3-D city models by adding aerial images to 3-D terrain models and shows land features and landmarks including 3-D buildings. The 3-D buildings are modeled using free SketchUp. These types of 3-D building models have, until now, been created using expensive software applications such as 3-DMAX and Maya, and the compatibility of the data format of these 3-D models is a problem. In general, however, common formats including VRML are used to maintain the compatibility of 3-D building model data.

Recent cutting-edge technologies

From around the year 2000, aerial 3-D mapping using LiDAR has become common and the accuracy has been greatly improved. In addition to that, many people have also opted to build 3-D models by integrating LiDAR data with oblique photographs. The following are two of the latest examples of how 3-D data are actually collected.

**High-resolution LiDAR data** Conventionally, it was difficult to create accurate DEMs of forest areas because trees prevent the laser from reaching the land surface. Today, LiDAR data collected from a helicopter are 3-D data containing over 20 points per square meter. Through high-resolution LiDAR data, it is not only possible to create detailed DEMs and contours but also 3-D models with even the height of trees represented. As a result, it is now also possible to estimate the volume of trees in forests.

For instance, based on the 20-point/m² LiDAR data obtained for forests in Kyoto prefecture, a 25-cm DEM was made, from which maps showing detailed land surface shape and tree heights can be created (Figure 8). The performance of LiDAR equipment is likely to further improve in the future and we can expect to obtain more detailed LiDAR data. Meanwhile, development of methods to recognize ground surface, buildings, trees, and other objects, as well as to clean out noise from images is an urgent matter. It is also important to develop software for rapid display of detailed groups of points and for converting such data into vectors.
Extremely realistic 3-D city models using oblique photography 3-D city models up to now have been 2.5-dimensional models created by measuring the height of buildings. However, detailed full-3-D models have become possible through using aerial oblique photography. Specifically, this method involves taking pictures at direct and slanted angles at the same time to obtain an enormous amount of overlapping photography (multilayer) images using an oblique

Figure 7 MapCube. Source: CadCenter Corporation.
camera to construct extremely realistic 3-D city models. This technology can be used to collect 3-D data not only from an airplane but also from a low-flying helicopter or using a vehicle MMS (mobile mapping system) from land (Figure 9).

Figure 10 shows the comparison between a conventional 2.5-D model and a detailed full 3-D model of the Yokohama seaside district. In the case of the full-3-D model, oblique photography is applied to construct a super-realistic 3-D city model without the need for texture mapping of photographic images into shape models. In particular, this makes it possible to show the detailed shape of the sides of buildings and to apply texture mapping.

Future of virtual city models

The needs for 3-D city models are growing and expanding rapidly in various fields, including geography, urban planning, design, architecture, environmental visualization, and many more. The development of methods for creating 3-D city models is an important topic in academic and commercial environments (Lin and Batty 2009). Presently, there are various terms used to denote 3-D city models, such as “virtual city”, “cybertown”, “cybercity”, and “digital city” (Dodge et al. 1998) and there are a large number of 3-D city models across the world, ranging from CAD models through various 3-D GIS to VRML web content.
Figure 9  New technologies of 3-D data acquisition using oblique photography. Source: Pasco Corporation.
In the case of Google Earth, for example, virtual city models can be easily explored using walkthrough and flythrough functions. On the other hand, ESRI CityEngine allows users in GIS and CAD to easily generate 3-D cities from existing 2-D GIS data. However, while ESRI CityEngine can promote virtual city models under the GIS environment, creating 3-D city buildings is still costly and time consuming. In response to this issue, Google has provided the toolkit, SketchUp and BuildingMakers, necessary for creating 3-D building models via the web. By encouraging the public to freely create 3-D buildings, based on volunteered GIS, Google has set off an apparently very successful trend in the creation of 3-D building models.

3-D GIS data acquisition technologies are expected to become further developed in the future, and detailed virtual city models may be built based on the improved technologies. Virtual city models may become easy to display and use via the web or a portable device. With the anticipation of further development in 3-D GIS data structure and data acquisition, it is necessary to consider how the technologies can be utilized in the future.

CONSTRUCTING 3-D GIS

Further reading

Foster, Shaun, and David Halbstein. 2014. Integrating 3-D Modeling, Photogrammetry and Design. Berlin: Springer.

The “construction of nature” is the idea that nature, rather than or in addition to being a given in the world and an object of inquiry by humans, is a human or social construction, the outcome of human activities or imagination, often called social or produced nature. This idea, which is commonplace in social constructivist and postmodern literature, has been understood in diverse and contradictory ways due to ambiguities about which nature we are dealing with (the nonhuman, biological, or material world; the whole reality), and whether we are dealing with nature itself or with humans’ representations of nature. This entry attempts to disentangle the confusion that results from this multiplicity of “natures” and proposes a reassessment of the idea in this light. It shows that, depending on how nature is defined, the “construction of nature” is either a trivial idea (if dealing with representations of nature) or implies metaphysical paradoxes (if dealing with nature itself). It argues that (i) radical deconstruction should be pursued but should target the multiple representations of nature produced by humans; and that (ii) defining nature itself as a unique, nonsocial, nonconstructed reality is one of the conditions for successful deconstruction and, more broadly, for the production of relevant knowledge about the biophysical and social worlds and their interactions.

Collingwood (1945) presented a history of the idea of nature that identified three key periods, each corresponding to a particular way of seeing the world and a particular conception of nature. First is the “Greek view of nature,” according to which nature encompasses all things found in the material world and has a mind which is the source of its regularities. Animals would participate intellectually as well as materially in the ordering of the world, making it a live and intelligent organism whose mind and body are made of the same substance.

Second is the “renaissance view of nature,” which appeared during the sixteenth or seventeenth century. The natural world is not viewed anymore as an autonomous organism with intelligence. It is a machine to be commanded from outside, through divine laws created and imposed upon it. Matter and mind are made of different substances, which raised the question of the direction of the causal relation between the two.

Berkeley’s (1710) answer to that question is that the material world is produced by a universal spirit (God), which reveals itself to human minds through an ordered language that we call nature. Nature is thus God’s construction as revealed to humans. This conception contributed to the rise of radical idealist views that consider that nature and the reality itself can only exist as outcomes of the mind. Kant (1838/1781), by making a triple distinction between mind, things, and nature, gave an answer conducive to
less radical idealist views. He showed that “the proper object of scientific knowledge is not mind or things in themselves but nature,” which is “mere phenomenon, a world of things as they appear to us, scientifically knowable because their ways of appearing are perfectly regular and predictable” (Collingwood 1945, 119). The “thing” in itself that constitutes the substance of the world would be something other than nature. It would be inaccessible by experience, and philosophy may be more relevant than science to produce knowledge about it.

These two answers regarding the causal relation between mind and nature show that three different things are typically called nature: (i) the world out there as it is holistically, independent of what we know about it (Nature); (ii) the subset of this world that is intelligible to humans (Kant’s nature); and (iii) the representations of Nature or of Kant’s nature produced by humans (the so-called social or produced “natures”). The frequent conflation of these three concepts may be the main cause of heat and confusion surrounding academic debates about nature. Note that Kant’s nature is the most ambiguous one because even if it is real (there are intelligible phenomena out there), it is defined from an anthropocentric perspective, because only humans can tell what is intelligible to them.

The third conception, the “modern view of nature,” developed during the nineteenth century. Change was increasingly seen as being ubiquitous, leading to the notions of progress in the social sciences and evolution in the natural sciences. The machine metaphor was abandoned because a machine is something finished. It does not change unless it is redesigned, broken, or wears out. The material world was considered again as carrying within itself its own design but this design was no longer seen as something static and perfect. It was considered dynamic, improving, which led to blurring frontiers between long-established categories that describe it. Pairs like structure and function, matter and movement, time and space, were seen as single things, consistent with recent discoveries in physics. It was recognized that the way we see the world depends on when and how we observe it. This conception strengthened claims that certain knowledge about nature was impossible and provided an additional basis on which to argue for the “social construction of nature.”

The construction of nature

In spite of this modern view that considers that nature is dynamic, the view that nature is a static world in balance prevailed until the second half of the twentieth century among scientists, and still dominates today among policymakers and in collective imaginaries. The idea that nature is a construction arose as a reaction against this view. It gained more momentum during the 1960s and 1970s when it was realized, within emancipatory intellectual and social movements like feminism, that invoking an objective and immutable nature was used by dominant groups to legitimate control over minds and bodies and block social changes. Foucault (1982), outlining the connections between power and knowledge, provided philosophical and sociopolitical arguments for contesting this domination. At the same time, social scientists studying laboratories from an anthropological standpoint identified and described the processes that led to the “social construction” of scientific facts (Latour and Woolgar 1979). Inspired by these “postmodern” and “social constructivist” ideas, scholars in the social sciences and humanities emphasized the ever-changing character of the natural world, its hybridization with the social world, the inseparability of sciences and politics, and the impossibility of knowing nature, or of
CONSTRUCTION OF NATURE

knowing it with certainty, depending on the level of radicalism adopted. The idea of nature was considered irrelevant (Latour 2004) or had to be reinvented (Cronon 1996), or multiple truths about nature had to be accepted. Increasingly, nature itself, and not simply the idea of nature, was considered an outcome of human activities. This encouraged emancipatory claims that nature should be managed on behalf of social choices.

The critique of the social construction of nature

Consistently, with its rejection of an objective nature, the “construction of nature” idea led to the disputing or rejecting of the possibility of producing objective knowledge in general. Statements were generally ambiguous, though. They can be represented on a line of increasing radicalism that goes from the trivial (knowledge about the reality is partially socially constructed) to the radical (knowledge about the reality is entirely socially constructed) and the counterintuitive or paradoxical (the reality itself is socially constructed, and multiple). The most radical views triggered a counterattack from biophysical scientists, leading to the so-called science war (Gross and Levitt 1997; Lingua Franca 2000).

Some social scientists also criticized radical or ambiguous constructivist views. Gingras (2000) and Bourdieu (2001) argued that the use of counterintuitive, paradoxical statements was a strategy aimed at creating a hype conducive to mediatizing scholarly work in a context of great demand for radical new ideas that could turn the establishment upside down, while ambiguity enabled the maintaining of a link with common sense in order to retract if the approach was deemed too adventurous. Bourdieu (2001), in order to escape from that hype while making advancement in the sociology of science, proposed a reflexive method of inquiry where science is considered a collective, human activity framed within a given history and social domain, but is also recognized for specificities that make objective knowledge possible. He argues that scientists’ collective agreement with social rules such as control by peers, barriers to professional entry, or acceptance of testing through conducting experiments, are conditions for the possibility of producing objective knowledge about nature. He further investigates social phenomena and processes that have the potential to bias the production of knowledge, such as belonging to a particular social class and the appropriation of a habitus. He recognizes the subjective character of knowledge but emphasizes the need to redress social biases, and identifies the mechanisms that science, as a social institution, has already put in place to do so.

The “construction of nature” today

A recent synthesis (Castree 2014) helps summarize the advancements made possible by the “construction of nature” literature, in spite of and beyond the epistemological and ontological confusion and paradoxes created by the most radical or provocative views.

First, we read in this literature that “nature” is not a given, waiting to be analyzed, experienced or interacted with.” It is, instead, “a way of categorizing and labelling the world” (Castree 2014, 34). The nature that is at stake here is Kant’s nature. It is not Nature, that is, it is not the reality or the “thing” reality is made of. It is, rather, a structure that is superimposed upon Nature in order to make sense of it. This structure can be real, in the sense that there can be something real out there, a subset of Nature, that matches with it, but it is not necessarily real, because it is defined by humans and they
can be wrong. In spite of this, it constitutes the grid that humans, and more particularly scientists, use to render the world intelligible. It is a representation that is being used to produce representations. This is why it absolutely must be questioned. Behind that grid, and whatever it is that actually exists that the grid matches with or not, there is a broader reality, which we called Nature. It is precisely because Nature exists out there beyond the grid that an essentialist view of Nature needs to be retained, as a justification to questioning the grid. The mistake of mainstream positivist science and social constructivism alike was to adopt the essentialist view of nature for the Kantian nature (the grid), instead of adopting it for Nature. This may result from what Bhaskar (1979) called the “epistemic fallacy,” a frequent mistake made by both social and natural scientists and which consists in confusing natural laws, which are invisible generating mechanisms or tendencies, with patterns of events, which are visible, intelligible phenomena provoked by natural laws but to which these laws are not reducible. Once this point is clarified, we can say that Nature is in fact a given, waiting to be analyzed, but this analysis is usually done using a template (Kant’s nature) that is often also called Nature, is frequently confused with it, and is used to render the world and its people intelligible; that is, the conflation of Nature with Kant’s nature is used to exert illegitimate control over people, which brings us to the second point.

The second key statement found in the “construction of nature” literature is that reference to nature gives authority to govern people and ideas. It is so because nature is perceived as being nonsocial, an “ontological given” (Castree 2014, 98). It is nonsocial indeed, if one refers to the essential, non-Kantian Nature. But this essential Nature, although it exists (unless the existence of reality is denied), is unknown, or uncertainly known, and unknowable entirely, so humans cannot claim full authority on behalf of knowledge about it in the conduct of their affairs. Moreover, the nature about which true knowledge claims are made is in fact the Kantian nature, that is, the subset of Nature that is rendered intelligible to humans by its regularities. Accepting authority claims derived from knowledge about Kantian nature alone risks reducing humans and the world they live in to much less than what they actually are, through reification. Through this process, the whole domain that is located in between Nature and Kantian nature, which may be accessible to some extent through philosophy and collective experience, would be denied existence, or considered as if it did not matter.

The third key proposition of the “construction of nature” literature is the argument that representations are “performative” (Castree 2014). That is, the representations of nature and the world, and the grids used to create these representations, determine the way we shape the world materially, through reification. In the end, the things in the world out there reflect the ideas we have about them, even if these ideas did not reflect them in the first place. In other words, representations are “constructs that can themselves construct” (Castree 2014, 139). The world progressively becomes the outcome of the mind but indirectly, as a consequence of humans using their increasingly comprehensive but partially false knowledge to transform it as they wish. The great influence on politics of atomistic views of the social world developed by economists is probably the most terrible, tremendous, and striking case of such a reification process taking place. Humans are redesigning their environment, but also themselves, in that process. We are just starting to question the consequences this can have on us and our environment. We are discovering that limits are set by the way the world actually works; that is, they are set by Nature, not by the Kantian nature that is used as a template
to create human designs. This is why, again, the essentialist view of Nature needs to be retained, as a remedy to the reification of Kantian nature.

Fourth, it is a great challenge to escape the performative character of social constructions because “the question of ‘what do we know, believe, feel and do?’ is umbilically connected to the question ‘who or what is seeking to shape our attitudes, values, emotions and actions?’” (Castree 2014, 98). The production of knowledge and meanings is inseparable from identity, politics, and power, and scientists are not free from these influences. The knowledge they produce about nature is determined to some extent by who they are, which institutions they belong to, and what their social or political agendas are. The more they hold power, or depend on powerful institutions, the more their political agendas and those of the institutions they belong to pervade their work and bias their results, which justifies questioning the knowledge they produce. This is particularly true when scientific work is embedded in unequal social relations like postcolonial north–south relationships, and when the topic and issues at stake are heavily mediatized, as in the case of environmental conservation.

These findings justify pursuing the “construction of nature” agenda. They further show that science may not suffice to understand the relationship of humans with their world, at least for as long as it limits its inquiry to Kantian nature and/or confuses it with Nature. Some questions cannot be answered using the dominant scientific mode but need to be agreed upon in order to collectively confront future changes. Knowledge with no or highly uncertain “scientific” ground might be necessary to fill knowledge gaps in between Kantian nature and Nature. This might explain why myths, which are produced by a larger collective than the scientific community and are socially constructed to a greater extent than scientific knowledge, always played important and positive roles in shaping relationships between humans and nature. They might still be necessary today, sometimes against scientific knowledge, if science fails to account for this space in between Nature and Kantian nature.

A “new” definition of nature?

Today, there is agreement that the “construction of nature” idea enabled progress in the understanding of the natural and social world we live in, in spite of the metaphysical paradoxes and epistemic battles generated by radical or provocative views. How, then, to keep on advancing in social-constructivist research about nature while conserving an essentialist view of Nature as object of scientific inquiry? We suggested that finding a solution relies on clarifying what we mean when we use the term “nature.” For this reason, we conclude by proposing a definition of nature, as well as of a term that is often used interchangeably with it: “the environment.”

We suggest using the term “Nature” for the world out there, as it has been created, by god or by itself, or as it has always been. Nature in the Kantian sense does not fit this definition and should be called otherwise, in order to avoid confusion. If we refer to the work of Bhaskar (1979), it may be that Kantian nature is the “domain of the actual,” where are found patterns of events and regularities generated by Nature, while Nature in the sense we propose here is the “domain of the real,” where are found the laws that generate these patterns. Nature, then, looks like it is another term for reality. But it emphasizes the facts that reality works through its own rules, and that these rules are part of the reality itself. They are the natural laws that organize reality and generate regularities. They have always been there and will always remain, although one
CONSTRUCTION OF NATURE

could discuss whether they are immutable or changing. We believe natural laws are immutable but, as they never act alone and combine in infinite and unexpected ways, patterns of events change. Hence humans cannot change natural laws but they can play with them, combining them in various ways to generate particular patterns of events, that is, particular regularities that enable increasing knowledge and control of the world. Humans can change the domain of the actual (the things that happen) but not the domain of the real (the generative mechanisms of the things that happen). They cannot change nature, but they can change the things that nature creates, by playing with the laws of nature.

Hence Nature is the essence of all things and cannot be socially constructed, by definition. Only representations of it can be socially constructed. The most influential of these representations today is a system of intelligible processes that humans produce through the activity they call science. This system matches to some extent with things or phenomena that exist, because there is indeed an intelligible “world” out there. But this “world” is only a subset of the world. It is defined by a series of features which are mere human representations, some of them true, some of them false. This is why it must not be called Nature.

Another definition of nature, less anchored in philosophy and more operational in everyday life, might also be necessary. In common language, Nature, by opposition to culture, is often defined as the sum of things that are not humans, or that are not the outcome of human agency. We believe that these definitions contribute to the confusion, and we propose, instead, to define nature as aspects that are not the outcome of human agency, together with the generative mechanisms of these outcomes, within things which are, as a whole, the outcome of both natural and cultural processes (of both natural causes and human choices). As humans play with the rules of nature, the things they produce are always hybrids of nature and culture. They are the outcomes of natural necessities as well as human choices and designs. Skyscrapers carry nature in the material used to build them and culture through the design of their architects. Architects need to know the rules of nature to choose the right materials, but nature alone could never build the skyline of large cities. The world inhabited by humans is coproduced by nature and culture. But the outcome of this coproduction is not nature, if we retain the definition above. How should we call it then? It is, simply, our environment. Maybe the second greatest cause of confusion surrounding the “construction of nature” idea, after the conflation of Nature, Kantian nature, and “natures,” is the misguided conflation of the terms “nature” and “environment.”

Consumption

Juliana Mansvelt
Massey University, New Zealand

Consumption is the set of social relationships, discourses, and practices that focus on the sale, acquisition, use, and disposal of commodities. While a commodity can be understood as a good or service that is sold in a market, consumption itself is much broader than a momentary act of purchase. Consumption incorporates a range of practices that are both material and symbolic, and that may extend from spaces of market exchange to sites of wasting. Consumption has an important role to play in material survival and wellbeing and is important in the ways things are valued and devalued economically, socially, and symbolically. Consumption of commodities is necessary to the continuation of the capitalist mode of production, but also has a significant role in the uneven social reproduction of society, in the production of meaningful social relationships (or socialities), and in the construction of real and imagined people and place identities. As a set of social relations, discourses, and practices, consumption plays a significant role in the formation of built environments and material culture, and is integral to the maintenance and expression of everyday life. A central concern of much writing on consumption has been to understand the connections between production and consumption and between economy and culture.

As a sphere of social processes involving purchase, use, disposal, and wasting of commodities, consumption occurs in place, but also has an important part to play in how spaces are created at a range of scales from the body to the global. Bodies, homes, workplaces and play spaces, cities and rural areas, and nation-states all provide a context for consumption, and are made meaningful through consumption practice as spaces of meaning, experience, and imagination. Consumption also intersects with age, gender, sexuality, race, and other dimensions of subjectivity to influence identity formation. Consumption creates and reflects a range of morally inflected social relations between people, and between people and things, across the life course, over time, and in place, for example, reflecting geographies of love, care, hate, and grief. Geographical research on consumption is currently characterized by a wide range of theoretical approaches and empirical studies, which examine the spatialities, subjectivities, and socialities of consumption in both contemporary and historical contexts.

The emergence of geographic research on consumption – disciplinary contours

While consumption has been an integral part of the functioning of societies and the uneven manifestation of social relations and spatial structures throughout history, it was not until the last few decades that substantial numbers of geographers turned their attention to its role and expression. Most prior geographical consumption research focused on the mapping, modeling, and description of consumer behavior, commodity provision, and the collective consumption of goods and services. A relative explosion of interest in the manifestation, role, and conceptualization of consumption in
CONSUMPTION

the 1980s and 1990s appeared to have emerged from both disciplinary and societal change which became most visible from the 1970s.

The 1970s were also a period in which the continued viability of Keynesian politics and welfare states as a means of securing the economic wellbeing of citizens in many capitalist countries was being questioned. Governments subscribing to neoliberal ideologies sought to roll back the operations of the state and to open state-managed or provided services in areas such as health, transport, education, and housing to market forces. These societal changes emphasized the individual as a “citizen-consumer” of goods and services. Citizen consumers were viewed as rational economic agents, who if given the right information would make efficient market choices. At the same time, political economic changes associated with globalization re-shaped geographies of production and commodity networks, influencing consumption practices. The deregulation of economies, reductions in trade and tariff barriers, and opening up of state economies to financial, information, people, and commodity flows, combined with developments in information and communication technologies, improvements in transportation, logistics, and innovation networks, and the development of flexible systems of production, provided new possibilities for where, what, and how commodities were produced, moved, and sold. These changes also facilitated trade, media and cultural flows, and the exposure of more individuals to a wider range of consumption goods, services, and consumption spaces whether they live in circumstances of lack or plenty. The development of advertising, branding and marketing firms in the earlier part of the twentieth century, and of a range of retail spaces (from markets to malls and the Internet) have also encouraged consumers to reflect on the representational nature of commodities and their inferred importance in mediating everyday relationships and practices. Social changes have been significant too; new forms of consumption practice, access and exposure to an increasingly commodified world of goods and services, and the growing visibility of both real and virtual consumption spaces have provided consumers with a diverse range of ways in which bodies, identities, social relationships, culture, experience and meaning can be constructed and negotiated. However, not all such social, political and economic changes surrounding consumption have been positive. Access to consumer goods and services is still marked by stark inequalities both within and between nations, and the wider ecological, environmental, and social effects of current levels of consumption and resource use (including that contributing to climate change) are of concern to many.

As consumption seemed to occupy a more visible place in social and spatial relations, human geographers, in common with other social science scholars, increasingly turned their attention to the manifestation and operation of consumption. Disciplinary changes were also relevant to the intensification of interest in consumption; the rise of postpositivist conceptualizations of society and space – including humanist, Marxian, and feminist geographies – prompted geographers to view the role and function of consumption with a more critical lens, shifting the emphasis from description and modeling toward explanations of the functions of consumption in capitalist societies. A number of geographers were keen to address what they believed were the productionist and masculinist underpinnings of theories of consumption based on Marxian political economy, aiming to study consumption as a meaningful sphere of social processes in its own right. The development of postcolonial and poststructuralist theories challenged many of the assumptions implicit in earlier foundational theories of consumption.
In emphasizing diversity and difference, these perspectives supported a more reflective and situated analysis of consumption, its historical emergence, and its role in configuring social and spatial relationships. Research on consumption continues within both positivist and critical human geography, although the explicit identification of researchers as geographers of consumption seems less evident than in the early 1990s to 2000s, perhaps as a consequence of the increased recognition of the legitimacy of consumption research, and of the growing complexity and diversity of geographical work on consumption. Research on geographies of consumption is now more evident as an integral part of research in other subdisciplinary fields. Geographers less often assert the value of and need for consumption research, but continue to contribute to understanding of the ways in which consumption impacts on commodity networks (including those concerned with waste and sustainability), how it is entwined in moral and ethical geographies, how it involves the intersection of human and nonhuman relations in place, and to the role of consumption practice in reproducing a politics of embodiment, mobility, and identity.

Consumer spaces

Much of the early postpositivist work on consumption by human geographers was concerned with how consumption was produced in place and emphasized the more spectacular spaces of consumption such as malls, theme parks, and fairs. This writing was primarily informed by Marxian political economy, which understood these sites as representational spaces designed to encourage consumption and the realization of surplus value. While this research was critiqued for its productionist and masculine focus, research on shopping malls, fairs, and theme parks and other consumer spaces continues to reveal the significance of these spaces as part of contemporary consumer culture. Many of the early studies drew on traditions of reading landscape within cultural geography, highlighting how imagined geographies and the created environment of retail space had a significant role in encouraging practices of consumption (Goss 1999). In focusing on the production and manifestation of these spaces, however, such studies tended to emphasize the production of space for the consumer, rather than by the consumer, an aspect subsequently addressed by ethnographic research which has highlighted the practice, experience, and embodiment of consuming. Work on spaces of consumption now encompasses a diverse range of first- and second-hand retail spaces (malls, stores, high streets, markets, and the Internet) but also examines how sites of work and leisure such as homes and gardens, work, and tourist spaces are shaped in and across different contexts. The bulk of research focuses on urban areas although geographers have highlighted the impacts of the commodification of rural places and nature. Rather than endeavoring to understand these sites of consumption as discrete entities, much geographical research examines how these spaces are embedded in and connected to social, political, cultural, and economic relations across a variety of scales.

Identity, embodiment, and consumer practice

From the 1990s, geographers using ethnographic methods have studied the practices, experiences, identity, and embodiment of people as consumers, providing opportunity to consider the mundane but significant work that comprises consumption. This acts as a foil to beliefs that consumption is a frivolous, wasteful, and always
CONSUMPTION

pleasurable realm of social life. Initially focusing on shopping, geographers have turned their attention to appropriation and possession, and the use, reuse, and disposal of commodities in order to understand their significance in the constitution of people and place relationships and identities. With regard to acquisition of commodities, a number of geographers have argued that the purchase, display, and use of commodities, while linked to cultural imperatives to construct consumer identities and lifestyles, is more often a means of expressing sociality – that is, of establishing and maintaining relationships with significant others. Research on consumption practices (such as shopping, drinking, and eating) has consequently revealed the complex ways in which consumption practice and commodities are managed and negotiated in everyday life. Geographers have demonstrated that discourses of race, age, class, gender, and sexuality are both a reflection of and an instigator of forms and practices of consumption. In recognizing that consumer identities are heterogeneous and ephemeral, geographers have revealed how these alter and are framed differently in response to life course changes and transitions. The role of consumption in shaping parental and familial relations and in relation to both heterosexual and homosexual identities has also been a focus. While work on meanings and experiences of consumption practices have predominated, more recently the embodied, sensorial, performed, and emotional constitution of consumption practice has been given greater consideration.

Commodities and commodity networks

A third area of geographical investigation relates to commodities. Most of this work has centered upon commodities that have a lasting material form, rather than services, although there have been some studies of consumption of financial and tourist services. Commodity studies of food have been prevalent, but music, consumer durables, drugs and alcohol, and apparel/fashion have also featured. The role and function of commodities as objects of material culture has been emphasized and insights from material geographies and actor network perspectives have informed geographers’ interpretations of the consumption of things.

Geographers have been interested in the ways in which things in commodified and noncommodified moments and spaces enable insight into how places and social relations (such as families, homes, friendship, communities) are constructed. For example, it is possible to understand housing-related consumption as a materialization of the imagined construction of home (Jacobs and Smith 2009). Geographers have also considered how the material properties of commodities imply certain competencies, revealing the ways commodities influence and accommodate human practice. This research has demonstrated how the properties of nonhuman things can be important in the construction of visceral and emotional experiences of activities such as cooking, listening to music, and DIY (Do It Yourself). Accordingly, commodities can be understood not simply as repositories of value but as artifacts of memorialization, identity, embodiment, and emotion. Geographers have also begun to unpack the ways in which mundane consumption practices help shape wider political and economic geographies, such as how the materiality of household disposal is connected with municipal systems of recycling and disposal (Bulkeley and Gregson 2009) and how the acquisition of air conditioning can become a symbol of nationhood and state citizenship (Hitchings and Lee 2008).

The second tradition of consumption research centered on the commodity emphasizes the
social and spatial lives of commodities through commodity chains from production to disposal, often following the work of anthropologist Arjun Appadurai (1986). Geographers have been concerned to understand not just commodity trajectories and how things move in and out of the commodity form as they are produced, acquired, used, disposed of, and wasted, but also the spaces through which these processes occur, and how the social relations, discourses, and practices surrounding commodities and commodity flows are themselves produced across different places and scales. Much of this research has focused on following agricultural and food commodities (Cook 2006), but geographers have also been interested in addressing the productionist focus of much commodity chain analysis to consider how the consumption of commodities, consumer practice and consumer anxieties reverberate through commodity networks (Jackson 2006). As part of research on the shaping and movement of commodities, research on commodity cultures surrounding commodities such as food and music has provided insights into the ways in which cultural and economic practices are shaped transnationally. The connection between processes and cycles of production and consumption and their complexity in a globalizing world has also been illuminated by work on wasting, which seeks to look beyond purchase and acquisition of commodities to understand how the materiality of waste and disposal practices influence a range of other production and consumption activities (Gregson et al. 2010).

**Ethical geographies and sustainable futures**

Through geographical research on consumer spaces, practices, and commodities, geographers have highlighted the ways in which ethical relations are shaped with near or distant others and the kind of moral politics created. In common with work on moral economies, this research has recognized that consumption is not a neutral sphere of social relations, but rather comprises an arena for the exercise and expression of power. Consumers, for example, are encouraged to care through purchase of fair trade, slow, “green,” and cruelty-free products, and “Cool Aid” consumerism (Andrews et al. 2011). A great deal of work on ethical consumption has explored the formal shaping of ethicality across commodity chains and networks with an emphasis on how consumers are enrolled and engaged in caring at a distance. In studying consumers, and particularly household practices of consumption, geographers have shown how sustainable practices may be constrained or enabled by structural, political, and economic contexts. Hence geographers have revealed that behavioral change of individual consumers is not in itself sufficient for sustainable consumption to be achieved. They have demonstrated the desirability for green consumerism, for example, to be aligned with other consumption imperatives, actions, and preferences. While recognizing that all consumption practice is political and underpinned by forms of moralities, research on “ethical” forms of consumption such as farmers’ markets and food security schemes has highlighted the need to interrogate the unintended (and sometimes negative) effects of such practices on others.

Geographical research on consumption has not only revealed the material and representational structuring of places for consumption, but has provided insights into the place of consumption in contemporary and historical social life, emphasizing the complex ways in which consumption is shaped and made meaningful in and across space. It has highlighted not just the ways in which places are made meaningful for consumers, but how consumption is a meaningful
CONSUMPTION

social practice in place. Through studying consumption spaces, consumption practice, commodity trajectories, and material attributes, geographers have provided important insights into operations of power and the moral geographies that underpin them. While the bulk of consumption research is based in Anglo-American contexts more research from other nations (especially in the Global South) is emerging.

Attention to the uneven political and moral constitution and expression of consumption, and to concerns about resource use, sustainable futures, and the environmental impacts of consumption including deforestation, food insecurity, declining biodiversity, pollution, and climate change, provide further possibilities for the extension of consumption research and for developing greater intersections between human and physical geographies. In terms of reflecting on the role of consumption in securing alternative futures, there is still much work to do.

In its strictest sense, the term “containerization” applies to goods of all kinds that are placed in large steel containers which can be transported by many different modes. It is a technology that developed in the 1960s for ships, but which has greatly facilitated the movement of goods between different transport modes. Its impact has been very extensive: transforming shipping and seaport operations and locations; changing relationships between port cities; reshaping the organizational interactions in port city regions; and facilitating the globalization of international trade and industry.

Prior to containerization, freight had to be loaded or unloaded separately between the dockside and the ships’ holds in a manner that had evolved little since Antiquity. It was a system that required a lot of labor and handling was a lengthy process. Cargo ships would spend on average three weeks in port unloading and reloading. Shipping lines generate revenues only when the ships are at sea moving between ports, and port calls are a cost factor. The number of revenue-generating voyages was limited prior to the adoption of containerization.

Because of their standard size, containers can be lifted between ship and shore by specialized gantry cranes thereby obviating the need for human resources, and can also be moved around port terminals and stacked by other mobile equipment. They can be placed on trucks, rail, or barges for onward delivery with speed and efficiency. Containerization thus represents a revolution in mechanized cargo handling, facilitating both scale economies and improvements in speed of handling.

While there had been growth in container traffic in American waters ever since the first ship owned by Malcolm McLean sailed from New York to New Orleans in 1956, the first international sailing did not take place until 1966. The economies of containerization were recognized more widely thereafter, beginning a massive conversion of general cargo into containers. This conversion of existing traffic has been one of the principal factors of growth in container traffic.
shipping, but it has been greatly supplemented by the growth of trade around the world from the 1970s to the present. Today less than 10% of nonbulk cargo is handled by noncontainerized ships. Recently a new factor has become evident with the conversion to containers of certain kinds of bulk cargoes. These include lumber and timber as well as grains.

The growth in containerized trade globally has been spectacular since the 1980s, exceeding gross domestic product and population growth by large margins. If measured by the number of containers handled in ports around the world, traffic has grown from 36 million TEUs in 1980 to 601 million in 2012 (see Figure 1). The trajectory of containerization has been marked by significant regional shifts. Today, East, South, and North Asia are the most important markets, Europe is second, and North America third. This is reflected in the dominant trade lanes, with intra-Asia routes accounting for most traffic today, Asia-Europe second, Asia-North America third, and the transatlantic fourth.

Container shipping has been a factor in the process of globalization of industry and commerce. It has provided a safe and inexpensive way of shipping components and finished goods around the world. The size of the box means that it can accommodate large quantities of goods. For example, it is estimated that for a pair of running shoes sold in the United States for over $100 the transport cost from China is 25 cents. Of course, globalization has been enabled by other factors such as trade facilitation features, but data cited by the United Nations Conference on Trade and Development (UNCTAD) (2013, 23) suggest that between 1970 and 1990 bilateral trade facilitation accounted for 45% of global growth, that membership in the General Agreement on Tariffs and Trade (GATT; the precursor of the World Trade Organization) accounted for global growth of 285%, but that the container as the driver of world economic growth was responsible for growth of 790%. Evidently there is an interdependent relationship between containerization and globalization: the global spread of industrialization and the growth in consumption has provided the shipping industry with greater demand and new markets that it can uniquely serve.

**Figure 1** Global container traffic 1980–2011.

**Containerization and the shipping industry**

The growth in world trade precipitated a significant increase in the size and capacity of container ships. Scale economies are significant, especially where voyage lengths are great. For long trade lanes, such as North Asia-Western Europe, costs per container slot of a 2000 TEU ship were double those of a vessel with twice the capacity. These economies were made possible by improvements in engineering and ship design.

The first specially built container ships appeared in the late 1960s. These were ships with a capacity of 1000 TEUs. The progression in the 1970s was to double the capacity and increase
the speed. By the early 1980s the capacity had doubled again to in excess of 4000 TEUs. By this time vessels reached the maximum size to be able to traverse the Panama Canal, hence they are referred to as Panamax. This represented a plateau that was not exceeded until the late 1980s, when the first post-Panamax ships were deployed. By 1996 the largest ships reached 7000 TEUs and within 10 years had grown to 14,500 TEUs. These megaships entered the market just in time to benefit from the boom preceding the premarket collapse of 2007–2008, and several companies placed orders for vessels of this capacity. The addition of significant new capacity coincided with a global reduction in world trade, and resulted in serious financial difficulties for the carriers. Nevertheless, in 2011 Maersk (the largest carrier) placed an order for 18 new super post-Panamax ships of 18,000 TEUs. The first of these ships began entering into service in 2013.

Thus, in the space of just less than 50 years, from the first international sailing of a container ship in the 1960s to the present, container vessel capacity has increased 18-fold. In no other transport system has such growth in size taken place. The world fleet of fully cellular container vessels has risen spectacularly, from nothing in 1960 to 206,577,000 deadweight tons in 2013.

Container shipping has required significant capital investments to build vessels that are increasingly large. Thirteen of the top 20 carriers in 1979 had disappeared by 2013. Many of the older companies who had played a major role in the conversion to containerization were among those that disappeared, while many newer companies have entered. Thirteen of the carriers in the top 20 in 2013 are Asian, many of which are either subsidiaries of major industrial and banking conglomerates, such as the Japanese MOL (Mitsui OSK Lines), NYK (Nippon Yusen Kabushiki Kaisha), and K-Line (Kawasaki Kisen Kaisha) or the Korean Hyundai and Hanjin, or largely state-owned, such as COSCO (China Ocean Shipping Company) and APL (American President Lines). However, family firms continue to play a big role in the industry. The top four carriers, three of which are European, are largely under family ownership, and there are four other family firms in the top 20. The family firms have been among the most dynamic of the entire industry, introducing new vessel types, developing new networks, and entering new markets. Their organizational structures are simpler than those of the other corporate firms, and are thus better able to respond quickly to changes (Slack and Fremont 2009).

The demand for containers and the growth in vessel size necessitated important spatial and operational restructuring of container shipping. In seeking to serve global markets, the carriers have designed a range of network configurations, including end-to-end, line bundling, trans-shipment, and relay (Ducruet and Notteboom 2012). Trans-shipment has become an important feature of the industry, accounting for nearly 30% of all container traffic. It is especially important in the Mediterranean and Caribbean seas, involving ports such as Gioia Tauro, Italy, and Kingston, Jamaica.

The global nature of the market has led many carriers to combine in strategic alliances, enabling them to pool resources and mount combined services. This has been the practice of most of the Asian carriers. On lesser trades, where demand may be limited, even the big European carriers may offer joint services with regional shipping lines or may buy space on ships operated by other lines, a practice called slot-sharing.

A major challenge to shipping has been the increase in the cost of fuel (bunker). Between 2005 and 2012 the price of bunker nearly
CONTAINERIZATION

tripled, from $138 per ton to $639 per ton. At these prices fuel costs represent over half of operating costs. This has necessitated action by the container shipping lines. They have added a surcharge to their customers and they have reduced the speed of their ships from 20–23 knots to 15–18 knots in order to conserve fuel, a practice called slow steaming. Orders for ships with greater fuel efficiency have been placed as well. Slow steaming means that delivery times are lengthening, requiring adjustments along supply chains. However, the speeds are now below the optimum efficiency for many older vessels, and may produce more emissions and require more maintenance as a result. The new shipbuilding orders are for ships with engines with greater fuel efficiency that can operate at lower speeds. This is a feature of the new orders by Maersk for 18,000 TEU ships whose twin engines have been totally redesigned to reduce fuel consumption and emissions.

Containerization, intermodalism, and supply chains

The box is eminently designed to be transferred from dockside to other modes of transport. There are no global data on the modal split, but it can be safely said that most containers in the world are moved by truck to and from dockside. In part this is due to the spatial location of producers and consumers. In much of the world, such as Japan, China, South America, Australia, and Africa, markets are located in coastal zones and can be served most effectively by trucking. The opportunities for transfers to other modes are limited therefore. In the United States, however, many large markets are located hundreds of kilometers from ports, and thus rail is an important factor in inland distribution (Plant 2002). This has led to an innovation, where the contents of maritime ISO containers are transloaded into larger capacity domestic containers 53 ft in length in the port cities, which are then transported by rail to inland hubs from where they are delivered by truck to local customers.

Europe is an intermediate case. Many markets are coastal and others are at distances within the competitive range of trucking. Rail transport is limited to certain corridors, from Hamburg to Central Europe for example, but as the rail industry regulations are being reformed, more and more services are being developed (Debrie and Gouvernal 2006). A further inter-modal development in Europe is the use of rivers and canals, especially along the Rhine corridor.

Container shipping has reduced unit transport costs by sea, but on land distribution costs are frequently higher. Land connections and market access have become an important focus for reducing costs and improving efficiency along supply chains. Two elements are at work: first, attempts to relieve growing congestion in ports; and second, managing the supply chains. Logistics plays a major role in both areas. Inland ports have been established that evacuate containers directly from the port terminals by shuttle services, and where preliminary sorting, storage, and onward shipments to distribution centers are made (Rodrigue et al. 2010). The distribution centers are located close to major markets. It is there that containers are stripped or filled, as the case may be, and their contents are sorted, labeled, and assembled. These port-focused networks are managed by third-party logistics providers, or major shippers themselves. This logistics-based integration of the maritime industry with the inland distribution systems is giving rise to a new form of spatial phenomenon, port regionalization (Notteboom and Rodrigue 2005).
Containerization and local and regional impacts

The local impacts of containerization have been profound and not always beneficial. The victims of containerization have been the dock workers (Levinson 2006). In the past, gangs of longshoremen toiled physically carrying cargoes to dockside, where slings and ships’ hoists lowered them into the holds and where the goods then had to be stacked. They were a significant labor force that had established their homes in proximity to the ports, forming distinctive communities. Furthermore, the sailors spent weeks in port and there developed businesses, such as bars, rooming houses, and brothels in “sailor towns.” All this changed with containers. Modern gantry cranes can load and unload boxes at rates of 30 lifts per hour per crane. If 20 of these boxes are 40-footers, the hourly rate is equivalent to 50 TEUs. If the contents of each container weighs 8 tons, one crane with one driver can handle 400 tons of goods per hour (in many Asian ports these rates are higher). This volume of cargo would have taken many gangs many days to handle. Thus, the old system of labor in ports had to change, with painful consequences for the workers, their families, and communities.

At the same time, containerization required ports to expand to new sites. These facilities were often far removed from the old port areas, divorcing further the port from the old port city communities (Hoyle 2000). This has been captured in models of port morphology that reveal the spatial separation of terminals and the increasing dimensions of new sites. These intraport models are being integrated with interport models of port system development as well as with inland networks (Notteboom and Rodrigue 2005).

The relocation of container terminals from the old port sites has afforded many port cities opportunities to redevelop urban sites that were redundant. These redevelopment schemes, such as London’s docklands, or San Francisco’s Fisherman’s Wharf, have been transformative in attracting commercial institutions, gentrifiers, and tourists, but few have taken into consideration the nearby communities that suffered the dislocations and hardships of the transformative changes of containerization.

Future trends

Today containerization is a well-established global intermodal transport system and has now achieved a state of maturity. A challenge for the future will be an old problem – how to match supply with demand. The demand is cyclical, as market conditions fluctuate, but ships have a lifespan in excess of 20 years. In addition, in developing vessel capacity to meet the demand shipping lines face problems, since the provision of new ships is a lengthy process, in which the design, the securing of financing, the placing of the order, the construction, and the sea tests extend over several years. Alternately, they may seek to lease ships. The Baltic Exchange in London is where this takes place, and its index is a widely held indicator of global economic activity. In periods of high demand for vessels the rates are very high, and conversely in low demand periods the index is low. Thus, when high market growth occurred, such as the period between 2005 and 2007, the Baltic Exchange index was very high, and many ship owners decided to place very large orders for new vessels, only to find that on delivery the market had collapsed, leaving them with extra capacity on their hands and facing greatly reduced freight rates.

For the last 20 years or more experts in the industry and in academia have forecast that vessel size increases would cease, only to see size passing 5000 TEUs, then 10 000 TEUs, and then 15 000
CONTAINERIZATION

TEUs. In 2013 Maersk’s new 18 000 TEU vessels entered into service. With this history it would be foolish to predict no further increases in size. While each increase in size limits the number of ports that can accommodate the vessels because of the increasing dimensions, there are always ports willing to invest in dredging deeper channels and expanding terminals. The ultimate limits may be established by the Suez Canal (24 m) and the Straits of Malacca (25 m).

The intertwined concepts of center and periphery, denoting the relative positions of given entities in space, are widely used not only in the social sciences, but also in urban design, physics, and the history of science. In the case of physics and the study of the atom, we know that electrons are tiny particles that randomly wander around a central nucleus, wherein are located the protons and neutrons, the particles that contain the bulk of the mass of the atom.

In the context of the social sciences, the core refers to regions that have consolidated their hegemony in terms of leadership in science and technology and economic power, that is, the highly industrialized countries in Europe and North America and some Asian countries.

Even before the end of World War II, Polish economists such as Kalecki (1993) and Rosenstein-Rodan (1943) were concerned about the future of the countries of central Europe; in particular, with how to overcome the effects of late capitalism that impacted on them and put them in a peripheral position in relation to the Western European countries. Their question, essentially, was: What is the future of this periphery?

For liberal or neoclassical economists, underdevelopment was only a delayed stage in the onward march of capitalism. In 1958 W.W. Rostow presented his theory of the stages of economic growth as a universal evolutionary process through which every society necessarily has to pass. There are five stages of growth: the initial stage of a traditional society; a transitional stage; the stage of takeoff or “boot”; a phase of “maturity”; and finally the age of mass consumption. This route, which is the path of capitalism, was founded on the premise of progress, rooted in Western culture, and on technical progress, which was seen as neutral and as an expression of rationality (Rostow 1958).

A different theory of development had been offered by Raúl Prebisch 10 years earlier, in 1949. In his introduction to the first economic survey of Latin America, The Economic Development of Latin America and Its Principal Problems, he elaborated the thesis of “unequal exchange” that structured center–periphery relations (Prebisch 1950/1949). The appearance of this publication was also the occasion of the launch of the executive secretariat of the Economic Commission for Latin America.

In his 1964 book on the dynamics of Latin American development, Prebisch analyzed the problem of external bottlenecks that the region was subjected to, and indicated the congenital weakness of the periphery because of which it remained unable to retain the fruits of its technical progress. These regions imported manufactures, the unit values of which increased rapidly, while the unit values of their primary exports rose slowly. Attempts were made to overcome this imbalance via industrialization through import substitution policies. But his interpretation did not neglect politics, because he realized that economic development could not accelerate without the transformation of the social structure. And he could see that democracy would be threatened without an articulated process of income distribution.
For many Latin American developmentalists, a sociocentric concept of development would have to mean, at the very least: (i) recovering a critical and long-term vision; (ii) establishing as a fundamental axis a role of the state which assumes responsibility for contributing to the definition of a national strategy in the medium and long term with a view to achieving greater democracy and overcoming poverty; and (iii) focusing on citizenship, that is, the creation of participatory institutions that would facilitate decentralization, regionalization, local initiative, and a profound cultural change.

During the second half of the twentieth century, a change in the developmentalists’ understanding of the concept of development seems to have occurred. The transformations that had been taking place within capitalism itself, and their perverse social effects, in turn produced a partnership that was assuming new forms of articulation and action. Among these were the movements of peasants, slum dwellers, ethnic communities, environmentalists, gender activists, youth, consumers, human rights activists, and, more specifically, those social segments that had traditionally been marginalized, even including middle-class sectors. All of these groups began to draw up more comprehensive demands featuring new nontraditional social actors. Among these new demands were ones relating to solidarity, participation, and partnership, and to forms of development that were not limited to economic growth and that, until then, had never been visualized as processes of development. But, at the same time, during the extended periods in which nonrepresentative political regimes in many peripheral countries implemented structural adjustment policies demanded by the International Monetary Fund, strong bonds of a shared perception of predatory self-interest between large segments of the upper and middle classes, who aspired to achieve North American levels of consumption, had also emerged and became consolidated. This process was further reinforced by the political alienation of the rest of the population.

A theme that has a central place in the work of Celso Furtado (1983) is underdevelopment, a theoretical challenge on which he worked all his life. For him underdevelopment is an autonomous historical process, in the sense that it is not a stage through which economies have to pass in order to achieve a higher level of development. Although Furtado recognized this autonomy as necessary for the completion and maturation of the phenomenon, he also understood that an underdeveloped economy should not be considered in isolation from the international division of labor in which it is embedded. He also recognized that underdevelopment is essentially a phenomenon of cultural and political domination.

He believed that an explanation of the process of capital accumulation should lie at the very base of the theory of economic development. Choices and economic decisions are policies. However, investments and allocations decided by economists are regarded as something unambiguous. This supposed “axiological neutrality” of the procedures of positive economics was not accepted by Celso Furtado, and he posed arguments and questions of a different order: “What are the relationships that exist between social stratification, systems of domination and the changes that occur in a society as a result of accumulation? How can economic development be integrated into the process of social change and how does it relate to the decision making systems and structures of power?” (1976, 25).

To analyze the state of the periphery in the period since the mid-1980s, which has witnessed a technological revolution and a strong and concomitant process of globalization, it is essential to establish a link between technology
and development theories, mainly because the periphery has tended to remain a passive recipient of innovation and not a focus of creativity (Costa Lima 2008). It is from this perspective that Furtado (1998, 26) propounded the concept of a “technological imperative,” which holds that the trend of globalization is such that markets will impose their logic and rhythm on the world economic space.

In the 30 years after World War II the history of capitalism has been characterized by a marked geographic concentration of industrial activities, alongside a more egalitarian distribution of income, in core countries. These trends are the result of the struggles in these countries of organized workers which led to a rise in real wages, as well as of workers’ demands that their governments adopt policies to protect domestic markets and the fact that these countries did not suffer colonization. The dynamism of the capitalist economy thus grew out of the interaction of two factors: technical innovation, which is reflected in increased productivity and achieved mainly by reducing the demand for labor, and the expansion of the market with higher wages.

It is important to note the inherent logic of capital: that the development of a society is not independent of its structure, and, furthermore, that increases in the efficiency of the system, which are generally identified as the principal indicator of development by conservative economists, are not a sufficient condition for satisfying the basic necessities of the population. It may even be the case that the introduction of more sophisticated techniques leads to a degradation of living conditions of the bulk of the population. In other words, the technical advances may benefit only certain social groups (Furtado 2000). It is, therefore, important to consider the quality of the development, to ensure that the efforts made to innovate and promote technological development benefit the largest possible number of people rather than generating or reinforcing a structure of privileges.

There exists a rich corpus of theory on development, including, among others, the writings of heterodox authors like François Perroux (1969), Gunnar Myrdal (1957), and Albert Hirschman (1958), who criticized the concept of stages and spoke instead of asymmetries, dualism, and dependence. There are also Marxist authors who rejected developmentalism and dualism altogether, preferring the concepts of imperialism and the colonial past which, they believed, impeded the process of autonomous national development in the periphery. It is in this tradition that Andre Gunder Frank (1966) presented the thesis of the “development of underdevelopment,” which was further explored by Samir Amin (1967) and Arghiri Emmanuel (1969), who dealt with the mechanisms of global accumulation, from which one can escape only by rupture, or a clear break with the prevailing realities created by capitalism. World-systems theory, which is mainly attributed to Immanuel Wallerstein (1974), but was also enriched by the contributions of Amin and Frank, is rooted in classical sociology, Marxist economic policy, and the thinking of dependency theorists.

The works of Emmanuel and Amin explain the extent of the leakage suffered by the peripheral countries as a result of deteriorating terms of trade, that is, disparities are perpetuated by the unequal exchange that prevails between the countries at the periphery and those at the center. For Amin, the transfer of the surplus to the center, in various forms, is the central issue, and these mechanisms of primitive accumulation feed capitalist expansion (Costa Lima 2011, 146).

According to Chase-Dunn (2007, 1060), the modern world system can be understood structurally as a stratified system: first, composed of central societies that are economically, culturally, and militarily dominant and in competition
with each other; and, second, by peripheral and semiperipheral regions. Some dependent regions were, of course, successful in improving their relative positions within the broad center–periphery hierarchy, but most had to remain in their peripheral and semiperipheral positions. This structural approach allows us to analyze the cyclical profile of social change and the long-term pattern of development in a historical and comparative perspective.

In the early twenty-first century, the center–periphery structure has continued to remain intact in global comparative terms. The center, with its large international capital, has not only gained a global specialization, but has also undergone radical technical transformations in production. The role of the dependent sphere as an exporter of capital continues through the permanent mechanism of debt leakage, and this situation leads to political, social, and economic instability, with predatory effects on the environment.

The drastic changes brought about by globalization and financialization have rapidly transformed the social reality and interpretive categories. The consolidation of financial hegemony, mediated by stock exchanges or by mutual and pension funds, redefines a new geoeconomic orientation under the control of the United States. In this new context, Latin America has completely abandoned its project of development, whether autonomous or dependent, and is now working under conditions of financial bankruptcy that require external control by national banking systems, through privatizations, and also by the states and their instruments of intervention. As Fiori (2001, 82) eloquently affirms: “financial capital diluted and softened to the maximum possible extent the variable frontiers of its economic territories, moving from country to country and from one world region to the other, without creating any permanent attachment, much less any kind of ‘civilising’ project for the periphery of the system.” This turns the countries of the periphery into hostages to the logic of international movements of capital and subject to their moods and the crises created by them.

The contemporary theoretical and empirical discussion arising out of globalization processes—which focuses on changes that are taking place in space, technologies, production processes, the maintenance of social inequalities, regional dynamics, territories, the phenomena of metropolitanization, the environment, and the role of the state—began to require an inter-, multi-, and transdisciplinary approach to these new realities and phenomena (Costa Lima 2013). How can the fact that economic activities tend to concentrate in a finite number of well-defined points in space be explained? How can the new hierarchies and centralities of development be explained?

In geography, the first studies that sought to identify an urban structure organized around a center/periphery dichotomy were more descriptive than properly paradigmatic or theoretical. In general, the empirical findings about urban structure and the distribution and/or segregation of the population in certain areas within the city could be observed in the studies of Georg Simmel and Max Weber, who largely influenced the research developed by the Chicago School. In 1925 Ernest Burgess conducted a pioneering study, which proposed the construction of an analytical model that included the expansion of the city around a central point, and identified several concentric circles as one moved toward the periphery which spatially delimited the various forms of sociofunctional clustering of a city.

From a functionalist perspective, segregation, dispersion, and urban inequalities were examined in analyses focused exclusively on the individual, based on the notion that his/her housing decisions would be exclusively guided
by tastes, preferences, and social networks. These were examined, therefore, in a reductionist manner that made the social production of space a product of individual rationality, leaving aside economic and structural variables.

Differentiated and critical approaches came into vogue which sought to understand the areas and urban spaces that were peripheral, distant, precarious, and devalued in the property market. These also focused on the conflicts that occurred, on the one hand, because of the violence of the status quo and marginalization, and, on the other, because of demands for the allocation of urban space from the poorer sections of the population whose access to alternative housing was foreclosed by the market or the state, thus creating irregular settlements, built without order or outside the law, on protected or inappropriate land. At the other end was a center, well-equipped, valued, and with a large number of highly skilled jobs and services. It is in this context that the confrontation takes place – between the unused and closed properties awaiting an increase in market value and the possibility of low-cost housing and renovation projects that, in the process of execution, expel the poorest sections of the local population. It is here, therefore, that the theories created in the countries of the North and the South are clearly differentiated from one another, with regard to their application to advanced industrial regions or to the regions of low development. The regional disparities are not just international phenomena but are also national in scope.

Efforts are underway to further develop theories on the geographic concentration of economic activity. Cities are perceived as places where material and immaterial exchanges happen, where networks of various forms and contents settle in continuous, endogenous, and exogenous flows. They are places where innovation happens, producing information and knowledge. But these cities also have their networks of hierarchies, structured in a center–periphery manner.

In recent years, a growing number of economists have turned their attention to this phenomenon and, in a broader sense, to their impacts in relation to regional development. Since the early 1990s the new economic geography (NEG) has provided several theoretical studies of regional and urban structures. As stated by Fujita, Krugman, and Mori (1999), cities have increased their importance as the basic units of international economic systems.

Since the late 1990s, income inequality, as measured by the Gini coefficient, has increased in almost half of the developing countries, but, according to the data presented by Joseph Stiglitz (2012) in his latest book, inequality has also increased significantly in the United States, the richest country in the world. The Nobel laureate speaks about the growing inequality of income and wealth in the United States since the 1980s. In the Preface, he notes that “there are moments in history when people around the world seem to stand up to say that something is wrong.” His data are conclusive on the effects of economic policies that generated inequality of income and wealth in the United States after 1980, namely that 25 years ago the richest 1% of Americans owned 33% of national wealth, and that in 2007 that figure had risen to 40%. In 1976 the richest 1% received 9% of national income compared with nearly 25% today. The real income of a typical male full-time worker has stagnated for more than one-third of a century.

As Dunford and Yeung (2011) point out, global economic inequalities, in general, have been increasing over 200 years. According to them, the reason for this is that very few economies in the pursuit of economic and social modernization had managed to achieve sustained growth. More recently, the rise of Asia has been an important step in the reconfiguration of
global development, precisely because a number of large emerging market economies have rejected the prescriptions of the Washington Consensus. One of the reasons for this was, thanks to increased global integration, a sharp increase in the global workforce. A second and more important reason was that, in Asia, as a result of currency devaluations, strong growths in exports were achieved in some countries. These emerging countries, which had earlier been debtors, were transformed into creditors while rich core countries became debtors.

Dunford and Yeung’s (2011) central argument is that, in all likelihood, the group of emerging economies, especially China, will sustain its recent advantages of growth albeit in the context of slower global growth. In the Western world, a set of strategies designed to restore sustained growth has proved insufficient, and the recent economic crisis will have an even bigger and more stubborn negative impact in the developed world because these countries do not have an alternative model of growth in reserve. China, on the other hand, has the potential to sustain relatively high growth rates for many years. To do so, however, it will need to bring about profound changes in its development model. If it manages to do so, and if the other major economies in the BRIC group, India, Russia, and Brazil, also continue to grow, there is a strong possibility that these emerging countries will lead global growth. If this happens, then, within 25 years, Asia will account for 66% of global GDP. The global configuration created by the Industrial Revolution, colonialism, and imperialism would then be reversed. Inequalities of income per capita will still continue for a longer period, but the center–periphery relationship will have undergone substantive changes.

The global economic crisis that began in 2008 has given rise to perplexities and changes in our understanding of global phenomena. Economic inequality in all its forms has forced as many as 1.57 billion people to live in a state of “multidimensional poverty” (PNUD 2013). In any event, after the big changes taking place in emerging countries, led by China, new concepts are still worth designing with a view to developing new perspectives on the long-established center–periphery structures which are becoming ever more complex. Given this context, the question is to what extent the realities subsumed within the current dynamics of North–South and center–periphery relations are likely to change, along with their interpretation.

Corporate environmental responsibility

Abigail Efua Hilson
Royal Holloway, University of London, UK

Corporate environmental responsibility (CER) is a voluntary activity by corporations to assess and minimize their ecological footprints in the course of conducting business. These activities fall outside the legal requirements of organizations to reduce the levels of pollution, emissions, and environmental degradation associated with their business activities.

Organizations were previously perceived as closed systems, whose links to their environment and society were of little interest. As a result, organizations existed for the sole purpose of making a profitable return for their owners or shareholders. In recent years, recurring corporate scandals over loss of livelihoods, destruction of the natural environment, and the collapse of financial markets have inspired a rethink of how organizations can and should operate. Specifically, how their existence affects society and the environment is now being formally considered. Today, organizations are considered porous or open systems. The activities of organizations transcend the periphery of their immediate boundaries and affect the general society and natural environment.

Corporate activities have resulted in water pollution, waste generation, natural resource use and exploitation, harmful emissions, and accelerated levels of energy consumption. In response to the realization that corporate activities can be far reaching, organizations have been called on to consider their social and environmental impacts through corporate social and environmental responsibility programs. There is some regulation of corporate environmental impacts by governments; however, for the most part, corporate environmental responsibility is voluntary. The application of corporate environmental responsibility across organizations worldwide varies widely as it is a voluntary exercise. For example, in 2010, in the course of its oil drilling activities in the Gulf of Mexico, BP plc caused a catastrophic accident dubbed the Deepwater Horizon oil spill. This spill resulted in the death of 11 people and unprecedented destruction to marine and wildlife. It is widely held that BP took a lackluster approach to its environmental obligations and that this had caused the accident. Environmental groups attribute the spill to the absence of adequate regulation of the ecological impacts of industries by government. Corporate environmental responsibility is a phenomenon that has gained traction in recent years, especially in the face of climate change. This entry reviews the concept of corporate environmental responsibility by outlining its origins and how it is currently being practiced, and offers a brief discussion of its anticipated future.

Evolution of the concept of corporate environmental responsibility

In order to understand how corporate environmental responsibility has evolved, it is instructive to trace its antecedents. Corporate environmental responsibility is a subset of the broader term or activity corporate social responsibility (CSR), hence it evolved in tandem with the concept
CORPORATE ENVIRONMENTAL RESPONSIBILITY

and practice of CSR. Until recent years, CSR was the umbrella term for all social and environmental initiatives undertaken by organizations. Over time, it became necessary to distinguish between environmental and social responsibility as it was recognized that business activities have direct effects on the environment. Environmental advocates now demand that businesses be accountable to the environment in its own right as a stakeholder.

This demand that business take notice of the environment has been met with intense debate. Critics charge that operating with an environmental conscience runs counter to the very purpose of business: making a profit. Milton Friedman (1962) rejected the suggestion that businesses have any wider social and environmental responsibilities, and contended that the market should be the final arbiter of what they do. To focus on anything else, like the wider impacts of the business on the environment or society, would not only be inefficient and but also represent a gross misappropriation of shareholders’ investment.

At the time Friedman publicized his argument, the corporate social and environmental responsibility agenda was only beginning to take shape. Andrews (1973) describes how the issues of corporate responsibility had been gestating in the years prior to Friedman’s infamous declaration. The academic discourse prevailing at the time was that business was accountable to three stakeholders; namely, its investors, its employees, and its consumers. The emphasis here was on demonstrating a social conscience and not necessarily an environmental conscience. Moura-Leite and Padgett (2011) provide a useful account of the evolution of corporate social responsibility, drawing on the seminal works of Bowen (1953) and Drucker (1954). Bowen (1953, xi) is said to have spawned the modern period of CSR by asking the question “What responsibilities to society are businessmen reasonably being expected to assume?” Bowen’s text sought to spark debate by underscoring the importance of the several hundred largest businesses at the time to “centres of power and decision making,” furthermore highlighting how “the actions of these firms touched the lives of citizens at many points” (1954, 6, 4). The latter, explain Moura-Leite and Padgett, helped to advance the importance of including “public responsibility as one of the eight key areas in which business objectives should be set” (2011, 530). Drucker famously asserted that managers must “consider whether the action is likely to promote the public good, to advance the basic beliefs of our society, to contribute to its stability, strength, and harmony” (1954, 388). This foundational work provided an impetus for scholars to develop working definitions of CSR that aligned closely with the business ethics of the day.

Friedman’s (1962) critique of CSR was issued in the face of an emerging environmental movement that expanded the scope of corporate responsibilities. Rachel Carson’s book Silent Spring, written in 1963, captured the public conscience and helped to spark a radical overhaul of environmental regulations, as well as facilitating a change in the general attitude toward industrial pollution worldwide. Pressure was put on regulators by both the general public and environmentalists to restrain the environmental destruction wrought by businesses.

In response, many in the business world seized on the idea of corporate environmental responsibility as a way to earn their social license to operate. Critics, however, complained that there was no definition of the concept of social and environmental responsibility, making it easier for businesses to define the concept in line with their own purposes. CER was and continues to be an increasingly perplexing problem for corporate strategists to find an appropriate posture for what
may be called corporate citizenship, environmental responsibility, or social responsibility. Among the things that make it difficult are two prevalent myths: that the activities relating to environmental or social responsibility are in fundamental conflict with the interests of the profit-seeking investor; and that the motivation for such activities lies only in a sense of noblesse oblige on the part of the group formulating the strategy and, again, is not in the equity holder’s interest.

The criticisms against social and environmental responsibility continued into the late 1990s. The general sentiment among those against the CSR movement was that business executives were against the concept. One scholar asserted that “executive interest in corporate social responsibility is waning” when new standards for pollution control and safety came into effect (Shanklin 1976, 75). Toward the mid-1970s, however, a much broader body of analysis – one more positive in outlook – began to take shape. A large share of this literature popularized the merits of CSR (e.g., Gavin and Maynard 1975; Carroll 1974; 1978; 1991; Carroll and Beiler 1975). A series of complementary studies argued how, in addition to their profit-making motives, large businesses were beginning to show a willingness to address environmental and social concerns more proactively. It was at this time that organizations had begun to alter their structures and to appoint corporate social responsibility officers. These officers were responsible for managing community development and environmental concerns. The discussion at this point was showing how organizations were embracing mounting societal and environmental demands and how this new approach to business was in the best interest of organizations.

The conceptual work of Archie B. Carroll (1974; 1978; 1991) helped transform business attitudes toward community development and environmental management. In 1991 Carroll developed the “pyramid of corporate social responsibility,” a hierarchical model of the various business responsibilities, starting with economic responsibilities (the foundation of all other business activities), legal responsibilities, ethical responsibilities, and philanthropic responsibilities at the apex. Carroll’s pioneering model, which even today is still portrayed as landmark, spawned a new genre of CSR scholarship. The insights it offered continue to serve as the foundation of the case for CSR being practiced by organizations around the world.

Gradually, many organizations have begun to embrace the call to respond to the environmental agenda. Incidents such as the Exxon Valdez oil spill in 1989, the Bhopal disaster in 1984, and the more recent Fukushima nuclear disaster in 2011 have continued to raise awareness on the importance of environmental responsibility. Most of these disasters have resulted in huge sums of money being spent on litigation. Curiously, ethical businesses have been rewarded by increased consumer loyalty. Today’s consumers are prepared to shell out more for sustainable products. Buzz words such as “biodegradable,” “organic,” “carbon offsetting,” “FSC certified,” “eco-friendly,” and “renewable” attract consumer attention. People are “going green” – making environmentally friendly choices in the products they buy. Companies are therefore expected to do the same. Today’s organizations are not expected to exist solely for the motive of profit maximization but are also required to align with the social, environmental, and regulatory structures within the countries they invest in. Investments in CER programs are now perceived as a requirement for companies to
get the necessary buy-in from the communities within which they operate. That is part of what is termed the “social license to operate.”

Another condition that has contributed to the widespread investment in CER programs is the role that governments have played in encouraging businesses to minimize their ecological footprints over and above the requirements of the law. The activities of firms in the extractive industry, for instance, result in significant environmental impacts. One way to fend off regulation from governments is through CER reporting suggesting that governmental intervention is unnecessary, because business can be trusted to manage the environment responsibly. Extractive industry firms have been quick to highlight their numerous contributions to society through comprehensive sustainability reports. In the 1980s they were heralded as trailblazers for environmental and social responsibility programs in the developing world. In line with idea of the “triple bottom line” corporate reporting put forward by Elkington in 1994, these firms published and continue to publish extensive sustainability reports on their social and environmental efforts. Elkington (1994) urged organizations to consider their social, environmental, and financial performance and not just to focus on the traditional measure of financial performance. Elkington’s suggestions spawned a new wave of corporate reporting. The annual financial reports typically released by public companies were now accompanied by social and environmental reports.

Companies outside the extractive industries soon followed suit. Social and environmental reports, typically dubbed “sustainability reports,” are now published for stakeholders to see how companies are making a contribution to society and taking care of the natural environment. Several theories have been advanced to explain why companies publish such reports. It is argued that, fundamentally, companies publish these reports for the sake of legitimacy. Irrespective of the reasons given for corporate disclosure of environmental activities, the increased presence of these voluntary reports perhaps points to the fact that a lot of companies have embraced the call to take responsibility for their society and the environment seriously.

Visible negative effects of corporate activities have also increased the need for corporations to operate sustainably as the natural resource base of the Earth is finite. The past century has witnessed several corporate disasters, which have led to this call for action. The Exxon Valdez oil spill alone affected 1300 miles of shoreline. The carcasses of more than 35,000 birds and 1000 sea otters were found after the spill, but, since most carcasses sink, these are considered to be a small fraction of the actual death toll. The best estimates are 250,000 seabirds, 2800 sea otters, 300 harbor seals, 250 bald eagles, up to 22 killer whales, and billions of salmon and herring eggs.

Typical steps in corporate environmental responsibility planning

The concept of CER continues to be applied differently across industries and between organizations. As CER is voluntary, organizations are free to evaluate their internal and external processes in order to identify the perceived impacts on the environment. Generally, organizations take three steps to address their CER. Figure 1 depicts this dynamic process.

Step 1

The initial step is to identify the environmental impacts of all business activities. This includes reviewing the company’s supply chain, internal processes (administration and manufacturing,
Step 1

where applicable), and its service or product delivery outlets to identify the ecological impacts of such activities. Such assessment often also involves an extensive stakeholder analysis.

Step 2

The next step is to evaluate the extent of the damage to the natural environment. Within this step, organizations prioritize the environmental impacts they identify in step 1. At this stage, stakeholders are grouped in order of significance. As organizations perceive their primary stakeholders as the most important stakeholders, issues that affect these stakeholder groups are given priority. Cost–benefit analysis is often performed at this stage to determine how best to address these ecological issues. Organizations also consider the prevailing standards in their industries and align their choices with those of the industry. Table 1 shows a selection of international sustainability frameworks, guidelines, and “best practices” typically adhered to by organizations. The standards guide organizations in reporting their environmental and social efforts.

Step 3

After prioritization of the environmental impacts, companies take steps to mitigate their ecological impacts. Typically, responsibility plans include reducing energy consumption, recycling to reduce landfill disposal, reclaiming mined lands, reducing hazardous waste, reducing water usage, replanting trees, and using sustainable wood and other products.

It is now commonplace to find environmental sustainability links on corporate websites. Most organizations have a corporate environmental policy. Such policy documents are composed of environmental codes, details of environmental principles or standards that the organization subscribes to, and environmental standards and codes specific to that organization.

Future directions in CER

Despite gaining significant traction over the years, there is still considerable room for improvement in the area of corporate environmental responsibility. While companies operating in the developing world have managed to deflect negative attention by projecting positive images of “community development” and “environmental management” in localities affected by their operations, extensive corporate lobbying in the developed world has slowed down environmental regulation. There is widespread belief that corporations will continue to deflect attention through innovative reporting; extensive public engagement; the assembling of dynamic corporate relations departments; and the skillful manipulation of the local media. An
emphasize on outcomes has led to organizations adopting a narrow view when making environmental decisions, the effects of which can be detrimental when it comes to a disempowered, marginalized stakeholder such as the environment. Companies are using their CER programs as a tool for enhancing their legitimacy. This is especially true in areas where activism for the environment is strong. The accounting literature has discussed, extensively, the positive role that voluntary sustainability disclosure plays in an organization’s efforts at gaining or enhancing legitimacy. In some instances, it is argued that organizations with strong environmental and social programs use sustainability reports to claim superiority in the area of CSR or to counter a perceived legitimacy threat. CER was used to deflect criticisms and to regain legitimacy following the Exxon Valdez oil spill in 1989 and the BP oil spill in 2010. Academic scholars note that there were increased self-laudatory environmental disclosures, focusing heavily on preventive measures and emergency response, which, as demonstrated, were made purely in response to heightened public pressure.

If these trends continue, it is anticipated that CER will, for the most part, continue to be a facade, a mere tool that companies use in order to gain or enhance their legitimacy, to the detriment of society and, more importantly, future generations.

Corporate financialization

Manuel B. Aalbers
KU Leuven/University of Leuven, Belgium

The rise of financialization

The concept of “financialization” has rapidly become popular in social science. On April 22, 2011, there were 1950 and 4680 hits, respectively, for “financialisation” and “financialization” on Google Scholar (Engelen 2012). Almost 40% of those were added between the beginning of 2009 and April 2011. Three years later, on April 22, 2014, there were, respectively, 5940 and 12600 hits for the UK and US spelling of the concept. This means that 64% was added in those 3 years – a true explosion of the concept of financialization. What is it that makes this concept apparently so attractive to academics, and what do they mean when speaking of “financialization”?

It would be hard to deny that the global economic crisis in 2007–2008 and its persistence in the following years explain part of the popularity of the use of the term “financialization.” The economic crisis is often framed as a financial crisis caused by unscrupulous financial practices in both the global financial command and control centers (London, New York, and so forth) and the daily life of consumer banks and their customers. There is a feeling that both the economy at large and daily life have become more financialized: that is, finance is thought to play a bigger part in both the Economy with a capital “E” and in the many economies with a minor “e.” The burgeoning literature on financialization tries to answer the who, what, how, why, when, and where questions of the presumed financialization of the E/economies. One might assume geographers would have prioritized the “where” question, but they have rarely studied the where in isolation of the other questions. Furthermore, political economists of different stripes and different disciplinary backgrounds have also included the where question in many of their analyses.

The literature on financialization is truly multidisciplinary, in the sense that most contributors to the financialization debate appear to rely on literature from different disciplines. The authors of the 19 most cited (i.e., at least 100 citations in Google Scholar) publications on financialization have backgrounds in economics, sociology, political science, cultural studies and arts, history, and geography, and most of these papers reach their high citation scores by receiving cross-disciplinary citations. Whatever may divide these approaches, there appears to be a shared conviction that mainstream, neoclassical theories provide little fertile ground to understand the contemporary financialized economy. Most of the economists active in financialization debates rely on Keynesian, Marxist, or, more generally speaking, heterodox and political economics. Many of the noneconomist protagonists rely on either some form of multidisciplinary political economy or on some combination of post-structuralist and cultural-economy accounts. Many of the financialization protagonists suggest or explicitly argue that a great deal of work within their discipline or subdiscipline for too long has either ignored finance or presented an outdated view on the role of the financial sector in contemporary capitalism.
CORPORATE FINANCIALIZATION

Financialization also has been criticized, either because the concept is considered imprecise, vague, and chaotic or because the presented evidence supporting the financialization claim is disputed. To some extent, the critics are right: financialization can be a very loosely defined concept that covers many processes, structures, practices, and outcomes at different scales and in different time frames. Furthermore, sometimes financialization is the *explanandum* (the phenomenon to be explained), sometimes the *explanans* (the thing that explains), and at other times it is not even clear which of the two it is. In that sense, financialization is not that different from other concepts whose academic (and media) popularity rose quickly and which are simultaneously criticized for being imprecise and vague – globalization and neoliberalism are cases in point.

The popularity of each of these concepts lies, at least in part, in their imprecision: that is, in their ability to transcend different lines of argument, originating from different disciplines, and taking place at different scales. It is the inability of existing perspectives, concepts, and data to deal with the complex realities of contemporary societies that explains an important part of the popularity of such imprecise concepts. Moreover, these concepts become popular so rapidly exactly because in the real world it may be hard to tell the *explanandum* from the *explanans*. Part of the intellectual journey of the use of concepts is that they problematize existing conceptualizations and understandings of what caused what. While this may initially create more confusion, it also reflects an, often implicit, acknowledgment that we do not live in a closed system in which causations are linear, one-dimensional, and single-scalar. The literature on financialization thus is part of a larger attempt to understand the nonlinear, multidimensional, multiscalar complexity of contemporary societies/economies. This entry, by adding a little to the complexity, seeks to shed light on the different elements of the financialization literature and their interrelations.

**Defining financialization**

The financialization literature is commonly divided into three different conceptualizations: financialization as a regime of accumulation, financialization as the rise of shareholder value, and the financialization of daily life. This division has become problematic: a great deal of the literature makes connections between these strands or moves outside the arguments presented within them. Thus the following 10 themes are proposed as encompassing contemporary scholarship on financialization:

1. financialization as a historically recurring process that signals the autumn of hegemonic powers
2. financialization of banking: that is, the rise of nonbank financial institutions
3. financialization of the economy in narrow terms: that is, the financial sector becoming increasingly dominant in economic terms
4. financialization of nonfinancial firms: that is, traditionally nonfinancial firms becoming dominated by financial narratives, practices, and measurements
5. financialization *within* nonfinancial firms: that is, traditionally nonfinancial firms increasingly partaking in practices that have been the domain of the financial sector
6. financialization of the workplace: that is, employees and their labor practices increasingly shaped by financial narratives, practices, and measurements
7 financialization of the (semi-) public sector: that is, government, public authorities, education, health care, social housing, and a range of other sectors becoming dominated by financial narratives, practices, and measurements

8 financialization of public policy: that is, the financial industry’s concerns becoming increasingly privileged in the policy domain

9 financialization of households: that is, financial motives, rationales, and measures becoming increasingly dominant, both in the way individuals and households are being evaluated and approached, and in how they come to make decisions in life

10 financialization of the discourse: that is, finance becoming increasingly dominant as a narrative and metaphor, as a language to see/view/measure/assess/evaluate all things economic and noneconomic.

Here financialization is not separated out as a regime of accumulation, although it shares a focus with the first and third elements. A regime of accumulation is more than the sum of different elements: understanding it means focusing on both macro and material aspects as well as meso, micro, and discursive aspects. The seventh and eighth elements separate two quite different processes underlying the financialization of the state (which also includes the first, third, and tenth elements). Indeed, it is impossible to think of financialization as an accumulation regime without considering the role of the state in its different constitutive elements. The ninth and tenth elements are both about the “financialization of daily life,” but it is important to realize that the financialization of the discourse plays an important part in all the other elements distinguished here. A definition of financialization encompassing these dimensions would be: the increasing dominance of financial actors, markets, practices, measurements, and narratives, at various scales, resulting in a structural transformation of economies, firms (including financial institutions), states, and households.

This entry on “corporate financialization” focuses on the first eight elements (for the financialization of households, see inter alia Martin 2002; Aalbers 2008; Langley 2008). While not ignoring financialized discourses, these will not be discussed separately from the other elements. Of course, all these elements are related, which is why they are not discussed as different conceptualizations of financialization (although that would arguably result in a less vague and more precise definition) but rather as different dimensions of a complex phenomenon that can only be understood – whether as explanans, explanandum, or purely as discourse – by a strong awareness of their interdependence. For analytical as well as practical reasons, however, it may be necessary to study some elements in relative isolation; holistic understandings do not always fit together very well with empirical research projects. In what follows, these elements will be discussed one by one.

Financialization as a historically recurring process

The “-ation” part of financialization suggests that it is not a state or end result but an action, something that is made. Many financialization scholars situate the beginning of financialization in the 1970s with the rise of neoliberalism, the industrial crisis in the West, the breakdown of the Bretton Woods system, and other developments. Others have pointed at financial deregulation and the associated changes on Wall Street and the City of London in the 1980s, including technological developments and the rising influence of
CORPORATE FINANCIALIZATION

pension funds and other institutional investors. The decline of communism and the fall of the USSR at the end of that decade are also mentioned as contributing factors, in part because they discredited noncapitalist alternatives and underwrote how neoliberal and financial discourses became hegemonic. Structural changes in welfare states are also seen as crucial, although it is not always clear to what extent welfare state changes drive financialization and to what extent financialization drives welfare state changes. More generally speaking, financialization is part of and key to structural transformations of advanced capitalist economies. According to some scholars, we have been here before, and financialization thus should be understood as a recurrent phase in capitalist development.

When studying the historical trajectory of financialization, the work of Giovanni Arrighi (1994) has been very influential. Building on seminal contributions by Braudel and Wallerstein, Arrighi argues that hegemonic capitalist powers in the autumn of their hegemony can be characterized by a phase of financial expansion. Earlier hegemonic capitalist powers – Genoa, Holland, England – had already started their decline when their economies became financialized internally but also financially hegemonic externally. Arrighi sees the financial expansionary phase as a response to overaccumulation. Capital is switched to the financial sector to avert a crisis, but the real economy and hegemonic power nevertheless decline. Yet, financial power typically remains with the declining hegemon while the next hegemonic power is in its initial stages. Typically, the old hegemon finances the new one, not because they want to hasten their own decline, but because they see this as the best way to keep on realizing return on investment. The “autumn hegemon” produces a rentier class that comes to dominate the real economy but continues to produce profits that can extract financial rent. Typically this financialized stage of the declining hegemonic power benefits fewer citizens than in the prefinancialized state. This tends to undermine middle-class consent, and social polarization and inequality increase.

The historical parallels appear clear and partly justify the focus of financialization scholars on the United States, which can be considered to be in the autumn of its hegemony, having entered the financial expansionary phase and the associated decline in middle-class consent and rise in income inequality and social polarization. From this perspective, other OECD (Organisation for Economic Co-operation and Development) countries can be seen as under American hegemony, with the United Kingdom as the United States’s closest ally. That does not explain, however, how and why the City of London in some ways has become more important than – or at least as important as – the main financial center of the “autumn hegemon,” Wall Street. It also does not explain how US debt is, in fact, increasingly financed and backed by foreign, particularly Chinese, capital. This could be a new development in the historical trajectory of declining hegemons, which in an era of globalized finance no longer need their own excess capital to enable financial expansion. It could be equally a sign of financial power and of the real decline of the hegemon. Arrighi’s analysis suggests neither the one nor the other: the fall of world hegemonic powers is at least as slow as their rise, and the seemingly paradoxical combination of increasing financial power and decreasing political-economic power more generally is just another fundamental contradiction of capitalism. For our purposes, it is important to keep in mind that the different elements of financialization may often be more advanced and visible in the United States than elsewhere but that financialization is increasingly visible in
other Western and non-Western countries. This does not necessarily mean that financialization is as advanced elsewhere, but that the trend in different places and at different scales often goes in the same direction.

Financialization of banking

It appears counterintuitive to separate banking from finance. But finance is not just the business of banks. First, the role of banks has shifted from more or less passive intermediaries towards active financial actors. Second, traditional banking has become less important vis-à-vis other financial actors and activities with the explosion of nonbanking financial institutions, ranging from pension funds and mortgage companies (so-called “nonbank lenders”) to private equity and hedge funds. As finance has moved beyond its traditional intermediating functions, it has come to be seen as a growth industry in its own right.

In the popular discourse, banks make money through the difference between interest charged on loans and interest given on savings, but the real moneymakers for most financial institutions, including banks, are leveraging and charging fees. This may have happened to varying degrees in different countries, but no Western country on either side of the Atlantic and ever fewer non-Western countries have escaped the trend towards transaction- and leverage-based banking business models – some speak of a financial services revolution (Moran 1990). For many banks, issuing loans is primarily interesting because they can be repackaged into new financial products for which fees can be charged. Furthermore, once the loans are repackaged and sold, the money can be reinvested in other financial products. Thanks to the financial leveraging powers of banks, this pumping around of money, mostly between financial institutions, could continue unprecedented for some years. The crisis that started in 2007–2008 slowed down the leveraging and debt machine, but has not stopped it.

Not only do nonfinancial firms rely less on banks for their finances, but banks also invest less in the so-called real economy and increasingly put their money in financial assets: “During the 2000s, lending for finance, real estate and household purposes replaced ‘productive’ lending as the driving force in the loan portfolio of banks” (Lapavitas and Powell 2013, 371). This appears to be an international trend, although there is quite some variation in who receives most of the loans (e.g., real estate firms, homeowners, financial intermediaries). All in all, we can speak of a debt explosion, not just in volume but also in the geographical scope of debtor–creditor relations.

Financialization of the economy in narrow terms

Financialization is, among other things, a pattern of accumulation in which profit-making occurs increasingly through financial channels rather than through trade and commodity production (Krippner 2011). Due to the slowing down of the overall growth rate and the stagnation of the real economy, capitalism has become increasingly dependent on the growth of finance to enlarge money capital (Sweezy 1995). Therefore the capital accumulation process becomes financialized, focused on the growth of finance to benefit actors within financial markets, such as investors, rather than benefitting the real economy. Furthermore, some commentators argue that financial investment is replacing physical investment.

To illustrate this argument, different authors cite different statistics to show that a whole range of financial markets have grown rapidly since the 1970s. The market for derivatives, in particular,
CORPORATE FINANCIALIZATION

has virtually exploded between 1990, when
the market was almost too small to measure,
and 2006, when the number of outstanding
contracts added up to $370 trillion, as the Bank
for International Settlement has demonstrated
(BIS 2008). Krippner (2011) demonstrates that
finance has become the dominant source of
profits since the 1990s, a trend that may be par-
ticularly pronounced in the United States but can
be witnessed in most OECD countries. For the
27 member states of the European Union (i.e.,
before the accession of Croatia), EUROSTAT
has calculated that the FIRE (finance, insurance,
and real estate) sectors together contributed to
29% of gross domestic product (GDP). Even in
Germany, which is said to have a less financialized
economy, the FIRE sectors contributed more to
GDP than industry (respectively, 30% and 20%).
Financial assets held by institutional investors
as a percentage of GDP grew rapidly in all
OECD countries and now represent more than
200% in countries like the United States and the
United Kingdom and around 100% in countries
like Germany and France, increasing threefold
(United States) to tenfold (France) between 1980
and 2001 (Deutschmann 2011). By contrast, the
wage share of national income has fallen across
the board, although less so in countries with
strong labor unions (Epstein and Jayadev 2005).

Financialization of nonfinancial firms

Nonfinancial firms have always been dependent
on credit, but the rules and logics of Wall Street
are increasingly becoming the rules and logics
outside Wall Street. The corporate narrative has
also become financialized. The idea of share-
holder value has become dominant in how firms
“ought” to be run, and senior managers have
become responsive to such demands: “Managers
were no longer considered as skilled professionals
but as agents of shareholder value maximization”
(Deutschmann 2011, 358). Financial numbers
had to be framed to make them appear promis-
ing. Many senior managers became busier with
communicating positive stories to convince
credit rating agencies, market watchers, and
stockholders than with innovation or production
gains (Froud et al. 2006). The increasing finan-
cialization of nonfinancial firms has been noted
for a wide range of industries: for example, the
car industry, the so-called new economy, real
estate, retailing, computing, pharmaceuticals,
insurance, aviation, and infrastructure.

An important driver of the financialization
of nonfinancial firms has been the ownership
of publicly traded firms. In the 1950s, US
households held approximately 90% of corpo-
rate stocks. Fifty years later their share was just
42%, whereas the share of institutional investors,
including pension funds, had increased to 46%
(Crotty 2005). Furthermore, since the 1980s
nonfinancial firms are increasingly led by CEOs
with a financial or legal background (Fligstein
1990). The ideology or myth of shareholder
value is prioritized in leveraged buyouts, stock
repurchases, mergers, and acquisitions over
long-term profitability or firm survival. Many
financialized firms seem able to prop up their
stock prices or impress the rating agencies for
some time, but the effective return on capital
rarely goes up structurally and appears more
vulnerable to both conjunctural and structural
shifts in the industry.

One reason that it is important to consider the
financialization of nonfinancial firms, beyond
the creation of shareholder value, is that many
companies are not publicly listed and traded, but
are still financializing. Financialization changes
the way money is made in many industries: there
generally is a narrow focus on outsourc-
ing and short-term profits at the expense of
integrated development, long-term investment,
and nonfinancial innovation. As a result, nonfinancial firms have increased financial flows to the financial sector through interest payments, dividends payouts, and share buybacks (Lazonick and O’Sullivan 2000; Crotty 2005). The financial market’s and financialized management’s response to unsuccessful cases of financialization is typically more, not less, financialization.

Financialization within nonfinancial firms

If profits are the bottom line, firm management may be expected to engage in activities that generate the highest profits. As the profit rates in the financial industry for some time were higher than in most of the so-called real economy, some nonfinancial firms became mixed nonfinancial/financial firms. Derivatives, in particular, proved hard to resist for many formerly nonfinancial firms. As a result, nonfinancial corporations increasingly derive profits from financial activities and own a greater proportion of financial relative to nonfinancial assets (Krippner 2011; Lapavitsas and Powell 2013).

Optimists say that if a nonfinancial firm realizes high profits through investments in, say, derivatives, this results not in “crowding out” real investment but in additional funds becoming available to investments in the nonfinancial parts of the firm. Critics, however, argue that this overlooks the fact that once a firm is investing in financial assets, it will most likely use profits to expand such activities – that is, if such financial investments create higher profits than nonfinancial investments, they will be tempted to shift more money towards investments that deliver higher profits. The bigger problem of the optimistic argument is that financial investments tend to be quite volatile and may jeopardize the survival of the firm, or at least its nonfinancial activities.

An important consequence of this element of financialization is that statistics of the “real economy” versus the “financial sector” become blurred. Measuring financialization as the increasing dominance of the financial sector in GDP statistics and financial firms’ profits misses an important dimension of financialization. There clearly is more room for studies that investigate how traditionally nonfinancial firms increasingly partake of practices that used to be the domain of the financial sector. It is crucial that such studies include the practices of publicly traded companies as well as nonlisted firms. Research methodologies focusing explicitly on individual firms, such as developed by Julie Froud and colleagues (2006), are important in this respect.

Financialization of the workplace

Financialization does not only change the senior management of the firm through the ideology of shareholder value, but also impacts employees throughout the firm, from CEOs to partners and senior and junior employees. Financialization can be an employee control strategy. Faulconbridge and Muzio (2009) and Alvehus and Spicer (2012) demonstrate this in law and accountancy firms, respectively, including effects on recruitment, human resource management, management by objectives, career systems, and client control. Financialization aims to transform the working lives of employees into an investment activity in its own right, using billable hours as both a measure of profitability and investment in future higher pay, and possibly entry to the firm’s partnership. Working lives are transformed in this financialized system of controlling and steering “human capital” and come to be defined in monetary terms and discussed in terms of investment, trade, speculation, and leverage.
Employees, in return, play the system, not only by increasing the number of billable hours but also by offloading work downstream (Alvehus and Spicer 2012). Financialization puts pressure on workers’ wages, the amount of hours they work, and the rights they have or can exercise (Lazonick and O’Sullivan 2000).

One does not have to be a skeptic to see parallels here to the ways academic work has become not only commodified but also financialized, with publications in indexed journals replacing billable hours as financialized time and academics investing their time to leverage them for tenure, promotion, and grants. Although most academics are still interested in knowledge per se, it would be hard to dismiss the evidence pointing to a gaming of the system not unlike that in law and accountancy firms. The transformation of the working lives of people in law, accountancy, academia, and elsewhere is uneven but rarely entirely voluntary, as the principle of “up or out” (you need to achieve a certain rank within a fixed period of time) can apply in these fields, forcing employees to play along to some extent.

Financialization of the (semi–) public sector

States and semipublic industries are increasingly dependent on financial markets and are also evaluated in similar ways to firms. Rating agencies provide scorecards for governments, not only national governments but also local ones. States are not only evaluated like companies; with the popularity of New Public Management, both public and semipublic institutions also became managed more akin to private firms than at any time in the past. One important consequence is a redefinition of citizens into consumers and a further redefinition of consumers as financial assets or cash cows (Allen and Pryke 2013).

The spread of New Public Management and of the domination of financial narratives, practices, and measurements is not limited to government institutions, but is also apparent in the working of other public authorities as well as semipublic and commodified sectors such as education, health care, and social housing. Both Engelen, Fernandez, and Hendrikse (2014) and Beverungen, Hoedemaekers, and Veldman (2012), for example, argue that universities have become increasingly financialized. Academic management is controlled by, and controlling, employees though financial metrics, measurements, and increasingly also narratives. This is not only visible in university annual reports but also in the expectations it has of its employees.

The financialization of universities and other semipublic sectors is not limited to a combination of the above-mentioned elements of financialization – that is, of nonfinancial firms and of the workplace – but it is also an example of financialization within traditionally nonfinancial companies, as universities become involved in deriving profits from investments in derivatives. The consequences are mostly negative: “less professional autonomy, more administrative chores, more overhead, more standardization, higher throughput and less academic exchange” (Engelen, Fernandez, and Hendrikse 2014, 16). Indeed, “by extending its leverage and balance sheet, [it] is in danger of strangulation by debt, risking the funding streams to the activities for which it was established: teaching and research” (Engelen, Fernandez, and Hendrikse 2014, 16).

Financialization of public policy

In contemporary capitalism, we can witness a “great risk shift,” in which households can rely less on public institutions for their long-term security and become increasingly dependent
CORPORATE FINANCIALIZATION

on private firms (Hacker 2008): in particular, financial institutions. The state actively promote this movement away from the state and into financial markets. In fact, a combination of commodification/privatization and de/re-regulation has created such markets, sometimes out of thin air. The state is no bystander in the financialization of the economy, firms, households, and of the state itself. It has actively promoted financialization, although rarely in a linear and one-dimensional way – state institutions at different scales and with different responsibilities have often acted in diametrically opposing ways.

The global financial crisis that has been dragging on since 2007 made this painstakingly clear. In this crisis, “the financial industry has managed to externalize its own problem and to transform it into a problem of the state” (Deutschmann 2011, 384). States became “victims of the transformation they helped to bring about, and have been forced to bail out their debt-encumbered banks and financial systems … the state role of ‘risk absorber’ is expanded for the private market sector rather than for the citizenry” (Christopherson, Martin, and Pollard 2013, 352). The public management of the financial crisis can be seen as an example of “socialism for the rich and capitalism for the poor,” in which the state protects the interests of the financial elite at the expense of most of its citizens (Aalbers 2013).

Lobbying plays a significant role in this financialization. A study by Corporate Europe Observatory, together with the Austrian Federal Chamber of Labour and the Austrian Trade Union Federation, suggests that the financial industry spends at least 120 million euros a year on lobbying the European Committee through more than 700 organizations. They are estimated to outspend trade unions and civil society by a factor of more than 30. Furthermore, of the 17 European Union (EU) official advisory councils that the researchers investigated, 15 were dominated by the financial industry. Although it is hard to measure the success of 600 million euros of “investment” in 5 years’ time, it would be hard to imagine that this would not bring the industry at least 600 million euros in beneficial regulation. In other words, finance-to-EU lobbying is likely to have provided the industry with much more than an additional 600 million euros in savings. Indeed, in a financialized political environment it will be difficult (but not necessarily impossible) to get anything done that runs counter to the expected benefits of the most powerful group.

Geography and corporate financialization

Geographers have repeatedly stressed that financialization is an inherently spatial phenomenon that should be much more central to economic geographic analysis. Local, national, and macroregional institutions act as filters of how financialization plays out and is perceived. Often, financialization is not much limited by existing institutions, but these institutions are mobilized and transformed to enable financialization. This is why the structural transformation of the state is intrinsically linked to the process of financialization: the state filters financialization processes while financialization at the same time furthers the transformation of the state itself. Human geographers have contributed to the idea that there are not only varieties of capitalism (VoC) but also varieties of financialized capitalism (VoFC) that do not entirely flow from the expectations of the VoC framework of liberal market economies versus coordinated market economies. The embeddedness of national political economies in global capital markets is
not limited to liberal market economies, as one would expect based on a reading of the VoC literature. Small, open economies like those of the Netherlands, Belgium, and Ireland appear both globalized and financialized (Engelen 2012).

A singular focus on national economies, however, stifles a full understanding of financialization, not because the national scale is irrelevant but because it is only one of the many relevant scales, including but not limited to the global, macroregional, and metropolitan scales. The financialized economy is perhaps not concentrated in global cities (although the financial industry is); yet, these cities are command and control centers for both the financial industry and the globalized, financialized economy more generally. Furthermore, national statistics can both over- and underestimate levels of globalization and financialization. Thus the Netherlands appears to be one of the major investors in many countries, but such statistics largely reflect the attractiveness of the Netherlands as a tax shelter rather than real or Dutch globalized investment: money flows through rather than from the Netherlands.

Financialization, globalization, and neoliberalism are interdependent. Offshoring, for example, whether financial or nonfinancial in nature, may be motivated by financialization but its effect is economic globalization. Furthermore, both globalization and financialization are often promoted and furthered through a neoliberal agenda, sometimes through false pretenses of leveling the playing field while in fact redrawing the field in favor of corporate and financial elites, and their shareholders. Duménil and Lévy (2004) suggest financialization causes neoliberalization, but it is hard to disentangle the causal relationships for two concepts that are both so widely defined and in fact part and parcel of each other.

Although the literature on financialization has exploded, many avenues for research remain underexplored. For financialization to be taken seriously, not only by academics but also by policymakers and the public at large, financialization needs to be measured more rigorously in different countries and in internationally comparative ways. It is important to focus on all dimensions of financialization. It is justified for studies to isolate one aspect from the others to make empirical investigation possible in the first place, but this should not take away from the inherent complexity of financialization, nor should it be limited to the aspects of financialization that can be researched relatively easily through readily available statistics. Qualitative and discursive analyses, including corporate case studies, are equally important. Furthermore, geographers and other social scientists should not ignore the study of spaces of financial exclusion, expropriation, and exploitation. Finally, the financialization of the state is also an important avenue for future research. Research into the financialization of public and semipublic institutions is still in its infancy, while the interlinkages between finance and power have also been too much assumed rather than put to empirical scrutiny.

Corporate identity – meaning and concept

The term corporate identity (CI) is most simplistically a combination of the words identity and corporation. That identity is closely related to geography or space has been described often in academic debates (Lynch 1960). That corporations are strongly linked to a location and that corporations are always part of the local economy and, therefore, important determining factors for regional development is obvious, but the linkage between the concept of “corporate identity” and geography is less clear. To understand why it is worth applying the concept to place and geography it is necessary to examine the concept of CI.

CI is the strategic concept of how to position a corporation. In doing so, it is important to look for the defining traits of identity and integrate them into a congruent action concept. As shown in Figure 1, CI consists of corporate behavior (e.g., values, norms), corporate design (e.g., logos, corporate colors, architecture) and the corporate communication strategy (e.g., public relations, information). Taken together, this constructs the corporate image as the set of means and narratives by which a corporation is known, and through which people tell stories about it.

CI has been a topic of interest since the period of mass industrialization of the early twentieth century. New forms of corporations – like publicly listed commercial companies – were established at this time and brand identities started to become relevant. Since the 1960s and 1970s CI has become an issue for nearly all corporations, becoming ever more complex since the 1980s, as all corporate activities have come into sharper focus and increasingly strategic. Various features of identity, philosophy, culture, behavior, communication, and appearance have been brought together into one strategic approach. This increasing significance of CI has gone hand in hand with the dissolution of common social values. With globalization, identities have become increasingly hybrid, liquid, or overlapping.

Even if corporate identity is linked to an overall image of a corporation in the minds of customers, investors, and employees (or of a city or region, in the minds of its residents), meaning that communication is important, CI is more than communication. It should be based on realistic positions and visions that must be transformed into reality (corporate behavior) before a communication strategy (corporate communication and design) can be applied. Identity, in this context, is to be seen from an individual as well as from a collective point of view.

Bringing together corporate identity and place is relevant because cities, regions or national states, and corporations benefit from each other’s identity and image in a reflexive process. In recent years, many stakeholders studying the
influence of regions on corporations, and vice versa, have turned their attention to culture and identity. Country image identifiers and product nationalities are growing in importance as competition and standardization in globalizing markets reduce uniqueness and stimulate the demand for authenticity and provenance. Relatedly there has been growing discussion regarding what some authors term the “experience economy” – shorthand for the many intangible qualities surrounding consumption decisions. As such there is an iterative movement back and forth between how people act (both as consumers and as social citizens) and the representation of a place.

Cities and regions compete to attract capital and creative people by using certain images. Due to a high level of communication, interaction, and mutual reference, common regional identities emerge, which then can differ from those of other cities and regions. For cities with a long tradition of being recognized as a place of knowledge and knowledge-intensive services (e.g., London, Paris, or Hong Kong) it is easier to distinguish themselves via a corresponding image. This is much more difficult for cities and regions which are affected by structural change or are too peripheral to be well known.

**Place identity, or “Who are we?”**

Since the 1980s, the “world city hypothesis” (Friedmann and Goetz 1982) has addressed the extraordinary importance of certain cities, those that are highly integrated and create a common hegemonic space. Proponents of this thesis claim that transnational corporations compete for power and control of global economic space and its urban nodes. World cities remain important but, nowadays, smaller cities and regions also are searching for their own specific identities and unique selling points.

It is not possible to create an image out of thin air but, generally, it is vital that an image is rooted and seen to be authentic within the region. It is possible to create radical departures from tradition but they must be consistent and actually lived. Although lighthouse projects have been widely criticized, cities like Bilbao with its Guggenheim Museum, or Dubai – where it seems possible to construct everything from mega buildings to ski parks and whole islands – have succeeded in creating an identity and image with an impact both internally and externally. Especially for cities in Western pluralistic societies, where the government is based on participation and a focus of quality of life is important, it is not enough to create an image without considering the actual living and working conditions and the involvement of civil society. Today, quality of life, sustainability or new urbanism seem to be keywords in this regard. This value change is caused by different aspects, including an increasing awareness of ecological problems and a growing hedonistic orientation, partly expressed in an increasing demand for
authentic emotional products. This could be connected with a backlash against increasing, disorienting globalization, to be compensated by collective identifications through regional, religious or ethnic affiliations. Expressive aesthetic manifestations, indicated by growing numbers of museums and accentuation through architecture, are also increasing importance. However, this not only symbolizes an aesthetic turn in public spaces but also stands for the need to profile one’s own place in the face of global competition.

Dealing with places’ identity means trying to answer the question of “Who are we?” There is no general answer to this question: cities and regions are subjective and intangible, and, unlike corporations, are always contradictory and paradoxical. A helpful starting point, however, could be trying to identify the relevant subject and target groups (who belongs to “us”? ) and what is the relevant space or area for each topic.

Who belongs to us?

In regional science it is increasingly recognized that regional success does not only depend on companies; a triple helix network of business, science, and politics is central (Etzkowitz and Leydesdorff 2000). More recently, taking into account how new forms of knowledge sharing, decision-making, and participation have become powerful, civil society also has come to be considered a success factor – resulting in a quadruple helix (Carayannis and Campbell 2012). Yet, while the innovative societal power of regional bottom-up approaches cannot be ignored, civil society is not always active in contributing to a viable city life. Therefore, the analytical concept for exploring existing regional identity must be distinguished from the political agenda of making civil society part of the city image (which might be considered wishful thinking). Political agendas, urban life, protest culture, and participation have to be fostered, and political spaces and places have to be provided for these processes.

Social movements and civil society initiatives often have local origins, but some spill over between countries (e.g., from Tunisia to Egypt) and across organizations (e.g., the Spanish Occupy movement was inspired by the Arab Spring movement). This new spatial form also is a chance for cities to enhance their global connectivity. And, at the same time, this raises the issue up of how much political space and place should be given to which groups. Different target groups require different aspects and the question arises as to what extent values and norms like sense of responsibility, (family) tradition, perseverance, and pragmatism play a role in a process of identification for a region or city.

As cities always have multiple identities, the right balance instead of the dichotomous choice has to be found. London, for example, symbolizes the capital of finance for a certain target group but the capital of punk rock for others – both valid identities – for corporations, and for other actors, and thus worth communicating.

What is the relevant space?

Regional networks, social capital, environmental factors, and cultural issues and identities can all have locational potential, capable of shaping a region’s or city’s strategic position, and should be a starting point for an independent and distinctive strategy, whereas the reference areas typically go beyond strict administrative boundaries and locate themselves only partly on a local level.

The concept of space has been totally rethought and detached from geography by some researchers in recent years. In relational understandings of space, space is constructed
through processes of cognition, imagination, and retrospection. Space only exists by anthropological acting, that is, people have to interact in order to create space. Many contemporary researchers dealing with questions about place and space agree that the bordering container space has to be redesigned and regions have to be understood as looser subspaces or fields, relevant to specific target groups (economic, intellectual, artistic, etc.). Each such space has its own logic and development dynamic, but also interacts with the others. Understanding a place’s identity thus requires multilevel perspectives. Consider, for example, the three perspectives illustrated here.

First, a global scale perspective means being aware that proximal spaces within a city matter, while recognizing that it also is possible for spaces to develop and connect globally. Knowledge spaces can be developed internationally because regional knowledge networks sometimes include international companies or their affiliates. Economic development should take into account the most important supra-regional spatial contexts, connected to regional fields of knowledge and supporting the local and international integration. Indeed, globalization encourages thinking beyond space as a single region or national state, both in academic circles and the media. For example, the *Times Magazine* highlighted “Nylonkong” as a new space, consisting of the three cities of New York, London, and Hong Kong. “Linked by a shared economic culture (...), connected by long-haul jets and fibre-optic cable, and spaced neatly around the globe, the three cities have (by accident – nobody planned this) created a financial network that has been able to lubricate the global economy (...)” (Elliot 2008, 31). Nylonkong illustrates the idea of relational space: it cannot exist without traders, compatible business cultures and identities, and interconnecting transactions.

Second, a regional-scale perspective means developing awareness that the spaces where compact knowledge potential lies, knowledge spillovers occur, identities are developed, and images are shaped need not be limited to a particular administrative region. It is not enough, as was done with respect to defining some metropolitan areas, to stretch the boundaries. It is less the size of an area that ultimately matters but more its mix of spaces; having the right balance of areas for each specific activity.

For world cities or global urban agglomerations with a good reputation and a long-standing tradition, the surrounding space is not so important to their identity. It is different, however, for cities and regions with “less reputation” – whether peripheral or urban, prosperous or structurally weak, whether world-market- or locally oriented. Successful positioning within international competition requires different strategies, which will depend on the type of city. Cities lying within the hinterland of attractive metropolitan areas, for example, characterized by a narrow economic structural link with the metropolis, face three development options.

1 Occupying a complementary position in relation to the metropolis. This entails a risk of high dependency, as well as uncertainties stemming from possible competition with other small towns in the vicinity of this metropolis.

2 Sharpening the city’s profile to compete with the metropolis, promoting the advantages of smallness while in reach of the metropolis (lower land costs, better living conditions, etc.). The danger here is that the city’s individual profile is not distinct and thus would not stand out.

3 Positioning the city as a “dormitory town.” This can be an attractive economic alternative, extending the function of the city from
a pure “sleep function” towards meeting demand for leisure activities and recreation.

These three perspectives are ideal types that cannot be implemented as urban policy on a one-to-one basis. The strategy of a city (from corporate behavior over design to communication) and its positioning with respect to city types will vary greatly.

Third, from a local scale perspective it is necessary to be aware that certain districts affect different identities that depend only partly on the general orientation of a city. For certain districts, different cities can have more in common and carry out more transactions – due to similarities – than do single districts within each city. For example, some economic sectors compete between the districts of the City of London and Wall Street (New York) rather than between London and New York; or, to take another example in Germany, between Friedrichshain-Kreuzberg (Berlin) and St. Pauli-Karolinenviertel (Hamburg). The creative economy is dependent on fast changing trends, so its actors seek to be close to the source of new trends, namely the subcultures that typically arise in certain metropolitan districts.

With increasing segregation, neighborhoods have become increasingly homogenous, each accommodating citizens seeking the same kind of living conditions, activities that fit with the cultural infrastructure, and specific consumption bundles. As stereotypes like rich and poor or working class districts have become apparent, personal identities are more closely linked to those of the district. Districts can have a bad image, of course, such as old-industrial urban districts with historical layouts but bad housing conditions, or post-World War II districts with a large amount of social housing, concrete tower blocks, and more or less monoculture structures. For a strategy of regeneration, it is not enough to campaign for a better image; it is necessary to change the conditions and break the monoculture. This means attracting new users to the space: residents, enterprises, shops, restaurants, and so on. Economically less successful areas and deprived neighborhoods also offer opportunities for new ideas and unconventional, innovative business practices. Urban planners widely believe that deprived urban places with vacant buildings and tolerance for “otherness” can be significant hotspots for the creative economy (Florida 2002). Thus, cities have set up local business development agencies in deprived districts to exploit this potential. Transforming the identity of such districts, converting formerly poorly reputed districts into, creative, viable, and young urban quarters, can benefit the city’s image also. On a more local level, neighborhoods position themselves by focusing on certain lifestyles and targeting specific groups. Changing identities means not only applying the quadruple helix but also developing a broader understanding of the relevant actors; this should involve such actors as social workers, churches, sport associations, and so on.

Reconnecting: place identity shaping corporate identity

The interrelation of places’ entities includes corporations, competences, values, norms, brands and products, profile identities, and images. This is a complex process and it is nearly impossible to detect a general mechanism of action. Here, the discussion is restricted to the reflexive interrelations between companies, brands, products, and regions. Even if identities are neither static nor homogeneous, cities and regions possess some kind of shared ideas and values about how companies operate, and the kinds of products produced and their quality. On this basis, specific
outside perceptions can help establish brands. In the following this is illustrated first for branding and brands; how corporate identities and reputations, and those of regional networks, are based on a regional or city identity, as well as vice versa, are then examined.

Products, brands, and places

Nations and regions have images, or “brands,” that stakeholders often attempt to manage or at least influence. In turn, many products have an association, sometimes positive and sometimes negative, with a region or place. These associations interact and shape each other. Country-of-origin (COO) research has tended to focus upon how geographical associations may assist the marketing of certain products, with the role of symbolic value and identity being important.

The role of such symbolic meanings in the consumption of goods and services was semi-nally described by Veblen (1949). This is now more acute than ever, given the need to differentiate one’s product from the many others in the marketplace with similar functionality or technical specification. This requires reference to immaterial qualities or symbolic value. The race for innovation that has defined the post-Fordist economy has given us high-quality products. Increasingly, however, their functionality is taken for granted; consumer choices are determined by the symbolic value of the product or the company behind it. The strength of a brand thus stems from a combination of how it performs and what it stands for.

Successful global brands typically originate from a place with its own brand image, with the product often strongly linked with that image – whether it is an Italian sports car, associated with the qualities of style, speed, and innovative design, a chic and classy French perfume, or Japanese consumer electronics that associate implicitly with the merits of high-tech expertise and affordable quality. Goods produced within any given region are imbued with an associated symbolic value – whether weak or strong, positive or negative (Anholt 2003) – associations that typically are activated implicitly in consumers’ minds by the mere presence of country-of-origin (COO) information. The basic idea that a product’s COO can consistently influence consumers’ judgment of it is simplistic; a more nuanced understanding of the concept is required in the age of globalized supply chains, complex corporate ownership structures, and the international division of labor. This requires explicitly recognizing that a single product is designed, assembled, manufactured, and so on increasingly across in different places. Indeed, there is evidence that COO might often be incorrectly identified by potential consumers.

Firms and specific territories

The French term “terroir,” without a direct English translation, essentially refers to being from a defined geographical area or terrain, and also the customs and idioms inherent in that particular location. It is about the physical environment as well as the constructed and the cultural one. There is growing realization that terroir does not apply solely to physical products; different nations (and the subregions thereof) possess their own “intangible” assets or specializations – places that in many ways are directly in competition with each other for highly skilled labor, inward investment projects, for tourists and visitors, and so on. A common identity can be developed if corporate and regional cultures coincide. With identity and the relevant kinds of knowledge varying widely, depending on industry and place, agglomerations
emerge, with geographical specialization. Urban spaces and metropolises are of great importance for sophisticated knowledge-based services, with cities and districts attracting a creative culture, knowledge distribution, education, and so on, gaining in importance in recent years. This is not simply due to the availability of skilled labor, important trade partners and customers, or random meetings and the presence of qualified employees. As financial centers, cities like New York, London, and Tokyo have so-called surplus-meaning. Transnational companies locate in these locations for reasons connected to identity and image, triggering cumulative effects in the sense of a self-fulfilling prophecy. Location-based sources of industrial advantage (clusters, innovations systems, creative cities, etc.) are well rehearsed in the economic geography literature, but beyond providing the “industrial systems” that deliver innovative products, successful places also must offer spaces and channels for the negotiation and communication of immaterial value (Jansson and Power 2010). It follows that the attributes needed for the production of successful functional products, and for realizing their successful immaterial or symbolic aspects (or indeed brands), are place-based. These platforms or “brand channels” are different from the 1-D place-branding initiatives associated with the boosting of places of poor repute; they are a complex set of interactions enabling the transmission of what can be termed “concurrent place myths” – myths because these are powerful and lasting perceptions that go beyond straightforward brands; concurrent because large, diverse places are likely to possess multiple myths co-existing simultaneously. The key point, here, is that the interaction between product and place should firmly be placed on the policy agenda.

Over time, regional identities and mentality can foster a specific demand, shaping the attributes of the regional products (e.g., long-lasting, good quality). For regions, this basis in the “real” economy may ultimately be less important than perception and identity – they can define the prestige of a region and sometimes become an important location factor for companies (“a good address”).

This is obvious for world cities but also true for such peripheral regions as the City of Solingen in Germany, well known for its knives. The image and brand “made in Solingen” used by its famous large companies helps create the regional identity. Solingen’s historical significance and expertise in producing tools, blades and cutlery strengthen this field of competences. There is a high number of small and medium-sized highly specialized manufactures, closely cooperating with business in the design sector, and offering the possibility of innovating new products in very small and special series – a positive feature and unique selling point. This example illustrates how a firm’s image or reputation is connected to the competences and identity of a region. It be should be recognized, however, that past industrial strengths can hamper a region’s shift into new spheres of economic activity; working practices, skills, cultures, and mentalities contribute to inertia and lock-in. Consider the case of Sheffield, UK, a city once also famous (and to a degree still today) for producing steel goods, cutlery, and so on; it has encountered a difficult transition into a new economic climate, with steel manufacturing largely now absent.

While small companies cannot foster a regional identity or create a worldwide image on their own, a network of regional companies can make this possible. Networking, a reflexive phenomenon, influences cultural change and regional identities. Networks emerge through collective and evolutionary processes, connecting
network members with different cultural backgrounds, company size, world of production, position in the value chain, and so on. Again, the important question is how networks establish an identity and for which target groups. Networks or clusters and city’s regions’ CI influence each other in a reflexive way: well-known examples worldwide include Silicon Valley, the Third Italy in the Emilia Romagna, or the ICT cluster in Bangalore. Here, not only the identity of brands and corporations but also the cluster’s or network’s identity is based on the place identity, and vice versa.

In summary, identity and image are determined by the real entities of places (behaviors, economies). To find their own identity, places must focus on structures and conditions, on different spatial layers, and on different thematic activities as discussed. To minimize the risk of anonymity, places should identify consistent patterns and shared internal attributes. Although place and corporate identity are different concepts, they are fundamentally interrelated. A corporation will not have a single identity or image but these are manageable, whereas places have many internal and external identities and perceptions – or myths – capable of reaching different internal and external groups. Thus, reflexive interrelations between companies, brands, products, and places exist and influence each other, meaning that ultimately the processes establishing corporate identity are inseparable from those shaping place identity.

Corporate retailing

Shuguang Wang
Ryerson University, Canada

Retailing is the business of selling goods directly to end users. As such, it is the essential link between production and household consumption. From the political economy point of view, all consumer goods have surplus values locked up in them, and the surplus values are not realized until the consumer goods are purchased by consumers through various distribution channels (Blomley 1996). The accumulation of capital is achieved through “repeated acts of exchange” between consumers and retailers (Ducatel and Blomley 1990, 218).

In a typical capitalist market economy, the retail sector consists of diverse types of retailers. Some of them are corporate retailers, which operate multiple stores in the form of a chain and which have a complex organizational structure. Others are independent retailers with a single store location. In terms of ownership, corporate retailers can be further differentiated as publicly traded companies and privately owned chains. Relative to independent retailers, corporate retailers are small in number, but they command the largest share of the consumer market. Table 1 lists the top 30 corporate retailers in the world. They are based in seven advanced economies: the United States (12), France (5), Germany (5), the United Kingdom (2), the Netherlands (2), Australia (2), and Japan (2).

Since the mid-1980s, a series of revolutionary changes have taken place in the retail industry worldwide amid the process of globalization of the world economy. The new trends and characteristics are embodied mainly by corporate retailers, and have led to the retheorization of the orthodox retail geography and the emergence of a new retail geography with a major paradigm shift. As the retail planning process becomes more complex, so too does the role of retail geographers.

Characteristics of the contemporary capitalist retail economy and recent trends

Significant restructuring has taken place in the retail industry

In the contemporary capitalist retail economy, retail chains continue to be the most important form of retail concentration. Without exception, all corporate retailers are chain operators, as the retail chain provides a way of introducing scale economies while avoiding the restrictions of market size. Retail chains often account for 70% or more of the total retail sales in a metropolitan market. The 1990s and 2000s witnessed a significant restructuring and reshuffling of retail chains, leading to concentration of retail capital in the hands of a few “super leagues” (Marsden and Wrigley 1996). Some sought to acquire, or to merge with, others to consolidate resources, and rose to the status of global corporations. For example, in 1991 the French firm Carrefour took over two other domestic hypermarket chains, Euromarche and Montlaur, and in 1999 it merged with Promodes to create the largest European food retailing group and the second largest worldwide (at the time).

Source: Deloitte (2014).
In 2002 the American electronics retailer, Best Buy, expanded by acquiring a Canadian retail chain, Future Shop. Large corporate retailers are better able to invest heavily in information technology and centralized distribution systems, the use of which enables them to more effectively perform their competitive functions of reducing the turnover time of commodities (Hughes 1996). Meanwhile, many other chains were not as fortunate and subsequently went under. Eaton’s, a Canadian department store chain with a history of more than 100 years, was one such victim.

**Big-box stores have emerged as new leading retail formats**

The rapid progress of suburbanization in the late 1950s and the 1960s required that cities be planned following the principle of hierarchical organization. Accordingly, a hierarchy of shopping centers was incorporated in this form of city planning, consisting of neighborhood, community, and regional shopping centers. Each type of shopping center had a clearly prescribed tenant mix, trade area size, and even physical form (Casazza 1985). In the 1970s a newer and larger type of shopping center — the super-regional shopping center — began to be built. These centers often combine entertainment and recreation with shopping under one roof, becoming new palaces of consumption. Typical examples are the West Edmonton Mall in Canada (493,000 m²) and the Mall of America in the United States (466,000 m²). As suburbanization continued, the metropolitan city became multicentric, and a network of retail nodes evolved to serve the expansive city. Each regional and super-regional shopping center became a node, spatially distributed in a hierarchical fashion analogous to central places in Christaller’s Central Place Model.

By the late 1980s, retailing had become an important and dynamic economic sector in many developed nations. As well, major technological innovations took place in the distribution system. Highly computerized goods-tracking and inventory control systems enabled direct communications with, and direct shipping from, manufacturers (Hughes and Seneca 1997). In the process, it has led to the emergence of a new retail format, known as “big-box” stores. At first, such stores were freestanding outside shopping centers; but eventually several big-box stores began to cluster together at one location in the form of a planned plaza, commonly called a “power center” (also known as a retail park). In less than 10 years, this new format has been adopted by a variety of retail businesses. These new retail spaces have been created and manipulated by the innovative retailers and commercial real estate developers to induce consumption. The big-box stores and power centers have become leading nodes in the Western retail system, widely blamed as the cause of the “graying” of regional and super-regional shopping centers and the demise of department stores in North American cities.

**Retailer–supplier relationship has tipped toward retailers**

For many years, the producers of consumer goods effectively dictated the brands and types of products being sold in the retail market, as well as their price. Corporate retailers are no longer passive receivers of consumer goods supplied to them by producers. Since the late 1980s, retailing has been shifting from being the sales agent for manufacturing and agriculture to being the production agent for consumers, and the balance of the retailer–supplier relationship has tipped toward the large retail chains. While still mediating between consumers and producers, they are no longer neutral mediators. Instead,
they induce consumers to select goods with larger profit margins. They erode manufacturers’ share of the surplus value by influencing patterns of consumption in their own favor and by using their bargaining power to lock manufacturers into retailer-led supply chains (Hughes 1996, 99). They also aggressively develop own-label products as a competitive strategy. With their significant purchasing and bargaining power, they manage to exploit negative working-capital cycles by negotiating for extended credit payment periods, reducing circulation costs and accelerating the accumulation of capital (Marsden and Wrigley 1996). Pressure is often placed on suppliers to develop just-in-time production programs and factory-to-warehouse distribution systems to match retailers’ demands.

Internationalization of retailing has intensified

As their home markets became saturated, large retail chains were motivated to explore foreign markets, using a variety of entry paths ranging from licensing and franchising to joint ventures and wholly owned subsidiaries. Almost every successful large retail chain has been seeking possibilities of expansion into other countries. Initially, they chose markets that were closer in terms of physical and psychic distance, in order to minimize cost and the degree of uncertainty about sourcing and operation. In recent years, the major international retailers have increasingly turned their attentions to emerging markets in Asia and Latin America. For example, Walmart became an international company in 1991. By 2012 it had more than 5000 stores in 26 countries. Carrefour, which went international in the 1970s, intensified its overseas operations since the late 1980s, and now operate 9500 stores in 32 countries. For many multinational retailers, revenue from overseas operations has become an increasingly important part of their business success, or even survival.

Distribution channels have diversified

In the past, goods were distributed to consumers in a linear fashion: manufacturers sold large quantities of products to wholesalers, which in turn sold the products to retailers (see Figure 1). Since the 1990s the distribution system has become much more complex. In many cases, either wholesalers or retailers are bypassed. For example, some producers sell products directly to end users through self-operated factory outlets. Certain wholesalers (such as Costco and Sam’s Club) also sell goods directly to households.

In the early 1990s a new agent of retailing and form of retail space came into being: online shopping and web stores. Online shopping is one form of electronic commerce, whereby consumers purchase goods (or services) from a seller over the Internet, without having to visit a brick-and-mortar store. Shoppers must have access to a computer connected to the Internet and a method of electronic payment – typically a credit card. Once a payment is received (usually through a third-party e-commerce business that facilitates online money transfer between consumers and retailers, such as Paypal), the goods can be shipped to a prescribed address via post or courier services, or picked up by the consumer from a nearby store. This type of electronic commerce is used for business-to-consumer (B2C) transactions and mail orders, and led to the creation of Amazon in 1995 and eBay in 1996. The 2000s saw an increasing amount of retailing using online websites, electronic payment, and delivery of merchandise to consumers via a courier service. Initially, online shoppers were deterred by fraud and privacy concerns, such as the risk of cyber theft of credit card numbers and identities. In recent years, such
risks have been greatly reduced by the use of Secure Sockets Layer (SSL) encryption and firewalls, and “e-tailers” improving their refund policies. As a result, more and more consumers are encouraged to shop online for convenience and saving, as web stores are open all year round with no after-business hours and no restrictions of location or distance.

Most people tend to think that web stores are purely virtual space, but “e-tailers” must set up physical facilities such as warehouses and regional distribution centers by either constructing new buildings or leasing existing spaces, in order to reduce delivery time and cost. These facilities require heavy monetary investment. Not all merchandises have the same level of suitability for sale online. Yet, “e-tailers” have been expanding their offerings and taking market shares away from the brick-and-mortar retailers.

In North America, Amazon continues to be on the march, successfully moving into merchandise that Walmart and other brick-and-mortar retailers traditionally have sold. In China, Alibaba’s online portals handled 1.1 trillion yuan (US$170 billion) in sales in 2012, more than eBay and Amazon.com combined (Economist 2013). More retailers responded to the new shopping pattern by offering both multichannel retailing (selling in-store and online in parallel) and cross-channel retailing (order online but pick up in-store).

The increased popularity of online shopping is leading to another revolution in the retail industry. In the new world order of retail, shoppers have become more tech savvy, often using smartphones to shop, order, and pay. Or, they go to a store to look at and feel a product, and then buy it online from Amazon or Alibaba, turning brick-and-mortar stores into showrooms.
The new geography of retailing: a paradigm shift

Retailing is a subject of study by two schools of scholars and students, business management and geography, but they approach the subject from different perspectives. The former concentrate on consumer behavior and business organizations, including logistics, merchandising, marketing, in-store display, and customer service; whereas the latter have traditionally focused on the selection and determination of business locations and the delimitation of trade areas in localized markets.

Retail geography, which originated as marketing geography but lately has been called business geography by some, became a separate field of study in the mid-1950s in the United States. William Applebaum is widely regarded as the chief architect of this field of study. He emphasized that marketing geography should be viewed essentially as an applied, rather than as a purely academic, subject (Applebaum 1954). He also considered that the best place to develop the field of marketing geography was in business itself. Marketing geography was further developed and advanced by prominent geographers such as Brain Berry and David Huff. In its first 40 years, retail geography was primarily concerned with the identification (i.e., areal expression) of the demand for various goods and services and with the spatial arrangements for supplying them through an efficient distribution network (Davis 1976). In general, this orthodox retail geography, as it is called by some contemporary retail geographers, was founded on a predictive and instrumentalist epistemology. Most of its ontological presumptions are linked to the neoclassical economic view of the world, such as central place theory, the gravity model, and distance decay function, which conceive space as a neutral container, at most affecting transportation costs. It focused primarily on the retailer rather than on the supply chain as a whole, and on the geography of stores while neglecting the geography of such important trends as the centralization of retail distribution operations. The traditional maxim of “location, location, location” as a study focus was well reflected in orthodox retail geography (Jones and Simmons 1993).

The early 1990s witnessed a major paradigm shift in the study of retail geography: orthodox retail geography was retheorized by Wrigley, Lowe, and a few other European economic geographers, and a new geography of retailing was advocated to reflect the important changes in the global economy highlighted in the preceding section. The new geography of retailing has three important characteristics in comparison with the orthodox retail geography (Lowe and Wrigley 1996).

First, it takes a political economy approach, seeing retail capital as a component of a larger system of production and consumption (Blomley 1996). This extends the scope of study to include production spheres in the system of circulation activities, particularly the production–commerce interface (the changing relations between retailers and suppliers). Aided by advanced technologies, retailers have developed logistically efficient stock control systems and centrally controlled warehouse-to-store distribution networks. These systems permit shorter and more predictable lead times, with important implications for the configuration of new retail spaces as well as the reconfiguration of existing retail spaces.

Second, it concerns the geography of retail restructuring and the grounding of global flows of retail capital (i.e., sinking of capital into physical assets in overseas markets) and its geographical expressions (i.e., spatial outcomes) in the form of retail facilities of different formats. Innovative retailers, teamed up with developers, create differentiated spaces of retailing in
the same or different markets, organized to induce consumption (Ducatel and Blomley 1990).

Third, it calls for much more serious treatment of market regulation because the regulatory state is an important force, influencing both corporate strategies and geographical market structures. Lowe and Wrigley (1996) argue that orthodox retail geography was remarkably silent about regulation and the complex and contradictory relations of retail capital with the regulatory state. With the exception of a discussion concerning the constraining influence of land-use planning regulations, the transformation of retail capital appeared to take place in a world devoid of macroregulatory environment shaping competition between firms and the governance of investment. In this sense, regulations include both public interest and private interest interventions, with the former concerning relations between retailers and consumers, and the latter concerning relationships between retailers and suppliers (including producers).

The retail planning process and the role of retail geographers

The success of a retail corporation in business development depends on a well-defined planning process, where retail geographers can play an important role. As illustrated in Figure 2, the retail planning process starts with the retail company setting up its development goals and objectives on the basis of the company’s market position and resources (see Box 1 in Figure 2). The goal of resource-rich and competitive companies is usually to grow or expand. There are two general types of growth strategies: nonspatial and spatial. The former refers to driving sales from existing stores, the latter to expanding the network by adding more stores at more locations.

For companies with mediocre performance, the goal is often to maintain the status quo and improve the performance of existing stores. Less competitive and weaker companies are most likely to choose to reduce scales of operation by closing unprofitable stores or selling off the entire operation.

If a company decides to expand, the next step is to select a target market (Box 2). A market can range in size from a country or region to a city or town. Alternative strategies include expanding in an existing market or entering new markets. A suitable market is selected based not only on extensive analysis of market conditions but also on a careful examination of the retail environment, particularly when a new market is being considered. Some countries are defined as having developed markets, with well-established trading rules and regulations, and others as emerging markets, which converge toward the developed markets in advanced economies. While they may not have reached the level of market efficiency with strict standards in accounting and securities regulation to be on a par with advanced economies, emerging markets are nonetheless sought after by multinational retailers because of the prospect of high returns. They experience faster economic growth, although investments are also often accompanied by high risks due to political instability, domestic infrastructure problems, and currency volatility. Within most countries, there exist considerable or even significant variations between subnational markets in terms of both market condition and retail environment. Some regions are more mature and more affluent markets than others. Different provinces/states and even municipalities often have different regulations and bylaws that directly or indirectly affect retailing operation and expansion.

Market conditions are assessed for both the demand and supply of consumer goods (Box 3).
Typically, demand is estimated on the basis of population size, population composition, and disposable income, which determine demand quantity and purchasing powers. In some cases, the level of automobile ownership is also considered because it affects consumer mobility and therefore shopping behaviors. Population projection is an important consideration in market condition analysis as well, as it facilitates decision-making about the scale of retail development necessary to meet future demand while minimizing investment risks and potential sunk costs.

On the supply side, market condition assessment includes both retail structure analysis and competition analysis. This helps to gauge the level of market saturation, the strengths and weaknesses of potential competitors, and the market space left for new entrants. For example, Walmart introduced its Sam’s Club to Canada in 2006. In the next three years, it opened six club stores in southern Ontario, where Costco had already established a strong presence with a large base of loyal customers. As the result of an underestimation of the competitiveness of Costco in Canada in its planning process, the six
The retail environment includes regulations, local attitudes (toward certain retailers and formats), and infrastructures (Box 4). Different countries, but also provinces and municipalities, can have different regulations, such as tax laws, anticompetition laws, land-use bylaws, and foreign investment policies. Within the capitalist market economy, governments rarely own or operate retail stores, except for a few selected consumer goods, such as the nonmerit goods of alcoholic beverages and cigarettes; in Ontario, Canada, for example, all liquor stores are owned and operated by the Liquor Control Board of Ontario, a provincial government enterprise. While retailers enjoy a high degree of freedom in business decision-making, governments do intervene in the retail industry with regulatory measures, often in the form of public policies, to mitigate negative impacts. In turn, these policies, which are supposed to reflect a society’s values, impose limits on retailers’ freedom to deal with competitors and to conduct business with suppliers and consumers, affecting retail operations and the overall market structure.

Governments also regulate the distribution system and the relationships between retailers and suppliers and between retailers and consumers. Dawson (1980) has generalized five types of public intervention that commonly exist in Western capitalist economies: (i) location restriction through land-use planning and zoning bylaws to minimize spatial externalities; (ii) price control to protect consumers from inadequate advertising and predatory selling practices, and to generate revenues for governments; (iii) optimization of business structure through fair competition laws to prevent monopoly and encourage innovation; (iv) promotion of business efficiency by controlling new entries into a market to avoid excess retail capacities and waste of economic resources; and (v) protection of consumer wellbeing and safety through licensing/inspections and compulsory labeling. Dawson also pointed out that few policies are directed toward retailing but numerous indirect policies aimed at other sectors impinge on retailing. These various types of public intervention are often imposed by different levels of government and implemented at different spatial scales (Jones and Simmons 1993).

In Western democracies, the public attitude toward a particular retailer is also an important consideration in retail planning. In the United States, anti-Walmart sentiments in some communities have derailed the retailer’s plan to enter a number of local markets. The opposition is not just against the big-box format; it has also opposed the way Walmart conducts business, including its anti-union corporate culture, low wages, and heavy-handed treatment of suppliers. While Walmart now operates 4800 outlets across the United States, it has been unable to enter New York City – the United States’ largest metropolitan market. In 2012 Walmart planned to open its first store in Brooklyn, but met strong oppositions from many members of the local community and unions (Greenhouse and Clifford 2013). Despite having spent nearly $10 million in news media to project a positive image of the retailer to New York City’s citizens, Walmart was forced to abandon its plan. This signifies that retailers must explore local temperaments in the planning process before it goes too far; elected municipal officials cannot afford to ignore the concerns of their constituents. Although retailers can appeal government decisions, the process can be lengthy and costly.

Once a market is chosen, the retailer must decide what format of retailing is most appropriate and profitable there (Box 5). The choice of which retailing format depends on market conditions. Formats include the department
CORPORATE RETAILING

store, supermarket, supercenter, membership club, warehouse retail store, and factory outlet. Some retailers operate in more than one format. Walmart entered Canada in 1994, choosing the discount department store format. This proved less profitable than expected, so it later introduced both the supercenter and Sam’s Club to Canada. Its supercenters are flourishing, despite the failure of Sam’s Clubs. When Walmart entered China in the mid-1990s, it introduced and experimented simultaneously with three formats: the supercenter, Sam’s Club, and the neighborhood supermarket. Again, the supercenters are the most successful, but Sam’s Clubs grew very slowly: Walmart has opened 362 supercenters in China, but only 10 Sam’s Clubs; neighborhood supermarkets were a failure, with only two stores.

Consideration of retail formats and selection of market entry paths often go hand in hand (Box 6). Alternative paths include organic (or internal) growth, merger, acquisition, joint ventures, and franchising. Each entry path has its merits and limitations, as detailed by Birkin, Clarke, and Clarke (2002).

Organic growth refers to the process of opening new stores in an existing market or a new market. From a real estate point of view, this can be achieved through the construction of new buildings on retailer-owned land or in leased properties. Birkin, Clarke, and Clarke (2002) differentiate between two types of organic growth: hierarchical diffusion and contagious diffusion. The former refers to the opening of new stores, first in the largest cities, and then working systematically down the national urban hierarchy. The latter refers to the diffusion of retail outlets from a single city to adjacent cities in the same region or province. While organic growth gives the retailer more control over the pace of store development and operation, its spatial growth can be slow as a result of the lengthy process of store location selection and the difficulty of acquiring properties, particularly in foreign markets.

Merger and acquisition can produce fast network expansion and rapid geographic growth in markets where the retailer is currently un- or underrepresented. Through merger and acquisition, the retailer can also eliminate competition from the target market. However, buying a large existing chain requires a large up-front investment. Achieving organizational and cultural fit in the stage of implementation and integration can also be very costly.

Joint venture is mostly used when a retailer enters a foreign country, where it usually forms a new business entity with a local partner, either by choice or as dictated by the host country government. Before China’s admission to the World Trade Organization (WTO), most foreign retailers entered by forming joint ventures with a local partner, as required by the Chinese government. The retailer in question can benefit from the local partner’s native knowledge of market conditions and the local retail environment. The local partner can also be instrumental in searching for business sites and obtaining government approval. Depending on the nature of ownership, the investing retailer may not be able to implement its business plan smoothly without friction with its local partner, especially in equal-ownership or minority-ownership joint ventures. Thus joint ventures often result in a takeover or buyout of the local partner, turning the joint venture into a wholly owned subsidiary, as has sometimes been the case in China.

There are two main forms of franchising: direct franchising and master franchising agreements (Quinn 1998). The former links the franchisor and the franchisee directly. In the latter, the franchisor grants the master franchisee the right to subfranchise to others within an exclusive
territory. This method of growth has been especially popular in recent years for international growth, where the franchisor is less familiar with the local market. Intermediary organizations are often in a stronger position to handle cultural and language issues. Franchising can also produce fast store network expansion with less capital investment and therefore lower risks. However, the level of profit is also low, and the franchisor’s control over the operation of the franchisees can be weak.

For the purpose of organic growth (i.e., new store development), detailed location analysis is necessary (Box 7), usually after approval has been obtained from the relevant government authorities: nation-states in the case of foreign markets, and local governments in domestic markets. Location analysis includes site selection, market condition analysis at the store level, search for suitable and affordable real estate, pro forma analysis, review of zoning bylaws, trade area analysis, and projection of sales potential. Retail chains often also conduct location-allocation analysis, which is concerned with the selection of multiple store locations simultaneously to serve a spatially dispersed population (i.e., to allocate a given spatial distribution of demand to a specific number of outlets). Location-allocation modeling seeks to determine how many stores are needed in the target market, how many can be supported, and where they should be located.

Spatial expansion of a store network must be supported by a network of distribution centers. For retailers operating large chains, the deployment and construction of distribution centers is also an important part of retail planning (Box 8). A distribution center operated by a corporate retailer is a specialized warehouse stocked with goods to be redistributed to the retail outlets in the same regional market. It is a vital part of the entire order fulfillment process, enabling a single location to stock a vast number of products.

After the business is opened, store performance is continually monitored (Box 9). Depending on ongoing performance, corporate goals/objectives are revisited and adjusted. Again, strong performers and profitable retailers are most likely to choose to grow and expand; mediocre performers may decide to maintain the status quo and focus on improving performance of existing stores; and poor performing retailers are forced to contract (Box 1).

As illustrated in this section, the retail planning process is complex, requiring knowledge from multiple disciplines and involving the participation of experts with different professional backgrounds. Retail geographers with training in spatial analysis are equipped with techniques and tools to play an important role in market condition analysis and location analyses, as highlighted in Boxes 3 and 7 in Figure 2. Analytical methods and tools also have been automated with the use of geographical information systems (GIS). Thus Esri Business Analyst now offers a comprehensive suite of tools including the calibrated Huff Model and various location-allocation models that meet different criteria in response to different constraints. These tasks reflect the typical concerns of orthodox retail geography, but the conceptualization of them is now informed and improved by political economic theorizations in the new geography of retailing.

Geographical research on producer services has been dominated by questions about the role of services in processes of corporate globalization. Producer services such as accountancy and law facilitate the globalization of manufacturers, and producer service firms themselves have actively globalized over the past 40 years, both to serve existing home-country clients overseas and to penetrate new markets. This has led to significant interest in how internationalization theory can be applied to producer services. Recognition of the growing centrality of producer services in the economy dovetailed with the growth of postindustrial economies in Western Europe and North America, with research highlighting how by the late 1980s and early 1990s urban economies were increasingly founded upon producer service activity, in particular in relation to finance (Sassen 1991).

Studies can be broadly grouped into two clusters. First, research sought to describe and explain the spatial organization of producer service firms within countries. In this work, particular attention was paid to the urban geographies of producer service firms, with observations being made that in Western Europe and North America it was not unusual to find in excess of 90% of producer service employment in cities (Bryson, Daniels, and Warf 2004). This metropolitan bias inspired a genre of work on the causes and effects of uneven geographies of producer services, not only across the urban–rural divide but also between cities as spatial divisions of city-based labor emerged within countries. Second, attention also turned to the geographical dimensions of the drivers, processes, and outcomes of producer service globalization. By focusing upon the geographies of the overseas activities of producer service firms in sectors including accountancy, advertising, engineering, and law, it was shown that a range of motivations for globalization were leading to concentrations of global producer service firms in selected world cities (Sassen 1991), with a range of organizational strategies being deployed to establish offices and service clients.

Urban fix

The rise of the producer service corporation has a distinctive geography that is characterized by the clustering of firms within a relatively small number of cities. This urban concentration of producer services counteracts claims that the growing importance of information and communication technology renders service sector activities footloose and geographically mobile as part of what O’Brien (1992) termed “the end of geography.” For authors such as O’Brien, services would be rendered highly mobile since the knowledge and information that is central to their operation could, theoretically, be circulated
globally, thereby removing locational constraints. However, research in economic geography and cognate social sciences from the 1980s onwards has demonstrated that, far from being evenly distributed globally, producer services are one of the most, if not the most, geographically concentrated sectors of economic activity. It has been demonstrated that a small number of leading cities, globally and at the national level, act as nodes within networks, housing significant clusters of a range of producer services. Saskia Sassen (1991) most clearly articulated this urban geography in her work on what she terms the “global city.” For Sassen, London, New York, and Tokyo form a powerful triad in the global economy, housing the majority of headquarters and commercial activity of producer services—a triad that also controls flows of knowledge, capital, and people that drive the contemporary global service economy.

In order to understand why this urban geography typifies producer service firms, it is necessary to focus on the nature of knowledge used within firms in this sector, reflecting its importance as the “raw material” of producer services. In particular, it has been demonstrated that the bespoke, specialist knowledge that is developed at the boundary between the producer service firm and their client requires close interaction, typically involving face-to-face contact and hence geographical proximity. Moreover, in addition to this client–provider relationship, product development within producer services benefits from cluster-based traded (i.e., formal transactions between actors in a cluster) and untraded interdependencies (understood as the informal benefits of being co-located, such as being able to take advantage of a specialist, highly skilled labor market or more informal interaction through sociocultural activities in clusters).

Understanding of the distinctive urban nature of producer services is very well illustrated by financial services where research has consistently demonstrated the dominance of a small number of cities in the international financial system. London and New York are key examples of such international financial centers (IFCs). Thrift (1994) identifies four elements that explain this urban hierarchy. First, the nature of financial services firms themselves serves to encourage them to co-locate in IFCs as they compete with each other for labor and clients but also simultaneously cooperate in sharing intelligence about financial markets and taking advantage of the highly skilled labor markets that characterize IFCs. Second, IFCs incorporate diverse and deep markets for financial services that allow firms to enter and exit relatively easily and learn about market pricing information. Third, the culture of IFCs highlights their role as key places of information processing and knowledge generation. As such, they serve as clusters of highly skilled individuals who co-locate to interact with colleagues and competitors in both informal and formal settings—activities that are central to the operation of the international financial system in terms of learning about new products, client demands, and subtle market pricing signals. Fourth, IFCs generate important external economies of scale due to the depth and liquidity of financial and producer services within them. These include the ability to share fixed costs such as infrastructure related to market settlement and drawing on the associated clustering of related producer services, notably law and accountancy, which have become more important to financial services as a result of the rise of financial products such as securitization from the 2000s onwards (Faulconbridge and Hall 2014).

London and New York have been widely identified as the leading IFCs. Similar patterns of urban concentration in a small number of cities can be seen for other producer services. For example, leading law firms are overwhelmingly
headquartered in the United States or United Kingdom, with those based in the latter leading corporate international expansion into Asian markets. This international expansion is being facilitated through the opening of offices in new markets (rather than servicing markets from a distance relying on ICT) because legal regulations are country specific and hence lawyers can only offer advice in the country in which they are registered to do so. Moreover, the information upon which legal transactions and products are based is often confidential and sensitive. As a result, it is best exchanged through trust-based relationships which are predominately facilitated through face-to-face interaction, thereby requiring an office presence in markets to be served.

Whilst the dominance of a small number of global cities is well documented across a range of sectors, more recently, attention has shifted to new features of the centrality of cities for the locational choices of producer service firms. Two strands of research stand out as particularly significant. First, the relationship between leading global cities and the clusters of producer services in smaller urban settings has been documented, with particular attention to countries such as the United Kingdom which are heavily dominated by one global city. This is valuable because it demonstrates how clusters of producer services in smaller cities such as Birmingham, Manchester, and Leeds, in the case of the United Kingdom, interface directly with the global economy by developing their own connections and functionally specific clusters.

Second, the changing geographies at the global scale of the clustering of producer services in cities have been explored. At one level, this has shown the growing importance of Asian cities as places for the clustering of producer services. In part this reflects the stagnation of the Japanese economy and the associated decline of Tokyo as a global city, as identified by Sassen (1991), when compared to New York and London. However, it is also being driven to a very considerable extent by the growing power and reach of China in the global economy and the desire for producer service firms from Europe and North America to open offices there in order to service a rapidly expanding market. While the geography of concentration in China in terms of city location is still unfolding, established clusters in Singapore and Hong Kong are facing increasing competition from emerging clusters in Shanghai and Beijing (Lai 2012).

A further important trend in terms of the city location of producer services is the relationship between global cities and the offshore activities of producer service firms, particularly in terms of finance. Here, building on earlier work on offshore financial centers, it is shown how global cities rely upon a network of offshore activities for their own economic growth as well as, particularly in the case of London, acting as a quasi-offshore center themselves as producer service firms use the dense highly skilled labor markets to devise new products and forms of service delivery associated with the growth of offshoring.

Rise of the producer service multinational corporation

At the root of the corporate spatial organization of the producer sector in the world economy has been the emergence of the producer service multinational corporation (MNC), especially in the latter quarter of the twentieth century. The rapid growth of the producer service MNC has effectively been the “driver” (Bryson, Daniels, and Warf 2004, 76) for the internationalization of producer services and responsible for their intensive locational preference for the urban fix of a metropolitan area. Across different producer service sectors, from logistics and distribution to
banking, finance, insurance and real estate, and business services, MNCs dominate the accumulation of global revenue, size of market share, and ultimately, levels of profitability in their specific sector, leaving small and medium-sized firms in their wake.

The growth of the producer service MNC can be explained and documented in two different ways: first, by focusing on the main (theoretical) reasons postulated for the growth of producer service MNCs – which are both external and internal to the firm; second, by examining the way in which producer service MNCs have grown and internationalized their investments outside their home country (via new office expansion or mergers and acquisition activity, for example) through waves of foreign direct investment (FDI) in host countries aided by regulatory factors, such as the General Agreement on Trade in Services (GATS).

**Externalization and internalization**

There is a very long tradition of literature on the producer service MNC benefiting from the externalization of functions by other firms. Over the last 25 years or so many firms, both MNCs and small and medium-sized enterprises (SMEs) in all sectors of the economy (primary, manufacturing, public administration), have externalized previously in-house functions to specialist producer service firms. Externalization has occurred not only for specialist business services such as accounting, advertising and marketing, consulting, human resources, legal services and real estate, but also more recently in activities such as logistics and distribution (reflected, for example, in the rise of DHL and Federal Express) and education (see Bryson, Daniels, and Warf 2004). Such services, once internalized in MNCs, are very likely to be externalized and thus create a derived demand for specialist producer services that can be called upon using quite flexible contractual arrangements for the supply of specific services and bespoke expertise. It is often the case that the global producer service MNCs maintain repeat business arrangements with a mix of clients from the private and public sectors provided, of course, that they deliver reliably and incorporate state-of-the-art knowledge and expertise.

Another aspect of externalization has been the rapid growth of producer service business-to-business demand for other producer service inputs from a wide array of buyers and co-suppliers who require both specialist products and bespoke advisory services. The genesis of 24-hour global financial markets and global financial centers, in Europe, North America, and Asia, and more recently in mainland China and Brazil, Russia, and India, has fostered unprecedented demand for producer service inputs, particularly in co-location and interdependency with other producer services. The proliferation of business-to-business (B2B) producer service inputs has acted as a major catalyst for the geographical expansion and coverage of producer service MNCs throughout the world, particularly in the “advanced” producer and business services. For example, during the late 1980s and 1990s, the major US law firms entered markets in Asia and Europe in response to demand from their US corporate clients (mainly wholesale banks, insurance companies, advertising agencies) operating out of cities such as London, Frankfurt, Singapore, and Hong Kong. The ICT revolution and introduction of fiber-optic technology and infrastructure were important vectors which aided the internationalization of producer services throughout that period, but at the turn of the new millennium, the rise of the Internet age and e-commerce (mainly B2B) has certainly provided new technologies, practices, and processes that producer service MNCs use to market and sell their products and advisory
services to external buyers in more innovative and efficient ways.

In parallel with the rise of the producer service MNC, in response to new demand from external buyers, a series of internal processes which are a cornerstone of a firm’s strategy for entering and penetrating new markets have developed: the ability to deliver (sell) a rich knowledge base and often bespoke expertise to clients (buyers) at the point of demand. In essence, producer service firms have entered into international production through the establishment of branch office networks directly in the marketplace, either via the growth of wholly owned subsidiaries or through mergers and acquisitions with local host firms. Since producer service MNCs are offering knowledge, expertise, and intelligence that is mainly embodied in their professional workforce of accountants, brokers, advertising creatives, consultants, head hunters, lawyers, and wholesale bankers, the most efficient mechanism for delivery is through a physical entity that ensures close co-location between the buyer and seller. Producer service MNCs have therefore invested in extensive international office networks outside of their home country to sell to buyers directly in the market. This has the added benefit of enabling them to protect and enhance their corporate reputation and trust relationships with buyers and, importantly, co-suppliers.

There are two other internal factors driving the rapid office expansion, both in terms of the numerical expansion of offices worldwide and in terms of an increase in their actual size (e.g., number of professionals employed): sector-specific concentration, and product diversification and innovation (see Bryson, Daniels, and Warf 2004). Throughout many producer service sectors, a small group of very large MNCs (which may range from 4 to 10 firms in any one sector) dominate global revenue, market share, and profitability, followed by a larger group of other (smaller) MNCs, often with regional coverage, and then a constellation of literally thousands of SMEs and sole traders. This concentration emerged from the late 1970s/early 1980s as many of the successful firms merged to create global producer service firms. Such concentration is very well advanced in sectors such as accounting, but also in advertising, consulting, legal services, and logistics, amongst others. Often firms that have merged with their competitors have done so to increase the reach of their office networks into selected geographical world regions rather than to fulfill rationalization or restructuring objectives typical for firms in other sectors of the economy.

Foreign direct investment and globalization

The rise of the producer service MNC has resulted in rapid growth in FDI. For example, between 1990 and 2002, the estimated world outward flow of FDI in finance and business services increased from US$447,937 million to US$3,305,192 million (an increase of 638%), and much of it has financed the establishment of wholly owned offices and merger and acquisition (see UNCTAD 2004). Such FDI decision-making by producer service MNCs has reaffirmed their structural characteristics (concentration and diversification) and consolidated their locational preferences for world cities. The global regulatory environment has encouraged this growth in FDI, especially the ongoing efforts to liberalize international trade and investment in services, embodied in the GATS, introduced in the early 2000s by the World Trade Organization.

Organizational spaces

As a result of the internationalization and city-based geographies of producer services,
a number of distinctive forms of organization have developed. These are designed to exploit the local-global geographies of producer service firms, in particular because of the importance of the production and leverage of knowledge as part of the process of delivering advice to clients. Two distinctive modes of spatial organization have been noted.

First is the project team. In many cases, the delivery of producer service work to the client relates to a specific problem or task as part of a time-bounded project. For instance, lawyers may be called on for advice in relation to a merger or acquisition, whilst consultants may be used for advice about the introduction of a new computer system. Such work requires specific types of expertise that only certain employees of the producer service firm might possess. As a result, a distinctive means of service production is the temporary project team (see Grabher 2001) that is established for a specific client project, and then disbanded upon completion of the advisory task. Of particular interest, in relation to corporate spatial organization, is the geography of the project team.

In line with earlier discussions of the interrelated processes of internationalization and localization in cities, project teams have local-global geographies that inflect in important ways the nature of the advice provided to clients. Locally, project teams are often assembled not only by including workers based in the office of the producer service firm in question, but also by exploiting particular advantages of the city-based geographies of firms discussed earlier, by bringing in expertise from other co-located firms. Such city-based project ecologies are especially important for creative producer service firms such as advertising (see Faulconbridge et al. 2011).

Project teams can also have global geographies. Grabher (2001) highlights how the global office networks of firms, including the social networks of individuals within them, allow project teams to be staffed with workers not just from the office managing the project. Individuals may be selected to be part of a project team based on their expertise and how they can contribute to the success of a project rather than on where they are located.

Secondly, and related to project teams, another important spatial characteristic of the organization of producer services is labor mobility. Partly as a result of the local-global geographies of project teams, but also related to wider strategies of talent management within firms, portfolios of labor mobility (Millar and Salt 2008) now exist within producer services. At one level these portfolios exist around interfirm mobility. At the city level there is extensive churn of individuals between competing producer services that is facilitated by the urban ecologies mentioned earlier. Globally, there are also significant flows in elite labor markets; individuals and their careers are defined by their mobility between key sites of producer service work. This mobility is facilitated by executive search firms, which are producer services that specialize in helping their clients to identify mobile talent that can be recruited to fulfill a range of specialist and senior management roles (Beaverstock, Faulconbridge, and Hall 2015).

At another level, these portfolios are associated with intrafirm mobility, often as part of the internal labor markets of a firm. A key feature of these portfolios is the different temporal duration of the multiple forms of mobility that exist. Mobility ranges from the short term, such as business travel which may last a few days or weeks, through to longer-term rotations or secondments which last a few months, and expatriation, which can be for several years (Millar and Salt 2008). Underlying all of this mobility of workers is the need for firms to
CORPORATE SPATIAL ORGANIZATION AND PRODUCER SERVICES

manage their most fundamental asset, the human resources that can most effectively produce and leverage the knowledge required to deliver the best advice to clients.

The importance of temporary project teams and portfolios of labor mobility has two further implications. One important effect arises from the management practice of those running producer service firms. Such practice requires an acute awareness of the spatialities of the work of firms, meaning both their embeddedness within a city and also the global relational networks that make work possible. For instance, those managing firms must become part of the professional communities made up of competing firms, regulators, and industry commentators in the cities where they work, this being mediated through professional associations as well as more informal social gatherings in the bars and restaurants. Partners and CEOs must also undertake frequent business travel associated with the management of global producer service firms. This not only allows the work of project teams to be monitored and controlled, but also enables corporate cultures and strategic planning to be overseen on a global basis. In particular, this means carefully handling institutional and cultural differences that affect work in different office settings around the world, and ensuring that a balance exists between global integration and local responsiveness as far as work practices are concerned.

A second important implication of the local-global geographies of producer service organization relates to the impacts on the practice of clients. In some cases, particularly when a producer service firm is not global, clients are primarily looking for a locally tailored service which is sensitive to place specificities. For example, advertisers may be expected to provide advice about engaging with clients in a particular country or region (Faulconbridge et al. 2011), and in such cases, producer service firms help ensure the local appropriateness of their clients’ practices. When global producer service firms are involved, advice is more likely to be sought on the adoption of global practices. Here, the role of the producer service firm is to help create and/or provide advice about globally recognized approaches to a particular issue. For instance, global law firms are hired to offer advice about globally recognized bankruptcy practices that correspond with local legal requirements and the expectations of international institutions such as the International Monetary Fund. Global architecture firms are used by clients seeking building designs that are globally recognized, iconic world city styles, not local vernacular architectural styles. In both cases, the firms are likely to be part of the production of these global standards, both through their work for other clients, which helps to define global practices, and through collaborations with other producer services. In all cases, however, firms must also be able to advise on the local application and implications of global standards. As such, local embeddedness and global integration are not either/or options; both are necessary to be effective in delivering the most innovative and profitable work.

Case studies

Accounting

At year–end 2012 the “Big Four,” PricewaterhouseCoopers (PwC), Deloitte, Ernst & Young (E&Y), and KPMG (in rank order) had accumulated global revenues of US$100.2 billion, were present in over 150 countries each, had upward of 700 offices each (except KPMG, which had 650+), and employed a staggering 539,724 professional staff (partners and fee earners) (Accountancy Age 2013). These global networks, along with other international
accounting organizational forms such as associations or alliances of independent member firms, have penetrated new markets and internationalized their functions by supplying clients with a range of services through corporate offices located in national capitals, regional cities, and other important metropolitan areas. In effect, the internationalization of accounting is a metropolitan-based activity where firms supply services such as: audit and assurance; corporate finance; consulting and advisory; insolvency and business recovery; and other specialist activities such as executive search, technology, corporate social responsibility, and change management.

The internationalization of accounting firms actually started during the nineteenth century, but the phase of opening up new offices outside of firms’ home countries only really gathered pace from 1945. The period between 1945 and the end of the 1980s saw the growth of firms’ office networks in Asia, Europe, North and South America, and Africa and the Middle East. Between 1975 and 1985, the leading 20 international accounting firms expanded their office networks by more than 122%, from 2026 to 4622 (Daniels, Leysh, and Thrift 1988). Importantly, this period also marked the beginning of the concentration of the sector with the establishment of the “Big Eight” through various mergers and acquisitions between UK, European, and US multinational firms. The lineages of today’s “Big Four,” PwC, Deloitte, E&Y, and KPMG, are essentially the outcome of mergers and acquisitions activity between the “Big Eight” in the 1990s, for example the creation of PwC following the merging of Price Waterhouse and Coopers & Lybrand in 1998.

The corporate office is the firm-client interface for firms in different worldwide locations, from the “Big Four” to small and medium-sized enterprises. Usually, it is wholly owned or leased by the accounting SME or global network such as the “Big Four,” or by an association or alliance of independent member firms. In 2012, the leading global accounting associations and alliances were: GGI (388 member firms in 101 countries); Praxity Global Alliance (60 in 109); The Tag Alliance (259 in 94); and Leading Edge Alliance (190 in 102) (Accountancy Age 2013). Global accounting firms (networks, association, and alliances) require a physical office in a city because clients and co-suppliers (such as lawyers or corporate bankers) expect accounting professionals to be co-located. Like many other advanced producer services, global accounting firms adopt extensive international mobility programs to ensure that professional staff circulate within and between international office networks.

Executive search

Executive search producer service firms originated in the United States in the 1960s and 1970s. They were spinoffs from management consultancy firms when consultants providing the service began setting up dedicated companies which specialized in hiring executives in senior management positions, such as chief executives and chief finance officers. Faulconbridge, Hall, and Beaverstock (2008) document how, from its US origins, executive search quickly internationalized, first through London and then more widely in Western Europe, followed by Russia, South America, and Asia in the 1990s and 2000s. Key firms driving the internationalization of the industry include Korn Ferry, Heidrick & Struggles, Russell Reynolds, and Spencer Stuart. In 2014, these four firms had between them nearly 100 worldwide offices, led by over 300 partners (plus many thousands of junior consultants). Offices are located in major world cities, reflecting the important role of other
producer services as clients. In common with other producer services, internationalization was inspired by a desire to follow existing clients who were themselves internationalizing, to tap into new markets but also, and particularly important for this industry, to respond to internationalization in labor markets as elite labor became increasingly mobile (Faulconbridge et al. 2009).

Two things are noteworthy about executive search firms. First, globalization has been achieved using a variety of organizational forms. This includes wholly owned offices, best friend networks where global firms collaborate with local firms to serve a particular market, and hybrid forms where multiple local firms adopt a global brand but remain independent entities (Beaverstock, Faulconbridge, and Hall 2015). Second, executive search illustrates the way in which global spaces of organization have worldwide effects, in this case on elite labor markets. Through internationalization, executive search firms have promoted a particular model of elite labor recruitment that involves using search firms but also assessing candidates using particular models of talent (Faulconbridge et al. 2009). As a result, executive search firms now define the “rules of the game” in elite labor markets. In addition, the internationalization of executives stands out as a distinctive example because of the way firms have sought to create a new industry through internationalization. Since executive search firms did not exist in the form they do today until the 1960s, their internationalization has spread a new model of elite labor recruitment and created a whole new producer service industry. This is significant because it reveals the way that producer service internationalization responds to existing demand for services, but also actively constructs demand to render firms profitable (Beaverstock, Faulconbridge, and Hall 2015).

Executive education

Geographers interested in producer services have not given much attention to executive education, even though education is increasingly understood as a service sector. It is, for example, included in tables showing the contribution of exports by sector to national economies. This oversight has recently been addressed on the basis that educational services, and particularly education offered to professionals after completion of their first or undergraduate degree – executive education – deserve more attention as part of ongoing work on the globalization of producer services. Indeed, executive education is central to the knowledge networks that other producer services rely upon and that shape their city-based geography.

Executive education replicates the forms of internationalization and preference for city-based offices typical of many producer service providers. For example, the size and country of ownership of firms operating in the sector are dominated by a small number of large firms predominately headquartered in the United States, including the Apollo Group, Pearson Education, and the Washington Post Company. Beneath these is a long tail of small, specialist boutiques (Hall 2015). Moreover, rather than being passive agents in education markets, and in common with other relatively “new” producer services such as executive search, executive education firms play an important role in “making” education markets by educating clients about the nature and value of the services being offered. This serves legitimate executive education and hence stimulates demand (Hall and Appleyard 2011). Finally, the highly variegated institutional contexts that give rise to distinctive national and regional education landscapes mean that educational service firms demonstrate high levels of territorial embeddedness. These institutional contexts are shaped and reproduced through
the combination of formal regulations with more informal expectations about the nature of education and styles of learning in different countries (see Hall and Appleyard 2011). Moreover, this variegation is complicated in the case of educational service firms because they have diversified beyond their initial service offering. For example, several leading business education firms, notably the Apollo Group, have entered the executive education market having previously specialized in compulsory schooling and private universities. As a result, this sector demonstrates a diverse range of organizational architectures in which the management of international offices is typically highly localized and organizationally specific.

Corporate world and work: Indian women in the IT sector

Saraswati Raju
Jawaharlal Nehru University, India

The chaotic global reshuffling and flows of capital, information, goods, ideas, and human beings across subnational and transnational borders, which is unprecedented in terms of scale and the number of actors involved, is increasingly seen as a frictionless “space of flows” that is overtaking a more heterogeneous “space of places.” Such discourses imply the erosion of local differences; geographical constraints on social and cultural outcomes are seen not only as weakening but also as destabilizing the physicality of places. Places are seen as irrelevant, expunged in what some see as “the end of geography” (Graham and Marvin 1996; Graham 1998).

Undoubtedly, the traditional conceptualization of spaces as self-enclosed preconstituted autonomous containers has become highly problematic. This entry proposes, however, that places and geographical locations continue to matter – not in the sense of Cartesian space but as sites of continuous negotiation and renegotiation. This is evident from an examination of the sociospatially localized manifestations of gendered identities in the world of work, and particularly in information technology (IT) – the presumed epitome of frictionless global flows.

A topic as broad as corporations and work is beyond any single encyclopedic entry. This entry focuses on technological innovations that have resulted in the restructuring and reorganization of work epitomized by IT, IT-enabled services, and business process outsourcing (BPO). These services have facilitated time-space distanitation and redefined the boundaries of production and consumption. While they have expanded the limits of what it means to be an individual worker, there still exist regionally specific sociocultural constructs within which labor dynamics play out.

Confining the discussion to Asia in general and India in particular, the entry is organized as follows. It first discusses the outsourcing and offshoring of labor, then deals with the segmentation of global and local labor forces, before turning to the question of how nation, the work, and domestic spheres are entangled with the gendering of Indian IT labor.

Outsourcing and offshoring labor

With the collapse of the communist bloc, the entire planet now seems drawn into capitalism, with few exceptions. Some of this reflects the age-old spirit of competition in the “pursuit of profit and individual satisfaction,” but information and communication technologies provide new means of realizing global production networks (Castells 1999, 2). Growing interdependencies, mutually beneficial even as they are exploitative, make this brand of capitalism simultaneously “very old and fundamentally new” (Castells 1999, 2). Outsourcing and offshoring production, to reduce corporate taxes and avoid such mandated benefits as social security, safety measures, managerial and labor cost, is symptomatic of such globalization.
Rarely used until the 1970s, the term “outsourcing” refers to the contracting out of economic activities and labor to a third party. It started appearing in dictionaries from the mid-1990s, and has become a buzzword in contemporary globalization discourses. Contracting and outsourcing, while related, are not synonymous. Whereas contracting out suggests a passive exchange of services between corporate bodies, outsourcing is “what one company actively does in relation to another, and that means that the two managements are active agents” (Gupta 2010, 19). In short, managerial discourse dominates outsourcing. Core concerns in such a discourse, Gupta observes, are lower labor costs and the speculative shift of capital from distinctly productive to overtly speculative investment. Debates surrounding outsourcing became murkier with the spread of neoliberal globalization and the offshoring of outsourced activities. Such offshore outsourcing affects a relatively small proportion of low-profile jobs, but their relocation from developed North to developing South has generated complex normatively loaded debates and anxieties.

In this increasingly integrated global economy the IT and IT-enabled industries have received particular attention. The associated shift from Fordist mass production to more flexible accumulation has been marked by “complex transnational production networks [spread across the globe] rather than through vertically integrated multinational companies” (Upadhya and Vasavi 2008, 12), facilitated by the IT sectors. These networks may constitute a very small part of the global labor force, but are presented as “new generation ventures,” dispersing to hitherto developing countries such as India. A key aspect of this has been the emergence of virtual workspaces: call centers are such sites, one of the most rapidly expanding areas of work globally. (Incidentally, this is coupled with a heightened sense of the possible loss of Northern jobs, particularly in the United States.)

The corporatization of IT lies in its very nature. Abraham (2008) characterizes this as (i) improved telecommunication technology with concomitant cost-effectiveness; (ii) standardized software platforms that homogenize skill requirements across organizations (and geographical locations); (iii) availability of a desirable labor pool for multinational and domestic companies that is fluent in English, Spanish, French, and German in parts of the developing world; and, crucially, (iv) the substantive wage differentials between developing and developed countries (particularly the United States). Offshored labor can also take advantage of the time differences: day wages in India are far lower than (overtime) night wages in the United States, the classical argument of time–space compression. Taken together, these features make offshoring a profitable venture for corporate IT giants.

IT work is essentially based on manipulating symbols in computer systems, dubbed the “textualization” of work (Upadhya and Vasavi 2008, 12), rather than on material objects. As a result, “production and services have become dematerialised, disembodied, and divided amongst workers located in geographically distant site[s].” In these technologically mediated organizational structures, the workers are expected, in terms of training, skills, and behavioral norms, to operate in a contextually isolated manner, valorizing a singular model of “global corporate culture” (Upadhya 2008, 105).

At a more generalized scale, those benefiting from the development of the information technology enjoy material and symbolic privileges: the workforce is urban, largely young, with a high level of education and professional skills. India’s high-end airports, gated communities, and mushrooming high-technology parks in rapidly growing cities reflect elite lifestyles that
at times are better than those of their counterparts in developed countries. The gradual move up from routine coding and maintenance jobs requiring no special problem-solving skills to specialized positions in the value chain places workers at the upper end of the global economy (Radhakrishnan 2011b). Even if this is just the symbolic language of code, it has provided Indian workers with relatively better options, higher wages, and the opportunity to join the elite global network of IT workers, itself seen as an advantage (Aneesh 2006, quoted in Radhakrishnan 2011b). The resultant overlapping of an educated urban workforce with the IT professional sector has given rise to a new vocabulary of social differentiation, to a “new” middle class: new largely in terms of lifestyles marked by burgeoning conspicuous consumption (Fernandes 2000).

IT workspaces also are “new”: open, nonhierarchical, and informal work settings, in direct contrast to earlier traditionally framed or bound hierarchical and formal places (Harvey 1989). They represent a merging of diverse management styles, developed in the United States and drawing “American values of egalitarianism, teamwork and individual initiatives … into a single dominant model – an ideal type ‘global’ corporate culture that every company, worker and manager must work towards in order to compete in the global market” (Upadhya 2008, 105). Interlinking local with global and compressing time, these transnational spaces also imitate the physical ambience of the US IT culture. “The interior office environments of most large IT firms in India are designed to look like their Silicon Valley counterparts, or more accurately, to look placeless, as if they could be ‘anywhere’” (Radhakrishnan 2011a, 61; emphasis added). Radhakrishnan cites an Indian IT professional calling this feeling of being “anywhere” a “space wrap.”

In these workplaces, a worker is an individuated entity, rewarded for his/her initiatives and managed primarily through indirect and subjective techniques of cultural anchoring (Kunda 1992, quoted in Upadhya 2008, 106).

If the industrial era consisted, in terms of the labour process, of taking a population of peasants and craftsmen and bringing them into socialized conditions of labour, the information age is exactly the reversal. It is the de-socialization of labour and the increasing flexibility and individualization of labour performance. (Castells 1999, 8)

The individuated worker also is invested with socialization processes associated with becoming “global”:

… a cosmopolitan sensibility that connotes status and refinement outside the workplace, as well as added bonuses with it. Such a strategic approach to culture that begins in the IT workplace, stemming from the capitalist imperative to streamline differences for the sake of efficiency, becomes a way of understanding culture more generally, as corresponding notions of “India” take shape alongside competing notions of the “global.”

(Radhakrishnan 2011a, 55)

**Labor market segmentation**

Such processes are not without contradictions, however. Even as the global technical worker is being created by virtue of working across transnational borders, conflicting cultural images are being produced that require a segmented workforce serving capitalist interests. According to Upadhya (2008, 103), such segmentation of labor is not straightforward but

a dialectic process in which pre-existing cultural communities, gendered identities or racially marked groups are transformed into labour
forces that perform particular roles in the production process, which in turn marks these social identities with the stamp of capital. For instance, the type of work that is performed or the working conditions have implications for the reconstitution or reinforcement of masculinities or femininities … The interactions between capital and cultural identity become more complex as globalization gathers pace and both “cultures” and identities get increasingly commoditized, becoming … capital itself.

While India takes pride in its claim to be the world’s emerging power in the technically advanced IT sector, its workers are often projected as cyber coolies, placed at the lower end of the commodity chain. Such representations persist even as developing economies are increasingly internationalized and integrated into the global system. For instance, Japanese transplants in Malaysia, producing mature goods in a competitive international environment, continue to occupy relatively low-value activities in mass assembly while engaging in limited product design or process innovation. This segmentation parallels piece-rate production from the “global assembly line” export-oriented garment subcontractors in Sri Lanka and/or Bangladesh (Upadhya 2008). As Vo (2007, 198), puts it:

The globalisation processes of uneven development, interdependence between equals and those who are less equal alongside interactions of conflicting and common interest, within which state institutions are embedded, do not simply sustain a single and homogeneous pattern of firm behaviours.

In contrast, by creating segmented labor markets, firms hail and appropriate regionally specific cultural discourses and differences, to be used as a “strategy of control” (Upadhya 2008, 102). This can be seen in the engagement of child labor (especially girls) in the corporate cultivation of Bt cotton in Andhra Pradesh in south India. Here, the notion of purity/impurity associated with menstruation is used to justify employing pre-pubertal girls to pick (pristine) white cotton in the fields — quite conveniently disguising the “beneficial” aspect of employing child labor. Similarly, the overarching construct of Indian women’s primary location being the private sphere of domesticity conveniently legitimizes the progressive informalization of women’s paid labor and their concentration into home-based work — a cheap labor supply beyond the reach of protective labor legislation (Raju 2013).

**Gendered geographies of IT labor: the case of India**

Under these circumstances, a key geographical question is: How far do national contexts influence the international transfer of multinational corporations’ management practices? Radhakrishnan (2011a, 55), outlining the cultural terrain at work in the corporate world, defines its global culture as characterized by (i) a sense of placelessness and the insulation of work sites; (ii) standardized communication style and skills, which she calls low context, as clues are verbal rather than situational or relational; and (iii) nonhierarchical organizational/managerial styles. Together, these indicate a potentially empowering environment at work, which, it is assumed, will filter through into personal lives. That is, the ensuing cultural flows between these two spheres — the global culture at the workplace and the local in home spaces — would be “more fluid than they appear at first.” However, contrary to such expectations, research shows a much complex situation for multinational corporation (MNC) operations in developing and transitional economies, whereby they have to adopt a “very high level of flexibility,” and in some cases compromise and confront conflicting institutional
constructs (Vo 2007, 199). One such, often invisible, divide, is profoundly gendered, whereby women are encouraged to negotiate the merging of the two identities – being a woman and working in an MNC. The overwhelming constructs, however, continue to lock them up in “Indian middle-class cultural norms of respectability and domestic femininity” (Vo 2007, 203–204).

The IT industry invokes the rationality of merit as the marker for upward professional mobility, but the overall lower percentage of women professionals in the upper echelons does not reflect such a claim. IT women consistently explain their absence from these echelons, however, in the “language of personal choice,” ignoring “the ways in which its articulation in the everyday lives of IT professionals explicitly overlooks the specific conditions of its production in the history of India” (Radhakrishnan 2011a, 91). The improved access to employment opportunities and financial independence, seen in progressive educational attainment in accordance with the contemporary corporate world in India, should presumably enable women to exercise “their reasoned agency” (Sen 1999, xii). Does this happen, however? Does paid employment in the corporate sector necessarily increase women’s freedom and agency, especially under conditions of globalization? For the information and communication technology (ICT) and BPO sectors, the answer has to be “only superficially.” Despite the glamour and an invoked sense of articulate modernity (Tara and Ilavarasan 2011), women in IT and BPO sectors continue to operate within the paradigm of thus far and no further, the no further limit being (re)constituted by persistent gendered constructs that continue to encode women’s primary place within domesticity, even as the confining vocabulary may undergo some cosmetic changes. For example, although the line between long and erratic hours of IT-sector jobs and women’s responsibilities toward the home and family gets blurred, questions regarding priorities arise – women rarely privilege career aspirations over family life.

Krishna (2001, 412) argues that contemporary labor geographies should be placed beyond the limits of the nation-state instead of being bounded by a self-spatialization that “names itself as a destiny, a genius, a culture, a civilization, or homeland – a contiguous and identifiably discrete and separate entity.” Such a position is problematic, however, when viewed from the contextually spatialized world of women’s labor. Krishna advances a “meta-myth” (Bradley 2000) of globalization that is highly contentious in a country like India, with its irresistible “ironies and resistances” of local making (Appadurai 1996, 29). Indeed, such makings seem to have become hegemonic in India’s contemporary corporate culture where, despite women’s participation in an elite IT professional work culture, corporate norms and expectations are woven into a distinctive and self-conscious “Indian” idiom of “respectable femininity” that spills over into their everyday lives (Radhakrishnan 2011b, 195).

Kagitcibasi’s (2005) concept of the “autonomous-relational” self is helpful in understanding this. He questions the oft-posed separation of autonomy and/or agency, and their intersections with relatedness or heteronomy. For him, the separation between autonomy and/or agency and relatedness has a root in the Euro-American cultural context, with its ideological background of individualism. Autonomy and heteronomy are thus two ends of the same spectrum. An individual can have an interdependent but also independent self, in a “dialectic mutuality” or “coexistence of opposites.” These selves are embedded within societally encoded gendered constructs, which are internalized during socializing processes (D’Mello 2006, 139). In the Indian context,
there is very little scope for mutually dialectical exchanges in the constitution of women’s identities. Instead, the independent self (the articulation of which could have been drawn from education and paid work status) annihilates itself under self-efficacy and self-definition, notwithstanding the other means through which a relational self is overwhelmingly present, in the making of the self.

From her empirical study of professionals in the field of information technology in Mumbai, D’Mello seems to reiterate Kagitcibasi’s observations:

The autonomous-relational self … is operationalized among IT workers, in ways that are more dichotomous than dialectically mutual. The breadwinner ideology predominated as a central aspect of masculine identity constructs, while the relational self occupied center stage in feminine identity constructs. Individual responses as well as the coping means used by women reinforce the view that the relational self was the predominant pathway [for women] … Negotiating for power and equality in the family system [was found to be] a challenging task, threatening disintegration of family relationships … many women [in her study] compromised their own career aspirations. (D’Mello 2006, 152)

Similarly, Radhakrishnan (2009) argues eloquently that the larger consciousness surrounding women’s place in urban India, now being constructed in a family, largely coincides with the emergence of India’s new middle class. Working women, particularly those in professional IT sectors, signal the arrival of a “global” nation (Radhakrishnan 2009, 197). Notwithstanding this global image, the nationalist (work) culture continues to draw on an idealized construct of (Hindu) women based on a powerful dichotomy between the inner and the outer, material and spiritual, and home and market, which is inevitably gendered. Contrasting with its earlier emphasis on the spiritual, according to Radhakrishnan, the contemporary construction of middle-class women hinges on the notion of family (and the location of women within it). Using Bourdieu’s notion of symbolic capital and his conception of gender and the family, she proposes the concept of “respectable femininity”: the essentialized framing of women within the domestic sphere, a positioning within the family’s perceived “normalcy” “legitimated through middle-class status” (Radhakrishnan 2009, 197). Placed within this framework, the symbolically authoritative dominance of the middle class allows the conception of “family first” to bear on the national consciousness, opening “up space for grappling with the embeddedness of gender” (Radhakrishnan 2009, 197). This shapes the labor market outcomes, even for those in new generation employment such as IT, in terms of upward mobility within the profession, as women internalize familial priorities over their professional aspirations beyond certain thresholds, despite individual negotiations and interlinkages with the global economy. IT women thus enact a highly competent “professional” femininity that continues to remain “markedly Indian” (Radhakrishnan 2009, 200–201, 209).

In summing up, a few priorities for future research will be identified. This “markedly Indian” manifestation of gendered constructs is intercepted, in a nuanced manner, by localized differences in the overarching patriarchal structures that prevail across India. The IT sectors are predominantly located in the southern Indian cities of Bangalore and Hyderabad—social spaces that have been relatively more gender-egalitarian than elsewhere, especially in comparison to northern Indian cities and states (Raju 2011). Other hubs are emerging, such as Faridabad, closer to Delhi and located in a highly patriarchal Northern social space. It will be interesting to
see how the microenvironment of these spaces works to further constrain and/or encourage professional women as they negotiate/contest well-entrenched, albeit localized, gendered structures. More generally, what kinds of strategies do women adopt in distinct subnational regional contexts in this regard?

The IT industries do provide emancipatory spaces to women, with the potential also to enhance women’s bargaining position in domestic spaces. However, there is very little geographical research examining the discursive interfaces between public and private spheres, in terms of the work–life balance, strategies and negotiations, domestic struggles in daily lives, and so on.

The heterogeneity of women workers also needs more attention. Paul’s (2013) research in the city of Kolkata, based on a purposive sample of about 360 women working in the IT and IT-enabled services contrasted with women workers in traditional sectors such as teaching, underlines the heterogeneity of women workers marked by their age, education, and socioeconomic background, and their differentiated responses to various professional and familial challenges. Paul’s study also interrogates how questions of emerging new places of consumption such as shopping malls, and women’s spatial interaction with them, intersect with the sectors they work in. Few professional women have been able to break through the glass ceiling in their careers. The conditions propelling them to the positions they occupy, the replicability of those conditions, as well as the institutional, social, and structural changes required, are further unexplored areas with exciting possibilities for research, by geographers in general and in the Indian context in particular.

Corporations and global trade

Martijn J. Burger
Erasmus University Rotterdam, Netherlands

One of the characteristic features of contemporary globalization is the historically unprecedented increase in foreign trade. Between 1970 and 2013, worldwide trade rose by almost 1000% in real terms. This outpaced growth in worldwide real gross domestic product (GDP), which only quadrupled in the same period (Figure 1). In the economic geography and international economics literatures, this remarkable growth in global trade has been attributed to several social and economic developments. These include increased economic wellbeing, declining transportation costs with advances in shipping and information and communication technology, trade liberalization in terms of a reduction in tariff and nontariff barriers to trade, and the increased outsourcing of production processes across borders and the related rise of global value chains. Several studies also have shown that trade has been an important source of growth for many countries over the past decades (Badinger 2005; Bradford, Grieco, and Hufbauer 2006).

Nonetheless, there are signs that corporate internationalization remains restricted to the “happy few” (see Mayer and Ottaviano 2008) in that firm participation in global trade is surprisingly uncommon. Data obtained from the Organisation of Economic Co-operation and Development (OECD) Eurostat Trade by Enterprise Characteristics (TEC) shows that only 4.5% of US firms export abroad. A similar share of firms from the European Union (EU) member countries engages in intra-EU trade, while only 2.7% of EU firms export to countries outside the EU. The bulk of trade is driven by only a handful of large corporations, exporting many products to many countries. The top 50 US exporters by export value account for about 30% of US export value and the top 50 EU corporations account for about 40% of intra-EU export value and 30% of extra-EU export value. Likewise, the top 1000 exporting firms account for approximately two-thirds of trade in both the United States and European Union. At the same time, firms’ propensity to export varies by sector. For the United States and Europe, firms in the final goods sector generally import and export more frequently than firms in the intermediate goods sector (Bernard et al. 2007); goods generally are more frequently exported than services (Burger et al. 2014).

Conventionally, trade theories seek to explain the volume of trade between countries in terms of either differences in relative productivity across different industries and in the availability of specific types of labor and physical capital goods or by increasing returns to scale, specialization, and consumer demand for variety (Helpman and Krugman 1985). As Helpman (1999) notes, these theories are reasonably able to explain the architecture of the global trade network, but depend on the oversimplified assumption of the representative firm. In these theories, a model firm is used to explain the trading behavior of all firms within an economy, an approach that hides the differences between firms that also demand theorization.

Recent work on trade, however, increasingly recognizes the fact that global trade is
concentrated within a few firms, and that the architecture of the global trade network is mainly shaped by *firms’ participation in trade* (the decision to trade, the number of products traded, and the number of countries with which firms trade) rather than *the average amount of trade per firm*. Further, it is becoming commonly accepted that firm heterogeneity is associated with firm participation in trade, which in turn shapes the pattern of international trade flows. In particular, reducing barriers to trade (e.g., through trade liberalization or decrease in transportation costs) alters the organization of firms through adjustments they make in the range of products offered in foreign markets and their decisions about whether to serve foreign markets through trade or overseas facilities (i.e., FDI) or to outsource foreign production (Bernard *et al.* 2007).

Accordingly, since the early 2000s attention has gradually shifted from countries and industries to firms and products as the unit of analysis. This shift has been accompanied by increased availability of firm-level trade data as well as product-level trade statistics in Eurostat and the United Nations COMTRADE databases. Within the empirical literature on corporations and global trade, two topics are commonly addressed: (i) trade participation and firm characteristics and (ii) geographical scope of trade.

Studies examining firm participation in exports have found that exporting firms are generally larger and more successful. Focusing on inter-firm differences within industries, Bernard *et al.* (2007) find that, compared to nonexporting firms, exporting firms are larger in employment and sales, have a higher capital stock to total employment ratio, a higher nonproduction workers to total employment ratio, higher value added per worker, and pay higher wages. Although most of the literature focuses on exports, similar results are found for importing versus nonimporting firms (Bernard *et al.* 2007).

Following Melitz (2003), the direction of causality is not simply from export performance to firm characteristics; more productive firms are better able to overcome the barriers to foreign trade in terms of fixed export costs (i.e., costs that exporting firms incur irrespective of the amount they export). Thus the finding that exporting firms are more capital-intensive and skill-intensive can be related to the fact that exporting forces firms to make use of more advanced technologies in order to cover these costs (Burstein and Vogel 2010; Sampson 2014). Exporting firms also tend to produce higher quality products, typically requiring more skilled workers (Verhoogen 2008), and also higher marketing costs, requiring a more intensive use of nonproduction employment (Arkolakis 2010). Melitz also shows that globalization increases aggregate productivity: lowered barriers to trade through trade liberalization or reduced transportation costs change the landscape of firms. High-productivity firms tend to survive and expand whereas low-productivity firms contract or exit. This shakeout improves average productivity within industries.
The geography of trade

Apart from the fact that most firms do not trade, the majority of exporting firms export only to one country, yet the majority of trade is concentrated in a few corporations exporting many products to many countries. The fixed export costs firms incur when entering a certain country, for example, related to cultural differences or compliance with regulation, vary across export destinations, as do demand for their exports (key to ensuring that profits cover the fixed export costs).

As a result, countries differ in terms of their popularity as export destinations. Eaton, Kortum, and Kramarz (2011) find that: (i) firms are more likely to export to larger markets, (ii) firms exporting to less frequently targeted countries are more likely to export to more frequently targeted countries, and (iii) firms exporting to less frequently targeted countries also sell more in their home country. According to Helpman, Melitz, and Rubinstein (2008), the variation in entry costs across countries also explains why there is no trade at all between many countries. Low demand levels and high fixed export costs can make exports infeasible even for the productive firms that engage in exporting.

Further reading

Corporations or large business organizations are a major focus of interest in economic geography. While they have a longer history stretching back to the nineteenth century in some cases, multinational corporations (MNCs) became recognized as major economic actors in the 1960s and 1970s as the international economy became increasingly integrated. More recently, much of this research has been conducted under the rubric of globalization, with MNCs becoming emblematic of the increased mobility of capital across space, which enables them to shift resources and operations between locations in response to changing economic conditions. Informed also by the neoliberal nostrums of competitiveness and entrepreneurialism, these strategies encourage localities and regions to compete for investment on the basis of cost and flexibility, sparking fears of a “race to the bottom” as wages and social entitlements are ratcheted downward.

The local state also emerged as a distinct object of analysis in the 1970s, defined by one prominent British-based researcher as “both the local presence of the national state agencies, such as the police and courts, and those functions, such as housing and education, that are defined as local responsibilities” (Cockburn 1977, 363). The concept of the local state has subsequently become broader and more diffuse, operating through a range of networks and partnerships involving private interests and voluntary sector agencies alongside traditional government bureaucracies, as signaled by the adoption of the term “local governance.” The geographical definition of the local state can also be somewhat elastic, sometimes encompassing regional government and agencies, suggesting that it might be more accurately defined as the subnational state.

Like their national counterparts, local states play an important role in coordinating and mediating social relations, such as those between capital and labor, but also across other axes of difference such as race, gender, and age. Local states are neither neutral arbiters between the often competing claims of different groups nor the exclusive instruments of any particular group. Rather, as suggested by the strategic-relational approach developed by Jessop (1990), local states incorporate an unevenly structured set of institutional capacities or powers that are more or less open to different groups, depending on the strategies that they adopt toward it. Thus, local and national states have become increasingly skewed and “tilted” toward business and economic interests since the 1980s through the adoption of neoliberal strategies of competitiveness, while the interests of labor and lower-income residents have often been marginalized. At the same time, however, local states remain important sites of contestation and struggle as particular initiatives can spark local opposition and protest.

The nexus of relationships between corporations and local states has been an area of great interest in geography since the 1980s as local states have adopted “entrepreneurial”
strategies based on place promotion and the attraction of external investment. This reflects local states’ roles in mediating and coordinating social relations, particularly in terms of forming partnerships with local business interests and seeking to mold and package local assets such as labor according to the needs of external corporations. Here, local states are key players within the development of local labor control regimes (LLCRs), defined by Jonas (1996, 329) as "relatively stable institutional environment[s] for capital accumulation, albeit circumscribed by struggle and the periodic crises to which capitalism is prone." LLCRs typically involve cooperation between local state institutions and employers to regulate local labor markets and manage wage and work expectations, fostering reciprocities between the realms of production, reproduction, and consumption.

Over time, research on the corporations–local states nexus has broadened away considerably from the original concern with local economic development to cover a wider range of state practices, corporate strategies, and forms of social and political mobilization and struggle. This is reflected in the remainder of this entry, which is organized into three main sections covering corporations, local state strategies, and subnational economic development in the Global North; work on the intersections between labor, corporations, and local state practices in the Global South; and debates on social movements, resistance, and corporations that help to link issues and concepts in the Global North and South.

**Corporations, local states, and economic development**

The effects of economic restructuring and deindustrialization in the 1970s and 1980s created severe unemployment and poverty in many industrial regions of Western Europe and North America. One of the main ways in which local states responded to deindustrialization was by developing new strategies to promote economic development and attract external investment. This is part of a profound shift in the purpose and ideology of local state intervention, famously encapsulated by Harvey (1989) as a shift from urban managerialism to entrepreneurialism. Managerial approaches, prevalent in the 1960s and 1970s, viewed the role of the local state as supporting collective consumption and social reproduction (Cockburn 1977). Urban entrepreneurialism, by contrast, saw localities focus on the need to generate growth and employment. This can be seen as supporting the development of new LLCRs emphasizing the need for workers to be flexible and responsive to the needs of investors.

Urban entrepreneurialism is associated with the development of new forms of local governance based on partnerships between local authorities and business. In many cities in the industrial Rust Belt of the United States, such as Pittsburgh, Detroit, and Boston, local governments and local business interests involved in the exchange of land and property such as developers, construction companies, and realtors came together to promote and redevelop the city through the attraction of external investment. In a highly influential formulation, these interests were described as “urban growth machines,” supported by their shared interest in the expansion of the local economy as the ultimate source of tax revenues and profits (Logan and Molotch 1987). Urban entrepreneurialism is closely associated with intense interurban competition as cities and localities have become “hostile brothers” (Peck and Tickell 1994), engaged in often similar strategies designed to attract corporations and new facilities to their areas.
In the United States, many cities created public–private partnerships to leverage private sector investment and to compete for limited redevelopment funding from state and federal governments. Another key instrument is the establishment of special purpose, business-oriented agencies to regenerate an area. For example, urban development corporations were set up in certain run-down inner city areas of England and Wales in the 1980s. Other measures designed to attract investment by external corporations include the designation of special economic areas or zones offering tax and other financial incentives and simplified planning procedures. A good example of this type of measure are the enterprise zones and special purpose districts established in the United States by local government and the enterprise zones created in the United Kingdom by national government, first in the 1980s and again since 2010. In addition, tax increment financing has been widely utilized in the United States to fund the redevelopment of blighted districts, allowing local states working in partnership with private developers to raise finance by selling bonds which are subsequently paid off by the additional property taxes generated by redevelopment.

Urban entrepreneurialism is also associated with the creation of a new urban landscape, based on the regeneration of former industrial areas (e.g., Baltimore’s Harborplace, London’s Docklands, and Bilbao’s Abandoibarra area). These strategies have created new jobs in sectors such as tourism, retail, culture, and leisure, although many of these jobs tend to be low-paid and part-time, compared to the often better-paid full-time manufacturing employment lost through deindustrialization. In many cases, the benefits of regeneration have failed to reach low-income groups in disadvantaged inner-city neighborhoods or outlying public schemes or projects.

The second strand of literature covered in this section is research on the role of subnational governments and development agencies in attaching and “embedding” inward or foreign direct investment (FDI), focusing mainly on the regional rather than the local scale. Attracting FDI has been a key component of local and regional economic development policy since the 1960s, particularly in old industrial regions suffering from the contraction of traditional industries. The experience of high levels of unemployment has supported the introduction of new forms of labor control involving highly selective modes of recruitment by incoming investors, while also requiring substantial state support for the process of labor market adjustment.

Early studies of FDI in developed economies, however, suggested that inward investment could lead to relations of dependency as local economies became increasingly subservient to the needs of large MNCs. In the 1970s, the term “branch plant economy” was coined to reflect how some of the older industrial regions of Western Europe and North America were being repositioned within the wider space economy of capitalism. The concept is defined by functional truncation due to a lack of higher-status activities such as strategic planning and research and development, limited linkages between MNC plants and the local economy, with many components and materials being imported, and a high degree of external ownership and control.

The negative branch plant stereotype became increasingly questioned in the 1980s and 1990s, however. Compared to the low-skill assembly line activities of previous investments, the new wave of inward investment into the United Kingdom and United States from Japanese and German companies was geared toward the creation of locally integrated industrial complexes that were more firmly tied to their host
CORPORATIONS AND LOCAL STATES

regions. This more optimistic scenario hinges around a number of organizational changes taking place in MNCs themselves in response to globalization, characterized as a shift away from centralized bureaucratic hierarchies to flatter and more decentralized structures, meaning that more decision-making powers and higher-level operations are devolved to local branch management. In these circumstances, it is argued that investment can become strongly embedded in host regions. For instance, the Japanese car manufacturer Nissan set up a manufacturing plant in the northeast of England in 1986 which has expanded to employ over 5000 workers directly and to support a significant regional supply chain. At the same time, regions can use the global knowledge networks of MNCs to upgrade and improve their competitiveness. For example, Japanese branch plant investments in the Great Lakes region of the United States during the 1980s were seen as instrumental in rejuvenating the regional economy, through the transfer of “best practice” management and production techniques to local firms.

The evidence to support such claims is mixed, however, with research finding little evidence of increasing embeddedness in peripheral regions of the United Kingdom (Phelps et al. 2003). At the same time, case study analysis has pointed to the increasing volatility of inward investment and the enduring significance of global market trends and corporate decision-making processes. These long-standing concerns have been reinforced by some high-profile plant closures in peripheral regions of the United Kingdom in recent years, together with the relocation of many facilities to the lower-cost regions of Central and Eastern Europe. The electronics sector has proved particularly vulnerable, with both the German firm Siemens (1100 jobs) and the Japanese firm Fujitsu (600 jobs) closing semiconductor plants in the northeast of England in 1998, while Scotland’s “Silicon Glen” lost around 40% of its jobs between 1998 and 2006. Companies that have relocated from the United Kingdom’s regions to take advantage of lower costs in the Czech Republic include Japanese firm Matsushita (from Wales, costing 1400 jobs) and US firms Compaq (Scotland, 700 jobs) and Black and Decker (northeast England, 600 jobs).

The role of local and regional states in attracting and managing inward investment from corporations can be understood in terms of the concept of “strategic coupling,” which is closely associated with the global production network (GPN) approach in economic geography. Strategic coupling occurs through the activities of local and regional state institutions in shaping and molding regional assets to fit the strategic needs of lead firms in GPNs. Such activities include providing financial support; preparing sites and assisting with infrastructure and services; coordinating the supply and training of labor; developing local supply chains; working to generate technology transfer; and offering a host of “aftercare” services to existing investors. In some cases, this can result in “corporate capture,” whereby MNCs are able to appropriate regional institutional capacities to serve their interests at the expense of other actors such as indigenous firms and workers. This often reflects MNCs’ capacities to engage in regulatory arbitrage, effectively playing off localities against one another to achieve the most favorable deal in terms of financial and institutional support.

Strategic coupling should be seen in dynamic terms, focusing attention on processes of decoupling and recoupling (MacKinnon 2012). Decoupling involves rupturing the relationship between a region and a GPN through plant closure and disinvestment. Recoupling, by contrast, is related to the attraction of repeat investment,
recombining existing plants and regional assets with a new round of investment. Local states will often support local plant management in their efforts to attract repeat investment through a range of direct and indirect services; decoupling typically involves local states undertaking an ameliorative role often involving the establishment of task forces to deal with the effects of closure, particularly in terms of providing support to redundant workers.

The concept of strategic coupling reflects the adoption of a largely positive perspective on FDI and regional development, stressing the scope for cooperation between local states and lead firms in GPNs. As has been emphasized, this is consistent with the strategies of many local states to attract and retain investment. In certain circumstances, however, local states can also play a redistributive role, redirecting resources toward particular groups and areas. This is particularly apparent in the mining sector, where the unprecedented commodity boom of recent years has generated windfall profits for corporations. This has fostered a renewed, if highly uneven, resource nationalism and “resource regionalism” in the form of increased political pressures for revenues to be used to benefit local communities. In the state of Western Australia, for instance, increasing royalty rates levied on the major mining corporations have been distributed to the mining regions of the state through the Royalties for Regions fund. Decoupling and plant closures can also spark contestation and resistance from labor and local residents, exerting pressures on local states. In many cases, local states remain distant from local protest campaigns, but there are examples of local (and national) state personnel supporting these campaigns, such as that opposing the proposed closure of the Nestlé-owned plant of St Menet in Marseille.

Local labor control regimes, corporations, and uneven development

Work on strategic coupling usefully draws attention to the multifaceted and contested nature of relations between corporations and local states. An understanding of such relations can be extended through thinking about some of these relations historically and in the contexts of the Global South. Such a focus can shed light on important aspects of the uneven histories and geographies of cooperation between corporations and local states. Examining the shifting relations between corporations and particular LLCRs offers a useful way of tracing different relations between capital and labor in diverse spatial and temporal contexts.

Colonial labor geographies were shaped by particular, often racialized, relations between corporations, imperial state formation, and labor organizing. This can be exemplified by shipping companies such as Elder Dempster, which held “the monopoly of carrying freight, specie and mail between the UK and the west coast of Africa from about 1910 until the 1930s” (Sherwood 1994, 130). Elder Dempster was just one of a number of shipping companies which, together with local state actors in port cities such as Cardiff and Liverpool, and the National Union of Seamen, practiced unequal and racialized labor practices. The company was notorious for the “gross discrimination” it practiced against seamen of colour “with the connivance of the unions and the government” (Sherwood 1994, 130). Corporations such as Elder Dempster, then, shaped LLCRs which were in part concerned with regulating flows of mobile labor between port cities in West Africa and the United Kingdom. These exclusionary practices were in turn contested by organizations such as the Colonial Seamen’s Association.
In the postcolonial period such exclusionary and racialized geographies of labor were challenged, albeit with uneven consequences. Independence had important effects on the geographies of corporations, not least the collapse of shipping lines in the postindependence context. Further, many postcolonial nations adopted economic policies such as import substitution models directed at “national and subregional markets” (Pérez Sáinz 1999, 116–117). The Cold War context of postcolonial state formation meant that LLCRs could be shaped in important ways by attempts to circumvent left-wing political interventions at the level of the local state. The AFL-CIO, for example, began in the 1950s to fund segments of the Guyanese labor movement that were hostile to the moderate left-wing political leader Cheddi Jagan for fear that he might regain power in Guyana and “turn British Guiana into another Cuba” (Herod 2001, 186). These strategies used new local housing projects “to sway the local working class’s political loyalties” (Herod 2001, 186).

Links between anticommunist US foreign policy and right-wing military dictatorships in Latin America were significant in shaping the emergence of neoliberalism in the 1970s and 1980s, most famously in relation to the neoliberal economic project of Augusto Pinochet in Chile after the ousting of Salvador Allende in September 1973. Anticommunism also shaped many LLCRs in pernicious ways during the 1970s and 1980s in contexts such as Guatemala. Thus in the 1970s and 1980s workers in the Coca-Cola plant in Guatemala City, who were organized through the Coca-Cola Bottling Company Workers’ Union (STEGAC), were at the forefront of struggles to maintain and reproduce a trade union movement in the face of severe repression by successive military dictatorships. These struggles took place in a context where the local state was deeply enmeshed in relations between the military and capital, linkages which facilitated the extreme and violent repression of STEGAC. While the immediate postwar period had seen a massive upsurge of trade unionism in Guatemala, the US-sponsored coup against Jacobo Árbenz in 1954 ushered in decades of repression which drove the labor movement in Guatemala underground. Workers in the Coca-Cola franchise bottling plant in Guatemala City were central in resisting this repression, especially during the 1970s and 1980s:

[STEGAC] suffered more violent attacks in the 1970s than any other single union. Because of this, by 1978 the union had gained potent support from international labor and human rights groups that allowed it to survive in the late 1970s and to persist under military rule in the early 1980s. (Levenson-Estrada 1994, 176).

Such dense linkages between a transnational corporation and particular local political contexts emphasize the need to think about the diverse ways in which corporations and local states intersect. Understandings of processes of neoliberalization, however, have often been narrated in a rather undifferentiated way. Thus Sangameswaran argues there is an important need for ongoing processes to “be analyzed not only with reference to neoliberalism but also other processes at the local, state and national level” (2009, 230). An attention to local state strategies can be a significant contribution to such an approach to neoliberalization. The rejection of economic policies such as import substitution has been integral to economic strategies such as India’s New Economic Policy and embrace of neoliberalism since 1991. This had very tangible effects such as allowing companies like Coca-Cola to operate in the country. Neoliberalization has also been produced through the strategic use of spaces such
as “export processing zones” (EPZs) or “special economic zones” (SEZs).

These zones are configured to directly expand “exports with the introduction of special enclaves subject to duty-free imports and extensive tax concessions. The intention of these quasi-autonomous SEZs is to attract foreign direct investment to set up manufacturing and other enterprises for the international market” (Oza 2010, 243). These sites have been seen as significant for the ways in which they bypass local government. There is evidence that panchayats (local assemblies) and urban local bodies are marginalized from decision-making processes in the siting of SEZs. The incentives enjoyed by corporations locating in SEZs can also have further negative consequences on local states, not least in terms of lost tax revenue.

The uses of SEZs and EPZs have had particular effects in relation to different sectors of the economy, such as the garment sector. They also depend on particular gender divisions of labor. Wills (2005, 1) notes that the “women workers upon whom the garment industry depends for its wealth are largely invisible, increasingly distanced from the major brand-name retailers in the industry by complicated chains of subcontracted production.” Yet these processes can intersect with local labor market conditions where labor is not entirely without some agency.

In the context of free trade zones in Honduras and Costa Rica, Pérez Sáinz argues that managerial hiring strategies intersected with the “contact networks of the workers themselves,” observing that “cases have been identified in which firms have implemented relocation strategies with the aim of securing local labor markets.” Thus “one Costa Rican firm set up its second plant in a rural area in the Central Valley, claiming that in its original location, a Free Trade Zone, the hiring of labor is competitive and sometimes disloyally so” (Pérez Sáinz 1999, 121).

While SEZs and EPZs are spaces where corporations bypass engagement with local states, strategies of neoliberalization have also entailed much more direct linkages between the local state and corporations. This partly reflects the broader reorientation of the local state toward business interests in recent decades. A case in point is the privatization of key utilities in India as liberalization intensified after 1991. Thus in 1992 the Maharashtra State Electricity Board signed a memorandum of understanding with Enron, setting in motion the Dabhol Power project (run by the Dabhol Power Corporation (DPC)), the largest corporate-led commercial venture in Indian history, which also involved Bechtel and General Electric (all US corporations) as venture partners. This was part of a shift from a broadly Keynesian to a liberalized model of electricity supply; until 1991, the Indian power industry had been nationalized. Priya Sangameswaran has observed similar dynamics in the water sector in Maharashtra. She notes that the emphasis of discourses of self-sufficiency in urban local bodies is indirectly providing a push for private sector participation, and compromising the process of decentralization that is also simultaneously under way. Further, as in neo-liberal projects elsewhere, there is an emphasis on changing subjectivities and this has resulted in symbolic changes in the water sector. (Sangameswaran 2009, 228)

Such processes of neoliberalization have been contested. Thus the proposed site for the DPC power plants was the district of Ratnagiri in the state of Maharashtra, but opposition to “the project was triggered by local environmental concerns” generating significant resistance to this major neoliberal project even before it gained official clearance (Ahmed 2012, 1065). This resistance was partly mobilized in relation to local state actors. Thus Ahmed (2012, 1066) notes that activism “in the local communities
CORPORATIONS AND LOCAL STATES

forced a public hearing to be held at the Maharashtra State Secretariat in Mumbai on the 8 and 9 September 1994.” This raises significant questions about the relations between corporations and the local state and articulations of resistance, to be explored in the next section.

Corporations, militant particularism, and progressive localism

Waquar Ahmed’s account of the resistance to the Dabhol Power project argues that the anti-Enron protests started as a “form of environmental and livelihood militant particularism” (2012, 1067). He notes, however, that in this “struggle against a mighty corporation, local communities jumped scales by accessing spaces beyond the local to get publicity for their concerns” (2012, 1067). Through such strategies the campaign sought to connect the “particular struggle of the farmers and fisher-folks to a general struggle against the nexus of exploitative and manipulative global corporation and repressive state” (Ahmed 2012, 1073). The Bharatiya Janta Party (BJP) proved successful, however, in co-opting and colonizing such opposition. Ahmed details how an alliance of Shiv Sena with the BJP, the state-level and the national-level right-wing Hindu fundamentalist parties respectively, directed anger at a Congress state government that was seen as corrupt and supportive of Enron.

In framing the struggle against Enron in these terms, Ahmed draws on Raymond Williams’s account of the relations between militant place-based politics and wider claims for socialism. Williams’s account of “militant particularisms” was developed by David Harvey in his account of the “struggle to create a public and political campaign over the future of Rover’s car plant at Cowley” in east Oxford (Harvey and Swyngedouw 1994, 25). In this context Harvey and Swyngedouw drew attention to a campaign to keep a General Motors plant open in Van Nuys, California, in 1988 which combined “shop-floor struggle” and “wider community movements in this campaign” (Harvey and Swyngedouw 1994, 24). They argued that the way the Van Nuys campaign brought together “unlikely partners” such as “civil rights campaigners, local business people who would suffer from the closing down of the car plant, the women’s movement and local politicians” could serve as a potential model for opposition to the closure of the Cowley plant.

For Harvey, tensions were raised that made difficult a straightforward defense of the Cowley plant, because of its problematic environmental impact and the fact that these were “shit jobs.” Harvey and Swyngedouw’s account of the Cowley plant dramatizes the consequence of unfettered power of mobile capital on communities which they construct as much more limited and settled. Critics of this position, such as Noel Castree and Jeremy Anderson, argue that Harvey and Swyngedouw’s position overemphasizes the unfettered power of corporations in relation to local workers (Anderson 2009; Castree 2000). Yet such debates have frequently rather ignored the agency of the local state as well as the workers.

Indeed, while the local state has often allied itself directly with transnational corporations against local forms of resistance by labor and social movements, there are important cases of local state actors playing significant roles in relation to such resistance. Thus, when workers in Uddingston near Glasgow occupied a factory of the US multinational Caterpillar, protesting plans to close the plant, elements of the local state offered different forms of support to the occupation. The occupation, which lasted for 103 days in 1987, was a high-profile political event in Scotland, with local authorities playing important roles in supporting the occupation.
Glasgow District Council “donated £1,000 directly to the campaign while Councillor Lawrence McGarry of Strathclyde Regional Council’s influential economic development committee promised £10,000 towards the funding of an independent feasibility study of the plant” (Woolfson and Foster 1988, 91–92). There was also strategic use of the local state’s role in welfare provision to support workers involved in the occupation. Motherwell District Council, where there was a district unemployment rate of 18.63% in the month of the closure announcement, spearheaded

the implementation by local authorities of Section 25 of the Housing Benefit Act, which allowed local authority housing departments to give rent rebates to tenants who were Caterpillar workers, as they had also done during the miners’ strike [in 1984–1985]. Those who had mortgages and qualified under the Act, generously interpreted by Strathclyde region, also received rebates. (Woolfson and Foster 1988, 91–92)

The support given to the Caterpillar occupation demonstrates some of the ways in which key local state actors can facilitate and offer important forms of support to militant place-based resistance to events such as plant closures. There also are important examples of the local state adopting a more proactive role, seeking to contest some of the underlying dynamics which have led to such processes of closure. Thus in the mid-1980s, in a context of significant unemployment especially in sectors such as manufacturing, the Greater London Council (GLC) under Ken Livingstone and the Greater London Enterprise Board (GLEB) sought to develop a strategy which they termed “Restructuring for Labour,” which “threatened to curb the power of some of London’s employers” (Massey 2007, 83). Doreen Massey, who was closely linked with this strategy, has argued that it offered a dynamic response to the ways in which “capitalism itself was changing, away from the cost sensitive mass production of Fordism towards smaller-batch and higher quality production.” It also was aimed at producing “room for manoeuvre for improving the conditions of inner-city labor while still remaining competitive – in other words a less degrading strategy for working-class jobs than that on offer from the Thatcher government” (Massey 2007, 83). For critics such as Peter Nolan and Kathy O’Donnell, however, the project overemphasized the agency of local management in London and downplayed the power of large multinationals. This strategy was also produced in a context of entrenched political conflict between particular local state projects and the Thatcherite national state, which eventually resulted in the abolition of the GLC.

These political engagements have long shaped Massey’s influential theoretical interventions on the terms on which places are understood and mobilized politically. In particular, her arguments about a “politics of place beyond place” allow local state politics to be conceptualized in ways which dynamically relate them to wider, unevenly shaped, flows and connections. These interventions are important for locating the local state as part of a strategic engagement with the terms on which corporations act both within and between places. It also opens up possibilities for understanding the ways in which corporations might be challenged as part of post-neoliberal social relations.

There is now a renewed focus on the role that local states can play in fostering alternative development trajectories, in contexts defined by “austerity.” This can involve fostering a distinctly critical attitude to the terms of engagement of corporations with place. It can also emphasize how place-based movements and progressive factions of the local state have the potential to combine in productive ways. A significant
example is recent movements for the remunicipalization of electricity and water provision in major German cities such as Berlin and Hamburg. Beveridge, Hüesker, and Naumann (2014, 66) note that, after 12 years of water privatization in Berlin, a campaign involving local state actors, social movements, and left-wing political parties led to the German energy utility producer RWE agreeing in principle to sell its 24.9% share of the Berlin Water Company back to the city of Berlin in May 2012. The following year, after initial threats of legal action against RWE, the second private partner, French utility Veolia, also indicated that they would be willing to sell their 24.9% share.

They argue that these “decisions mark a remarkable turnaround,” creating the conditions for what was at first presented by various Berlin governments as impossible, then simply unrealistic and irrational – the remunicipalization of Berliner Wasserbetriebe (BWB). This also emphasizes how in a Europe marked by political strategies of austerity there remain possibilities for local state actors to offer different political responses to the postcrisis conjuncture.

Conclusions

This entry has engaged with the multifaceted relations between corporations and local states. It has delineated some of the key ways in which these relations have been theorized by geographers and other social scientists, and discussed the different terms on which these relations are constructed in different contexts. Further, attention has been drawn to the ways in which these relations can be configured in different ways and actively challenged, even if it would appear that local states have been reconfigured and reoriented toward business interests and corporations since the mid-1980s. The entry has also sought to engage with the mutating/changing terms on which these relations have been produced, particularly in relation to the evolution of neoliberal projects over time and across space.

In “austere” times it is tempting to see the possibilities for “local states” to challenge corporations as severely limited. In many cases this is clearly the case. However, it would be wrong to subscribe to a straightforward teleology of increasing neoliberalization. Austerity is itself an uneven project, with geographically uneven consequences, partly in relation to differentiated local contexts, often having the most adverse effects on disadvantaged localities which lack the resources and connections to navigate this latest form of crisis. At the same time a withdrawal of local state support and investment is not the only possible strategy within a political conjuncture defined by “economic crisis,” as indicated by the remunicipalization of services in German cities. This suggests that there are possibilities for forms of “progressive localism” that seek to and can involve the local state in challenging uneven power relations and, in certain contexts, the power of corporations, and in so doing generate outward-looking strategies that build connections with other places, through, for instance, various forms of public–public partnership.

Corporations and the law

Joshua E. Barkan
University of Georgia, USA

Much of the geographic research on corporations has examined the ways companies organize the production and distribution of goods across the spaces and territories of capitalist economies. Legal rulings and regulations are integral to this process, yet the geographic study of corporations and the law remains in its infancy. Nevertheless, the law provides an important avenue for research on corporate geography, particularly under conditions of economic globalization. Because laws and legal systems are almost always produced, implemented, and enforced within the boundaries of specific political jurisdictions, the attempt to shape and regulate socioeconomic relations that are increasingly transnational is fraught with tensions and contradictions. For this reason, laws play an important role in constituting the uneven landscape of contemporary corporate capitalism.

Although contemporary interest in corporate geography focuses almost exclusively on business firms, corporations were legal entities long before they were used for capitalist enterprise. In Western law, legal definitions of corporations date back to the ancient fellowships, leagues, societies, colleges, and guilds of classical Greece and Rome. These associations were created for a wide variety of social purposes including the carrying out of religious rituals, the organization of social and occupational classes, and the undertaking of public duties and administration (Radin 1910). Moreover, the religious conception of corporations as collectives of believers persisted after the rise of Christendom, with a variety of Christian sects organized in corporate forms. The Roman Catholic Church itself was conceptualized as a corporation under the Pauline term corpus Christi, which united believers into a unified body with Christ as its head. Ernst Kantorowicz (1957) has described how this religious image of the church was transformed during the twelfth and thirteenth centuries into the corpus mysticum. This new conception incorporated the sociological and administrative capacities of the church into a single body that encompassed “Christian society as composed of all the faithful, past, future, present, actual and potential” (Kantorowicz 1957, 195). Most importantly, it was this image of the corporation that provided a template for early modern political and legal theorists to conceptualize secular states as corporate political bodies led by secular rulers and monarchs rather than Christ.

The treatment of associations as corporate bodies meant that these collective institutions were treated as persons within the scope of the law. Although there are continuous debates concerning the nature of corporate personhood as either real (and therefore equivalent to natural persons) or fictitious (and therefore created by a legal authority), the organic metaphor established a collective subject of the law whose existence transcended the life or death of any individual member. What thus unites Roman collegium, monastic orders, early modern states, and even modern business corporations is that any individual member of these corporate bodies can leave these associations without threatening the legal standing of the association as a whole. In this sense, the primary importance of the
CORPORATIONS AND THE LAW

corporation is to provide a consistent legal designation for a group across time that enables them to pursue and accomplish some legally defined end.

If the temporal aspects of the corporate legal form were central to its development, so too were its geographic dimensions. Yet the relationship between the corporate legal form and space or territory was far less consistent than the relationship between corporations and time. Advocates of the natural entity theory of corporate personhood argued that the corporate nature of associations preceded the establishment of either the state or the law. In this sense, associations might have organic relationships to land that were only retroactively recognized by states through legal designations of property and territory. For instance, Otto von Gierke, the nineteenth-century political theorist and major proponent of the natural entity of corporate personhood, focused on the long history of German fellowships, arguing that they emerged out of the collective life of German communities during the medieval period and therefore antedated both the emergence of modern nation-states and the incorporation of Roman law into German legal codes. Many of these fellowships, such as corporate towns and “city commonwealths,” were geographically circumscribed and connected with specific places. In this sense, land could be an organic component of the corporate entity, but the jurisdictional dimensions of these corporations were secondary to the broader social relations that had produced the associations (see Gierke 1990).

In contrast, artificial entity theories, including the grant theory that shaped the initial development of Anglo-American corporate law, argued that corporations were creations of sovereign authority. Sovereigns issued grants to groups of individuals to encourage them to undertake actions that were deemed beneficial for the state and beyond the scope or capacity that any individual could accomplish. Corporations were created for a wide variety of purposes, such as philanthropic organizations, educational and religious institutions, and towns, as well as institutions for banking, transportation, and trade. Because corporations were viewed as creations of law, their legal standing – including their abilities to hold property, to sue and be sued, and to enter into contracts – was confined to locations in which the authorizing sovereign’s legal system was recognized. Sir Edward Coke famously codified this definition as part of the “essence” of incorporation in the 1612 Case of Sutton’s Hospital, arguing that corporations were always “of a place, for without a place no incorporation can be made.” Geographic elements were designated in the charters and “letters patent” that created corporate entities, and one of the primary purposes of incorporation was that it allowed for members to hold property collectively, including but not limited to land, under the common name and seal of the corporation.

For corporate institutions such as towns or hospitals, which were located in specific places, such geographic designations were fairly straightforward grants of property to corporate entities. Corporations whose enterprises spanned multiple distinct jurisdictions, however, could not rely on their chartered grants alone. This was especially the case with the European imperial companies of the seventeenth, eighteenth, and nineteenth centuries, whose participation in the project of European colonialism brought them into legal relationships of conflict and compromise both with representatives from multiple European states – including their home and foreign governments, along with other competing corporate entities – and with local rulers in the areas that European powers were seeking to colonize. For this reason, the development of international law, which coincided with
the growth of the imperial corporations, gave special consideration to the legal regulation of chartered corporations operating outside of the states in which they were chartered and, often, in international spaces such as the seas that were not under the *dominium* of any other recognized European state. For instance, Hugo Grotius, generally considered as the founder of modern international law, articulated the concept of the freedom of the seas as part of his defense of the Dutch East India Company’s appropriation of trade routes in Asia. In terms of the legal rights of corporations on land, Grotius argued that corporations had rights to appropriate territory that was not being used by its owners. Although foreign sovereigns had a right to police persons, including corporate persons, that entered their jurisdiction, they had no right to prevent them from occupying lands that were considered unused or “waste” (see Tuck 1999). In this manner Grotius’s legal arguments helped facilitate the colonization of indigenous lands by Dutch chartered corporations.

The treatment of foreign corporations in international law also shaped the development of corporate law and the corporate economy in the United States. Much of the initial British colonization of North America was carried out by chartered corporations and many of the colonies were governed under corporate charters. After the US War of Independence, the power to create corporations was reserved for state governments as corporations shifted from quasi-public entities of government to private entities created by contracts between states and shareholders. States chartered corporations to carry out much of the work of local development, including the construction of roads, bridges, and railways, the administration of poor relief, the organization of intellectual, educational, and religious institution (such as learned societies, universities, and churches), the government of cities and corporate towns, and the organization of business and manufacturing. Because individual states were considered independent sovereigns in their capacity of chartering corporations, US federal jurists turned to principles developed in international law to help regulate corporations that engaged in business outside the jurisdiction in which they were chartered. As with international law more generally, the regulation of foreign corporations in US courts through the nineteenth century facilitated the expansion of the corporate economy, with states generally recognizing foreign corporations outside of their home jurisdictions except in those rare cases where local state legislatures explicitly prohibited them (see Henderson 1918).

By the turn of the twentieth century, however, local forms of corporate regulation grounded in the issuing of charters were wholly insufficient for regulating a dramatically expanding economy. Liberal general incorporation laws by states such as New Jersey and Delaware provided easy access to the privileges of the corporate legal form, complete with limiting the liability of investors and authorizing holding companies. Moreover, political concerns over the growth of cartels, monopolies, and trusts in key industries such as sugar, oil, meatpacking, tobacco, and, most importantly, the railroads gave rise to new forms of corporate regulation. Beginning in the 1880s, the US federal government undertook a variety of regulatory steps to control corporate consolidation, including the regulation of railroad rates through the Interstate Commerce Commission in 1887; the creation of administrative agencies to gather economic information and make policy, such as the US Industrial Commission in 1898, the US Bureau of Corporations, and the Department of Commerce and Labor in 1903, and the Federal Trade Commission in 1914; the institution of antitrust laws via the Sherman Anti-Trust Act of 1890; and, finally, a series of
regulations on banking and finance as part of the New Deal, including the Glass–Steagall Act of 1933 and the creation of the Securities and Exchange Commission in 1934. Unlike earlier forms of corporate regulation that controlled corporations directly, through the mechanism of the state-issued charter, federal regulation focused on controlling the effects of corporate consolidation in the market and, primarily, in terms of prices. Forms of consolidation that hurt competition and artificially raised prices for consumers were targeted for regulation, although some limited monopolies were permitted in areas like public utilities and railways, where unrestrained competition might jeopardize the industry in its entirety. Key components of this regulatory compromise, which Martin Sklar (1988) has called the “corporate reconstruction of American capitalism” or more simply “corporate liberalism” and that geographers most commonly refer to, with a slightly different emphasis and historical timeline, as “Fordism,” held sway in US economic regulation up to the deregulatory movement associated with neoliberalism beginning in the 1970s.

What is critical about this story from a geographic perspective is that, in the context of the US economy, the federal government supplanted the localized form of early corporate regulation with a national project designed to promote the growth of corporate capitalism while limiting its anticompetitive tendencies. In other words, corporate liberalism depended on the national jurisdiction of federal law and administration to match the increasing geographic scope of the corporate economy. Yet, in terms of the international or global economy, there was never a globally coordinated system of law or regulation that could even provisionally stem the crisis tendencies of global capitalism. Instead, the last 100 years have witnessed the rollout of a variety of provisional measures and regional attempts to address specific aspects of corporate regulation. From the grand projects of economic regulation associated with international institutions – such as the League of Nations’ attempts to unify private international law, including the legal definition of corporations, beginning in the 1920s, or, later, the New International Economic Order’s struggles at the United Nations during the 1970s and 1980s to produce legally binding corporate codes of conduct that would protect the economic sovereignty of “third world” states—to the long history of bilateral and multilateral treaties, agreements, and compacts designed to regulate trade and industry, the modern international order has never had a standardized approach to corporate regulation. Like all international economic activity, corporate-led globalization transpires in an economic space governed by the uneven relations between international actors and institutions, including states, corporations, and global, transnational, and regional agencies. With respect to the legal definitions of corporations, however, fundamental issues such as their nationality or domicile and their responsibilities to conform to regulations issued by sending and receiving states, as well as international law more generally, continue to be debated by scholars and litigated in courts. Likewise, the investment decisions of multinational corporations are shaped in important ways by the uneven nature of the global regulatory landscape. Corporations regularly engage in regulatory arbitrage to find more profitable environments for their activities. Finally, in light of the challenges of global legal regulation, the international community has come to focus on “soft law” approaches to regulation that emphasize voluntary norms over legally binding codes, such as the guidelines concerning corporate social responsibility articulated in the United Nations Global Compact.
Given the wide range of contemporary issues involving the intersections of corporations, law, and geography, a comprehensive account of current themes, much less their different treatment in disciplines such as law, geography, and political science, is beyond the scope of this entry. Moreover, because the regulatory landscape associated with economic globalization is dynamic, detailed empirical accounts only capture snapshots of a constantly shifting terrain. Nevertheless, there are some persistent topics involving corporations and the law that are particularly central to the concerns of human geography. In terms of global issues, these include the transnational regulation of corporations and corporate activities in domains such as taxation, finance, labor, and the environment, broader questions about corporate social responsibility, and the responsibilities of corporations for the protection of human rights (see, generally, Crane et al. 2008; on taxation see Avi-Yonah 2000). These issues intersect with more geographically localizable concerns, such as the relations between corporations and indigenous communities (a particularly important topic in discussions about the human rights obligations of corporations) or the role of corporations in structuring and governing various places of production, from the increasingly ubiquitous export processing zones to the enclaves associated with diverse types of resource extraction (see Sawyer 2004). In addition, there are a host of topics that concern political questions about corporations, ranging from the legal basis of various forms of privatized government under both imperialism and neoliberalism to the extensive use of private corporations in military and police actions (Freeman and Minnow 2009; Mbembe 2001; Singer 2003).

Noticeably, these topics are either treated by legal scholars, on the one hand, or by geographers and other critical social scientists, on the other, but rarely in consort or conversation with one another. Thus much of the ethnographic study of the politics of capitalist production happens with little consideration of the legal dynamics that are essential to understanding issues like the mobility of capital or the structure of industrial relations. Likewise, legal discussion about attempts to harmonize corporate regulations of labor, the environment, or taxation often transpire without careful consideration of the geographic dimensions of these problems, operating not just between distinct national jurisdictions but with scalar dynamics as well. Future research on corporations and the law from an explicitly geographic perspective could address both of these gaps, while also giving much greater attention to the domain of legal politics and the politics of law in structuring social and spatial relations of capitalist economies. Research is also needed on the treatment of corporations, law, and economy in diverse legal traditions. Although there is a great deal of scholarship on the development of the corporation in European systems of common law and civil law, there is little comparative or integrative scholarship that examines other corporate entities in non-Western legal systems or the ways that non-Western corporate entities developed through colonial encounters of European and non-European legal cultures.

Corporations and the Anthropocene

Martin Perry
Independent research contractor, New Zealand

The Anthropocene is a controversial term used to distinguish the period of geologic time over which human populations are having the biggest influence over the planet’s environment in terms of atmospheric, geologic, hydrologic, biospheric, and other Earth system processes. The term has been proposed for formal adoption by the International Union of Geological Sciences (IUGS), the professional organization in charge of defining the Earth’s time scale. The IUGS has convened a group to advise it whether to officially declare that the world is currently living in the Anthropocene. Meanwhile, the Earth remains officially in the Holocene, the geological epoch starting from the end of the last glacial period around 11 700 years ago.

A potential start date of the Anthropocene is when humans had their first irreversible environmental impact affecting a natural ecosystem. This would date the beginning of the Anthropocene to about 50 000 years ago in the Pleistocene epoch and prior to the commencement of the Holocene. This was when humans contributed to the mass extinctions on most continents of megafauna such as mammoths and giant kangaroos. While significant in changing ecosystem dynamics, this impact may be considered modest in terms of its capacity to exert a geological impact. The next potential start date brings the Anthropocene forward by about 42 000 years to the time when humans began to practice various forms of agriculture. With agriculture came extensive land clearing achieved mainly through fire, which had atmospheric impacts as well as causing soil erosion of some land cleared of vegetation. Such change is significant but is also a product of natural processes as lightning produces fires too, so making the early Anthropocene hard to separate from the post ice age epoch.

The industrial revolution and its evolution into the atomic age are the prime candidates for identifying the onset of the Anthropocene. This is the start date favored by Paul Crutzen, the Nobel Prize-winning scientist who first caused substantial interest in the onset of the Anthropocene. The term itself is traced to Andrew Revkin and his 1992 book, Global Warming: Understanding the Forecast, in which he discussed how human contributions to climate change had created the “Anthropocene.” Crutzen suggests the term Anthropocene originated when he gave a conference presentation in 2000: “Where someone said something about the Holocene … I suddenly thought that this was wrong. The world has changed too much. So I said: ‘No, we are in the Anthropocene.’ I just made up the word [constructed by combining ‘anthro’ (human) and ‘-cene’ (epoch)] on the spur of the moment. Everyone was shocked. But it seems to have stuck” (Pearce 2007, 21). Further justifying the use of the term, Crutzen (2002) went on to say that: “The Anthropocene could be said to have started in the late eighteenth century, when analyses of air trapped in polar ice showed the beginning of growing global concentrations of carbon dioxide and methane.” Beyond the contribution to changing the mix of atmospheric gases, the first nuclear weapon test on July 16, 1945, is viewed as a further definitive
CORPORATIONS AND THE ANTHROPOCENE

step into the Anthropocene with the release of unique isotopes across the globe.

Critics of the concept argue the distinguishing feature of the present century may not be the widespread existence of global environmental pressures – 2 billion years ago cyanobacteria oxygenated the atmosphere and powerfully disrupted life on Earth – but the greater consciousness of the impacts of human activity on the environment. Epochs revealed by the Earth’s geologic record encompass millions of years whereas the existence of the Anthropocene is influenced by the perception of what people’s impact on the environment might be as well as what has resulted to date. The environmental journalist Fred Pearce (2007), for example, argues for the Anthropocene by referring to the possibility of critical thresholds being crossed that will result in abrupt global environmental change. Human-induced global warming has potential to create lasting environmental change in this way but it remains possible that variations in solar eradiation or the onset of massive volcanic and tectonic activity might ultimately define the post-Pleistocene period.

Regardless of whether the Anthropocene is accepted officially, the term is being used to reflect the widespread agreement that human populations are having impacts on the environment at the scale of the planet as a whole. Considering this and the evidence of a significant acceleration in human impacts since the industrial revolution, there are two main reasons to single out corporations as disproportionately responsible for changing the planet’s environment. First, economic power is concentrated in large corporations who are responsible, directly and indirectly through the businesses that serve corporations as suppliers and subcontractors, for the largest share of environmental impacts. Second, corporations exert influence across the political and economic environment to perpetuate a system that enables their continued dominance and precludes the emergence of more sustainable forms of economic activity that might lessen further human impacts on the environment.

The economic and technological power of corporations

Saleem Ali, in his commentary on the history of human relationships with the Earth’s resources, records how a sign by the entrance to the National Mining Museum, Leadville, USA reads: “More minerals have been consumed since the start of World War II than in all of the rest of human history” (Ali 2009, 8). He cites evidence from the USA Geological Survey that from 1975 to 1995 total consumption of materials increased by 67% in the United States. Arguably of more significance for the possible onset of the Anthropocene, the amounts of material used by weight had moved from 50% renewable in 1900 to only 8% renewable in 1995. The Bingham Canyon mine in Utah, USA, is one visible symbol of this consumption boom: the world’s single largest human excavation. Opened in 1906, the mine now measures around a mile deep and 2.5 miles across. The Grand Canyon is of similar depth and up to 18 miles wide but, as Ali observes, it took 6 million years for the Colorado River to carve the Grand Canyon; it took 100 years for humans to excavate the Bingham Canyon mine.

As well as the growing scale of material consumption, the last century has seen a growing diversity in the range of materials consumed. At the beginning of the twentieth century, around 20 elements of the periodic table were exploited for commercial product manufacturing. At the end of the century, manufacturing drew from all 92 of the naturally occurring elements and incorporated some of them in entirely novel
CORPORATIONS AND THE ANTHROPOCENE

materials such as various types of plastic and carbon composites created through intricate production processes involving hundreds of material inputs. Such materials have proved to be particularly persistent in the environment as they do not decay as readily as natural materials that can convert back to their elemental origins. A consequence is seen in the way that oceans have become repositories of discarded plastics that accumulate in concentrations created by the oceans currents, such as the north Pacific subtropical gyre between Hawaii and the California coast. In this part of the Pacific it is estimated that the volume of human-made materials (principally plastic fragments) accounts for six times that of naturally occurring oceanic zooplankton.

With the demand for energy to fuel economic growth has come an even more rapid growth in carbon emissions, increasing from 1500 million tons annually in the 1950s to around 7000 million in the 2010s (Marland, Boden, and Andres 2008). This is reflected in the increased concentration of carbon dioxide in the atmosphere: almost 400 ppm from approximately 300 ppm prior to the onset of industrialization, with this increased concentration generally accepted to be the cause of an increase in global temperatures of about 0.74°C over the past century (NASA 2011). As well as changing the Earth’s biosphere, rising sea levels, and shrinking ice coverage, global warming is linked to changes in the alkalinity of the ocean as a result of acidification by anthropogenic carbon emissions (Steffen 2011).

There is no precise accounting of the sources of these environmental changes. The responsibility of corporations is inferred from the coincidence of the increasing concentration of economic power in a comparatively small number of big businesses that operate with global reach alongside the deteriorating state of the Earth’s environment. This global reach is exercised through both the ownership of business assets around the world and their control of global supply chains by means of which notionally independent businesses are configured to serve a corporate customer. Moreover, the concentration of economic power is particularly high in sectors that have the greatest environmental impact, including mining, energy, chemicals, transport, and food.

The political power of corporations

More than their direct impact on the environment through resource extraction and pollution, corporations are accused of having so much power that they are able to “capture the state” (Korten 1995) and “rule the world” (Monbiot 2000). This accusation alludes to the way that corporations have more influence over patterns of development than it appears many national governments do. This influence has been linked to what has been called the “transnational power of withdrawal” (Beck 1997). By encouraging a perception that their operations are highly mobile, corporations are said to gain negotiating power over nation-states. The outcome is not necessarily reflected in governments simply consenting to the demands of corporations, who may decide that a better strategy is to allow governments to regulate their activity and then find ways of mitigating the impact of the regulation by identifying loopholes and means of compliance that do damage to their core strategies. An information asymmetry between the regulator and corporations, created by the corporation’s ability to control operational and financial data measuring various dimensions of its performance, its ability to draw on its worldwide resources, and its global mobility, can make it hard for governments to achieve their intentions through laws and other regulations. Moreover, the extent to which people and organizations have come to depend upon the
benefits created by corporations makes it hard to envisage alternative futures without them.

Geographers such as Peter Dicken (e.g., see Dicken 1997, 2011) argue that corporations are extremely diverse in their size and characteristics and that this should caution against treating them as a monolithic group yielding enormous power. Most large transnational corporations operate in only a small number of countries outside their region of origin and even those with extensive international operations tend to retain a home base. They tend to be national firms with overseas operations rather than truly placeless institutions. Having a home base means that corporations do not evade all forms of national regulation simply by locating activities overseas: the US Foreign Corrupt Practices Act 1977 and Alien Tort Claims Act 1789 are examples of national law extending to the overseas operations of transnational companies. Similarly the power of corporations needs to be judged against their need to adapt to shifts in technology, organizational opportunities, and markets. To survive, even big corporations must be learning institutions, and economic geographers see this as a key reason why most transnational corporations retain a national identity. Learning is something that both embeds corporations within their home country and drives them to seek integration within the social, economic, and political fabric of that place. Corporations may actively seek to shape the institutional and regulatory environment of their home country and may use their global reach to evade national regulation, as where they relocate their tax domicile away from the places where activities are actually conducted, but they are also to some degree carriers of the changing social and political environment of their home country. This is reflected, for example, in the tendency for transnational corporations to vary in their commitment to environmental and social responsibility according to the emphasis placed on these issues in their home country.

Geographers also point out that the power and influence of corporations is not simply a product of corporations extending their global reach: intensifying competition between nation-states also is part of the context. States compete with each other to enhance their international trading positions and to capture the economic benefits of international trade and investment from competitor nations. This is reflected, Peter Dicken argues, in governments deregulating aspects of their economies partly targeting sectors such as financial services and telecommunications where prospects for enhancing their share of global industries is thought to exist. Cooperation between states in the formation of regional trading blocs is another manifestation of inter-state competition. Trading blocs vary in their administrative form and objectives but providing an attractive environment for transnational corporations is typically part of the agenda. Where individual countries come together in a trade bloc, the greater ease of cross border transactions enables some corporations to grow and use their scale to expand globally.

The weakness of inter-governmental institutions for managing the global environment has been exposed as corporations have grown in importance. As discussed by Michael Blowfield and Alan Murray (2008), a governance vacuum at the global level is evident in the absence of entities with clear responsibility or accountability for issues such as human rights, poverty, or the management of the global commons. The entities that do exist, such as the World Trade Organization, are viewed as overly influenced by the interests of the wealthiest nations, or as limited to promulgating principles of good practice and promoting dialog but with limited means of enforcing change. In 1999, for example, the United Nations announced its Global Compact
to bring companies together with UN agencies, labor organizations, and civil society to promote responsible corporate practices and encourage compliance to UN development and environment goals. The Compact has succeeded in gaining affiliation from over 7000 businesses including most of the world’s largest corporations but questions remain over whether it is succeeding in changing business behavior (Rasche 2013).

Corporations and green growth

Partly encouraged by the UN Global Compact, statements of commitment to corporate social responsibility and sustainability are now commonplace among big businesses. Claims of a commitment to “zero waste,” “100% renewable energy,” “zero toxics,” “zero deforestation,” and “100% sustainable sourcing” are among the bold promises being made by major multinational companies such as Walmart, Nestlé, Nike, McDonald’s, and Coca-Cola. Yet it is not easy to disentangle the significance of the steps being taken from the rhetoric of corporate responsibility. A general judgment is that the steps being taken are more about helping big businesses to continue to grow than about promoting environmental protection (Dauvergne and Lister 2013).

Beyond the individual initiatives of corporations, there is a possibility that future economic growth can be “green.” The Organisation for Economic Cooperation and Development (OECD 2011) explains the concept of green growth as fostering economic growth and development, while ensuring that natural assets continue to provide the environmental services on which life depends. Exemplary activities seen as contributing to green growth include renewable energy, smart electricity grid technologies, biofuels, and improved recycling processes. As well as such technological innovation, the OECD recognizes that there is a requirement for environmental externalities and market failures to be more fully incorporated within economic decision making, to incentivize companies to adopt green technologies. The green growth agenda relies on the assumption that business will substantially reduce its impact on the environment once an appropriate price has to be paid for the use of the environment. Experience with carbon credits and emissions trading indicates that corporations accept this approach, but that such market-based approaches to controlling environmental challenges are hard to design in ways that remain effective (De Freitas and Perry 2012; Perry 2015).

Transnational civil society, in the form of transnational social movements, global mass media, and local grass roots groups is seen by some to be a potential counterweight to the power of corporate globalization. In this context, civil society refers to forms of social organization leading to collective action that exists above the scale of the individual but below that of the state. One attempt to quantify the scale of transnational civil society identified around 20,000 transnational nongovernmental organizations of which 27% were concerned with human rights issues and 14% with the environment, with women’s issues accounting for the next largest grouping (Willetts 1998). Although lacking the financial resources of the corporations that are the main target of much transnational activism they have proved effective where their campaigning has threatened the brand value and reputation of corporations. This is possible because much of the dominance of corporations relies on carefully constructed marketing and image generation, particularly in the case of corporations that directly serve end-consumers as compared with corporations that have a largely business clientele. Especially in areas bearing a potential environmental or
public health impact such as the chemical and food industry, the public have become more open to claims of corporate wrongdoing.

Campaign groups can succeed where environmental issues are turned into a competition for public attention rather than a reasoned discussion of available options. A paradigmatic example of the challenges that a publicly exposed corporation may face from transnational campaign groups is the 1995 controversy between Royal Dutch Shell and Greenpeace over the disposal of the Brent Spar oil-storage tank. Greenpeace succeeded in painting Shell as an environmental villain in the minds of consumers and many elected government officials, even though Shell had selected the best environmental disposal option and Greenpeace’s estimates of the volume of toxic waste involved were wrong. This case illustrates how even operating within the law may not provide corporations with necessary legitimacy to maintain public support. Yet it also illustrates the weakness of transnational campaign groups that depend on mobilizing public opinion against corporations. When public opinion is influenced more by perception than a rational assessment of available evidence it becomes challenging to effect concerted change based on systematic evidence of the relative importance of different environmental challenges to humankind’s future. Anti-corporate campaigning can be successful in individual cases, but has yet to demonstrate capacity to bring systematic change on a scale matching the concerns informing the Anthropocene.

Corporations and the nation-state

Henry Wai-chung Yeung
National University of Singapore

As two discrete concepts, corporations and the nation-state have been well studied in economic and political geography. Putting them together necessitates a significant reorientation in both subfields, however, toward a new geographical understanding of uneven capitalist global economy. According to Sheppard (2011), this new understanding can be described as geographical political economy. Grounded in the subfield of economic geography, this entry attempts to trace the growing importance of corporations or firms, the nation-state, and their relationships (firm-state) in contemporary geographical research since the late 1960s.

In retrospect, corporations did not receive substantive analytical attention in economic geography until the emergence of the geography of enterprise approach in the late 1960s and the early 1970s. The nation-state and its manifold relationships with corporations came to the forefront of geographical interests only in the late 1980s. In his Roepke Lecture at the 1989 annual meeting of the Association of American Geographers, Brian Berry (1989, 2) declared that “I believe that nation-states are primary agents shaping the economic geography, drawn together by other global actors – the multinationals that link the global economy.” This was his “realist” moment, reflecting then, and still now, a dominant intellectual paradigm in international relations and international political economy that places an overriding emphasis on the competitive and rational power politics of the nation-state in shaping the global economy. To him, corporations, including multinationals, are economic actors embedded in territorially bounded cultures or worldviews predetermined by the nation-state. These embedded economic actors then interact with nation-states to produce the comparative geography of the global economy.

By the mid-1990s, this firm–state interactive nexus had been firmly established as one of the central problematics of economic geography (the others including “geographical industrialization” and “industrial districts and clusters”). Described by Peter Dicken (1994, 101) in his 1993 Roepke Lecture as “exciting and challenging times in economic geography,” geographical analyses of these firm–state interactions along the global–local power nexus provided a very fruitful way forward for understanding economic globalization and its highly uneven consequences. These research agendas considerably influenced the dynamic development of the subfield in the subsequent two decades.

This entry has three principal sections. It first revisits the role of corporations in the emerging geographical political economy. It then examines the role of the nation-state as a regulatory and promoter of corporations in distinctive capitalist political economies. The final section focuses on the territorial embeddedness of foreign firms and a relatively new phenomenon in the complex firm-state nexus – the globalization of national capital in the form of sovereign wealth funds. The entry ends with a brief note on future research directions for studying the geographical political economy of these evolving firm–state relations.
Corporations in geographical political economy

While Weberian location theory dominated industrial and economic geography in the 1950s and the 1960s, little analytical attention was given to corporations because the primary objective was to identify the least-cost location of particular industrial activity. Having inherited many assumptions from neoclassical economics, such as perfect competition and information, profit maximization, and economic rationality, this Weberian geography approached corporations as a locational “black box” responding to competitive initiatives in accordance with the law of diminishing returns (i.e., production costs and market incentives) and producing economic outcomes in space.

By the late 1960s, there was a growing discontent with this Weberian theory on industrial and economic geography. The neglect of the organization of corporations was particularly frustrating. As noted in Storper and Walker’s (1989, 125) *The Capitalist Imperative*, “Neoclassical economics and Weberian geography beg the question of organization by treating the market as the mediator of all economic transactions, the plant as a production function, the firm as single plant, the industry as made up of representative firms producing a single product, and the region as a blank slate on which firms individually pick out the best spots to locate.”

This major dissatisfaction with location theory prompted a new behavioral approach after the late 1960s in the form of the geography of enterprise or “corporate geography.” The object of investigation in the geography of enterprise was neither an industry nor a region consisting of a large number of anonymous corporations. It was rather the single firm or a small number of representative firms or plants. During the 1970s, research in the geography of enterprise was primarily preoccupied with the motivations, locational decisions, and adjustments of individual corporations. Five interrelated fields of geographical inquiry characterize this behavioral approach (Hamilton 1974, 6).

1. The traditional problem of selecting the initial location of the industrial firm and its manufacturing plant.
2. The spatial forms and implications of the growth and changing organization of the corporation.
3. The corporation’s decision-making procedures employed in, and motivations for, choosing any kind of locational behavior.
4. The spatial adjustment by corporations to their existing or chosen environments or in changing the size or use or relative importance of existing plants or facilities within their control.
5. The comparative spatial behavior of corporations of different organization and scale, of industrial organizations in contrasting economic and social systems, and of corporations in diverse cultural environments.

This behavioral approach did not go far enough, however. Much of the research remained dominated by neoclassical approaches. While continuous transformation was occurring within the geography of enterprise approach, the late 1970s and the 1980s also witnessed an upsurge of a radical Marxist interpretation of geographical industrialization eloquently summarized in Storper and Walker (1989). But corporations and their relations with the nation-state continued to receive insufficient analytical attention.

During the 1980s, corporate geographers became much more aware of the weaknesses of the earlier corporate growth models and branch plant literature, in particular the separation of the
corporations from its structural and institutional environment. Growing analytical emphasis was paid to the spatial organization of corporations, as shaped by the interaction between the structural and institutional context of the corporation and its strategic predisposition.

The corporate growth approach in the geography of enterprise also was inadequate in its conceptual accounts of the structural context in which corporations were (re)produced. Although environmental factors were explicitly analyzed, these were conceptualized mainly in terms of interfirm competition and consumer markets. There was a serious lack of attention to inherent and asymmetrical power relations in intra- and interfirm corporate networks. Given any specific environmental context, theory gave far too much autonomous power to decision-makers in these corporations, an unintended consequence of its conceptual foundation in the behavioral approach. Spatial outcomes were merely expressed as a result of corporate strategies. Corporate actors were conceptualized as making decisions as if there were no institutional impediments and power struggles with other actors, such as the nation-state and nonstate organizations.

The role of the nation-state in shaping the territorial outcomes of corporate growth was mostly neglected. In his reappraisal of corporate location theory, Berry (1989, 3) argued that “[w]hile much is being written about multinational decision making, much less has been codified about the role of the nation-state in the new locational calculus.” Even when nation-states were mentioned in the branch plant literature, the intimate relationships and mutual coexistence between corporations and nation-states were only mentioned in passing, with little in-depth theorization of these complex firm–state relationships.

By the turn of the 1990s, leading scholars in the geography of enterprise were making a much stronger plea that “[w]e are perhaps approaching the end of the beginning; we are certainly not at the beginning of the end” (Dicken 1990, 243) and that “there is a real and continuing need for research into the ‘geography of enterprise’ and not just at the margins of economic geography” (Dicken and Thrift 1992, 288). Most importantly, the theoretical and empirical frontiers of research in this branch of corporate geography were redirected toward the firm–state nexus and the territorial embeddedness of business organizations. Both of these research foci were explicitly structural and institutional, approaching the sort of geographical political economy characterized in Sheppard (2011). The aim was to elucidate the complex ways and processes in which corporations interact with nation-states and become (re)produced in localized territories. As detailed in the next two sections, this shifting nature of conceptualization and empirical investigation presented an exciting challenge to corporate geographers who were increasingly interested in an emerging form of geographical political economy.

The nation–state as a champion of “national champions”

Since the early 1990s, the firm–state nexus has emerged as a leading frontier in geographical political economy. The nation–state is no longer an “environment” or “context” in which corporations thrive/wither and the global economy prospers/declines; it is rather the key architect of economic globalization and changing global economic governance. Despite the dire predictions popularized by such “ultra-globalists” as Kenichi Ohmae and Thomas Friedman, the globalization of economic activity by (trans)national
CORPORATIONS AND THE NATION-STATE

corporations has not inevitably led to the end of the nation-state and geography and the rise of a flat world. Much to the contrary, economic globalization has accentuated the dialectical relationships between nation-states and (trans)national corporations (Yeung 1998, 2016). In a recent Roepke Lecture, Harvard political economist Dani Rodrik (2013) argued strongly for the continued vitality of the nation-state in global economic governance (for a critique, see Agnew 2013). To him, geographical heterogeneity and institutional diversity among nation-states are the keys to a “sane globalization” that can “accept the right of individual countries to safeguard their domestic institutional choices” (p. 17).

In short, institutional differences among nation-states can make a huge difference to the successful formation and viability of domestic economic actors such as corporations and industries. But what exactly are these institutional differences? It is useful to introduce a simple typology of nation-states in today’s global economy. In Coe, Kelly and Yeung’s (2013, 100–108) Economic Geography: A Contemporary Introduction, the nation-state has been broadly categorized into four types with varying degrees of institutional capacity, political control, and policy orientations.

1 Neoliberal states: state institutions seek to keep a distance from corporations and industries. The main role of the state is to establish market rules via legislation and to enforce these rules through their regulatory mechanisms. Some contemporary examples are the United States, the United Kingdom, and New Zealand.

2 Welfare states: in these states, labor unions and state institutions play a more direct role in corporate governance and firm behavior. Corporations do not necessarily have a free rein in labor management. Instead, there are stringent labor laws and other state-sanctioned welfare provisions that shape the business and investment behavior of corporations. Well-known examples are France, Germany, and Scandinavian countries.

3 Developmental states: the state is relatively autonomous from the influence of interest groups, powerful businesses, and the population at large. This institutional autonomy – often achieved through authoritarian political control – enables the state to develop and pursue interventionist policies favoring economic development. To achieve their economic development objectives, these states exercise economic control through developing elite, state-sponsored economic agencies and strategic industrial policies. Many East Asian newly industrialized economies tend to experience such a state form (e.g., Japan, South Korea, Taiwan, and Singapore; see Yeung 2014, 2016).

4 Authoritarian states: these states combine a highly centralized political system with an increasingly open economic system. Many are former socialist states that have sought to liberalize their economies while maintaining strict political control. Their economies tend to be dominated by a mixture of state-owned enterprises (SOEs) and corporations (domestic and foreign). The state exercises its control over domestic economies through owning stakes in SOEs and strictly regulating corporations and industries. Authoritarian states are mostly found in central and eastern Europe (e.g., former Soviet republics), Russia, and Asia (e.g., China and Vietnam).

This great diversity of nation-states points to their highly variegated institutional relationships with corporations – domestic and foreign. In
CORPORATIONS AND THE NATION-STATE

most of these state types, the state performs a *regulatory* role by defining and enforcing the prevailing “rules of the game,” such as property rights, market regulation, and governance laws. Generally, corporations have a significant degree of freedom to make investment, production, and distributive decisions; their economic actions and fortunes are subject to market, not state, discipline. Depending on the specific nature of their economic strategies and policies, however, some of these nation-states also serve as a *promoter* of corporations. Directly involving themselves in steering the growth and development of domestic corporations, these states have become “developmental” in the sense that national economic development serves almost as their *raison d’être*. In this form, firm–state relations are particularly intertwined and mutually constitutive. In the name of certain national development objectives, the state favors a highly selective group of national firms commonly known as “national champions.”

A developmental state can deploy a wide range of policy instruments and/or even political coercion to favor particular corporations and/or industrial sectors (details in Yeung 2016). In the East Asian examples of Japan, South Korea, and Taiwan between the 1960s and the 1990s, the developmental states explicitly engaged in certain protective trade policies to nurture their chosen “national champions” and “infant” industries (e.g., Nippon Steel and POSCO in steel making, Toyota and Hyundai in automobiles, and Samsung and TSMC in electronics). These industry-specific trade policies were combined with strategic industrial policies and preferential financial tools to incentivize these corporations to enter new industries prioritized by the state for national development purposes. Relatively autonomous from pre-existing business and industry interests, these states’ ministries of industry developed comprehensive five-year development plans for nurturing new industries, initially through import-substitution programs, later through export-oriented industrialization.

In Japan and South Korea, the respective finance ministries or central banks also offered “policy loans” to distort deliberately the financial market system in credit allocation so that domestic corporations could “afford” to invest in these highly capital-intensive industries. Following state-led instrumental policies, these loans were priced so cheaply or even offered as grants to chosen corporations to help them overcome the initial, often huge, barriers to entry in new industries. In some extreme cases (e.g., South Korea’s President Park Chung Hee during the late 1960s and the 1970s) the state leader personally supervised the progress of these “national champions,” embodying and implementing national industrial policy. In lieu of a market-based credit allocation system, top state officials made allocation decisions based on a complex web of personal favors and crony interests.

While much of the enormous literature on these East Asian developmental states has been produced by political scientists, economic sociologists, development scholars, and East Asian area specialists since the late 1980s and throughout the 1990s (reviewed in Yeung 2014, 75–79, 2016), it is important to note that leading economic geographers, including Brian Berry (1989) and Peter Dicken (1994), also paid serious attention to these developmental state–firm relations. According to Berry (1989, 6), success of East Asian “development states” “centered on the ability of the central government to forge bonds of trust with the business community, the intelligentsia, and the working class. Linked to this is the idea that politics is the arena in which the vital decisions about the long-term economic health of the nation are to be made and the strong belief in meritocracy through competitive
examination and in the improbability of the human condition through communal self-help.”

Dicken (1994, 112) couched these developmental states in the context of the emergence of the “competition state,” which takes on some of the characteristics of corporations as they strive to develop strategies to create national competitive advantage. As such, the nation-state is much more than a contributor to the “environment” of corporations. Indeed, he argued that “it is not unreasonable to regard many of the current politico-economic tensions in the global economy as being a reflection of a clash between competition states occupying different positions within the market-rational/plan-rational space” (p. 113). While the developmental state belongs to the plan-rational political-economic system, the regulatory state epitomizes the market-rational variant. Geographical political economy can therefore be much better understood if the unequal power relationships and complex interactions between these state types and their domestic corporations are duly taken into account. This geographical political economy can be extended to an analysis of the state-led globalization of domestic capital.

Territorial embeddedness and the globalization of national capital

Insofar as the developmental state can serve as a champion of “national champions” (i.e., domestic corporations), the nation-state can also become a highly involved actor in shaping economic globalization in two ways. First, the nation-state can influence or shape the business and investment behavior of foreign transnational corporations (TNCs) coming into their national economic spaces. Generally speaking, the nation-state prefers to embed these TNCs territorially in order to maximize the positive spillover of their investment for local and regional economies. Second, and in somewhat more limited cases, the nation-state can become a global investor in its own right, actively steering the globalization of its own national capital. This two-way involvement of the nation-state in globalizing corporations has attracted very significant research in economic geography since the mid-1990s.

In particular, Dicken (1994, 117–121) has rigorously argued that the dynamics of firm–state bargaining relationships are the critical key to understanding and mitigating intense global–local tensions in today’s global space-economy. These bargaining relationships need careful geographical analyses because of their inherent complexity and evolutionary tendencies. As corporations from different countries of origin governed by variegated nation-states, TNCs embody different home state imperatives and are bearers of different business “recipes” or cultures. Even in the same broad industrial sector, a South Korean chaebol or conglomerate such as Samsung Electronics clearly operates rather differently from its key competitors – American high-tech electronics giants such as Apple (smartphones) or Intel (semiconductors). While these TNCs are primarily interested in new markets, technologies, and resources or lower costs of production, they organize their global production networks by searching and scanning different locations throughout the world (Coe and Yeung 2015; Yeung and Coe 2015).

From the perspective of the nation-state “hosting” these TNCs, nevertheless, the benefits of their presence must outweigh the costs over time. Revisiting the earlier discussion of the East Asian developmental state, at one time foreign corporations were not favored in industrial sectors designated for domestic “national champions.” The potential cost of foreign corporations dominating these sectors was perceived
CORPORATIONS AND THE NATION-STATE

as far greater than the low skill employment and limited technological linkages they might bring. But in many of today’s developing countries, endowed with much weaker state capacity and political control, nurturing and relying on emerging “national champions” is not an option for kick-starting their domestic industrialization. Despite the potential cost of crowding out domestic corporations, TNCs have become sought after through the provision of huge investment incentives and the removal of regulatory barriers. This discursive movement away from the “sovereignty at bay” view of TNCs by developing country states represents a significant shift toward a more neoliberal form of economic development. In more advanced industrialized nation-states, such pro-TNC stance also is increasingly evident with greater recognition of such benefits as enhanced employment, market access, and technologies or knowhow.

As foreign corporations and host nation-states enter into ever more complex bargaining and cooperative relationships, economic geographers have become particularly concerned with the territorial embeddedness of these corporations in specific localities and regional economies. When foreign corporations are more willing to localize their operations and engage with domestic corporations in these regional economies, they are deemed as territorially embedded. Crucially, the extent of this embeddedness can often be substantially enhanced through both policy initiatives of the host state at national and regional scales and the availability and quality of pre-existing industrial and/or market linkages. The territorial embeddedness of TNCs tends to be higher in well-established high-tech industrial clusters (e.g., Silicon Valley and Baden-Württemberg) and/or global cities (e.g., London and New York). Conversely, foreign corporations are less likely to be embedded in exports enclaves in developing countries or low-tech regions in industrialized economies.

With hindsight, this geographical specificity in firm–state relations is highly important both in theory and in practice. At the theoretical level, territorial embeddedness represents a key concept in “relational” economic geography, dating back to Dicken and Thrift’s (1992) early work (see Yeung 2005). It provides a useful conceptual apparatus to analyze how corporations, domestic and foreign, are grounded in territorial ensembles coproduced with the nation-state (Dicken and Malmberg 2001; Dicken 2003). It also paves the way for explaining the geographical political economy of regional development through global production networks (Coe et al. 2004; Yeung 2009, 2016; Coe and Yeung 2015).

In practice, territorial embeddedness presents a crucial opportunity for policy interventions by the host nation-state seeking to capture value and gains through the presence of foreign corporations. A variety of empirical studies have illustrated these dynamic firm–state relations in the context of continuous bargaining and policy initiatives. In China’s socialist variety of capitalism (Peck and Zhang 2013), for example, this bargaining relationship between the authoritarian state and foreign corporations is evolving rapidly. In studying China’s automobile industry, Liu and Dicken (2006) point to the critical role of state interventions in “obliging” foreign automobile corporations to embed themselves in different regional markets in China through developing joint venture arrangements with state-owned enterprises. In the North African and Eastern European apparel industry, Smith et al. (2014) and Smith (2015) have shown the continual role of host state policies in enabling domestic industrial upgrading through the presence of foreign corporations and their cross-border production networks.
CORPORATIONS AND THE NATION-STATE

On the other hand, the globalization of national capital is a relatively more recent phenomenon, associated in particular with the rise of sovereign wealth funds (SWFs). Since the mid-2000s, it has begun to attract growing analytical attention from economic geographers (Clark et al. 2010; Clark, Dixon, and Monk 2013; Yeung 2011; Haberly 2014). In theory, SWFs represent merely a common organizational form of strategic investment and asset management corporations. But due to their wholly state ownership, with liabilities limited to these sovereign owners, SWFs are viewed as embodying and exercising more than market principles or market-based logic of portfolio management and financial venturing. Some market critics have argued that the investment objectives of SWFs are almost always intertwined with state objectives that range from domestic wealth preservation and economic needs to geopolitical interests and national security. If these SWFs wake up from their dormancy to become active or even strategic investment corporations in the global economy, this mixing of financial with political imperatives can threaten and potentially destabilize the global political economy. These dual roles of SWFs are often viewed through the lens of what is critically known as a “double bottom-line” mentality.

In globalizing national capital, the emergence of SWFs brings about several important reconfigurations of firm–state relationships that merit further discussion. First, the sheer size and scale of these SWFs confers enormous bargaining power on their investors, that is, state owners, when it comes to negotiating with potential investment target corporations. As the primary investment holding vehicles for nation-states and, in some cases, regional states, SWFs can manage investible funds and investment-class assets ranging from a few hundred million to a few hundred billion US dollars. The Sovereign Wealth Funds Institute estimates that the combined value of the world’s 74 largest SWFs exceeded US$6.3 trillion as of April 2014 (http://www.swfinstitute.org/fund-rankings, accessed on May 20, 2014). The top ten SWFs account for some 76% of this mammoth value, indicating an extremely high level of financial concentration in these top players. From a systemic risk perspective, these top SWFs may well be beyond “too big and too interconnected to fail,” since no individual nation-state or international organization, such as the International Monetary Fund, can mobilize sufficient financial resources to save a large but failed SWF.

Second, SWFs are quite diverse in terms of their historical, sectoral, and geographical origins. While some small public sector investors such as Texas Permanent School Fund (US$30 billion) can be traced back to 1854, the largest SWFs are much more recent. Among the top ten SWFs, Kuwait Investment Authority (1953) and Singapore’s Temasek Holdings (1974) are the oldest. The role of oil and gas wealth in constituting SWFs is also significant, accounting for four of the top ten and 59% of the total value. In turn, this sectoral specificity points to the unique national origins of oil and gas-related SWFs – from nation-states well endowed with these natural resources. Among the top ten SWFs related to oil and gas, only Norway is not from the Middle East. Meanwhile, a significant number of SWFs from China, Hong Kong, and Singapore are noncommodity in their origin, and represent national wealth accumulated from long periods of export earnings and successive budget surpluses.

Third, and not surprisingly, these SWFs have different foreign investment motives and horizons. Some SWFs are more passive in their approach to investing in foreign corporations. Others deliberately take a low profile in their foreign forays, investing in smaller stakes (typically below 1% of equity) and avoiding
direct intervention in corporate management. The above “double bottom-line” mentality should not necessarily be construed as the automatic basis for bad SWF behavior or investment practices. Comparing Singapore’s two SWFs (GIC and Temasek Holdings) to other nonstate global investors, for example, there is no guarantee that privately owned hedge and mutual funds will be more ethical or considerate of “national feelings” when making their investment decisions. Because of their direct links to Singapore’s developmental state and their deep integration with its national regime of capital accumulation, these SWFs are more likely to consider political risks carefully and act less aggressively in order to reduce potential negative reputational effects of their investments on national interests. On financial grounds, these two SWFs are likely to seek longer term returns to investment, providing steady capital and liquidity for host corporations’ assets (Yeung 2011).

This relatively passive approach to firm–state relationships contrasts quite sharply with some Middle Eastern SWFs, which not only have acquired majority stakes in iconic global corporations, but also have taken up directorships proportionate to their equity holdings. Coined “White Knights from the Gulf” by Haberly (2014), these SWFs have taken over some global leading firms in major industrial sectors, restructuring them into formidable industrial corporations in line with their state-led domestic industrialization strategy. For example, the Abu Dhabi Investment Authority (ADIA) spent several billion US dollars to acquire the US corporation Advanced Micro Devices’ loss-making semiconductor manufacturing facilities and Singapore’s Chartered Semiconductor, in order to establish GlobalFoundries in 2009 – a new corporate entity created to spearhead the development of semiconductor industry in Abu Dhabi. In the same year, Qatar Investment Authority acquired a 17% stake in Germany’s Volkswagen for US$10 billion, giving it a seat on Volkswagen’s supervisory board and a firm foot in one of the world’s most competitive automobile manufacturers (Clark et al. 2010, 2288; Haberly 2014, 17–19). The intimate role of SWFs in bringing together firm–state relations is clearly evident here. They serve as tools of engagement for a nation-state to gain access to global productive capacity unavailable in its domestic economy.

Coda

Taken together with the earlier discussions of the changing role of the nation-state in global political economy and the territorial embeddedness of foreign corporations, this globalization of national capital presents an exciting challenge to future economic-geographical research because of its multiple juxtapositions of different economic actors (nation-states and corporations), industrial sectors (finance and nonfinancial industries), and governance systems and jurisdictions (state-centric and transnational). As a relatively new and yet potent force in shaping global political economy, SWFs and their global reach are significant. Studying them geographically can help unravel the mutual dependency and co-evolution of different economic actors such as corporations (private and public) and nation-states. Such an analytical approach can advance economic geography well beyond the neoclassical and behavioral heydays of location theory and the geography of enterprise, bringing together the two major subfields of economic and political geography. This would effectively address the challenge outlined at the beginning of this entry – a reorientation toward new understandings of the uneven capitalist global economy.

Future geographical research into SWFs also can help transcend the sectoral boundaries and
industrial specificities in many existing studies of corporations. In financial geographies, these nation-state economic instruments are substantial and important subjects in their own right. But their economic and noneconomic linkages far exceed the financial sector itself and/or even most global financial networks. SWFs cut across different global networks, from production, innovation, or financial to social or even environmental. The underlying political power of this national capital and its market-making capacity has the potential to transform massively current geographies of the global economy.

The governance of the global economy remains an elusive concept and practice, partly because of excessive state-centrism in the social sciences (Agnew 2013; Yeung 2014, 2016). As explained in this entry, corporations and nation-states are the most significant actors in shaping today’s capitalist global economy. But their significance should not preclude or overshadow other actors, geographical loci, and cross-border flows and networks constituting the broader governance of this global economy. As argued cogently in Clark et al. (2010, 2274–2275), “overly territorialized models of capitalism that categorize countries differently according to static institutional criteria can easily obfuscate the deep interlinkages, interdependencies, and commonalities between different political-economic spaces.” Future directions in geographical political economy must eschew a simplistic form of universal capitalism and its underlying methodological nationalism; it should instead embrace a geographically variegated understanding of how individual sovereign forms of national capitalisms – neoliberal, welfare, developmental, authoritarian, and so on – become mediated through transnational flows: not just of people, products, and ideas, but more importantly of corporations and, ultimately, nation-states.

Corporations and corporate power

Corporations are legal entities or juridical persons. Corporations, as an organizational form, represent a group of people/shareholders/owners who are authorized to act as a single legal entity or person. In other words, corporations are afforded many of the legal rights of individuals, particularly in matters of property, contract, and torts. There are provisions in corporate law that allow for a variety of corporate forms, but in lay and scholarly discourse the term is most often used to refer to for-profit firms organized generally around the pooling of investment capital, the issue of transferable shares, and the vestment of oversight in a board of directors taken to be distinct from the management of the firm’s day-to-day operations. Ensuring limited liability for members or shareholders of corporations is fundamental to this organizational form. Common usage most often refers to publicly traded corporations, the shares of which are bought and sold on regulated public exchanges. There are, however, relatively large corporations that remain privately held, owned either by a small number of individuals or by a larger firm. Both privately held and publicly traded corporations come into existence and are regulated by state authority. They must be chartered by or registered with particular governments, a process that varies across jurisdictions but which is generally far more rigorous and more heavily regulated for publicly traded firms.

Charters for substantial joint stock companies were initially issued in the mercantilist period by regents, ostensibly for public purposes, but they contributed to the development of capitalism in the seventeenth and eighteenth centuries in their Western European core. European expansions were facilitated by corporate ventures like the Hudson Bay Company and the East India Company, whose efforts to control vast swaths of the planet received state approval and support in an attempt to consolidate imperial rule. The rise of joint stock firms also fueled a number of the earliest speculative bubbles, notably the South Sea Company in England and the Mississippi Company in France in the early eighteenth century. Both resulted in financial crises, engendering substantial anticorporate sentiment in their respective countries (Garber 1990). In the case of the English South Sea Company bubble, parliament responded by instituting a ban on charters for joint stock companies which remained in place until 1824 (MacKay 2003). In the United States, corporate law first took its inspiration from the English, and was initially characterized by ambivalence and a general sense that charters ought to be issued for public purposes, but it evolved independently over the nineteenth century as individual states, in competition with one another for business, adopted increasingly permissive laws (Maier 1993). Beginning in the 1880s, on the basis of what at least one historian has characterized as a “deliberate misuse of facts” (Graham 1938, 384), the Fourteenth Amendment to the US
Constitution has consistently been interpreted by courts to apply not only to natural persons (e.g., freed slaves) but also to corporations. In the 1890s and early 1900s Congress passed legislation aimed at curbing monopoly (e.g., the Sherman and Clayton antitrust acts), and additional regulation was passed into law during the Depression era. In spite of these limited efforts by the state to check corporate power, corporations have continued to play an increasingly central role in American life. In 2014 the Supreme Court extended the legal rights of corporations to political speech in *Citizens United v. FEC* in 2010 and to religious freedom in *Sebelius v. Hobby Lobby Stores*. Broad legal recognition and rights, coupled with increasingly sophisticated organization and communications, have converged to make possible corporate bodies with millions of employees worldwide, annual earnings in tens of billions of dollars, market capitalizations approaching one trillion dollars, with one-third of all international trade now between branches of the same corporation. Corporate holdings have become so Byzantine that it is often impossible to trace the chain of their ownership (Ellwood 2006). According to a study conducted in 2000 by the Global Policy Forum (Anderson and Cavanagh 2000), 51 of the largest 100 economies in the world were organized by corporations and not countries. General Motors was bigger than Denmark, and Walmart than Poland or Greece.

Transnational corporations (TNC) are firms with the power to coordinate and control business operations in two or more countries, even if they do not own them (Dicken 2007, 106). The chief international draws for TNCs are market size and their desire to access global labor and knowledge pools. As TNCs expand horizontally, across nations, they compete through market adaptation by modifying products to suit the requirements of local markets. The transnational corporate model emerged particularly during the 1930s, on account of political-economic factors incentivizing them to decentralize in response to national market differences. Corporations become transnational by developing or setting up new facilities or by acquiring or merging with local firms – the more common methods of entry to gain access to new products and geographical markets (Dicken 2007). As corporations grow, they have greater power to wrest concessions from regional and national governments with promises of job creation and increased national incomes.

Some proponents of economic globalization argue that TNCs are the new ambassadors of democracy. They insist that free markets and political freedom are bound together, with the introduction of the first leading to the second (Friedman 2000; Boockmann and Dreher 2003). They also insist that governments are inefficient and that bloated bureaucracies waste taxpayers’ money, prescribing privatization as a remedy. Even prisons and parks are being privatized as governments reduce public expenditure to meet market demands for balanced budgets. In the United States alone the total expenditure for prisons, jails, and other correctional facilities in 2007 was $74 billion (Ellwood 2006; Kyckelhahn 2010); hence corporations see a tremendous business opportunity here and continue to lobby and increase their share in the prison industrial complex.

Decreasing rates of profits on account of inter- and intracapitalist competition propel surviving corporations toward growing into monopolies and oligopolies. The most profound consequences of big business corporate capitalism are sociopolitical: monopolies and oligopolies are perceived to play a strategic role in capitalism’s tendency to endanger the institutions on which it depends (Marx 1906, 836–837). Capital, through its creative success and manifestation in
the form of corporate power, leads to its own destruction, undermining the very institutions on which it depends, for example the state or supportive political and civil organizations (Schumpeter 1950, 61). Public perceptions of corporate overreach in domestic politics and foreign affairs, as well as glaring examples of corporate irresponsibility with regard to consumer safety, ecological malfeasance, harsh labor discipline, and the socialization of risk have made corporations the subject of broad and intense criticism. Shifts in the spatial division of labor have intensified since the 1980s, driven by core capitalist investment in and relocation of semiautomated labor to developing countries, bringing the role of corporations front and center in debates about development and international relations. Although critics have argued that very large and rich corporations have essentially captured electoral systems in the United States, United Kingdom, and elsewhere (Ferguson 1995; Wolin 2008; Peet 2007), there is mounting evidence that large, publicly traded firms also exert considerable influence in global governance and development projects, for example, in negotiations over “free trade” agreements that codify rent seeking by firms from wealthy nations in poorer ones (Baker 2015), and in the increasing influence of a for-profit development–security assemblage embedded within the operations and policies of international institutions (Nagaraj 2015).

Multilateral organizations: trading and evading conflicts

Multilateral organizations are transnational institutions with the mandate to regulate generalized behavioral norms between three or more nations. They can be formal, with rules and procedures, or informal, representing coalitions of interests, like the United Nations or the European Union. They can be international in focus, fostering integration between countries such as the South Asian Association of Regional Cooperation or the World Trade Organization (WTO), or supranational, with power vested to govern certain aspects of member states. Multilateral organizations can be strategic (like NATO), political (e.g., UN voting blocks), sociocultural (UNESCO), or economic (the World Bank or WTO). Here, the focus is on multilateral organizations with direct or indirect relationships with economies and corporations.

Multilateral forms arose in the modern era to mediate matters of sovereignty and territoriality where uni- and bilateral solutions were inadequate, for example, the establishment of an international maritime order during the early era of European colonialism in the Americas and elsewhere. In the interval between the Napoleonic and Crimean wars, the five leading powers of the Concert of Europe – Austria, Great Britain, Prussia, Russia, and France – forged a multilateral convention aimed at preserving peace and fending off revolutionary threats to dynastic power (Ruggie 1993). By the mid-nineteenth century, the concert had effectively disintegrated as sociopolitical transformations dented the domestic legitimacy of participant regimes and reconfigured the European balance of power. Great Britain, the pre-eminent industrial capitalist state, moved to liberalize its own trade policy, later pursuing strategies that promoted bilateral liberalization. Increasingly, European bilateral trade pacts came to include most-favored nation provisions that guaranteed parity to each party, with concessions granted to third-party states in other bilateral agreements. Regardless of intent, in the latter third of the nineteenth century these engagements tended toward a multilateral form that coalesced into a liberal trade regime based
on free trade and the gold standard (Ruggie 1993, 20–21).

Whereas multilateral forms were only rarely embodied in formal organizations prior to 1900, multilateralism thenceforth became much more formal in the wake of war and shifts in global power. The ad hoc international gold standard, of which the British had been custodians, ruptured. During World War I, Britain’s payment imbalances afforded the United States an opportunity to transition from debtor to creditor. Having cemented its role as international financial, industrial, and military power, the United States was poised to take the lead in organizing “multipurpose, universal membership” international organizations: first the League of Nations and then the United Nations (Ruggie 1993, 22). The emergence of the United States as a dominant power after the two world wars has been critical to the character of the major international institutions that have evolved since. Their multilateral and formal status was not a given, but was contingent on the domestic and foreign policy positions of postwar America.

At the close of World War II, responding to a war-weary public ambivalence toward foreign entanglement and a need to engage Moscow, the Roosevelt administration moved toward a model of multilateral security collaboration in the form of a universal membership body, the United Nations. The United States also took on a critical role in the new international monetary order negotiated at the Bretton Woods Conference in 1944, based on fixed but adjustable currency exchange rates pegged to a gold-convertible dollar (Eckes 2014). The Bretton Woods Conference laid the groundwork for the International Monetary Fund (IMF) and the International Bank for Reconstruction and Development (IBRD, subsequently the World Bank). Later, the United States would call on UN member states to charter an International Trade Organization (ITO) with the aim of negotiating reciprocal trade liberalization. While the US Congress refused to ratify this charter, elements of the ITO proposal were incorporated into the General Agreements on Tariffs and Trade (GATT) (Goldstein 1993). In the late 1940s European anxiety over the tightening sphere of Soviet influence spurred collective security engagement for Western Europe and anglophone America in the form of the 1949 North Atlantic Treaty. With the Soviet Bloc Warsaw Pact, NATO, the United Nations, and the new international trade and monetary order (the IMF, IBRD, and GATT), the postwar international institutional framework coalesced into a world order characterized in the West by American hegemony, Cold War security anxieties, and more or less Keynesian, managed capitalism, driving reconstruction in war-wrecked Europe and Japan.

The strongly institutional forms of multilateralism that emerged after World War II are novel in their organization and scope. Under the security and economic regimes put in place in the wake of the war, the “first world” saw rapid economic growth and impressive industrial output, though Cold War tensions continued. By 1971, the costs of US engagement in Vietnam, which slowed productivity and export growth, and inflation prompted the 1971 Nixon shock in which the dollar was rendered inconvertible to gold. This was followed by the reconfiguration of the international monetary order from a gold-backed system mediated by convertible dollars and pegged currencies, to one of floating fiat currencies priced via currency exchange markets. Characterized by successive oil shocks, and high and rising inflation alongside high and rising unemployment, and slow growth, the stagflation of the 1970s proved amenable to an ideological shift among anglophone political elites away from postwar Keynesianism and the regulatory state (Peet et al. 2003, 117). Beginning in the
Reagan–Thatcher era, international institutions like the IMF, World Bank, and WTO (formerly GATT) were reconfigured along monetarist lines and refocused on minimizing state intervention in markets. These preferences were reaffirmed in the wake of the 1991 collapse of the Soviet Union and the relative prosperity in the West during the 1990s. These events and shifting intellectual currents ushered in the period of market triumphalism which informs contemporary international economic institutional policy and has legitimated a political economic and ideological tendency called neoliberalism, which is oriented toward rapid liberalization, fiscal austerity, minimal state regulation of markets and business activity, and privatization of state-owned enterprises (Peet et al. 2003; Klein 2007).

Summarizing, contemporary multilateral organizations are products of the historical circumstances of both world wars, postwar American power, and successive geopolitical and financial crises. Their historical development has been marked by an at least nominal emphasis on equality between member states in both security and trade agreements and by formal organization. Their rise to global prominence has paralleled the development of corporate personhood and the centrality of business corporations to daily life in much of the world. The rest of this entry will examine the overt and subtle interplay of multilateral institutions and business corporations.

**Corporate–multilateral interplay**

The relationship between business corporations and the state, while at times conflictual, is generally characterized by mutual necessity. On the one hand, the interests of corporations differ from those of the state, the former organized around the generation of profits for shareholders and the latter around material welfare and the social cohesion of its citizens. On the other hand, states need corporations, and corporations need the state. States need firms to produce goods and provide employment for their people. Business corporations need the state for both physical and social infrastructure, from roads and bridges to the enforcement of property rights and the production of an educated workforce. Conflicts arise, however, on the basis of disparate interests and objectives, the negotiation of which shapes much of the politics of the capitalist core and beyond.

Competitive pressures inherent in capitalism ineluctably drive firms in search of new markets and lower costs. To these ends, business corporations have often extended their operations across national borders in the pursuit of new markets, to exploit lower prevailing wages in developing countries, to secure access to raw materials, and to invest (Harvey 2005). From the perspective of the state, international expansion by domestic firms is a means to secure or maintain market position and is thus in the national interest. Public opinion is often split, however, largely owing to the perception that foreign investment by domestic firms translates to higher domestic unemployment and trade imbalance. Developing countries often feel pressure to attract inward foreign direct investment, competing to secure it via all manner of inducements from preferential taxation arrangements to relaxed regulations. The assumption is that foreign investment will create jobs, generate revenue, and stimulate growth (Ahmed 2011). Inward foreign direct investment can create problems in both developing and developed countries, which often derive from real or perceived threats to domestic producers, firms, and workers, or from nationalist sentiment aroused by economic activity that is seen as challenging national sovereignty and territoriality. As the logic of the world economy, in multiple forms, has transcended the scale of
Corporations and Multilateral Organizations

The nation-state, multilateral organizations have become more relevant than ever (Knox, Agnew, and McCarthy 2014).

To an extent, it is important to focus on the United States given its position as the world’s largest economy (backed by the world’s most powerful military) and its hegemonic position. In this context, the nexus between the US government, TNCs, and multilateral organizations assumes tremendous significance (see Figure 1).

In general, foreign direct investment has risen sharply around the world since 1990. In the case of the United States, between 1990 and 2010, outward investment increased about ninefold and foreign investment into the United States trebled, with inward FDI outpaced in dollar terms by US business engagement abroad. These changes reflect increased market liberalization, and shifts in the US domestic market and the global spatial division of labor (particularly in manufacturing). Increased business abroad strengthens motives to engage with global governance institutions like the WTO. American business corporations have evolved not only along lines of efficiency and organizational improvement but also in political management. Their massive influence over domestic politics within the capitalist core, particularly in the United States, is the vector sum of interinterest wrangling, but the general tendency has been the prying open of foreign markets and elimination of foreign capital controls and financial regulation. Business corporations manage the policy preferences of global governance not only through domestic politics, but also through expert opinion expressed via trade association and industry experts and intellectual apparatuses such as think tanks (Peet 2007).

For an example of the influence of corporations over international development work, one need look no further than the US Millennium Challenge Corporation (MCC), an aid agency formed in 2004 under the George W. Bush administration. The MCC provides aid to developing countries through development contracts. Candidate countries are evaluated on 17 criteria before they are offered such a contract and aid can begin. The evaluation of each of these criteria is conducted not by MCC but by a third party, such as UNESCO, IMF, and the World Bank (none of which is surprising). However, the “Trade Policy” criterion is evaluated by the Heritage Foundation (MCC 2015), a big business-friendly think tank whose funding remains largely opaque but has been associated with corporate interests, from ExxonMobil to Koch Industries (Robbins 2015). The MCC is not itself strictly multilateral as it works through bilateral development agreements, but its preferences are generally aligned with and diffuse into the broader international aid and development community with which it regularly interacts (IMF, World Bank, etc.). This exemplifies a direct flow of business corporate influence from corporations and their wealthiest owners and managers into a think tank with immense power.

Figure 1 Geography of corporate and multilateral power.
over the trade policies of developing countries desirous of US development monies and other aid. In this way, facilitated by the global governance institutions, the will of American business becomes the reality in developing countries.

Trade agreements are negotiations between states, acting in what their representatives take to be their national interests. In the process, insofar as that interest is often equated to the designs of the largest and best-connected domestic corporations, their will is often transmitted into global governance and multilateral endeavors. For example, the Trans-Pacific Pact has drawn fierce criticism for its rent-friendly intellectual property provisions that broaden and lengthen protections for intellectual property holders over and above the typical anxieties among labor groups over job losses. Correspondence obtained through Freedom of Information Act requests reveals a close working relationship between US trade representative staff, business corporation leadership, and paid lobbyists, almost certainly representing a level of access and influence unparalleled by any other segment of US society (MCC 2015). At the level of bureaucracy, domestic and international trade and governance personnel, corporate management, and policy think-tank funders and intellectuals very often overlap, engendering strong social ties often referred to in the US context as the economy–society–polity revolving door phenomenon (Vidal, Draca and Fons-Rosen 2012).

Such relations between powerful states and their corporations affect developing economies in different ways, engendering contentious debate over motives and outcomes. Claims that liberalization and foreign direct investment represent an unmitigated good, promising growth, technology transfer, and broad improvements in living standards, are challenged in the geographic literature by numerous case studies demonstrating a much more complex reality. Developing countries that enter into loan arrangements and other aid contracts with multilateral organizations do not do so on equal terms. When the IMF or World Bank extends credit to countries, the money comes with conditionalities that, since 1980, have centered on broad liberalization: lowering tariffs, eliminating subsidies for domestic industry, privatizing state-owned enterprises, eliminating capital controls, and other deregulation (Ahmed 2014). These reconfigurations of domestic policy and international trade relations can have deleterious effects for domestic producers and firms, while at the same time affording considerable opportunities for profit-taking by foreign firms.

Consider, as an example, the Indian power industry. In the early 1990s India received structural adjustment loans from the World Bank and IMF to cope with a balance of payments crisis. As part of structural adjustment, the Indian system of power generation was effectively privatized, with significant protections for the American firms (particularly Enron), which were granted power generation contracts that included pegged utility rates and guaranteed sales (Ahmed 2010). When the terms of the deal precipitated the collapse of Indian electricity distributors, US energy executives exerted pressure on the George W. Bush administration to threaten sanctions to enforce its terms. This episode makes clear the strong relationships between states, business corporations, and global governance institutions. American firms worked with the latter to secure strong market positions in the Indian power industry at very favorable terms, an opportunity afforded them by the coercive power of conditionality in international lending, the dominant role of the United States in the administration of global governance institutions, the promulgation of neoliberal politico-economic ideals, and the political influence of American corporations.
Contrary to the rhetoric of advocates for neoliberal reforms, the outcomes in cases like this look much less like a rising market tide that lifts all boats than a form of state-supported piracy.

Another linkage between business corporations and multilateral institutions is an emerging for-profit international development–security assemblage. The blurring of development and security has accelerated since 2000, in part owing to the prosecution of the “global war on terror,” such that by 2008 a World Bank president called for “bringing security and development together” (Nagaraj 2015, 606). Very large international development contracts are increasingly awarded to very large for-profit corporations, mostly originating in the anglophone West, and are created through successive rounds of merger and acquisition (Roberts 2014). As these firms have grown, they have broadened their scope, often evolving from engineering or agricultural consultancies into one-stop shops for international development contracting. In 2011 a single such firm, Chemonics, received enough USAID (United States Agency for International Development) funds to rank third among nations in terms of the dollar value of aid received. Recently, some of these firms have taken on roles as providers of security, accompanying American and British troops into Afghanistan, Iraq, and Pakistan. As the geopolitical meanings of development and security have blurred and converged, so too have the agendas of development corporations, whose bottom lines remain plump in times of war and peace. Corporations whose business has been to develop infrastructure, facilitate commerce, and foster civil society are now equipped to provide policing and private security services as well as logistical support to military forces deployed around the world.

Conclusion

Business corporations exert considerable influence on national politics, global governance, and international projects. The rise of corporate personhood in the capitalist core has enabled very large-scale accumulations of capital and investment in correspondingly large projects. Broad legal recognition and rights, coupled with immortality and limited liability for shareholders, enables business corporations to wield economic and political power that is readily convertible into influence over the ideology, policy, and operations of multilateral organizations. Corporations enjoy unparalleled access to and influence over international policymakers and bureaucracies, influence that is informed by the channeling of profits to corporate owners and managers rather than by national interests or politico-economic ideals (not even that of a free market for corporations), and that often exhibits undemocratic and antisocial tendencies. Some obvious ethical questions for future research emerge around the readiness of business corporations to embed themselves as easily in military invasions and occupations as in nominally humanitarian projects, and the degree to which corporate power emanating from rich countries underwrites arguably predatory global financial and development activity under the auspices of multilateral institutions – often at the expense of very vulnerable people.

CORPORATIONS AND MULTILATERAL ORGANIZATIONS

Corporations and e-commerce

Barney Warf
University of Kansas, USA

Essentially, e-commerce consists of commercial applications of the Internet. These include a variety of activities, including business-to-business (B2B) transactions and those linking businesses to their customers (B2C). B2B e-commerce constitutes the bulk of such activity and takes a variety of forms, including electronic data interchange (e.g., inventory data, digital invoices and contracts, purchase orders, and product updates), Internet recruiting, and advertising. (Related activities such as back office and call center relocations are not discussed here.) B2C e-commerce includes electronic retail shopping (e-tailing), Internet banking and gambling, distance learning, and entertainment, where the digital convergence of the Internet, telephony, and broadband cable has allowed companies to bundle these services.

This entry approaches e-commerce in two ways. First, it offers an overview of the varieties of types of e-commerce, including its B2B and B2C forms. It also includes the Internet’s effects on the tourism industry, higher education, and gambling. Second, it focuses on the geographies of e-commerce, noting that because it is embedded within widely varying social, legal, and cultural contexts, it takes a variety of forms in different places.

The varieties of e-commerce

E-commerce has decisively restructured how firms do business. The rising popularity of e-commerce forces firms to change their business models, giving rise to new products and processes and annihilating older ones in a ceaseless process of creative destruction. For the most part, these activities are restricted to large commercial actors, although the Internet also creates opportunities for small and medium-sized establishments (SMEs) to reach out to national and global markets (Grandon and Pearson 2004), a process that allegedly “levels the playing field” and obviates the advantages of size.

One important dimension is electronic data interchange (EDI) systems, which are widely used in B2B contacts. Common uses of EDI include low cost advertising; online product catalogs; the sharing of sales and inventory data; submissions of purchase orders, contracts, invoices, payments, and delivery schedules; product updates; and labor recruitment. E-commerce reduces delays and marketing and delivery costs, improves supply chain management, and has led to a greater emphasis on connectivity, ideas, creativity, speed, and customer service. For example, in insurance e-commerce has streamlined underwriting policies and centralized database management systems. E-commerce also has improved the reliability of product delivery, such as using radio frequency identification devices (RFID) on trucks and boxes of goods. B2B e-commerce includes electronic
advertising, which is relatively cheap, although its effectiveness varies considerably among national cultures. Internet advertising has proven to be difficult, in part because the Internet reaches numerous specialized niche markets rather than mass audiences.

B2C e-commerce, also known as “e-tailing” or electronic retailing, reveals the growing commercialization of the Internet: in 1993, 2% of all websites were commercial (i.e., “dot com”); by 2012, 70% were so categorized. Shopping on the Internet requires only access to cyberspace, a credit card (or a service such as PayPal), and a parcel delivery service. Such a mode allows effortless price comparisons and intensifies competition among suppliers. In 2012, global e-tailing sales were estimated to exceed $700 billion. The proportion of sales conducted over the Internet varies markedly by economic sector. E-shoppers tend to be relatively young, have above-average incomes, and to be relatively well educated. Web-based banking has experienced slow growth, even though it is considerably cheaper for banks than tellers or automatic teller machines. However, Internet-based payments of bills, mortgages, and insurance have grown rapidly. Of course, the use of e-tailing depends heavily on consumers’ confidence that private information placed online will remain secure. There are real concerns: 0.25% of Internet credit card transactions are fraudulent, compared to 0.08% of non-Internet transactions.

In the United States, e-commerce retail sales exceeded $224 billion in 2012. E-tailing comprised the vast majority of travel reservations ($8 billion/year), 62% of all banking transactions, 17% of computer sales, and 11% of book sales. Despite predictions that “click and order” shopping would eliminate “brick and mortar” stores, e-tailing has been slow to catch on, comprising only 4.6% of total US retail sales, perhaps because it lacks the emotional content of shopping. The most successful example perhaps is Amazon.com, started by Seattle entrepreneur Jeff Bezos, which now is responsible for 60% of all books sold online. Other examples include online auctions (e.g., eBay) and downloading of music files, which has provoked a firestorm of opposition from music companies concerned about infringement of their intellectual property rights and declining over-the-counter music sales. Indeed, e-books now comprise 10% of all book sales, and music downloads exceed purchases of CDs, sending sales of the latter crashing in a downward spiral of creative destruction. iTunes alone comprises 10% of all US music sales. Streaming on-demand downloads of movies, through companies such as Netflix, have increased their share as well. Internet-based sales of stocks (e.g., E*Trade) now make up 15% of all US trades. E-advertising forms only 1% of total revenues in the United States and is overwhelmingly focused on computer and software firms.

The Internet also has had important effects on tourism, the largest industry in the world by employment. Traditionally its most important role in the tourism sector has been travel and hotel reservation services. However, the Internet has enormously increased the ease of obtaining information about potential destinations, and tourism companies and institutions have changed their promotion and distribution channels accordingly (Buhalis and O’Connor 2005). Internet-based tourism enables companies to organize their activities in new ways, including better communications with clients and suppliers and easier agreements with business partners. For customers, the Internet facilitates price transparency, provides better visual and graphic information, and generates time savings.

Universities also have become involved in e-commerce, many investing heavily in web-based distance learning courses. Such programs
are designed to attract nonlocal and nontraditional students, many of whom may not be able to take lecture-based courses in the traditional manner, also reflecting the mounting financial constraints and declining public subsidies that many institutions face. Many see distance learning as a means of attracting additional students, and tuition, at relatively low marginal costs. The largest example of web-based teaching is the University of Phoenix, based in Arizona but with 400,000 students located around the world, making it the world’s the largest university. Some universities offer free online courses (MOOCs, or massively open online courses) to thousands of students at a time, giving birth to corporations such as Coursera.org. Distance learning has provoked fears that it accelerates the corporatization of academia and the domination of the profit motive; others question whether the chat rooms that form an important part of its delivery system are an effective substitute for face-to-face teaching and classroom learning. Others suggest that distance learning programs may be better suited to professional programs in business or engineering than in the liberal arts.

More morally ambiguous is the growing role of Internet-based gambling systems, which include a variety of betting services, especially concerning sports events, and even online slot machines in which gamblers may use their credit cards (Wilson 2003). (Some complain that online gambling does not adequately substitute for the heady experience of a gaudy casino in Las Vegas or Atlantic City.) Because the geography of legal gambling is highly uneven, the existence of such systems also challenges the laws of communities in which gambling is illegal. Offshore gambling centers have grown quickly, particularly in the Caribbean since Antigua licensed its first Internet casino in 1994. In 2011, an estimated 1000 online casinos, mostly in the Caribbean, attracted roughly 12 million users. More generally, e-commerce has provoked worries about images of child sexual abuse, tax evasion, and sales of illegal goods.

In most of the developing world (excepting China), e-commerce has grown modestly, hobbled by low disposable incomes, modest Internet penetration rates, lack of secure online transactions, and relatively infrequent use of credit and debit cards. Many SMEs in the developing world lack the human capital, computers, and support services to take advantage of Internet-based trading, financing, and product delivery. Nonetheless, some SMEs, such as in Africa, have used the Internet to carve out niche markets for their products (Moodley and Morris 2004) or to promote tourism (Wynne et al. 2001).

Geographies of e-commerce

Geographical scholarship on e-commerce has taken a variety of forms (see Brunn and Leinbach 2001; Malecki and Moriset 2008 for overviews). E-commerce lies at the intersection of literatures concerned with the spatiality of consumption, geographies of the Internet, transportation analyses, and recent perspectives on cities such as learning regions. For Janelle (2001), e-commerce is a means by which the Internet facilitates the globalization of regional and national economies. A major theme of such works is its potential to reduce transportation costs for both consumers and producers, although this assertion has been challenged (Mokhtarian 2004; Weltevreden and Rotem-Mindali 2009). Ren and Kwan (2009) studied the impacts of e-commerce on different types of consumers using travel diaries, noting that those who lived in remote regions with few retail opportunities were more likely to engage in e-commerce. Clearly e-commerce has changed the meaning of accessibility, reducing search costs, and enhancing competition among
CORPORATIONS AND E-COMMERCE

retailers. Another theme is the ability it offers to SMEs to expand their market reach. Some explore whether e-commerce may emancipate consumers from the “tyranny of the region,” that is, traditional retail landscapes, although Couclelis (2004) is dubious.

Because it will always be an imperfect substitute for brick-and-mortar retailing, e-commerce will never lead to entirely friction-free consumption. Therefore, there is no “one size fits all” model of e-commerce. Rather, its forms and impacts are highly dependent on the contextual specifics of individual regions. As Gefen and Heart (2009) point out, e-commerce is intimately wrapped up with cultural norms of trust, reputation, familial contacts, tacit knowledge, and other related dimensions. E-commerce is also differentially enabled and constrained by national legal systems, including intellectual property rights and the degree of security of online transactions, all of which conspire to give it a very real regional geography.

Despite the common view that cyberspace is placeless, e-commerce in many respects conforms to the locational logic of nonvirtual companies. For example, although the United States is one vast national market with relatively few internal cultural and political barriers, e-commerce is nonetheless unevenly distributed among its cities and regions. Zook (2005) offers a detailed portrait of the regional Internet economy of the San Francisco Bay Area, a churning hub of dot.com entrepreneurship in the 1990s and 2000s, with companies such as Yahoo!, Google, America Online, Ebay, and Mosaic (which later gave birth to Netscape and Hotmail). This analysis goes far to debunk the myth of the “spaceless” Internet economy, pointing instead to the reality of regional clusters in which agglomeration economies, including close linkages to venture capitalists, still figure prominently. As the largest single concentration of Internet-based firms in the world, the San Francisco–Silicon Valley complex operates, ironically, very much through the circulation of tacit information in narrowly defined social channels. Similarly, German e-commerce firms tend to consolidate spatially in distinct clusters, particularly in Berlin and Baden-Wurttemberg. Germany’s success in this regard reflects its long tradition of adopting new technologies, its history of mail order and catalog houses, and the politics of retail regulation (Aoyama and Schwarz 2004). In Italy, e-commerce supplements rather than substitutes for the highly successful model of industrial districts such as in Emilia-Romagna.

It is important to emphasize that e-commerce cannot be understood independently of its local and national cultural contexts; it is socially and spatially embedded. Telecommunications are an imperfect substitute for face-to-face contact, including eye contact and body language, which are essential to the transmission of tacit (as opposed to standardized) knowledge. Without the exchange of tacit knowledge, which is often irregular in nature, not printed, and changes quickly, it is difficult to establish trust. The creation of trust is a problematic process that is often time-consuming. For this reason, many businesses and consumers approach e-commerce with caution, which helps to explain its relatively slow rate of diffusion in cultures in which trust is impaired by prevailing cultural norms. For example, in economies traditionally based on cash and face-to-face interactions, such as in much of East Asia, Internet-based financial transactions diffused relatively slowly.

Conclusion

E-commerce is profoundly changing how and where corporations do business, accelerating product cycles, enhancing competition,
improving efficiency, and reducing uncertainty. As the Internet has steadily expanded in size and scope, it has become increasingly essential for ever larger numbers of firms to reduce costs, reach markets and clients, and manage their supply chains. Geographically, this process has enhanced the locational flexibility of many firms. It would be unwise, however, to assume that the growth of e-commerce unfolds in the same way everywhere. The implementation of e-commerce is profoundly shaped by national legal systems, labor markets, corporate cultures, and the views and practices of consumers, all of which exhibit significant spatial variations. In short, geography matters: no “one size fits all” model can explain e-commerce in diverse economic, political, and cultural contexts.

Corporatization of race: an American case study

Bobby M. Wilson
University of Alabama, USA

Many who have sought to disentangle the complexities of advanced capitalist societies have accepted the Marxist idea of the centrality of production in political economy. Corporations are the key operational units of capitalist economies. Each corporation operates in geographical space, with multiple locations and connections to suppliers and customers. Yet the structural imperative of the corporate world is not only production expansion but also consumer spending. In order to realize the profits undergirding long-term viability, corporations need everyone’s needs. Marx recognized the important role of workers as consumers. Historically, labor situated its politics at the intersection of production and consumption, building worker solidarity while also mobilizing workers’ purchasing power in its struggle with capital. Yet anglophone Marxist scholars have failed to grasp that transcritical moment when production and consumption intersect, making the distinction between the two a difficult dialectical synthesis. Just as much surplus value can be made in retailing as in production or manufacturing. Indeed, the world’s largest corporation, Walmart, is a retailer which subcontracts manufacturing. More generally, the offshoring of production, together with the decline of public sector jobs, brought about the disappearance of the black corporate working class. Yet, as US corporations closed domestic factories, they gradually shifted emphasis to distribution and consumption.

Combining case history and analysis, this entry examines how blackness and whiteness underpins the operation of corporations in the United States. Race-connected practices are not self-determined but are constituted by their corporate relations with production, distribution, and consumption. As the nation’s largest retailer, Walmart carries a meaning for consumers that extends well beyond the price of goods and services (Weston 2009). Since the 1880s, the court has ruled that corporations are in fact people entitled to free speech rights guaranteed by the Constitution. Race can be a barrier to capital’s expansion of commodity exchange, but it can also be used to facilitate such an expansion to build empires. In order for capital to govern production, distribution, and consumption, it also regulates race-connected practices to stay within reach of the black domestic market. This entry focuses first on how corporations in the United States were able to extract surplus under the rules governing the racial doctrine of “separate but equal.” It then examines how corporations culturally manipulated the black consumer to extract billions of dollars in profits from the black domestic market, thereby underdeveloping the black community (Marable 2000).

Separate but equal corporate regime

Race is just one of many barriers that capital seeks to overcome. Race-connected practices are diverse, fluid, and varied rather than fixed and monolithic. Race asserts itself in unexpected ways across time and space. Race, both in the
past and now, is a product of this tension. It cannot be seen merely as a reflection of racial ideologies. It must be situated within a framework that understands and critiques capitalism as an ideology that sustains and reproduces the capital relations of production.

While race can be a barrier that capital seeks to overcome, it can also be used to underpin capital through the production of differences marked by and constructed through race. Capital’s earliest renderings of the production of difference took the form of black slavery and the seizure of indigenous Indian land. The transatlantic slave trade became tantamount to the Western world’s first multinational corporation, which was responsible for the exportation of almost 12 million Africans to the so-called New World where they were sold as commodities on the slave market. From its origins as a manufacturer of soap, Unilever became a global corporation on the basis of profits from its African-based enterprises (Marable 2000). The seizure of indigenous land in America forced the removal of approximately 70,000 Native Americans to reservations beginning in the 1830s. Land taken from black families in the twentieth century became corporate country clubs, and the US South emerged as a leading sporting destination for corporate elites. Many of these gaming areas now include landing strips capable of handling corporate jets.

The racial doctrine of separate but equal regulated US race-connected practices. This doctrine lasted from the time of the Plessy (1892) decision to the 1954 Brown decision. Status was fixated in whiteness but also in the market. It meant that capitalists could separate themselves from blacks but had to remain within market reach. Race facilitated commodity exchange and consumption while also serving as a barrier to such an exchange. Blacks purchased racial pride and respect by consuming certain commodities. The corporate world thus drew on black consumption while also providing the sociospatial structure needed for the continuous authentication of whiteness.

The only decade when evidence shows that the corporation was out of the reach of the black consumer market was 1919 to 1929. It was the most extensive period of racial segregation but also a golden period for the growth of black businesses. It was a time in which virtually every black neighborhood or town claimed a number of independent black entrepreneurs who were providing goods and services to an exclusively black consumer market (Marable 2000, 146). For the white corporate world this lack of consumer demand was not sustainable, given the lessons learned from the Great Depression. Totally separate economies undermine capital’s need to continuously expand the sphere of commodity exchange and consumption and to avoid another depression.

White corporations eventually gained control of the black domestic market. Following the end of slavery, the US Supreme Court never affirmed a common law right for businesses that were open to the public to exclude blacks completely on the ground of race. Nor did the court deny property rights on the basis of race – for capital, access to market, and property ownership must be protected at any cost, even if it meant violating the separate but equal doctrine. For most of the twentieth century, the corporation charmed consumers with whiteness to create value and expand commodity exchange and consumption, bestowing exchange value on whiteness. This drove the accumulation of capital. All consumers were deemed white. Henry Ford manufactured his Model-T for the white masses who wanted not only the utility value of the commodity but also the fixed social relations encoded in it.

The 1893 World’s Columbian Exposition in Chicago, designed to advance the causes of
American nationalism, imperialism, and consumerism, exhibited commodities that ridiculed and denigrated blacks for the sake of white consumption. A prominent Midwestern flour-milling firm, R.T. Davis Milling Company, persuaded Nancy Green, a 57-year-old former slave, to become a living advertisement at the fair for the company’s Aunt Jemima Pancake Mix. Green played the role of a stereotypical plantation mammy, winning the milling firm an award at the fair. Aunt Jemima thus became a corporate brand that gained national acceptance as an early icon of America’s emerging culture of mass production and consumption. In this sense Green became what Baudrillard (1983, quoted in Mullins 1999, 43) terms a “simulacrum”: “she materialized a black caricature that never existed in reality, yet that caricature assumed the status of authenticity in the white imagination because of pervasive belief in it,” marginalizing the status of black women who historically performed domestic labor (Mullins 1999, 46). In Michel Foucault’s terms, this racialized representation is a privileged discourse that exercised, in this case, “inordinate influence on the definition, circulation, and naturalization of racial subjectivities and white superiority” (quoted in Rabinow 1984, 108; see 108–113). Race is thus mutually constituted through the formulation of a commodity exchange circuit, a totality with the distinct moments of production, distribution, and consumption.

Following the 1954 Brown decision, consumer demand for a wider range of products made greater choices possible — choices that would have been illegal or impossible under the separate but equal doctrine. As encoding commodities purely in whiteness became increasingly a liability, the corporate world, beginning in the 1960s, moved increasingly toward a more flexible regime of accumulation without the status fixated in whiteness. Separate was no longer considered equal, setting the stage for the Civil Rights Movement and eventually the creation of a more diverse market. The one size of whiteness no longer fit all, ushering in a more flexible regime of accumulation that could better exploit the many dimensions of pluralism. The corporation promoted the production of differences to expand markets. Differences pay. Consumption coincides with the many dimensions of identity: race, ethnicity, gender, sexuality, religion, and language, among others. Geodemographic marketing accelerated this kind of differentiation, which was missed from Marx’s Capital.

Pluralist-led market regime

A political and social push for an identity that is not fixed just in whiteness can be traced back to the 1920s, with the “New Negro Renaissance.” This was not only a period of incredible economic boom but also of cultural ferment. What was held to be “authentically” black began to change, as the popular musical form ragtime gave way to jazz in 1917, when some white New Orleans musicians, calling themselves the Original Dixieland Jazz Band, began to produce their encoded version of the music. Their whiteness paved the way for the widespread acceptance of jazz which entered the mainstream in white skin, even though black musicians had been playing in New Orleans since the turn of the twentieth century (Wynter 2002, 48). The race that gave blacks the everyday “blues” could now make money playing and singing the blues. It was mainly through white artists that much of “black folk culture, black inventiveness, black talent gave the twenties its distinctive image as the ‘Jazz Age’ and dictated the character of mainstream American popular music and culture for years to come” (Wynter 2002, 48). The one-size-fits-all of whiteness meant that black artists could not
CORPORATIZATION OF RACE: AN AMERICAN CASE STUDY

speak for themselves. The “King of Swing,” Benny Goodman, had no problem owning up to the black roots of swing, but many in the white community continued to have problems with this, fixating the dance form in whiteness (Wynter 2002, 48, 69).

By the 1940s, black jazz artists began to challenge this one-size-fits-all racial paradigm in cultural political economy. John Coltrane, Miles Davis, and other jazz artists were encoding a musical style that informed a new black self-consciousness in opposition to whiteness. These black artists rebelled against attempts to “whiten” jazz “to bleach away its African roots,” rejecting values that politically and culturally subjugated blacks (Kofsky 1998, 57). They were posited as the basis of collective identity, after having initially been rejected as a valid form of classification. Having defined the terms of domination in whiteness, “white” colonizers found their rule challenged by people asserting a counteridentity grounded in a celebration of blackness.

Richard King (1996) has observed how the struggles of the 1960s and 1970s were defining moments, driven by race and culture. The 1960s freed people to experiment with a diversity of lifestyles and identities. This cultural turn captured the different identities of a divided America, constructing and deconstructing the identities of blacks, but also women, men, homosexuals, Hispanics, Asians, and others. The movement was emblematic of a counteridentity grounded in blackness. Black ghetto formation during the first half of the twentieth century produced a new black ethos that contributed to an unprecedented degree of black nationalism, especially in Northern urban areas. Whereas the Civil Rights Movement initially sought to deal with power that resided mainly in the ideological state apparatus or in representative institutions like the state and church, the “Black Power” movement sought to address the power that resided in blacks themselves. It located its politics of resistance in the sphere of immanence, on an ontological rather than simply an economic or institutional basis. In doing so, it provided the basis for a new identity in the black community that was encoded in blackness, not whiteness. Resistance against whiteness, the highest justification for this new identity, took the place of political ideological differences and made the hitherto fixed borders more fluid.

At a very early stage of the Civil Rights Movement, with his nonviolent direct action campaigns and proposed march on Washington, A. Philip Randolph attempted to build black support for the Socialist Party of America based on class identity. Randolph kept the movement all-black, however. As Kenneth O’Reilly (1995, 130) put it, “The greatest antidiscrimination event in the first half of the twentieth century began by adopting discrimination as its own policy,” undermining the possibility of a class alliance between the Civil Rights and labor movements. This undermined the availability of class, one of the most powerful alternative means to overcome the vicissitudes of the “primal” identities acquired through family, school, and the market. Class identity was no longer suitable for the management and regulation of an increasingly postmodern society (Aronowitz 1992). But the new black identity also was unwilling to subject itself to a privatized existence in which political identity is at best sporadic. Instead of class, new social and cultural formations, including nationality, race, gender, and sexuality, now provided the basis for group and individual identities (Aronowitz 1992, 97). The managerial use of race was more acceptable than class for those of the disappeared working class, who cannot consume enough to be of interest to corporate America and its encoders. The emergent black consumer is the US black middle class,
leaving out of the picture the majority of blacks, including those of the disappeared working class.

Stokely Carmichael, later known as Kwame Ture, was one of the most prominent, firebrand young (student) leaders of this new identity formation. When Carmichael forcefully sounded the bugle for “Black Power” as a call to reclaim black heritage, it struck a deep chord among the young generation of blacks, many of whom had grown impatient with the “slow” pace of the Civil Rights Movement. When Carmichael forcefully sounded the bugle for “Black Power” as a call to reclaim black heritage, it struck a deep chord among the young generation of blacks, many of whom had grown impatient with the “slow” pace of the Civil Rights Movement. Huey Newton and Bobby Seale, inspired by the revolutionary theories of Frantz Fanon’s *Wretched of the Earth*, organized the Black Panther Party, which introduced a new understanding of black identity and its place in the United States. Socially isolated, economically excluded, and visibly frustrated by the continued absence of material progress, black youth not only had an intellectual fascination with the vision of black power but actually embraced it as their rallying cry, as a social and economic cause worth fighting for. The dissemination of black power throughout the black community signaled a clearly defined appropriation of a group identity, often referred to as “black America.” The emergence of this new paradigm of power provided for more diversity in the realm of culture and employment, countering the one-size-fits-all paradigm of whiteness that dominated the separate but equal regime.

To represent the strength and dignity of blacks, Carmichael countered the white rooster used to symbolize white supremacy in the state of Alabama with the symbol of the black panther. In his critique of the one-size-fits-all paradigm, Carmichael rejected the notion of the universal intellectual who represented all oppressed groups. Black power challenged the conventional identity of blacks with a new identity that held out the possibility of a black politics. It challenged the fixed binary logic of modernity, sweeping the black other into the forefront of politics. A new era had dawned for black America that the corporate world could not ignore, given its need to underpin the continual expansion of commodity exchange and consumption in an increasingly consumer-oriented, diverse society. The Black Power movement opened the possibility for a biopolitical practice to counter white supremacy. Capital transformed and now valorized the black body for consumption.

In seeking to dismantle the Jim Crow system in the South, the Civil Rights Movement was a reform movement that led to an increase in federal transfer payments to the black underclass and in affirmative action programs for admitting blacks to educational and employment programs. Since the unemployed made for lousy or poor consumers, the corporate world strongly supported the extension of these benefits into the realm of consumption. The Civil Rights Movement also set the stage for providing political and economic incentives for maintaining an individual’s sense of racial and cultural identity. But the desire for freedom as expressed in the biblical idiom of collective liberation, in the psychopolitical quest for a transformed sense of self, and in the political emphasis on participatory freedom (i.e., genuine self-determination encompassing both individual and collective dimensions), suggested that the movement had more in mind than the goals entailed by liberal reform (King 1996, 201–202). Martin Luther King retained some skepticism about black power but eventually realized the importance of building a greater sense of racial pride and potency, a new identity among blacks.

In short, the black community became more autonomous, speaking for itself not only as a producer but also as a consumer. Beginning as early as the late 1920s, “Don’t Buy Where You Can’t Work” campaigns were an important protest
strategy that spread from Chicago to corporations across America. In the 1930s the Harlem Housewives League mobilized women to boycott local chain stores for employment discrimination, arguing that blacks should be hired in proportion to the amount of money they spend in the stores. Through television, black activists began to speak in their own voice directly to audiences without the filter of white journalists (Bodroghkozy 2012). It was a black renaissance with a distinct economic bent. National liberation movements, women’s movements, the Civil Rights Movement, and other antiracist struggles are all inheritors of this cultural turn directed at undermining the separate but equal regime’s one-size-fits-all logic of whiteness.

The notion of beauty, so prominent in consumer culture, broadened beyond the classic Western one to take into account the standards of other cultures. The focus on bodies, the subject of a biopolitical power, was not to whiten skin or to straighten hair but to affirm blackness, to bring about a radical transformation of subjectivity to participate in a project of liberation, or a cultural rebound. The black body is also “beautiful.” James Brown’s “Say it Loud, I’m Black and I’m Proud” and Curtis Mayfield’s “People Get Ready” epitomized the cultural rebound that was taking place in the black community. Eager to accentuate and promote what they considered to be a positive racial identity, the black power generation took many of their cues from Africa to express black pride and culture. Dashikis became popular attire for many blacks during the 1960s, and “Afro” and cornrowing were the “natural” looks in hairstyling. Influenced by the existentialist movement, Richard Wright had already predicted this cultural rebound in the 1940s, publishing works such as Native Son (1944), Black Boy (1945), and The Outsider (1953).

For the sake of capital, black slaves were commodities to be bought and sold in the marketplace. By the time of the Civil Rights Movement, the corporate world, in its effort to expand commodity exchange and consumption, was becoming less dismissive of the black body. Capital had become interested not only in the commodification of the labor component of the black body but also in its cultural component. Under a market-led pluralist regime, capital could increase profit through the production of difference marked by race, not just abstract labor.

Recommodification of the black body

These many dimensions of cultural diversity quickly became encoded into the commodity form. For the corporate world to continue to capture and control the black consumer market, it would have to change how it approached blacks as consumers and possessors of exchange value. The one size of whiteness no longer fit all: status became more fixated on market pluralism. The black community came to embrace this recommodification of the black body as a sign of black progress. This is quite unlike slavery, when black bodies also were commodities to be bought and sold. Yet, the function of both recommodifications is the same: to underpin capital, in different ways.

Following the ghetto explosion of 1965, large corporations established departments of community affairs to combat the growing anticorporate influence in the black community. By 1967, corporate interests, led by the Ford Foundation, were deeply involved in financing most major civil rights organizations, a form of recompense to black America for its support of capital. Carmichael thus did not have the last word on black power. To stay within market reach of the black community, corporate market makers re-encoded, as black capitalism, the movement...
for “Black Power,” which had become the revolutionary cry of the black community. Weems (1998, 79) concluded that, “while many in the 1960s associated African Americans with the word ‘revolution,’ it was the corporate market marketers, the producers of media encoded texts, who had actually conducted a successful coup.” The producers of media-encoded text made it easier to penetrate the black community, simplifying its planning and programming for the sake of capital. As Earl Ofari (1970, 85) explained:

[With] the new alignment of the black politician, the black businessman (old black elite) has formed a new vested-interest power base in the black communities. Working hand-in-hand with corporate enterprise, the neo-black elites rapidly transformed the once expressive (and potentially revolutionary) cry of the black masses for black control of the black communities into capitalist control of the black communities. This only reaffirms the American ethic that everything is expendable, including principles. Everything from nail polish to Black Nationalism can be, and is, hustled as long as there is a prospect for private profit.

A call went out from within the black community for the desegregation also of the money market. Jesse Jackson urged black businessmen to move from civil rights to silver rights. Many black liberals and veterans of the Civil Rights Movement went along with this neoliberal shift. It was reinforced by the 1969 appearance of two magazines in the black community, Essence and Black Enterprise. With the aid of white corporate advertising, the new subjectivity that blacks were embracing recoded the commodification of blackness as a sign of black progress, not as a sign of whiteness. These magazines, along with their famed predecessor, Ebony, were visible symbols of black pride as well as of black America’s growing economic and popular cultural base. In its early issues, Essence carried a full-page self-promotional ad with a penetrating message that read: “Subscribe to Blackness.” In a small way, this ad bore testimony to black America’s defiant emergence from centuries of slavery, suppression, and segregation.

In the 1940s and 1950s the publisher of Ebony, John H. Johnson of Johnson Publishing Company, encouraged corporate America to reach out to the “black market” in the same way that it appealed to the white market; by 1964 he made the case for separate but equal racial retailing, almost in the same way that W.E.B. Du Bois had for a separate black economy over 30 years earlier. According to Johnson (1964, 119, 120):

The Negro market … is not a special market within the white market; it is, on the contrary, a general market defined, precisely, by its exclusion from the white market … Negro consumers tend to think, buy, and act in significantly different ways than white consumers … What Negro consumers want now is recognition of their humanity and an industry wide respect for the Negro image … [They] are growing not less self-conscious but more self-conscious … more critical … of media and products and services that deny them acceptable images … The basic factor here is the migrating mood of Negro consumers who have a new appreciation of themselves as non-whites … a newfound appreciation of blackness … It will be increasingly difficult to influence Negroes with ego ideals and ego models that are exclusively white.

For Johnson, the black body would no longer be fixated in whiteness. In the past, the black market was separate but not equal; now it had become separate but equal. Capital encoded in their commodities different identities and perspectives that would better capture and control the growing black consumer market, creating one of the greatest obstacles to a present-day black capitalist strategy.

The Congress of Racial Equality (CORE) organized a drive to convince 14 major corporations to make ads “a more realistic reflection of
the composition of the American population” by using the black body as a model in their advertisements. CORE argued that the positive use of blacks in advertisements would not adversely affect corporate sales. Corporations could still sell and realize surplus value (Advertising Age, September 9, 1963; December 9, 1968). Jesse Jackson’s Operation PUSH (People United to Save Humanity) and the SCLC’s (Southern Christian Leadership Conference) Operation Breadbasket also pressured corporate America, threatening a black consumer boycott, the most dreadful thing for capital to imagine. Martin Luther King also acknowledged the success of the consumer boycott strategy in Birmingham:

> It was not the marching alone that brought about integration of public facilities in 1963. The downtown business establishments suffered for weeks under our almost unbelievably effective boycott. The significant percentage of their sales that vanished, the 98 percent of their Negro customers who stayed home, educated them forcefully to the dignity of the Negro as a consumer. (quoted in Washington 1986, 602; emphasis added)

The corporate world needed little persuasion, however, knowing full well that it had to sell to the black segment of the market. It could mean the difference between making and not making a profit.

This compulsion was evident, at least in terms of buying advertising space in the black print media. Full-page ads in very early issues of Essence and Black Enterprise show that cigarette manufacturers, regardless of their growing concerns about the connections being made between smoking and cancer, were among those who led the way in showing a keen interest in the black consumer. The number of full-page ads increased noticeably in Essence within less than two years of its initial publication. Essence carried merely five full-page ads in its January 1971 issue, but within few months this more than doubled to a dozen. Significantly, the magazine’s corporate client base expanded to include some of the major corporations of the time, including Sears, Levi’s, Pepsi, and producers of Martex, Kleenex, Tampax, Wohl Shoes, and Elan (perfume). Even TWA, Pan Am, Earhart (luggage), and Modern Living by Nancy Heine-man (household furniture) began to buy ads that targeted black consumers without offending them. The gains that Black Enterprise posted in terms of securing corporate advertisements were no less impressive. By 1974, within five years of its inception, its advertisers included such corporate heavyweights as Merrill Lynch, New York Life, Metropolitan Life, IBM, AT&T, Amoco, Exxon, Gulf, GM, Ford, Chrysler, Xerox, Delta, Rouse Company, Puma, Polaroid, GTE, and CBS. In one 1974 advertisement about increasing diversity, marketers at CBS noted: men and women of all races desired. This said it all about the emerging new corporate paradigm.

Through advertising in the black media, white corporate interest was able to solidify its control of the black consumer market, realizing more surplus value. Leading companies bought product advertisements in the black print media whose circulation was predominantly concentrated among black households. In the mid-1960s the late H. Taylor Fitzhugh pioneered the concept of black consumer marketing as an executive at Pepsi-Cola whose ads also appeared in Essence (Graves 1997). Having spent several million dollars in black-oriented advertising, Pepsi-Cola saw its annual profits increase from $157.6 million to $250 million between 1960 and 1964. In its fortieth anniversary issue, Ebony contained 162 pages of advertising worth $6.2 million, offering a vision of a bland consumer culture in multiple shades.
These magazines were not simply icons and outlets for black pride and consciousness. Profit-oriented enterprises themselves, they clearly understood the need for capital to sell and realize surplus value. It is, therefore, no surprise that the black print media served as a confluence not only of black power and pride but also of power and pride in the expansion of the commodity form for the sake of capital. As the popularity and circulation of these magazines grew among black consumers, they provided a genuine alternative and hence competition to white magazines of their genre.

With the black print media acting as a powerful and most visible conduit, black households had effectively become the target of a separate but equal marketing campaign on the part of corporate marketers and producers of media-encoded text. The black print media, represented by *Black Enterprise*, *Essence*, *Jet*, and a host of other newcomers, clearly served a purpose in flexing their muscles to demonstrate black consumer power. The specter of black power was finally hitting the world of marketing research because capital has to sell. Corporate marketers of women’s beauty and personal care products, in particular, sought to sell both “beauty” and “status” to black women, but this time in its black form (Weems 1998, 91). The advertising campaigns for cosmetics and beauty products were particularly racially targeted. The black community had evolved into a potent segment of America’s consumer market.

Black-owned ad agencies used their professional expertise to target black consumers for various corporations and their products. Several of the major black-owned advertising agencies were established in the 1970s, one as early as 1956 but most in the 1980s. In 1992 they spent $785 million just to reach the black market segment alone.

Target marketing, instead of one size fits all, had emerged as the corporate strategy aimed at a particular demographic and lifestyle category at a time when lifestyles were becoming increasingly the basis of social distinction. While market segments are delineated by geography, age, and sex, others contain racial and ethnic components, differentiating them from the mainstream market defined by its dominant white American client base. Marketing segmentation rejects the production of blacks as a replica of whiteness; this leads to blacks, as well as other racial and ethnic identities, becoming a market niche encoded by corporate advertising. It amounts to the commodification of blackness as a cultural or aesthetic category. No longer viewed as dark-skinned white people, blacks had their own identity or culture which could be marketed just like any other commodity. Consumer choice is thereby diverted into a mechanism for differentiating on the base of various dimensions of diversity, underwriting the production, distribution, and consumption of commodities.

This has the effect of expanding markets across multiple borders: the more differentiated or segmented the market, the greater the number of target markets from which to realize surplus value. Culture and media industries accelerate segmentation and identity formation through creating specific delimited consumer markets. Something is provided for all, so none can escape the invisible hand of the market: distinctions are emphasized and extended in these postmodern times.

The postmodern cultural turn produced a brave new world with a greater emphasis on choice and product differentiation; on marketing, packaging, and design; on the targeting of consumers by lifestyle, taste, and culture rather than just by categories of social class. Identities are reflected in lifestyles that are closely associated with brands and the products they label.
This enables consumers to express individual sovereignty through identities, constructed by acquiring and displaying goods that convey information about them and their position within a constellation of social networks. Rather than seeing identity as fixated on whiteness, the one-size-fits-all strategy, identities are now considered plural and dynamic, hybrid and fluid. Consumers carry, as Mort (1989, 169) noted, “a bewildering range of different and at times conflicting identities around with them in their heads at the same time.” A flexible regime of accumulation reconstitutes the production and distribution of commodities to exploit this hybridity and fluidity in society. By recommodifying the black body to enhance consumption, a racialized and more diversified underpinning of the corporation has taken hold.

A flexible regime of accumulation

A main flaw of postmodern analysis is that it tends to ignore the social relations of production or the class structure of capitalism. Market makers, encoders of text, and consumers as decoders of text are not free of structural constraints. The postmodern cultural turn suggests an open and dynamic egalitarian culture, with constant cultural flows and mixtures. Exploiting this openness and mixture in the constitution of production, and the diversification of consumption and distribution, requires a regime of accumulation more flexible than the Fordist regime.

Whereas through the first half of the twentieth century Fordism was producing conformity, by the 1970s a flexible specialization regime was offering greater authenticity, individuality, difference, and rebellion as a market strategy. Corporations could now maximize profits through the social production of difference, marked also by race. Featherstone (1994, 404) notes: “Since the 1960s there has been a more general informalization and elaboration of previously restricted codes of behavior.” If the trauma of World War II meant that the corporate world faced a society mentally wedded to mutual cooperation and togetherness, 20 years later the Civil Rights Movement and the Vietnam War set the stage for a more fragmented society which the corporation was able to exploit in different ways.

Left to its own devices, the corporate world never abandons a profitable regime. The separate but equal regime had been profitable, reproducing the racial hierarchy and making money in the process. It was basically a producer-driven commodity chain whose primary objective was the production and consumption of whiteness. Through the mass production of standardized goods, it counted on adequate consumer demand but had little need to listen to the market. This regime defined the market as massive and white, paying little or no attention to differences within it. Feedback from consumption to production did allow some changes in the market to translate to changes in productive engineering, but this communication circuit was restricted, slow, and lacked flexibility.

The mass market became increasingly saturated as a result of rapid rises in productivity after 1945. Consumer markets began to stagnate, posing a noticeable constraint to economic growth in the industrialized world. The corporate world expanded mass production and consumption, increasing the competition for the consumer dollar. Mass marketing became highly competitive. But additional advertising and promotion yielded diminishing returns. The market for consumer goods was increasingly governed by replacement demand turnover and obsolescence rather than by the opening up of new markets, which had been possible throughout the 1950s and early 1960s. Having reached its maximum potential, mass marketing intensified efforts to open up new markets. But the fixity and
standardization of the separate but equal regime began to pose obstacles to the further progression of capital. A more mobile and flexible regime had become necessary, which was not fixated on whiteness or on a particular identity or status relation.

The separate but equal regime lacked the flexibility to exploit the growing demand for more differentiated products or hybridity in the marketplace. Thus, capital had to engage in the social production of difference. Wendell Smith (1956, 7) had already warned of the growing danger of product competition with mass production and mass marketing. He noted that the theory of perfect competition, the basis of neoclassical economic theory, assumes homogeneity, that one size fits all, but diversity or difference had become the rule. He proposed exploiting “market segmentations,” arguing that, in place of a mass market, goods would “find their markets of maximum potential as a result of recognition of difference in the requirements of market segments.” Concluding that “their core markets have already been developed,” Smith (1956, 7) advised companies that “attention to smaller or fringe market segments, which may have small potentials individually but are of crucial importance in the aggregate,” could be profitable. Capital could maximize its profits not just by rendering labor abstract but also through the social production of difference.

Consumption has become symbolic of social distinctions. Mass-produced products lack status or lifestyle differences, the sign value that targets a particular socioeconomic group to buy. Decades before Baudrillard’s (1983) cultural analysis of the commodity sign, the automobile industry had already started to encode its products in market segments, manipulating the sign value of its commodities to communicate messages about the status or lifestyle of the consumer. Growth required selling cars whose appearance and features become obsolete on an annual basis. It was better to divide up the mass market according to distinctive needs and desires. Instituting model and color diversity, the automobile industry placed its products in different geographical and social contexts to denote a specific rather than a generic product. Production became a bundle of changing characteristics designed, produced, and marketed to appeal to different market segments of the population.

With geodemographic analysis, the corporation is able to predict variations in consumption based on a host of demographic factors such as race and where a person lives. Mass culture becomes micro: smaller fringe markets matter. Commodities are branded on the basis of where they are made. Corporations are increasingly emphasizing localized production and consumption.

The cultural and racial discontent of the 1960s and 1970s made universal or mass marketing increasingly impractical, weakening the strategy of one size fits all. In the corporate world, the fixed relations that characterized the separate but equal racialized corporate regime became increasingly impractical and illegitimate. Corporations become less receptive to the notion of social purification.

It is not coincidental that the newly constituted regime corresponded to the historical era of discontent in the 1960s and 1970s. If it was not for the Black Power movement, the student revolts, the women’s movement, and other antiracist struggles, the corporate world may have been content to maintain the one-size-fits-all corporate strategy, happy to avoid the trouble of having to reconstitute production, distribution, and consumption. Instead, in the new social and cultural formations, capital saw the opportunity to create more value and to expand commodity exchange and consumption by recoding and decoding race, bringing the strange, the other,
into the space of the ordinary. According to Cohen:

social and cultural groups such as African Americans, women, youth, and senior citizens began to assert themselves in a way that came to be called “identity politics,” where people’s affiliation with a particular community defined their cultural consciousness and motivated their collective political action. Marketers, who had they not been in search of ways to avoid saturating the mass market, might have despaired at the splintering of the mass in the 1960s, soon seized the new opportunities for selling it offered. (2003, 308; emphasis added)

Needing to sell to realize value, corporations seized on the opportunity offered by the racial discontent of the 1960s and 1970s to do just that.

Conclusion

Consumption is diverse, fluid, and varied rather than fixed and monolithic. The tension between race and corporate capital’s need to expand commodity exchange and consumption asserts itself in unexpected ways across time and space. Race, then and now, is a product of this tension. It cannot be seen merely as a reflection of racial ideologies. It must be situated within a framework that understands and critiques capitalism as an ideology that sustains and reproduces capital relations of production.

From the consumption of whiteness, the one-size-fits-all paradigm, the corporate world has shifted to a market-led pluralism that recognizes different consumer market segments. This postmodern paradigm shift reached new heights as black cultural elements, once ignored in the marketplace, were widely marketed by corporations. As a result, blackness is no longer represented as the opposite of whiteness but as a commodity to be consumed by all. The classical black sound of rap, the new rhythm of consciousness and resistance, and its hip-hop cultural form are commodified to be bought and sold on the world market. This regime of accumulation is less fixated on whiteness and conformity, on maintaining fixed status relations. The consumerism of postmodernity, held to be incommensurate with the fixed relations of modernity, accommodates differences to expand markets. Contemporary producers of encoded texts welcome the youth-led and hip-hop cultural revolution as an ally in their own struggle to manage and regulate society for the sake of capital. Rap and hip-hop are prime examples of the commodification of race for the sake of capital, having become extraordinarily commercially successful worldwide. Rap is globally produced and consumed more than ever, and in diverse markets. The underlying motivation for positing race and culture as the bases of collective identity was social, but not far behind was the neoliberal need to express race and culture as a commodity form to realize surplus value.

The black print media reproduced neoliberalism in the black community. Yet it often blames black and brown populations for their economic circumstances and for failing to fight against structural factors that keep them economically subordinate. The black corporate world has “earned the confidence of the white corporate hierarchy and the capitalist state by keeping alive the bogus illusion of a black capitalism” (Marable 2000, 158). Yet over four-fifths of all black-owned US firms are small businesses, struggling against massive odds to not fall back into the ranks of the proletariat. Further, the black community lacks an effective voice to articulate the growing black demand for economic opportunities.

More research is needed on the ways in which the corporation reworks cultural elements to expand commodity exchange and consumption,
and the implications thereof. Has this reworking of culture elements produced a culture war over meaning and lifestyle? Can we put a neoliberal face on this culture war? Many condone this reworking of culture because it sells. Hip-hop reproduces neoliberalism by emphasizing narratives that laud violence, crime, and drug use in the black community. To expand commodity exchange and consumption, the corporate world welcomes all, even those from the ‘hood. It manages and regulates this life of diversity opportunistically to make money. Social networking sites such as MySpace and Facebook are invaluable in identifying niche markets of potential consumers for capital.

To what extent has this cultural manipulation of the consumer by capital contributed to the underdevelopment of the black community? The 1968 Report on Civil Disorder by the Kerner Commission documented the pent-up desire for consumer goods that television, movies, and advertising held up. While black consumer spending has increased, few dollars circulate in the black community. Black consumers are foot soldiers for corporate interest, siphoning away dollars from the black economy (Weems 2005, 253). For every $8 to $10 spent in the black community only $1 remains. An informal and predatory community, consisting of illegal practices such as drug trafficking and prostitution, develops as the poor person’s way to cut himself or herself in on the consumer society and to survive in a community that’s leaking a substantial amount of capital.

Further reading

Many who have sought to disentangle the complexities of advanced capitalist societies have accepted the Marxist idea of the centrality of production in political economy. Corporations are the key operational units of capitalist economies. Each corporation operates in geographical space, with multiple locations and connections to suppliers and customers. Yet the structural imperative of the corporate world is not only production expansion but also consumer spending. In order to realize the profits undergirding long-term viability, corporations need everyone’s needs. Marx recognized the important role of workers as consumers. Historically, labor situated its politics at the intersection of production and consumption, building worker solidarity while also mobilizing workers’ purchasing power in its struggle with capital. Yet anglophone Marxist scholars have failed to grasp that transcritical moment when production and consumption intersect, making the distinction between the two a difficult dialectical synthesis. Just as much surplus value can be made in retailing as in production or manufacturing. Indeed, the world’s largest corporation, Walmart, is a retailer which subcontracts manufacturing. More generally, the offshoring of production, together with the decline of public sector jobs, brought about the disappearance of the black corporate working class. Yet, as US corporations closed domestic factories, they gradually shifted emphasis to distribution and consumption.

Combining case history and analysis, this entry examines how blackness and whiteness underpins the operation of corporations in the United States. Race-connected practices are not self-determined but are constituted by their corporate relations with production, distribution, and consumption. As the nation’s largest retailer, Walmart carries a meaning for consumers that extends well beyond the price of goods and services (Weston 2009). Since the 1880s, the court has ruled that corporations are in fact people entitled to free speech rights guaranteed by the Constitution. Race can be a barrier to capital’s expansion of commodity exchange, but it can also be used to facilitate such an expansion to build empires. In order for capital to govern production, distribution, and consumption, it also regulates race-connected practices to stay within reach of the black domestic market. This entry focuses first on how corporations in the United States were able to extract surplus under the rules governing the racial doctrine of “separate but equal.” It then examines how corporations culturally manipulated the black consumer to extract billions of dollars in profits from the black domestic market, thereby underdeveloping the black community (Marable 2000).

Separate but equal corporate regime

Race is just one of many barriers that capital seeks to overcome. Race-connected practices are diverse, fluid, and varied rather than fixed and monolithic. Race asserts itself in unexpected ways across time and space. Race, both in the
past and now, is a product of this tension. It cannot be seen merely as a reflection of racial ideologies. It must be situated within a framework that understands and critiques capitalism as an ideology that sustains and reproduces the capital relations of production.

While race can be a barrier that capital seeks to overcome, it can also be used to underpin capital through the production of differences marked by and constructed through race. Capital’s earliest renderings of the production of difference took the form of black slavery and the seizure of indigenous Indian land. The transatlantic slave trade became tantamount to the Western world’s first multinational corporation, which was responsible for the exportation of almost 12 million Africans to the so-called New World where they were sold as commodities on the slave market. From its origins as a manufacturer of soap, Unilever became a global corporation on the basis of profits from its African-based enterprises (Marable 2000). The seizure of indigenous land in America forced the removal of approximately 70,000 Native Americans to reservations beginning in the 1830s. Land taken from black families in the twentieth century became corporate country clubs, and the US South emerged as a leading sporting destination for corporate elites. Many of these gaming areas now include landing strips capable of handling corporate jets.

The racial doctrine of separate but equal regulated US race-connected practices. This doctrine lasted from the time of the Plessy (1892) decision to the 1954 Brown decision. Status was fixated in whiteness but also in the market. It meant that capitalists could separate themselves from blacks but had to remain within market reach. Race facilitated commodity exchange and consumption while also serving as a barrier to such an exchange. Blacks purchased racial pride and respect by consuming certain commodities. The corporate world thus drew on black consumption while also providing the sociospatial structure needed for the continuous authentication of whiteness.

The only decade when evidence shows that the corporation was out of the reach of the black consumer market was 1919 to 1929. It was the most extensive period of racial segregation but also a golden period for the growth of black businesses. It was a time in which virtually every black neighborhood or town claimed a number of independent black entrepreneurs who were providing goods and services to an exclusively black consumer market (Marable 2000, 146). For the white corporate world this lack of consumer demand was not sustainable, given the lessons learned from the Great Depression. Totally separate economies undermine capital’s need to continuously expand the sphere of commodity exchange and consumption and to avoid another depression.

White corporations eventually gained control of the black domestic market. Following the end of slavery, the US Supreme Court never affirmed a common law right for businesses that were open to the public to exclude blacks completely on the ground of race. Nor did the court deny property rights on the basis of race – for capital, access to market, and property ownership must be protected at any cost, even if it meant violating the separate but equal doctrine. For most of the twentieth century, the corporation charmed consumers with whiteness to create value and expand commodity exchange and consumption, bestowing exchange value on whiteness. This drove the accumulation of capital. All consumers were deemed white. Henry Ford manufactured his Model-T for the white masses who wanted not only the utility value of the commodity but also the fixed social relations encoded in it.

The 1893 World’s Columbian Exposition in Chicago, designed to advance the causes of
American nationalism, imperialism, and consumerism, exhibited commodities that ridiculed and denigrated blacks for the sake of white consumption. A prominent Midwestern flour-milling firm, R.T. Davis Milling Company, persuaded Nancy Green, a 57-year-old former slave, to become a living advertisement at the fair for the company’s Aunt Jemima Pancake Mix. Green played the role of a stereotypical plantation mammy, winning the milling firm an award at the fair. Aunt Jemima thus became a corporate brand that gained national acceptance as an early icon of America’s emerging culture of mass production and consumption. In this sense Green became what Baudrillard (1983, quoted in Mullins 1999, 43) terms a “simulacrum”: “she materialized a black caricature that never existed in reality, yet that caricature assumed the status of authenticity in the white imagination because of pervasive belief in it,” marginalizing the status of black women who historically performed domestic labor (Mullins 1999, 46). In Michel Foucault’s terms, this racialized representation is a privileged discourse that exercised, in this case, “inordinate influence on the definition, circulation, and naturalization of racial subjectivities and white superiority” (quoted in Rabinow 1984, 108; see 108–113). Race is thus mutually constituted through the formulation of a commodity exchange circuit, a totality with the distinct moments of production, distribution, and consumption.

Following the 1954 Brown decision, consumer demand for a wider range of products made greater choices possible — choices that would have been illegal or impossible under the separate but equal doctrine. As encoding commodities purely in whiteness became increasingly a liability, the corporate world, beginning in the 1960s, moved increasingly toward a more flexible regime of accumulation without the status fixated in whiteness. Separate was no longer considered equal, setting the stage for the Civil Rights Movement and eventually the creation of a more diverse market. The one size of whiteness no longer fit all, ushering in a more flexible regime of accumulation that could better exploit the many dimensions of pluralism. The corporation promoted the production of differences to expand markets. Differences pay. Consumption coincides with the many dimensions of identity: race, ethnicity, gender, sexuality, religion, and language, among others. Geodemographic marketing accelerated this kind of differentiation, which was missed from Marx’s Capital.

Pluralist-led market regime

A political and social push for an identity that is not fixed just in whiteness can be traced back to the 1920s, with the “New Negro Renaissance.” This was not only a period of incredible economic boom but also of cultural ferment. What was held to be “authentically” black began to change, as the popular musical form ragtime gave way to jazz in 1917, when some white New Orleans musicians, calling themselves the Original Dixieland Jazz Band, began to produce their encoded version of the music. Their whiteness paved the way for the widespread acceptance of jazz which entered the mainstream in white skin, even though black musicians had been playing in New Orleans since the turn of the twentieth century (Wynter 2002, 48). The race that gave blacks the everyday “blues” could now make money playing and singing the blues. It was mainly through white artists that much of “black folk culture, black inventiveness, black talent gave the twenties its distinctive image as the ‘Jazz Age’ and dictated the character of mainstream American popular music and culture for years to come” (Wynter 2002, 48). The one-size-fits-all of whiteness meant that black artists could not
CORPORATIZATION OF RACE: AN AMERICAN CASE STUDY

speak for themselves. The “King of Swing,” Benny Goodman, had no problem owning up to the black roots of swing, but many in the white community continued to have problems with this, fixating the dance form in whiteness (Wynter 2002, 48, 69).

By the 1940s, black jazz artists began to challenge this one-size-fits-all racial paradigm in cultural political economy. John Coltrane, Miles Davis, and other jazz artists were encoding a musical style that informed a new black self-consciousness in opposition to whiteness. These black artists rebelled against attempts to “whiten” jazz “to bleach away its African roots,” rejecting values that politically and culturally subjugated blacks (Kofsky 1998, 57). They were posited as the basis of collective identity, after having initially been rejected as a valid form of classification. Having defined the terms of domination in whiteness, “white” colonizers found their rule challenged by people asserting a counteridentity grounded in a celebration of blackness.

Richard King (1996) has observed how the struggles of the 1960s and 1970s were defining moments, driven by race and culture. The 1960s freed people to experiment with a diversity of lifestyles and identities. This cultural turn captured the different identities of a divided America, constructing and deconstructing the identities of blacks, but also women, men, homosexuals, Hispanics, Asians, and others. The movement was emblematic of a counteridentity grounded in blackness. Black ghetto formation during the first half of the twentieth century produced a new black ethos that contributed to an unprecedented degree of black nationalism, especially in Northern urban areas. Whereas the Civil Rights Movement initially sought to deal with power that resided mainly in the ideological state apparatus or in representative institutions like the state and church, the “Black Power” movement sought to address the power that resided in blacks themselves. It located its politics of resistance in the sphere of immanence, on an ontological rather than simply an economic or institutional basis. In doing so, it provided the basis for a new identity in the black community that was encoded in blackness, not whiteness. Resistance against whiteness, the highest justification for this new identity, took the place of political ideological differences and made the hitherto fixed borders more fluid.

At a very early stage of the Civil Rights Movement, with his nonviolent direct action campaigns and proposed march on Washington, A. Philip Randolph attempted to build black support for the Socialist Party of America based on class identity. Randolph kept the movement all-black, however. As Kenneth O’Reilly (1995, 130) put it, “The greatest antidiscrimination event in the first half of the twentieth century began by adopting discrimination as its own policy,” undermining the possibility of a class alliance between the Civil Rights and labor movements. This undermined the availability of class, one of the most powerful alternative means to overcome the vicissitudes of the “primal” identities acquired through family, school, and the market. Class identity was no longer suitable for the management and regulation of an increasingly postmodern society (Aronowitz 1992). But the new black identity also was unwilling to subject itself to a privatized existence in which political identity is at best sporadic. Instead of class, new social and cultural formations, including nationality, race, gender, and sexuality, now provided the basis for group and individual identities (Aronowitz 1992, 97). The managerial use of race was more acceptable than class for those of the disappeared working class, who cannot consume enough to be of interest to corporate America and its encoders. The emergent black consumer is the US black middle class,
leaving out of the picture the majority of blacks, including those of the disappeared working class.

Stokely Carmichael, later known as Kwame Ture, was one of the most prominent, firebrand young (student) leaders of this new identity formation. When Carmichael forcefully sounded the bugle for “Black Power” as a call to reclaim black heritage, it struck a deep chord among the young generation of blacks, many of whom had grown impatient with the “slow” pace of the Civil Rights Movement. Huey Newton and Bobby Seale, inspired by the revolutionary theories of Frantz Fanon’s *Wretched of the Earth*, organized the Black Panther Party, which introduced a new understanding of black identity and its place in the United States. Socially isolated, economically excluded, and visibly frustrated by the continued absence of material progress, black youth not only had an intellectual fascination with the vision of black power but actually embraced it as their rallying cry, as a social and economic cause worth fighting for. The dissemination of black power throughout the black community signaled a clearly defined appropriation of a group identity, often referred to as “black America.” The emergence of this new paradigm of power provided for more diversity in the realm of culture and employment, countering the one-size-fits-all paradigm of whiteness that dominated the separate but equal regime.

To represent the strength and dignity of blacks, Carmichael countered the white rooster used to symbolize white supremacy in the state of Alabama with the symbol of the black panther. In his critique of the one-size-fits-all paradigm, Carmichael rejected the notion of the universal intellectual who represented all oppressed groups. Black power challenged the conventional identity of blacks with a new identity that held out the possibility of a black politics. It challenged the fixed binary logic of modernity, sweeping the black other into the forefront of politics. A new era had dawned for black America that the corporate world could not ignore, given its need to underpin the continual expansion of commodity exchange and consumption in an increasingly consumer-oriented, diverse society. The Black Power movement opened the possibility for a biopolitical practice to counter white supremacy. Capital transformed and now valorized the black body for consumption.

In seeking to dismantle the Jim Crow system in the South, the Civil Rights Movement was a reform movement that led to an increase in federal transfer payments to the black underclass and in affirmative action programs for admitting blacks to educational and employment programs. Since the unemployed made for lousy or poor consumers, the corporate world strongly supported the extension of these benefits into the realm of consumption. The Civil Rights Movement also set the stage for providing political and economic incentives for maintaining an individual’s sense of racial and cultural identity. But the desire for freedom as expressed in the biblical idiom of collective liberation, in the psychopolitical quest for a transformed sense of self, and in the political emphasis on participatory freedom (i.e., genuine self-determination encompassing both individual and collective dimensions), suggested that the movement had more in mind than the goals entailed by liberal reform (King 1996, 201–202). Martin Luther King retained some skepticism about black power but eventually realized the importance of building a greater sense of racial pride and potency, a new identity among blacks.

In short, the black community became more autonomous, speaking for itself not only as a producer but also as a consumer. Beginning as early as the late 1920s, “Don’t Buy Where You Can’t Work” campaigns were an important protest
strategy that spread from Chicago to corporations across America. In the 1930s the Harlem Housewives League mobilized women to boycott local chain stores for employment discrimination, arguing that blacks should be hired in proportion to the amount of money they spend in the stores. Through television, black activists began to speak in their own voice directly to audiences without the filter of white journalists (Bodroghkozy 2012). It was a black renaissance with a distinct economic bent. National liberation movements, women’s movements, the Civil Rights Movement, and other antiracist struggles are all inheritors of this cultural turn directed at undermining the separate but equal regime’s one-size-fits-all logic of whiteness.

The notion of beauty, so prominent in consumer culture, broadened beyond the classic Western one to take into account the standards of other cultures. The focus on bodies, the subject of a biopolitical power, was not to whiten skin or to straighten hair but to affirm blackness, to bring about a radical transformation of subjectivity to participate in a project of liberation, or a cultural rebound. The black body is also “beautiful.” James Brown’s “Say it Loud, I’m Black and I’m Proud” and Curtis Mayfield’s “People Get Ready” epitomized the cultural rebound that was taking place in the black community. Eager to accentuate and promote what they considered to be a positive racial identity, the black power generation took many of their cues from Africa to express black pride and culture. Dashikis became popular attire for many blacks during the 1960s, and “Afro” and cornrowing were the “natural” looks in hairstyling. Influenced by the existentialist movement, Richard Wright had already predicted this cultural rebound in the 1940s, publishing works such as Native Son (1944), Black Boy (1945), and The Outsider (1953).

For the sake of capital, black slaves were commodities to be bought and sold in the marketplace. By the time of the Civil Rights Movement, the corporate world, in its effort to expand commodity exchange and consumption, was becoming less dismissive of the black body. Capital had become interested not only in the commodification of the labor component of the black body but also in its cultural component. Under a market-led pluralist regime, capital could increase profit through the production of difference marked by race, not just abstract labor.

Recommodification of the black body

These many dimensions of cultural diversity quickly became encoded into the commodity form. For the corporate world to continue to capture and control the black consumer market, it would have to change how it approached blacks as consumers and possessors of exchange value. The one size of whiteness no longer fit all: status became more fixated on market pluralism. The black community came to embrace this recommodification of the black body as a sign of black progress. This is quite unlike slavery, when black bodies also were commodities to be bought and sold. Yet, the function of both recommodifications is the same: to underpin capital, in different ways.

Following the ghetto explosion of 1965, large corporations established departments of community affairs to combat the growing anticorporate influence in the black community. By 1967, corporate interests, led by the Ford Foundation, were deeply involved in financing most major civil rights organizations, a form of recompense to black America for its support of capital. Carmichael thus did not have the last word on black power. To stay within market reach of the black community, corporate market makers re-encoded, as black capitalism, the movement
for “Black Power,” which had become the revolutionary cry of the black community. Weems (1998, 79) concluded that, “while many in the 1960s associated African Americans with the word ‘revolution,’ it was the corporate market marketers, the producers of media encoded texts, who had actually conducted a successful coup.” The producers of media-encoded text made it easier to penetrate the black community, simplifying its planning and programming for the sake of capital. As Earl Ofari (1970, 85) explained:

[With] the new alignment of the black politician, the black businessman (old black elite) has formed a new vested-interest power base in the black communities. Working hand-in-hand with corporate enterprise, the neo-black elites rapidly transformed the once expressive (and potentially revolutionary) cry of the black masses for black control of the black communities into capitalist control of the black communities. This only reaffirms the American ethic that everything is expendable, including principles. Everything from nail polish to Black Nationalism can be, and is, hustled as long as there is a prospect for private profit.

A call went out from within the black community for the desegregation also of the money market. Jesse Jackson urged black businessmen to move from civil rights to silver rights. Many black liberals and veterans of the Civil Rights Movement went along with this neoliberal shift. It was reinforced by the 1969 appearance of two magazines in the black community, Essence and Black Enterprise. With the aid of white corporate advertising, the new subjectivity that blacks were embracing recoded the commodification of blackness as a sign of black progress, not as a sign of whiteness. These magazines, along with their famed predecessor, Ebony, were visible symbols of black pride as well as of black America’s growing economic and popular cultural base. In its early issues, Essence carried a full-page self-promotional ad with a penetrating message that read: “Subscribe to Blackness.” In a small way, this ad bore testimony to black America’s defiant emergence from centuries of slavery, suppression, and segregation.

In the 1940s and 1950s the publisher of Ebony, John H. Johnson of Johnson Publishing Company, encouraged corporate America to reach out to the “black market” in the same way that it appealed to the white market; by 1964 he made the case for separate but equal racial retailing, almost in the same way that W.E.B. Du Bois had for a separate black economy over 30 years earlier. According to Johnson (1964, 119, 120):

The Negro market … is not a special market within the white market; it is, on the contrary, a general market defined, precisely, by its exclusion from the white market … Negro consumers tend to think, buy, and act in significantly different ways than white consumers … What Negro consumers want now is recognition of their humanity and an industry wide respect for the Negro image … [They] are growing not less self-conscious but more self-conscious … more critical … of media and products and services that deny them acceptable images … The basic factor here is the migrating mood of Negro consumers who have a new appreciation of themselves as non-whites … a newfound appreciation of blackness … It will be increasingly difficult to influence Negroes with ego ideals and ego models that are exclusively white.

For Johnson, the black body would no longer be fixated in whiteness. In the past, the black market was separate but not equal; now it had become separate but equal. Capital encoded in their commodities different identities and perspectives that would better capture and control the growing black consumer market, creating one of the greatest obstacles to a present-day black capitalist strategy.

The Congress of Racial Equality (CORE) organized a drive to convince 14 major corporations to make ads “a more realistic reflection of
the composition of the American population” by using the black body as a model in their advertisements. CORE argued that the positive use of blacks in advertisements would not adversely affect corporate sales. Corporations could still sell and realize surplus value (Advertising Age, September 9, 1963; December 9, 1968). Jesse Jackson’s Operation PUSH (People United to Save Humanity) and the SCLC’s (Southern Christian Leadership Conference) Operation Breadbasket also pressured corporate America, threatening a black consumer boycott, the most dreadful thing for capital to imagine. Martin Luther King also acknowledged the success of the consumer boycott strategy in Birmingham:

It was not the marching alone that brought about integration of public facilities in 1963. The downtown business establishments suffered for weeks under our almost unbelievably effective boycott. The significant percentage of their sales that vanished, the 98 percent of their Negro customers who stayed home, educated them forcefully to the dignity of the Negro as a consumer. (quoted in Washington 1986, 602; emphasis added)

The corporate world needed little persuasion, however, knowing full well that it had to sell to the black segment of the market. It could mean the difference between making and not making a profit.

This compulsion was evident, at least in terms of buying advertising space in the black print media. Full-page ads in very early issues of Essence and Black Enterprise show that cigarette manufacturers, regardless of their growing concerns about the connections being made between smoking and cancer, were among those who led the way in showing a keen interest in the black consumer. The number of full-page ads increased noticeably in Essence within less than two years of its initial publication. Essence carried merely five full-page ads in its January 1971 issue, but within few months this more than doubled to a dozen. Significantly, the magazine’s corporate client base expanded to include some of the major corporations of the time, including Sears, Levi’s, Pepsi, and producers of Martex, Kleenex, Tampax, Wohl Shoes, and Elan (perfume). Even TWA, Pan Am, Earhart (luggage), and Modern Living by Nancy Heine-man (household furniture) began to buy ads that targeted black consumers without offending them. The gains that Black Enterprise posted in terms of securing corporate advertisements were no less impressive. By 1974, within five years of its inception, its advertisers included such corporate heavyweights as Merrill Lynch, New York Life, Metropolitan Life, IBM, AT&T, Amoco, Exxon, Gulf, GM, Ford, Chrysler, Xerox, Delta, Rouse Company, Puma, Polaroid, GTE, and CBS. In one 1974 advertisement about increasing diversity, marketers at CBS noted: men and women of all races desired. This said it all about the emerging new corporate paradigm.

Through advertising in the black media, white corporate interest was able to solidify its control of the black consumer market, realizing more surplus value. Leading companies bought product advertisements in the black print media whose circulation was predominantly concentrated among black households. In the mid-1960s the late H. Taylor Fitzhugh pioneered the concept of black consumer marketing as an executive at Pepsi-Cola whose ads also appeared in Essence (Graves 1997). Having spent several million dollars in black-oriented advertising, Pepsi-Cola saw its annual profits increase from $157.6 million to $250 million between 1960 and 1964. In its fortieth anniversary issue, Ebony contained 162 pages of advertising worth $6.2 million, offering a vision of a bland consumer culture in multiple shades.
These magazines were not simply icons and outlets for black pride and consciousness. Profit-oriented enterprises themselves, they clearly understood the need for capital to sell and realize surplus value. It is, therefore, no surprise that the black print media served as a confluence not only of black power and pride but also of power and pride in the expansion of the commodity form for the sake of capital. As the popularity and circulation of these magazines grew among black consumers, they provided a genuine alternative and hence competition to white magazines of their genre.

With the black print media acting as a powerful and most visible conduit, black households had effectively become the target of a separate but equal marketing campaign on the part of corporate marketers and producers of media-encoded text. The black print media, represented by *Black Enterprise*, *Essence*, *Jet*, and a host of other newcomers, clearly served a purpose in flexing their muscles to demonstrate black consumer power. The specter of black power was finally hitting the world of marketing research because capital has to sell. Corporate marketers of women’s beauty and personal care products, in particular, sought to sell both “beauty” and “status” to black women, but this time in its black form (Weems 1998, 91). The advertising campaigns for cosmetics and beauty products were particularly racially targeted. The black community had evolved into a potent segment of America’s consumer market.

Black-owned ad agencies used their professional expertise to target black consumers for various corporations and their products. Several of the major black-owned advertising agencies were established in the 1970s, one as early as 1956 but most in the 1980s. In 1992 they spent $785 million just to reach the black market segment alone.

Target marketing, instead of one size fits all, had emerged as the corporate strategy aimed at a particular demographic and lifestyle category at a time when lifestyles were becoming increasingly the basis of social distinction. While market segments are delineated by geography, age, and sex, others contain racial and ethnic components, differentiating them from the mainstream market defined by its dominant white American client base. Marketing segmentation rejects the production of blacks as a replica of whiteness; this leads to blacks, as well as other racial and ethnic identities, becoming a market niche encoded by corporate advertising. It amounts to the commodification of blackness as a cultural or aesthetic category. No longer viewed as dark-skinned white people, blacks had their own identity or culture which could be marketed just like any other commodity. Consumer choice is thereby diverted into a mechanism for differentiating on the base of various dimensions of diversity, underwriting the production, distribution, and consumption of commodities.

This has the effect of expanding markets across multiple borders: the more differentiated or segmented the market, the greater the number of target markets from which to realize surplus value. Culture and media industries accelerate segmentation and identity formation through creating specific delimited consumer markets. Something is provided for all, so none can escape the invisible hand of the market: distinctions are emphasized and extended in these postmodern times.

The postmodern cultural turn produced a brave new world with a greater emphasis on choice and product differentiation; on marketing, packaging, and design; on the targeting of consumers by lifestyle, taste, and culture rather than just by categories of social class. Identities are reflected in lifestyles that are closely associated with brands and the products they label.
This enables consumers to express individual sovereignty through identities, constructed by acquiring and displaying goods that convey information about them and their position within a constellation of social networks. Rather than seeing identity as fixated on whiteness, the one-size-fits-all strategy, identities are now considered plural and dynamic, hybrid and fluid. Consumers carry, as Mort (1989, 169) noted, “a bewildering range of different and at times conflicting identities around with them in their heads at the same time.” A flexible regime of accumulation reconstitutes the production and distribution of commodities to exploit this hybridity and fluidity in society. By recommodifying the black body to enhance consumption, a racialized and more diversified underpinning of the corporation has taken hold.

A flexible regime of accumulation

A main flaw of postmodern analysis is that it tends to ignore the social relations of production or the class structure of capitalism. Market makers, encoders of text, and consumers as decoders of text are not free of structural constraints. The postmodern cultural turn suggests an open and dynamic egalitarian culture, with constant cultural flows and mixtures. Exploiting this openness and mixture in the constitution of production, and the diversification of consumption and distribution, requires a regime of accumulation more flexible than the Fordist regime.

Whereas through the first half of the twentieth century Fordism was producing conformity, by the 1970s a flexible specialization regime was offering greater authenticity, individuality, difference, and rebellion as a market strategy. Corporations could now maximize profits through the social production of difference, marked also by race. Featherstone (1994, 404) notes: “Since the 1960s there has been a more general informalization and elaboration of previously restricted codes of behavior.” If the trauma of World War II meant that the corporate world faced a society mentally wedded to mutual cooperation and togetherness, 20 years later the Civil Rights Movement and the Vietnam War set the stage for a more fragmented society which the corporation was able to exploit in different ways.

Left to its own devices, the corporate world never abandons a profitable regime. The separate but equal regime had been profitable, reproducing the racial hierarchy and making money in the process. It was basically a producer-driven commodity chain whose primary objective was the production and consumption of whiteness. Through the mass production of standardized goods, it counted on adequate consumer demand but had little need to listen to the market. This regime defined the market as massive and white, paying little or no attention to differences within it. Feedback from consumption to production did allow some changes in the market to translate to changes in productive engineering, but this communication circuit was restricted, slow, and lacked flexibility.

The mass market became increasingly saturated as a result of rapid rises in productivity after 1945. Consumer markets began to stagnate, posing a noticeable constraint to economic growth in the industrialized world. The corporate world expanded mass production and consumption, increasing the competition for the consumer dollar. Mass marketing became highly competitive. But additional advertising and promotion yielded diminishing returns. The market for consumer goods was increasingly governed by replacement demand turnover and obsolescence rather than by the opening up of new markets, which had been possible throughout the 1950s and early 1960s. Having reached its maximum potential, mass marketing intensified efforts to open up new markets. But the fixity and
standardization of the separate but equal regime began to pose obstacles to the further progression of capital. A more mobile and flexible regime had become necessary, which was not fixated on whiteness or on a particular identity or status relation.

The separate but equal regime lacked the flexibility to exploit the growing demand for more differentiated products or hybridity in the marketplace. Thus, capital had to engage in the social production of difference. Wendell Smith (1956, 7) had already warned of the growing danger of product competition with mass production and mass marketing. He noted that the theory of perfect competition, the basis of neoclassical economic theory, assumes homogeneity, that one size fits all, but diversity or difference had become the rule. He proposed exploiting “market segmentations,” arguing that, in place of a mass market, goods would “find their markets of maximum potential as a result of recognition of difference in the requirements of market segments.” Concluding that “their core markets have already been developed,” Smith (1956, 7) advised companies that “attention to smaller or fringe market segments, which may have small potentials individually but are of crucial importance in the aggregate,” could be profitable. Capital could maximize its profits not just by rendering labor abstract but also through the social production of difference.

Consumption has become symbolic of social distinctions. Mass-produced products lack status or lifestyle differences, the sign value that targets a particular socioeconomic group to buy. Decades before Baudrillard’s (1983) cultural analysis of the commodity sign, the automobile industry had already started to encode its products in market segments, manipulating the sign value of its commodities to communicate messages about the status or lifestyle of the consumer. Growth required selling cars whose appearance and features become obsolete on an annual basis. It was better to divide up the mass market according to distinctive needs and desires. Instituting model and color diversity, the automobile industry placed its products in different geographical and social contexts to denote a specific rather than a generic product. Production became a bundle of changing characteristics designed, produced, and marketed to appeal to different market segments of the population.

With geodemographic analysis, the corporation is able to predict variations in consumption based on a host of demographic factors such as race and where a person lives. Mass culture becomes micro: smaller fringe markets matter. Commodities are branded on the basis of where they are made. Corporations are increasingly emphasizing localized production and consumption.

The cultural and racial discontent of the 1960s and 1970s made universal or mass marketing increasingly impractical, weakening the strategy of one size fits all. In the corporate world, the fixed relations that characterized the separate but equal racialized corporate regime became increasingly impractical and illegitimate. Corporations become less receptive to the notion of social purification.

It is not coincidental that the newly constituted regime corresponded to the historical era of discontent in the 1960s and 1970s. If it was not for the Black Power movement, the student revolts, the women’s movement, and other antiracist struggles, the corporate world may have been content to maintain the one-size-fits-all corporate strategy, happy to avoid the trouble of having to reconstitute production, distribution, and consumption. Instead, in the new social and cultural formations, capital saw the opportunity to create more value and to expand commodity exchange and consumption by recoding and decoding race, bringing the strange, the other,
into the space of the ordinary. According to Cohen:

social and cultural groups such as African Americans, women, youth, and senior citizens began to assert themselves in a way that came to be called “identity politics,” where people’s affiliation with a particular community defined their cultural consciousness and motivated their collective political action. Marketers, who had they not been in search of ways to avoid saturating the mass market, might have despaired at the splintering of the mass in the 1960s, soon seized the new opportunities for selling it offered. (2003, 308; emphasis added)

Needing to sell to realize value, corporations seized on the opportunity offered by the racial discontent of the 1960s and 1970s to do just that.

Conclusion

Consumption is diverse, fluid, and varied rather than fixed and monolithic. The tension between race and corporate capital’s need to expand commodity exchange and consumption asserts itself in unexpected ways across time and space. Race, then and now, is a product of this tension. It cannot be seen merely as a reflection of racial ideologies. It must be situated within a framework that understands and critiques capitalism as an ideology that sustains and reproduces capital relations of production.

From the consumption of whiteness, the one-size-fits-all paradigm, the corporate world has shifted to a market-led pluralism that recognizes different consumer market segments. This postmodern paradigm shift reached new heights as black cultural elements, once ignored in the marketplace, were widely marketed by corporations. As a result, blackness is no longer represented as the opposite of whiteness but as a commodity to be consumed by all. The classical black sound of rap, the new rhythm of consciousness and resistance, and its hip-hop cultural form are commodified to be bought and sold on the world market. This regime of accumulation is less fixated on whiteness and conformity, on maintaining fixed status relations. The consumerism of postmodernity, held to be incommensurate with the fixed relations of modernity, accommodates differences to expand markets. Contemporary producers of encoded texts welcome the youth-led and hip-hop cultural revolution as an ally in their own struggle to manage and regulate society for the sake of capital. Rap and hip-hop are prime examples of the commodification of race for the sake of capital, having become extraordinarily commercially successful worldwide. Rap is globally produced and consumed more than ever, and in diverse markets. The underlying motivation for positing race and culture as the bases of collective identity was social, but not far behind was the neoliberal need to express race and culture as a commodity form to realize surplus value.

The black print media reproduced neoliberalism in the black community. Yet it often blames black and brown populations for their economic circumstances and for failing to fight against structural factors that keep them economically subordinate. The black corporate world has “earned the confidence of the white corporate hierarchy and the capitalist state by keeping alive the bogus illusion of a black capitalism” (Marable 2000, 158). Yet over four-fifths of all black-owned US firms are small businesses, struggling against massive odds to not fall back into the ranks of the proletariat. Further, the black community lacks an effective voice to articulate the growing black demand for economic opportunities.

More research is needed on the ways in which the corporation reworks cultural elements to expand commodity exchange and consumption,
and the implications thereof. Has this reworking of culture elements produced a culture war over meaning and lifestyle? Can we put a neoliberal face on this culture war? Many condone this reworking of culture because it sells. Hip-hop reproduces neoliberalism by emphasizing narratives that laud violence, crime, and drug use in the black community. To expand commodity exchange and consumption, the corporate world welcomes all, even those from the 'hood. It manages and regulates this life of diversity opportunistically to make money. Social networking sites such as MySpace and Facebook are invaluable in identifying niche markets of potential consumers for capital.

To what extent has this cultural manipulation of the consumer by capital contributed to the underdevelopment of the black community? The 1968 Report on Civil Disorder by the Kerner Commission documented the pent-up desire for consumer goods that television, movies, and advertising held up. While black consumer spending has increased, few dollars circulate in the black community. Black consumers are foot soldiers for corporate interest, siphoning away dollars from the black economy (Weems 2005, 253). For every $8 to $10 spent in the black community only $1 remains. An informal and predatory community, consisting of illegal practices such as drug trafficking and prostitution, develops as the poor person’s way to cut himself or herself in on the consumer society and to survive in a community that’s leaking a substantial amount of capital.

Cosmography literally means the description of the universe; today, this would automatically be associated with astronomy, which as a discipline has very little to do with geography as it is taught in schools and universities. On the other hand, geography literally means description of the world, understood as and limited to our planet Terra. However, geography is a scientific discipline and, as such, not confined to description; geographers explain phenomena on Earth. Geology would have been an appropriate disciplinary name, but that was adopted earlier on for another subject with explanatory ambitions for only some of the phenomena on the Earth. Disciplines change their content, methods, and investigation themes over time. Geography was used as a term at the Museum in Alexandria about 300 BCE, but there are only feeble links from then to the discipline of today.

Even though cosmography seems far from geographic interest today, it is highly relevant for the historic understanding of the discipline. One simple reason is, of course, that understanding of the cosmos, or universe, was far more limited, say 200 years ago, than it is today. Cosmographic studies focused on the Earth and the closest celestial bodies. A second reason was that geography was not an institutionalized discipline; writers and teachers that have been listed in this entry as geographers could write and teach about what they found most interesting, they were not confined by any defined disciplinary matrix or paradigm. Many of them should be regarded as cosmographers rather than geographers.

Eratosthenes (276–194 BCE), who was chief librarian at the Museum in Alexandria, succeeded in calculating the circumference of the Earth with remarkable precision. Of equal importance was his development of systems of coordinates for the world, that is, latitude and longitude, which he used to locate places and to measure distances, thus making it possible to draw the first passably accurate maps. This work was termed geography but it is quite clear that its basis was a new understanding of cosmos, particularly that the Earth was a globe. From this early start the cosmographic approach was integral to the geographic task of mapping.

Until the end of the nineteenth century, voyages of discovery and the mapping of formerly unknown lands were closely associated with geography. Wayne K. Davies (1972, 11), for instance, maintained that geography enjoyed its strongest relative position among the sciences during the so-called “golden age” of exploration from the fifteenth to the nineteenth centuries. This was not due to the academic status of the subject during this period but to the work of a number of people who were actively involved with the mapping and description of the new lands being discovered. To the extent that they were working scientifically they could best be described as cosmographers.

Bernhard Varenius (1622–1650), whose *Geographia Generalis* was published in Amsterdam in 1650, was one of the first scholars to present a scientific understanding of the nature of geography. But his book includes much material that today would be treated as mathematical geography or as astronomy. It is divided into three parts:
COSMOGRAPHY

1. the absolute or terrestrial section, which describes the shape and size of the Earth and the physical geography of continents, seas, and the atmosphere;
2. the relative or cosmic section, which treats the relations between the Earth and other heavenly bodies, especially the sun and its influence on world climate;
3. the comparative section, which discusses the location of different places in relation to each other and the principles of navigation.

Varenius intended that the Geographia Generalis should be followed by what he called, in his Foreword to the book, “special” geography, in which descriptions of particular places should be based upon:

1. “celestial conditions,” including climates and climatic zones;
2. terrestrial conditions with descriptions of relief, vegetation, and animal life;
3. human conditions, including trade, settlement, and forms of government in each country (Lange 1961).

It was Alexander von Humboldt (1769–1859) and Carl Ritter (1779–1859) who laid the scientific foundations for geography as a branch of knowledge. These two men had many views in common and were united in their criticism of the casual and unsystematic treatment of geographical data by their predecessors. Humboldt was the last of the great polymaths. Penck (1928, 31) regarded him as a cosmographer rather than a geographer. He mastered a number of disciplines and put all his energy (and fortune) into travel and research in order to understand the whole complex system of the universe. In his great work Kosmos, with its subtitle Sketch of a Physical Description of the World, he attempted to assemble all the contemporary knowledge of the material world. Kosmos was published (1845–1862) in five volumes at the end of his life, while the results from his long and important journeys in Latin America (1799–1804) had been published in 30 volumes in Paris (1805–1834).

Cosmography was termed in a more limited way by Schmithüsen (1976, 10), as he saw cosmos as the Earth and not the original definition as the universe. But he defined it as an umbrella discipline including not only geography and cartography but also natural sciences, such as biology, geology, and geophysics, and social sciences, such as anthropology, which only achieved their independent academic standing towards the end of the nineteenth century. Exploration, and all these other fields of cosmographic activity, were also regarded as being part of geography by the general public because they were carried out, to a large extent, under the auspices of the geographical societies, and they became, in political terms, quite important for the establishment of geography as a discipline in universities and high schools.

Geography developed as an academic discipline partly on the basis of a cosmographic philosophy that was developed to give coherence to the different activities of the geographical societies. Gradually theoretical studies made an increasing contribution to the advancement of a specific geographical methodology. The chief emphasis remained, however, on geography as a science of synthesis, a science linking humanity and environment and creating a bridge between the social and natural sciences. The cosmographic tradition is still at the roots of the contemporary discussions.

Discourses of cosmopolitanism have recently surfaced in relation to the accelerated pace of globalization of capital flows, material production, cultural expressions, and consumption. On the one hand, cosmopolitanism is often cast as the humanist counterpart of globalization in line with visions of global democracy and world citizenship. On the other hand, given that cosmopolitanism’s normative orientation distinguishes it from the condition of globalization, more critical accounts make clear that, as the world becomes more globally connected, there are no automatic or immediately obvious pathways toward cosmopolitanism.

As an ideal, a desirable goal, and a dream, the notion of the cosmopolitan speaks of a spirit of openness as opposed to closure, and emphasizes the extension of bonds of inclusivity between people, societies, institutions, and organizations based on foregrounding the interests of humanity. Cosmopolitanism espouses a “universalism plus difference,” a culture of openness and acceptance, underpinned by the values of “inclusive heterogeneity, tolerance of difference and otherness, equitable (re)distribution of resources and privileges, recognition of others’ freedoms, (comm)unity in diversity, unqualified practice of fairness, kindness, and generosity” (Dharwadker 2001, 7). Cosmopolitans thus need to have the ability to function productively wherever they are, accepting of others by minimizing concerns over nationality, race, or class, and are connected to the Earth but not to a particular place (Robbins 1998). This inclusivity becomes an indication of a tolerance of all peoples as not similar to self, but rather as having a recognizable, expected, and accepted difference. Jazeel (2011, 89–93) goes one step further in advocating the “unlearning” of cosmopolitanism in order to be able to imagine a future of living together “not just with difference but … with radical, heretofore unimaginable, difference” within particular places which are “relationally intertwined, dynamic and turbulently moving on.”

Scholars have noted cosmopolitanism’s inherent politics and its elitism. Critics argue that discourses of cosmopolitanism merely articulate the ideology of the neoliberal managerial class (about living in a “global village”) while at the same time complicitly reinforcing the hegemony of this class. Robbins (1998, 4) decries its presumed detachment asemasculating, suggesting that

the cosmopolitan is held to be incapable of participating in the making of history, doomed to the mere aesthetic spectatorship that he or she is also held secretly to prefer, and that cosmopolitan identification with the human race serves as a thin, abstract, undesirable antithesis to a red-blooded, politically engaged nationalism.

Here, cosmopolitanism is reduced to a matter of “consumption” or “aesthetics” best embodied in the emergent culture of the transnational capitalist class whose globe-trotting lifestyles, connoisseur tastes, and disembedded social networks present a revolt against the nation-state. Elitist and exclusionary, such a version of cosmopolitanism is devoid of social or political transformative power. Harvey (2000, 557)
further points to the “banality” of a cosmopolitan vision in the absence of a recognition of geographical differences, and argues that a meaningful cosmopolitanism must go beyond some passive contemplation of global citizenship: “Cosmopolitanism bereft of geographical specificity remains abstracted and alienated reason … Geography uninspired by any cosmopolitan vision is either mere heterotopic description or a passive tool of power for dominating the weak.”

Cosmopolitanism must hence imply the presence of a geography, of places which are different from others; would-be cosmopolitans must thus learn to navigate a nonhomogeneous landscape. In this light, Jazeel (2011, 92) cautions against Eurocentric visions of universal humanity that may lurk beneath cosmopolitan thought, and advocates “opening out some of the concept’s more restrictive geographical imagination” to thinking of “place as inherently relational, … constituted by the coming together of narratives, trajectories and border crossings from elsewhere.”

Expectedly, scholarly geographical attention to rooting cosmopolitanism in place began with cities. In contrast to discourses on multiculturalism, integration, and social cohesion that usually frame discussions of diverse urban societies in terms of fixed ethnic identities, cosmopolitan logics have been invoked as a means to “avoid pitfalls of essentialism or some kind of zero-sum, all-or-nothing understanding of identity issues within a nation-state framework” (Vertovec and Cohen 2002, 3). Cosmopolitanism has been inserted back into discussions on urban diversity and emergent civil spaces, particularly in the context of the rising presence of transnational migrants and the increasing proliferation of contact zones that renders the contemporary globalizing city as a meeting place with the other. For example, Filipina domestic workers’ subversive “occupation” of the Central District of Hong Kong for weekend gatherings alerts us to the ways in which a city’s public space can be symbolically transformed into sites where alternative meanings about one’s identity are rewritten and reinscribed onto the city’s landscape. In a variety of urban contexts, studies of social interaction processes among residents make clear that demographic assortment alone is no indicator of cosmopolitan hospitality, and that geographies of encounter in the city are structured by sociospatial inequalities and insecurities.

Other scholars have begun looking for cosmopolitan beginnings in unlikely places: instead of concentrating our focus on the public face of the city as the quintessential reflection of cosmopolitanism’s topography, as is often the case in projects of urban boosterism, bringing into view the inner workings of more privatized, vernacular places characterized by relations of care and intimacy may help us in unlearning the normalized contours of cosmopolitanism. For example, Datta (2011, 3) proposes moving “beyond the public sphere into more private and affective spaces” of the city to search for a fragile “cosmopolitan neighbourliness” amid a Delhi squatter settlement in the context of communal violence.

Notwithstanding suspicions that cosmopolitan ideals are all too easily pressed into service to ideologically endorse neoliberal capitalism, geographers attentive to the difference that space makes have also argued that to ascribe the values of cosmopolitanism to only those who have the benefit of dwelling in a “global” space is tantamount to denying those living outside it a chance to express the same kind of human relationality. In this light, geographical scholarship has turned to notions of actually existing cosmopolitanism or cosmopolitanism from below to reflect on dimensions of social life that is grounded in more open, unfixed, provisional, and ethically conscious notions of the other. For example, Kothari’s
COSMOPOLITANISM

(2008) ethnographic work with Bangladeshi and Senegalese street traders in Barcelona associates non-elite cosmopolitanism with ordinary people such as street peddlers who are artful political subjects in their use of translocal social networks to acquire resources and respect, while other scholars have focused on non-elite forms of cosmopolitan modernity articulated among slum dwellers. By exploring changes in consumption patterns, possibilities for cultural learning, the development of new sensibilities, and the negotiation of cultural differences, scholars identify emancipatory hope for migrant domestic workers as potential working-class cosmopolitans despite the retrogressive contours of transnational domestic work. Through treating cross-cultural exchanges unfolding in different kinds of spaces from the flexibly open-minded to the severely constrained, the true breadth of cosmopolitanism can be more fully appreciated.

The creative cities concept emerged at the start of the twenty-first century as a new way to imagine urban planning and economic development. Rather than envision cities as centers of manufacturing and corporate offices, as had been the model in the twentieth century, advocates of creative cities emphasized human capital and suggested that, to thrive, urban economies must focus on leisure, entertainment, tourism, innovation, entrepreneurship, the arts, and, in general, human creativity. The two major articulations of creative cities were Landry’s (2000) notion of the creative city and Florida’s (2002; 2005; 2008) concept of creative class. Landry (2000, xiii, xv) maintained that “Cities have one crucial resource – their people. … [and] At the heart of creativity are creative people and organizations who have particular attributes: when these come together in one area they establish a creative milieu.” Florida (2005, 35) argued that cities are competing globally to attract such creative individuals: “The Creative Class is moving away from traditional corporate communities,” and is moving to “Creative Centers … [which have] high concentrations of creative economic outcomes, in the form of innovation and high-tech industry growth.”

Advocates proposed that urban policies should be designed to generate creative cities and argued that a vibrant cultural scene is essential to revitalizing both neighborhoods and economic development. To encourage the emergence of a creative city, for example, urban planners could revise existing zoning laws to allow live–work studios in former manufacturing buildings; create multiuse buildings that can aid new business start-ups; provide nontraditional office space for technology entrepreneurs; redesign transportation to reduce car use and suburban commuting and, instead, encourage the use of public transit, bicycling, and walking; subsidize city-wide broadband and wireless Internet access; give tax breaks to encourage environmentally sustainable urban design and buildings; and host myriad festivals, concerts, and other events. Typically cited examples of creative cities in the United States include San Francisco, Boulder, and Austin, where investment in the annual South by Southwest (SXSW) celebration of music, arts, and technology has branded the city a creative urban center. Calgary, Toronto, Amsterdam, Nagoya, Bilbao, and Sydney are also often cited as creative cities. The rapid acceptance of the concept was exemplified in 2004 when UNESCO established its Creative Cities Network (UCCN) in which member cities work “together towards a common mission for cultural diversity and sustainable urban development ... ‘Creative hubs’ that promote socio-economic and cultural development in both the developed and the developing world through creative industries” (UNESCO 2009–2014).

As making cities more creative has quickly become an unquestioned goal of international urban policy, critics maintain that they produce exclusive enclaves for urban elites. Peck (2005, 742, 766) argues that “the creative-cities script has found, constituted and enrolled a widened civic audience for projects of new-age urban economic development ... ‘Creative hubs’ that promote socio-economic and cultural development in both the developed and the developing world through creative industries” (UNESCO 2009–2014).
privileged actors,” in which “elite-focused creativity strategies leave only supporting roles for the two-thirds of the population languishing in the working and service classes.” McLean (2014, 673), in turn, proposes that creative city policy “initiatives put a positive spin on precarious creative industry work while simultaneously gentrifying neighborhoods, a dynamic that displaces low income residents — especially seniors, people living with disabilities, and the racialized poor.” The use of public monies to fabricate creative cities typically means reducing spending elsewhere and, therefore, creative cities may exacerbate urban inequalities.

Creative class culture

Ulrike Gerhard
Heidelberg University, Germany

Creative class culture refers to the circle of understandings, beliefs, and values of a distinctive group of urban dwellers, the so-called creative class, described by Richard Florida (2002). It is characterized by a modern urban lifestyle, expressed by the usage of and attraction to sidewalk cafes, bistros, small shops, and galleries. Thus, creative class culture can be assigned to gentrified inner-city neighborhoods with an older housing stock that has been redeveloped by a more affluent group of inhabitants or developers, displacing former residents and transforming the urban landscape and infrastructure. While creative class culture is strongly related to cultural capital assets, its specific consumption patterns show a slight bias to street level culture that disfavors customized mass products but instead looks for more authentic items and places (e.g., small, independent cafes instead of Starbucks coffee shops, whole food stores instead of big supermarket chains). Often, these preferences adhere to a higher socioeconomic status with a certain willingness to pay higher prices for more quality or individuality. Life and leisure plays an important part in creative class culture: “live the life” (Florida 2002, 166) is the attitude that includes intense, high-quality, multidimensional experiences and favors active recreation over passive pastimes (e.g., running or rock-climbing rather than watching television).

Despite these characteristics, creative class culture is a rather broad description of an urban lifestyle that can be found throughout the globalized world, characterizing a revaluation of the urban as a progressive ethos (e.g., democratic, participatory, modern) that is not new to urban theory (e.g., the Greek Polis, Louis Wirth’s Urbanism as a Way of Life). Cities function as nodes for the global space of flows that also entail flows of people. More recently, some of the most observed socioeconomic groups have been described under different headings: e.g., Yuppies (Young Urban Professionals), Bobos (bourgeois and bohemian), or DINKS (Double Income No Kids). The creative class concept, though, captures best a formal institutionalized class development infecting many cities across the world: the struggle of cities to compete for investments, affluent habitants, and global attention. Creative class culture thus emphasizes the economic value of a certain group of people, by neglecting that (i) not all members of that group are necessarily affluent, and (ii) a vast majority of inhabitants do not qualify as being “creative.” Thus, creative class culture can spur urban uneven development. Furthermore, it is a very dynamic concept originally characterized as individualistic, progressive, and assigned to childless households, one can now detect a maturing within the lifecycle – more established, family-oriented households, often with working mothers, increasingly adhere to that group as well. In urban geography and social theory, the term is therefore very useful to analyze the social and cultural impact of urban developments in the transforming knowledge society.

The last several decades have witnessed a major shift in capitalism. This transformation is marked by the rise of a “creative class,” a term coined by Florida (2002) to refer to workers who generate economic value through their creativity. This class encompasses knowledge, professional, and technical workers, as well as workers in the arts and cultural industries. These workers draw on intellectual rather than physical capacities to create meaningful new forms. This entry discusses the rise of a creative class and what it means for the nature of work. Criticisms of the notion of a creative class will also be reviewed.

According to Florida (2002), the transition to a knowledge-based or creative economy is tied to the crisis in an earlier phase of capitalist development known as Fordism. Fordism connotes an economic system that came into being in the post-war period. This system was based on the mass production of standardized commodities. A key problem with Fordism is that it afforded minimal possibilities for intuition, initiative, or creativity.

Fordism fell into crisis in the 1970s, when advanced industrialized countries faced increased competition from overseas producers. The costs of this system also became apparent in the low quality levels characteristic of mass production systems. These challenges gave way to a new competitive strategy based on the production of smaller batches of niche market products differentiated on the basis of their quality, symbolic value, or design. This transition has fueled the demand for new skill sets, and heightened the importance of creativity. Florida argues that workers in a variety of jobs, including those in manufacturing and services, are increasingly valued for their creative capacities.

This is especially so in creative class occupations. Florida (2002, 68) defines class as a social grouping or identity based on economic function. This grouping gives rise to a unique set of identities, desires, and consumption patterns. The creative class can be divided into two segments. The first segment is a super-creative core composed of scientists, engineers, professors, artists, writers, designers, architects, and entertainers. These workers engage fully in creative endeavors, producing new products, theories, artworks, or designs. They not only solve problems but also identify new challenges and needs. The second component of the creative class is made up of creative professionals working in financial services, law, health, and business management. According to Florida, these employees draw on complex bodies of knowledge and use their judgment to solve problems. These professions necessitate a high level of education. Workers may occasionally develop new products or methods but it is not central to their job (Florida 2002, 69).

The rise of a creative class is also related to new patterns of work. It is associated with greater opportunities for autonomy and initiative. Florida equates it with open concept workspaces, flexible hours, and a relaxed dress code. Creative class workers switch jobs frequently, creating horizontal labor markets. They value individuality, diversity, and meritocracy.
CREATIVE CLASS

Florida distinguishes the creative class from the working and service classes. The working class consists of those who work in production, transportation, repair, and construction, while the service class encompasses lower-wage occupations in health care, food service, office work, and caring. The creative class makes up approximately 30% of the workforce and is growing rapidly; the service class constitutes 43% of the workforce and is also expanding; and the working class accounts for roughly 25% of all employment but is shrinking (Florida 2002, 74). Florida maps this new class structure onto US cities, arguing that some cities have a higher concentration of creative class occupations (i.e., Washington, Boston, Austin, and San Francisco), and that these centers are more likely to experience growth. By comparison, major tourist centers such as Las Vegas and Miami have high concentrations of the service class. Other cities such as Grand Rapids, Memphis, and Buffalo are confined to being working-class enclaves.

While different class concentrations characterize different cities, Florida (2002) sees a relationship between the rise of the creative class and the service class. The creative class works long hours and has high incomes. As a result, they have a strong demand for restaurants, as well as for cleaning and child-care services. This fuels the growth of low-wage service employment, leading to polarization in some cities.

There are many parallels between Florida’s theory and other accounts of economic transformation. In the 1960s Bell (1973) described a major transition to a postindustrial economy, a move which he equated with the demise of the working class. A variety of more recent theories also chart a shift in advanced industrialized economies. Scott (2007, 1466), for example, cites the rise of a “cognitive-cultural economy” which emphasizes intellectual and affective labor. He includes high-technology industries, the service sector, neoartisanal manufacturing and cultural industries in this economy.

Autonomist Marxists such as Lazzarato also cite the rise of what they call “immaterial labor.” Immaterial labor refers to labor that produces the informational and cultural content of a good (Lazzarato 1996). It includes manual labor that has an increasing intellectual component, but also work that involves setting fashion trends, aesthetics, and consumer tastes. While there are many similarities between Florida’s notion of a creative class and immaterial labor, there are important differences. For Lazzarato, the rise of immaterial labor is accompanied by new techniques for managing communication and creativity, and for creating and controlling worker subjectivities. This new system threatens to be even more totalitarian than the old Fordist system because capitalists increasingly seek to incorporate the worker’s personality within the production of value (Lazzarato 1996). Immaterial labor is also highly precarious. Workers are often self-employed, working freelance or on contract. Work extends into leisure time, eroding the distinction between life and work. While Lazzarato does acknowledge some possibilities for cross-class mobilizing around precarious work, a much more negative picture is developed of the rise of creative/immaterial labor (see also Gill and Pratt 2008; Ross 2008).

There have been other criticisms of the notion of a creative class. Markusen (2006), for example, argues that the creative class represents a fuzzy concept – a category that unites disparate things under one umbrella while separating groups that may be similar. The notion of the creative class is based on occupational groupings, but some of these groups include uncreative as well as creative jobs. Business and financial occupations, for example, include claims adjusters, while
the category of engineer also includes drafting technicians. Some of these jobs may be creative but so too could many jobs designated uncreative by Florida – such as tailors. Markusen (2006, 1924) argues that it is problematic to label some workers as creative and others as not (see also Morgan and Ren 2012).

A further problem is that Florida tends to conflate creativity with high levels of education where there is no direct link between the two (Markusen 2006). The assumption of a common class position also disguises differences in training, career trajectory, and economic capital between different creative occupations. These differences have implications for the locational preferences and political values of creative workers. This suggests that Florida is not talking about class as defined by a common class interest, outlook, or behavior (Markusen 2006).

Others question the politics of Florida’s theory, which positions the creative class as the source of economic growth in a city region. As Peck (2005, 757) points out, this relegates the working and service classes to a passive role in economic transformation, and leads to policies focused on the interests of the creative class. This is problematic because this elite class is already well positioned to succeed in the new economy (Shearmur 2006–2007, 8).

Florida (2002) argues that, to attract the creative class, cities need to enhance the quality of place characteristics of an urban region, making investments in bike paths, streetscapes, and bohemian neighborhoods. This agenda provides funding for the arts, and for events that promote values associated with creativity, such as openness, diversity, and tolerance. Florida contends that attracting the creative class to an urban region will benefit everyone. However, as noted earlier, there is evidence that the presence of a creative class is associated with increased inequality (Donegan and Lowe 2008).

Cities around the world from Amsterdam to Singapore have been reorienting their economic development agendas in accordance with Richard Florida’s creative class thesis. Investments have been made in creative industries and in lifestyle amenities designed to attract the creative class. Creativity policies fit nicely with existing neoliberal agendas (Peck 2012). These policies support the desire of cities to attract foreign talent and become “global cities.” In Singapore, for example, creative city agendas are associated with a liberalized approach to homosexuality. However, the rhetoric of tolerance toward gays and lesbians stops short of genuine enfranchisement (Oswin 2012, 1636). Similarly, while talented “creative” workers are encouraged to join the “national family” and to bring their families to Singapore, other foreign workers, performing more “unskilled” work, have no rights to citizenship. Like gays and lesbians, these workers continue to be positioned as “out of place” in the creative/global city (Oswin 2012). This foregrounds the way in which a creative class politics is associated with a narrow, hierarchical, and polarizing vision of the city.

Richard Florida’s notion of the creative class highlights significant changes in occupational structure in advanced capitalism. It describes the rise of new forms of work, which rely on the intellectual and creative capacities of workers. However, critics suggest that there are many problems with the way he characterizes these changes and, in particular, with the notion that creativity is located within a specific class. This leads to the privileging of particular groups of workers in the new economy, which has contributed to increased inequality.

Crime

Robert Haining
University of Cambridge, UK

Crime is any action that constitutes an offense as defined by the criminal law of the country, and that is punishable by law. A crime involves an offense, one or more offenders, and one or more victims (who may be individuals, or may be communities). To study crime is to study one facet of societal risk (of becoming an offender as well as being a victim) and how that risk might be moderated through different forms of individual and social action. The study of crime overlaps many areas of the social sciences with different disciplines tending to focus on different questions, emphasizing different sets of factors (e.g., social-institutional structural, as opposed to environmental-situational, explanations). Geography has a particular interest in understanding why offenses take place where they do, the sorts of neighborhoods that produce, or are perceived to produce, disproportionate numbers of offenders, and geographies of victimization. Geography, in common with other disciplines, is also interested in the policing response, and since police forces are often organized on a territorial basis their response may involve geographical targeting, which is of particular interest. These questions of crime and policing are examined at many different scales as well as involving national and international (cross-cultural) comparisons. And geography, again in common with other social sciences, also has an interest in the wider consequences of crime. The study of the geography of crime and criminality, as well as contemporary responses to control crime and criminality, can be traced back to the formation of modern industrialized and urbanized societies in the nineteenth century. This field of study has been variously referred to as the geography of crime by geographers, environmental criminology, and, most recently, sociospatial criminology by criminologists (Bottoms 2012).

A common thread in these different disciplinary endeavors is to understand the role of place and space in explaining these geographies, where place concerns the attributes of specified areas at defined scales (for example, blocks and street segments, neighborhoods, communities, cities, countries), and space refers to the spatial relationships between places (concerned with such properties as distance, nearness, and proximity). Understanding may focus on the here and now of an observed pattern for some area and for some defined period of time (perhaps considered typical or representative), or it may focus on repetitive patterns for an area over short time periods (daily, weekly, seasonally) or on longer periods of time in relation to crime pattern trends. The last of these (for example, the seemingly inexorable rise in acquisitive (e.g., theft and burglary) and violent crime post-World War II in increasingly affluent Western societies) have at different times given fresh impetus to the field, challenging researchers and requiring policymakers, urban planners, and the police to develop new responses. Crime profiles shift over time as do public attitudes and people’s fears about crime (not necessarily well correlated with recorded crime levels) and these trigger shifts in research emphasis. These longer term shifts in crime, criminality, and public attitudes and explanations for them, usually involving aspects
of societal and technological change, have given rise to contrasting political interpretations and even paradigm shifts in the field of criminology as, for example, in the United States and Western Europe in the 1970s.

Viewing criminal behavior as a rational choice rather than a purely pathological act and placing rational choice theory (RCT) at the meta-theoretical heart of Anglo-American criminology has had a profound impact on research into crime since the 1970s, providing an important framework for organizing ideas about who commits crime and where. The offender is viewed as the self-interested individual who seeks rewards and who balances those rewards against the risks that must be faced. RCT is perhaps most relevant in the case of acquisitive crime where motivated offenders may seize the opportunity for personal financial gain in those circumstances where they perceive the balance of risk to reward to be in their favor. In the case of expressive crime (e.g., some forms of homicide, sexual assault) “reward” may be couched in terms of pleasure or release from pain. In both cases risk is defined in terms of the probability of being caught and punished, and the scale of that punishment. RCT is criticized for overestimating its role in criminal activity as well as overestimating human powers to access and then process complex information, so that “full rationality” is usually substituted with the concept of “bounded rationality”; however, the inclusion of decision-making theory into predatory criminal behavior provides an essential ingredient for an important theory in criminology – routine activity theory (RAT). Routine activity is defined as any recurrent or prevalent activity that provides for basic population and individual needs and includes, for example, activity associated with work, obtaining food, shelter, schooling – anything in fact that is part of everyday life.

RAT was empirically grounded in the rising crime rate (in terms of both violent and property crime) in the United States between 1947 and 1974 (Cohen and Felson 1979). These post–World War II years were characterized by rising affluence when it might have been expected that crime rates would fall, or at least not rise, as more people were able to satisfy their material wants. In fact, crime rates were to go on rising both in the United States and in many parts of Europe into the 1990s. RAT argued that predatory crimes, which involve direct contact between the victim and the offender, require the convergence in space and time of the likely or motivated offender and a suitable target (the victim) in the absence of guardianship – someone (e.g., security guard, police patrol) or something (e.g., locks and fences) – that would deter the act by significantly increasing the motivated offender’s risk of being caught or by simply acting as a discouragement. Cohen and Felson (1979) argued that even if only one of these elements was missing, a crime would not occur. It was RAT’s contention that changes in routine activity could influence crime rates by affecting this convergence and that it was not necessary to speculate about a rising tide of individuals willing to commit crimes. They argued that in the United States since 1945 there had been a massive shift in routine activities away from the home associated with more people enjoying a better life and that these shifts had increased the likelihood of criminogenic interactions.

RAT combines the idea of the rational, motivated offender, drawing on rational choice theory, while also recognizing the importance of the environment in the study of human relations in space and time drawing on ideas from human (or social) ecology. While opportunity, defined in terms of target visibility, attractiveness, and accessibility, is a crucial element in RAT, it also argues that this cannot be abstracted from
the lives of ordinary people and how they interact with the social and built environments. Human ecology, the study of the relationship between humans and their environment, had underpinned the work of the Chicago School of Sociology in the 1920s and 1930s. Early forms of social disorganization theory (SDT) argued that neighborhood delinquent behavior was not just a product of individual and family characteristics such as age and race, but was also influenced by neighborhood characteristics such as high levels of unemployment, population turnover, and single-parent households. But in RAT, the perspective provided by human ecology was extended to embrace the everyday lives and environments both of offenders and of their victims.

Routine activities provide offenders with suitable targets (opportunities). Daily routine activities, whether associated with work or with leisure, determine the location of property and people and their vulnerability to crime. But RAT embraces other aspects of “everyday routine.” Routine production activities affect what consumables are available and how easy they are to steal since goods of high value but low weight and small size make for ideal targets. While community organization may provide the circumstances under which crime thrives, technological advance is also important both through its creation of desirable objects to acquire and through its development of security and surveillance devices that determine how well people can safeguard themselves.

There is another important empirical observation. The geographical distribution of offenses tends to concentrate in certain places. Crime pattern theory (CPT) extends the underlying ideas behind RAT to suggest why this might be so (Brantingham and Brantingham 1993). CPT argues that offenders will selectively choose areas to target that are cognitively known to them because they lie within their “activity space” and will not venture into areas that are unknown to them – and areas are familiar or not as a consequence of the offenders’ own routine activities. Although certain areas in a city may offer very attractive targets (houses in wealthy neighborhoods might reasonably be expected to contain many high value goods), if would-be offenders are unfamiliar with these areas they might feel unsure about the level of risk – of being seen and caught – they are facing. This argument is supported by the empirical observation that neighborhood crime rates are often highest and most persistent in poorer neighborhoods with a large number of resident offenders. Offenders target poorer areas close to where they live because of familiarity, which enables them to make a more informed assessment of the balance of risk and reward. A further element is often added to this calculation: the principle of least effort. When adapted to offender behavior this principle argues that, other things being equal, an offender will not expend any more effort than is necessary to achieve the desired outcome, and since travel involves effort, if offenders believe they can meet their needs traveling a shorter rather than a longer distance then that is what they will do. This combination of elements provides an explanation of why better-off neighborhoods close to neighborhoods with many offenders (typically poorer neighborhoods) tend to experience higher crime rates than those of similar neighborhoods that are not close to high offender areas.

Crime pattern theory helps understand long and short duration crime hotspots. The study of crime hotspots has been advanced by police geocoding of crime sites and the use of modern computer mapping systems, together with processing algorithms to detect and highlight spatial concentrations of cases. When crime data are analyzed at fine spatial scales it has been observed that crime incidents tend to concentrate in a
small number of street segments, block faces, and other such “micro-places,” and often in proximity to bars, schools, and transit stops. This level of concentration tends to be stable over extended periods of time; moreover, there is also evidence of a high degree of stability in terms of which specific “micro-places” in any area are responsible for this concentration (Sherman, Gartin, and Buerger 1989).

Two further theories support current understandings of crime geographies: social disorganization theory (SDT) and situational action theory (SAT). SDT is associated with the recognition that there is a neighborhood effect in addition to an individual and family effect in generating delinquency. At the heart of SDT is the idea that poor neighborhoods that lack close social relationships among residents produce disproportionate numbers of young male offenders, a social group responsible for a large proportion of crime. There is strong overlap here with the concept of social capital, that close networks among residents bring benefits to individuals and groups, and that the absence of such networks creates various social problems. More recently, it has been argued that the central focus should be not on the lack of social relationships (middle-class neighborhoods often lack these too) but rather on the inability of certain, usually poor, neighborhoods to achieve what the community wishes for and that trust is absent in community relationships. This is referred to as collective efficacy, which acts as a mediating variable between neighborhood social structure and levels of crime and disorder (Bottoms 2012).

SAT also addresses the role of the social environment in crime causation (Wikström et al. 2010). Social disorganization theory tends to overestimate the neighborhood of residence of the offender rather than recognizing that people move around and are exposed to many social-environmental influences; routine activity theory is criticized for not explaining how convergence in space and time results in a crime taking place thus focusing only on the necessary, not the sufficient, conditions for crime to occur. SAT argues that since crimes are breaches of moral rules of conduct, to understand the occurrence of crime we need to explain why people break moral rules. The theory argues that the convergence in space and time between a person’s criminal propensity (their morality and ability to exercise self-control) and the exposure setting (the moral rules of the environment in which a person spends time and their enforcement) initiates a perception-choice process whose outcome may be an act of crime. This approach requires us to understand people’s activity fields: the various environmental settings people are exposed to in any given time period.

As this review has demonstrated, a rich literature has evolved in criminology examining the role of place and space in understanding offense and offender geographies. The links between criminology and sociology are deep as evidenced by the contents of the *Oxford Handbook of Criminology* (see in particular the contribution by Bottoms 2012). On the other hand, the links between this academic literature and geographical research were perhaps closest in the 1980s with the work of David Evans and David Herbert (1989). Be that as it may, the work of sociospatial criminologists in specifying the criminogenic attributes of neighborhoods, their deployment of rational choice concepts and routine activity theory to account for crime events and where they happen, and the place-specific signals that lead to (or do not provide sufficient discouragement to) criminal acts have provided fertile ground for more recent geographical work into women’s fear of crime and the victimization of racial minorities. The
attention of social geographers has been largely
drawn toward studies of different populations,
declared by race or gender or both, who are
at high risk either of becoming victims or of
becoming offenders. In the United States there
has been a long tradition of research into the
relationship between crime and race rooted
not only in the violence historically directed at
African Americans but also in the disproporti-
ately large number of African Americans (but
also native Americans and people of Hispanic
origin) held in incarceration relative to their
presence in the population. Although much of
this work is sociological in disciplinary origin
the contribution of the geographer Harold
Rose is notable. Rose’s study of lethal violence,
especially among young black males, is illus-
trative of this work (Rose and McClain 1990).
Feminist geographical research on crime, again
part of a wider thrust in sociology, has focused
on women’s fear of crime, linked to the effects
of poor urban design, as well as to women’s
experiences of crime and the underreporting of
some offenses against women, notably domestic
violence (Pain 2000). The latter research exposes
the contradiction for some women of the home
as a place of supposed safety and security but in
reality a place of abuse.

To date much of the work by geographers has
linked more closely with the concept of social
justice rather than risk. Social justice is con-
cerned with issues of what is or is not fair about
society and the extent to which everybody in
society enjoys an equal chance to succeed in life
and to realize their potential. When life chances
are not distributed equally (in this case, certain
groups are subject to higher rates of victimization
or are at greater risk of becoming criminals) a
“just” society is one where its members should
feel an obligation to address the inequality. The
concept of social justice has its critics: it lacks
objectivity and can quickly become politicized
around issues associated with individual freedom
and the role of the individual; however, in the
case of crime the term social justice brings to
the forefront ideas about what, at the societal
level, is the right thing to do to minimize
the risk of becoming a victim of crime or an
offender. In that sense the fruitful link between
these two modes of human understanding is in
society’s response to crime and how risk can be
reduced in ways that do not lead to, for example,
social exclusion or the stigmatizing of particular
subgroups such as certain racial and ethnic
groups, or young males. With risk reduction in
mind, we now turn from theories addressing
the risk of crime and the uneven geography of
that risk to examining social responses aimed at
mediating those risks through urban design and
policing.

At the center of many debates about the role of
urban design are two rather contrasting visions
of how to effect crime prevention through
environmental design. In both rational choice
theory and routine activity theory a central
feature in the decision to commit an offense is
the offender’s perception of the risk of being
catched. Natural surveillance increases would-be
offenders’ perceptions that any criminal act
will be observed, thereby increasing the risk of
being caught. Architectural design that promotes
natural surveillance means urban design that
improves visibility (through the placement of
physical objects and good lighting) and promotes
social interaction (by encouraging a diversity
of uses as well as through the creation of sites
where people will naturally congregate such as
parks). This vision of crime prevention is
described in the urban planner Jane Jacob’s work
on Greenwich Village, New York. An alternative
vision is presented in the work of architect and
planner, Oscar Newman. He argued that while
natural surveillance is important in curbing
crime it is not sufficient and that emphasis also
needs to be placed on social control (the idea that residents of an area should have a strong sense of ownership of and hence responsibility for their neighborhood) and security through such things as limited access (so that escape routes for would-be offenders are also limited). Just as Jacob’s ideas on urban design stressed influencing the offender’s perception of risk, so Newman’s ideas stressed imparting the perception of neighborhood security and solidarity in influencing offender behavior. Perhaps the most extreme expression of Newman’s vision is the gated community, but there are other examples including “alleygating,” which involves cutting off passageways between or through clusters of homes. This literature has a particular resonance for feminist and prefeminist research, which has emphasized how post-1945 urban design has led to architectural forms that have fueled women’s fear of crime in public spaces (Ceccato 2012).

Policing is the second area through which society seeks to reduce the risk of crime. A feature in developed Western societies has been the decline since the 1990s in levels of high volume crimes such as burglary and car crime and also some forms of violent crime (e.g., homicide) thereby reversing the post-World War II trend in such offenses. If such crimes are currently declining, however, others are increasing. Terrorism, people trafficking and human slavery, money laundering, and drug dealing, crimes often linked to globalization, are increasing. Hate crimes, particularly racially motivated hate crimes, are increasing (and significantly underreported) as are crimes associated with local disorder and linked to social fragmentation. Some forms of crime associated with the internet (e.g., fraud, sexual grooming) also appear to be on the increase. The range of these crimes and police responses are too large to overview here; hence, only two aspects will be considered: the role of crime mapping to support police activity and the implementation of neighborhood-focused reassurance policing. Geographers have provided direct inputs into crime hot spot detection and modeling through the use of local spatial statistics and GIS as well as into assessments of targeted programs (Craglia, Haining, and Wiles 2000; Li et al. 2013).

Crime mapping has enabled many police forces to add value to their routinely recorded crime and service-call data by helping to identify and empirically quantify high-risk locations (crime hotspots) where additional resources, such as more police patrols or situational crime prevention (SCP) measures, might be targeted. SCP, theoretically grounded in rational choice theory and routine activity theory, is concerned with the identification and implementation of strategies that seek to reduce the opportunities for offenders to commit crimes and to increase the risks they face if they do. Typical SCP strategies include: target hardening (putting in place security measures that increase the effort would-be criminals need to expend); improving surveillance; and deflecting potential offenders. They focus on improving the safety of buildings and streets by making physical changes, by involving individuals and communities in preventing crime, and through inter-agency collaboration. An interesting extension of the crime mapping agenda is geographic profiling, the geographical equivalent of psychological profiling, which is underpinned theoretically by crime pattern theory. But the reductions that have taken place in some crimes have not necessarily been matched by the public’s sense of safety. One response has been the introduction of reassurance policing, which is based on a detailed understanding of places and their crime and disorder problems and what needs to be done to address residents’ fears. Certain crimes as well as forms of antisocial behavior act as signals that
a community is under threat. Neighborhood reassurance policing will often focus on reducing such “signal” crimes and in some cases the response is geographically targeted, as in the case of Neighborhood Watch schemes and in the United Kingdom the implementation of No Cold Calling Zones to reduce doorstep cold calling often associated with distraction burglary.

The social scientist’s interest in crime extends to the broader social and economic consequences of crime. A few of these broader areas of interest include the damaging impacts of people’s experiences or fears of crime on health, at both the individual and population levels, on social relations and social exclusion, and on quality of life. High levels of crime also have economic consequences for house prices and for local business investment. Second, as research and scholarship have become more global there has been an increase in research into crime outside the developed countries of the West, raising questions about the universality of theories about crime and criminality built from Western experience and Western datasets. This trend has also given added impetus to research into crime outside the developed countries of the West, raising questions about the universality of theories about crime and criminality built from Western experience and Western datasets. This trend has also given added impetus to research into, for example, the impact of corruption and violent crime on economic development and the effects of political-economic transition on crime rates and crime profiles in, for example, China (post-1979) and the former Soviet Union and its satellite states in Eastern Europe. These areas are of relevance in economic, political, and social geography but to date geography’s representation in these fields is modest.

“Critical geography” is a term used to describe a diverse set of perspectives that are committed to practicing forms of emancipatory thinking and action. This approach is directed both within and beyond the discipline of geography, encouraging progressive social change while also challenging the processes and institutions through which geographical knowledge is produced. Under the circumstances, attempting to have an international or all-inclusive view of the field of critical geography poses a challenge since the term covers an array of Marxist, feminist, anti-imperialist, anarchist, antiracist, and poststructural approaches (Peake and Sheppard 2014). “Not only is critical geography everywhere,” writes Nick Blomley (2006, 90), but “it is diverse and inchoate.” Consequently an attempt to narrate an overarching definition operates in contradiction with the very objectives of the production of critical geographical knowledge where the desire to challenge dominant forms of power has involved a deliberate move away from high theory and the privileging of abstract textual issues (Harvey 2006). This diversity is partly a reflection of the proximity of this concept to other affiliated terms, most notably radical geography. Where radical geographies emerged in the 1970s, heavily influenced by Marxist thought, critical geography was a slightly later intellectual and political development. Like radical geography, it shares a desire to challenge inequality and oppression, but it is less wedded to structural interpretations of this process and consequently less focused on political economy. Where radical perspectives have sought to illuminate the underlying class conflict shaping geographical phenomena, critical geographies have interrogated questions of representation, culture, and language. The entry will return to this distinction later, after spending some time considering the evolution of this field of study within and beyond the discipline of geography.

Historical trajectory of geography

It is tempting to trace the emergence of critical perspectives in human geography to the widespread incorporation of social theory into geographical approaches in the late 1960s and early 1970s. But to do so would be to overlook the long tradition of critical dissent within the study of geographical systems and process. For example, Gerry Kearns’s (2009) account of the influence of Halford Mackinder’s imperialist perspectives of late nineteenth- and early twentieth-century Britain demonstrates the presence of contemporary thinkers questioning dominant imperial geopolitics. For example, Petr Kropotkin, a Russian émigré to the United Kingdom, studied the struggle of communities in eastern Siberia over limited resources, where he witnessed both forms of competition but also – crucially – practices of cooperation. The challenge for thinkers such as Kropotkin was to confront geographical perspectives that relied on principles of environmental determinism,
an approach based on a paradigm of social Darwinism where imperial incursions were justified on account of the supposed primitivism of native populations. Perhaps the most powerful element of such determinism was its claim to scientific neutrality, where exploitative and violent geopolitics were represented as necessary responses to adverse climate, topography, or other environmental conditions. In constructing a critical response, Kropotkin did not reject social Darwinism but, rather, accused such imperialist writers of misrepresenting evolutionary biology, where species success is not simply a product of struggle but also of cooperation and mutual aid.

This example sets out some of the established tenets of critical geography that have flourished over the latter part of the twentieth century. Perhaps the most prominent characteristic of this perspective is a challenge to the imagined objectivity and neutrality of science while exposing and confronting the power relations that underpin scientific “objectivity.” Certainly, much of the Marxist, feminist, and humanistic approaches that emerged in Anglo-American geography of the early 1970s confronted the underlying positivism of the spatial science practiced in the 1950s and 1960s. One of the precepts of being a part of science was to have rational and objective viewpoints – the “enlightened” way of seeing the world as orderly, neatly organized, and causally generalized. In a quest for an essentially rational order, the production of “truth” meant the use of methods that would lead to overarching theories. It was not surprising, therefore, that objectively produced knowledge, which could stand scientific rigor, scrutiny, and validation, took precedence over other forms of knowledge. Geography came to be seen as nomothetic (a science of general or universal law) rather than ideographic (place-specific or unique work), leading to increasing emphasis on spatial scientific approaches. Perhaps the most tangible evidence of this intellectual prioritization can be found in the quantitative revolution, which had marked an intellectual shift, particularly in Anglo-American geography, from the mid-1950s. This phase was characterized by theorizing and the adoption of statistical techniques of description and empirical verification in a positivistic manner. This approach, often termed spatial science, held that space itself was an external characteristic of the world with its own discoverable laws.

The challenges to spatial science were both plural and mutable. Early critical approaches were directed not toward creating new political or social theory but to addressing the absence of certain topics from geographical scholarship. In consequence, the early 1970s saw scholars drawing into the disciplinary concerns of geography issues as diverse as civil rights claims in the United States, rising global environmental concerns, the conflict in Southeast Asia, and Cold War conflict. Following this widening of thematic concerns, attempts began to consider how the observed inequality and oppression, operating at multiple geographical scales, could be adequately theorized by geographers. Initial works, first by David Harvey but later including James Blaut, Richard Peet, Neil Smith, and others, drew on Marxist approaches to connect geographical inequality to the operation of the capitalist economic system. In a move that has become a characteristic of critical approaches, their works drew attention to the dual practice of oppression (economic or social marginalization through unequal economic power relations) and practices of representation (the way the world is narrated and symbolized in policy and media environments). Critical geography in these terms was as much about trying to challenge and disrupt capitalist representations of the world as it was about building an overarching spatial theory of capitalism.
Interest in challenging the production of knowledge and unsettling powerful representations of the world were traits that extended beyond Marxist geography. At a similar time, a range of scholars, illustrated by but not limited to the Women and Geography Study Group in the United Kingdom, explored ways in which feminist political perspectives could both challenge conventional geographical perspectives and deepen Marxist critical approaches. The late 1980s witnessed debates regarding the merits of drawing on feminist and Marxist concepts to see if gender and class politics can be intersected, in particular around practices of patriarchy (Longhurst 2002). Such initial studies were largely simple descriptions and a mapping of the differential geographies of men and women in terms of their disparate access to services, employment, and facilities while also addressing women’s position and status within the discipline. Later, scholars started offering newer and more complex interpretations of place and their intersections with the existential specificities of women’s lives, as well as new insights into women, gender, and gender relations. And yet, these developments were essentially taking place in an Anglo-American context. Elsewhere in the world, such as in India, collective thinking and open debates about such intellectual concerns were largely absent, while the intellectual frameworks within which these issues were discussed continued to remain firmly on empirical terrain.

The situation changed somewhat with the inclusion of gender. Although the initial themes studied in South Asia appear rather archaic when placed against issues that have been explored in the Anglo-American world, the very entry of gendered subjects was to push the limits of geographical analyses to critical thinking in opening up a terrain of investigation into asymmetrical power structures between men and women, their differentiated spatial relationships and practices, challenging the established androcentric tenor of the discipline. One of the preoccupations of critical thinking has also been decentering gender as the primary category of analysis. For example, the presumed linear developmental trajectory of education, access to gainful employment, and women’s empowered status is being critically looked at to situate gendered subordination in complex and multilayered structural environs marked by caste, class, religion, and ethnic differences, mediated through spatial locations. India offers a case where spatial and spatially embedded social structures and norms have significant holds on gendered relations, notwithstanding the argument that gender relations cannot be conceptualized as fixed and static (Raju 2002; 2011).

In tandem with the emergence of feminist critical perspectives, scholars sought to draw on burgeoning postcolonial scholarship to consider the ways in which geographers could offer critical accounts of both enduring forms of imperial practice and the mechanisms through which non-Western voices were silenced in the geographical discipline. Often the “third world” was seen as providing empirical “case-studies from … exotic others for the consumption of powerful knowers in the centre” who are from the Anglo-American worlds (Simonsen 2004, 526). As with feminist approaches, postcolonial critical geography is thus focused as much at the sites, bodies, and language through which geographical knowledge is produced as it is on specific colonial histories or relationships. In this way, this wide body of postcolonial scholarship has sought to illuminate the inequalities between colony and metropole while simultaneously exploring how processes of knowledge exchange, representation, and claims to expertise allowed such inequities and oppressive practices to be masked, reproduced, and, on many occasions, celebrated.
CRITICAL GEOGRAPHY

The diversity of intellectual perspectives did not end in the 1980s. The years since have seen a constant process of extending, challenging, fragmenting, and integrating different theoretical approaches in order to sharpen the tools of critique and social change. Perhaps the distinctive approach of the 1990s was the more wide-ranging incorporation into critical geography of poststructural approaches, in particular practices of deconstruction inspired by the work of Michel Foucault and Jacques Derrida. This move has oriented attention to the relationship between the production of space and its representation and, in particular in the work of Foucault, tracing the historical genealogies through which social categories gain meaning and significance. Language is no longer regarded as a neutral medium of communication but it is seen as the means through which particular hierarchies, classifications, and forms of inequality are normalized and reproduced. Such a focus on words turns inward on the discipline itself, where scholars such as Sparke (2005) have sought to deconstruct the etymology of geography to understand the practice as geo-graphy, quite literally, “earth-writing.” In these terms, geography is less a distinct academic discipline than a discourse through which particular imaginations of the world are stabilized and established as truth and which also provides the tools for resistance and subversion.

Critical geography and geopolitics

The turn to deconstruction as a form of critique fostered diverse reactions and responses within and beyond geography. The emergence of a field of critical geopolitics provides a lens to explore such contestation. Critical geopolitics, just like critical geography, is a diverse field which some see less as a coherent body of work and more as a style of scholarly analysis, or simply as a never-met aspiration. But the term has been applied to the body of work emerging in the late 1980s and early 1990s that sought to decode powerful accounts of international affairs, and in particular the foreign policy accounts of major Western powers. Starting with the policy prescriptions enacted toward the end of the Cold War, and proceeding through similar texts confronting the 1991 Operation Desert Storm in Iraq, through the interventions in the fragmentation of Yugoslavia, and on to the US-led “war on terror,” this work has sought to illuminate the ways in which political agendas are legitimized through specific representations of global space. Ó Tuathail and Agnew (1992, 192), two key proponents of early critical geopolitics, suggest that the purpose of this critical perspective is to rethink geopolitics as a “discursive exercise” by which “intellectuals of statecraft spatialize international politics in such a way as to represent it as a ‘world’ characterized by particular places, peoples and dramas.”

The reason for pausing on critical geopolitics is to investigate the response to this style of discursive technique, a set of reactions that provide a telling microcosm for broader concerns about critical geography. In particular, debate has focused on what is “critical” about critical geopolitics. Where initially the critical credentials of this scholarship were signaled by the disruption of powerful narratives about the world, increasingly feminist and postcolonial scholars have confronted the ability of such accounts to offer alternative visions of the world. One concern is that a rather straightforward toolkit for critical deconstruction can be established that neither encourages transformative politics nor gives voice to those who suffer the consequences of violent foreign policy incursions. In addition, feminist scholars of geopolitics have argued that these initial works
within critical geopolitics had little consideration for their own embodiment (mainly the works of men) or situated nature (in elite Anglo-American universities). In response to these concerns, work adopting a feminist geopolitical perspective has sought to reorient the focus of geopolitical analysis away from formal state pronouncements to everyday sites through which geopolitical ideas circulate and are challenged. Consequently these approaches foreground alternative loci of security, whether in civil society, the community, or the family.

Where feminist and postcolonial scholars have critiqued the transformative potential of critical geopolitics, more recently scholars have begun to challenge the emphasis placed on representation. Rather than simply analyzing and deconstructing policy texts, these interventions have drawn attention to the ways in which geopolitical discourse is performed through bodies, materials, and institutions. Such work could be framed as a more-than-representational turn in critical geopolitics, or as a rematerialization of critical geopolitical inquiry that moves beyond texts and images to consider the wider economic and social contexts of their existence. But there is a problem here. Scholars in critical geopolitics have always been interested in the wider material context within which texts and other forms of representation are produced; look at the fine-grained historical analysis included in the works of scholars such as Ó Tuathail or the biographical positioning of the life and work of noted US geopolitical Isaiah Bowman in Neil Smith’s (2003) account of early twentieth-century US geography. In addition, discourse is never simply textual or merely representational, it is always also a performance that can be traced through its production (as scholars have provided behind-the-scenes accounts of journalistic and policy practices), its performance in particular arenas, and its various receptions by different audiences. These are processes as material, mutable, and dynamic as any other.

**Critical and radical geography**

The vexed question of the relevance of critical geography necessitates revisiting the distinction between radical and critical geography. Considering the wide array of perspectives outlined earlier, it is no surprise that some scholars have sometimes become dissatisfied with the “critical” label as being too diffuse and inclusive, claiming instead that their work and political practice is “radical,” reflecting the longer lineage of Marxist geography conducted under this latter label. Supporting this position, Purcell (2003) critiques the coherence of critical geography, arguing that “islands of practice” have emerged, independent of each other and working on parallel forms of political oppression. Within this narrative, scholars interested in capitalism were often intellectually and politically isolated from those engaged in studies of patriarchy, racism, or heteronormativity. Similarly, there existed disconnects between scholars exploring global processes and those involved in local-scale processes.

Drawing a line between radical and critical continues to be a fraught practice (not least as many would – and do – self-identify with both). Geographers have presented radical geography as a diverse field that is interested in undertaking scholarly work that has explicit relevance for people’s everyday lives. At the same time, much of the work that is gathered under the label of “radical geography” has remained wedded to structuralism, thereby seeking to illuminate and challenge the frameworks of power that reproduce inequalities (broadly understood) and legitimize oppression. But there is also a question about the location and privileges of knowledge production, where radical scholars have claimed
CRITICAL GEOGRAPHY

that the “radical” elements of critical geography have been lost as feminist, Marxist, and post-colonial practices have been incorporated into the disciplinary structures of Anglo-American human geography. But, in many ways, critical geography has also attempted to retain a sense of distance from traditional disciplinary institutions and practices. One example would be the establishment of the International Critical Geography Group (ICG), a coalition of scholars from across the world (the 2005 ICG Conference in Mexico had 35 participants) which challenges nationally aligned geographical societies while thinking through transnational practices of critical geography. Similarly, the journal ACME, established in 2002, defines itself as an international e-journal for critical geographies and is organized around a fully open access format, subverting the restrictive financing model of more mainstream geographical journals.

Critical geography and relevance

A controversial issue in critical geography has been social relevance. Some argue that social relevance can be acquired by establishing a bridge between academia and (political) activism. A few geographers examining gender are also trying to bridge the gap between research and praxis by getting involved in activities of civil societies and action research, and by positioning themselves between academia and policy implementers. And, yet, what constitutes such activism and should it be pursued? Whether critical issues should be attended to from within academia rather than by joining direct action outside remains contested and unresolved. A number of critical geographers have also sought to move away from such bifurcation between the academic and activist categories, arguing for a more nuanced reading of the locations and identities for critical geography. There can be a third space between academia and activism, a space of continual flux and movement wherein there can be activism within academia and academic endeavors within activist settings (Blomley 2008).

In the South Asian context, the question of geography’s relevance has to be placed in a wider frame. There the rigid definition of what constitutes geography and what does not, which of the strands are appropriate and which are not appropriate, has to be continually challenged, reworked, and contextually grounded. This challenge has to happen without giving up (despite interdisciplinary exchanges and discourses) one’s training as a geographer because of the disciplinary edge geographers have in decoding the spatial embeddedness of social relations and social formations, and providing a nuanced analytical framework of interdependencies between the environmental bases of spatial attributes and the social and historical processes leading to a theory of social causation. Such integration could open up the tremendous possibilities for context-specific critical geographies. Recent research shows that geographers are well equipped to address issues of rising fundamentalism and ethnic reasservations as reactionary outcomes of the hegemonic appropriation of resources and opportunities. Scholars have related these concerns to questions of distributive justice and the role of civil society, distorted spatial relations in a globalizing world, and marginality issues in the context of international capital flows.

In sum, a grounded recognition of how contextualized understanding of the processes of knowledge production has to position critical geography in multiple ways, dispossessing a desire for a monolithic construct of the content of critical geography. Critical geography is now an established branch in much of Western academe and critical geographers occupy places
of eminence. Critical geography has ushered in not only normative changes in human geography, but also, in the process, transformative effects on the discipline itself, for critical geographers are using a wide range of critical social theories to address substantive issues related to race, caste, class, colonial power, and inequality.

Critical GIScience

Nadine Schuurman
Simon Fraser University, Canada

In 1999, Schuurman published a monograph entitled Critical GIScience: Theorizing an Emerging Discipline. This work outlined the emerging phenomenon of human geographers engaging with the computationally based subdiscipline of geographic information systems (GIS). The monograph examined the human developers of geographic information science (GIScience), as well as the technology, through the lens of critical human geography (Schuurman 1999). Though this was the initial use of the term, “critical GIScience” has broad antecedents in GIScience, human geography, and social theory. The use of the term “critical” in human geography and social theory more generally is a means of marking the work as an inquiry into a range of perspectives that include gender, social construction, and science and technology studies (STS), as well as Marxism.

The word critical is derived from the Greek word *kritikos*, which focuses on questioning and analyzing phenomena, especially those that might otherwise be taken for granted. Over the past 50 years, a number of social theorists have identified their work as “critical,” with the implication that they are looking at social and practical implications of a given event, practice, or movement, rather than taking its existence at face value.

The critical movement in human geography was definitely a chief influence in the development of critical GIScience (Leszczynski 2009). Since the 1950s, there have been fault lines in the discipline between those committed to quantitative analysis and those who pursue more human and social axes of inquiry. GIS, as they emerged from the mid-1960s to the 1990s, were squarely lumped in with quantitative geography. In the mid-1990s, two parallel developments altered this division. First, the National Center for Geographic Information and Analysis (NCGIA) was formed and started to integrate historical and participatory aspects of GIS into its agenda (Goodchild and Mark 1993). Second, human geographers, influenced by STS and critical theory, began to question the agenda of GIS (Sheppard 1993).

By the 1990s, STS and critical human geography converged into a series of critiques of GIS. Perhaps the earliest (and most viral) of these was by the late Neil Smith when he linked the first Gulf War directly to GIS technologies. In 1993, a meeting was held in Friday Harbor, Washington, to examine some of the suspicions being cast on GIS. This meeting was attended by a number of GIS scholars, as well as by human geographers, and resulted in a special issue of the *Cartography and Geographic Information Society Journal* in 1995.

It was in this special issue that accusations of gender bias, Cartesian perspectivalism, military links, and issues of race emerged as a collective set of criticisms. They were informed in large part by the emerging literature on STS, as well as by emerging feminist and critical geographies. Their goal was to illustrate the axiom that the direction of science is not separate from its surrounding culture; indeed, they are inseparable. More specifically, the concerns and direction of science are closely related to the important issues of the day. Bruno Latour famously describes this inter-
twinement of scientific and societal priorities by illustrating how scientific discourse was shaped during the development of smallpox vaccine.

For the most part, influential STS scholarship has focused on scientific inquiries in physics and biology. However, STS-informed critiques of GIScience had perhaps a greater impact in the discipline of geography – perhaps because geography is a small enough discipline that ripples in the pond are noticed.

If the journal special issue was a ripple, the next disturbance was a tsunami. In 1995, close on the heels of these early criticisms, a new book entitled *Ground Truth*, edited by John Pickles, was released (Pickles 1995). This compilation addressed various perceived flaws as well as the positive potential of GIS. For the most part, however, its tone was somewhat derogatory, and it included entries that did not display a sophisticated understanding of the underlying technology nor its representational challenges. The edited book, and its contribution to critical GIScience, is well documented in Schuurman (2000). A positive outcome of this challenge to the technically oriented and philosophically detached GIScience research community was to force consideration of some of the issues that had been raised in STS, such as theoretical underpinnings to semantic heterogeneity (Harvey and Chrisman 1998), the potential role of algorithmic choice in scientific outcomes, and the absurdity of implicating GIS in the woes of the world.

This abbreviated history of critical GIS is elaborated on elsewhere (Schuurman 2000). However, it is important in setting the context for the development of a cadre of scholars that took the issues associated by critical GIS very seriously. For many, this became their career path. It is these scholars who, today, are beginning to explore mapping-related artifacts of georeferenced Internet-based data and services collectively referred to as Web 2.0, as well as neogeography.

Web 2.0 is often synonymous with social media. Neogeography, coined by Andrew Turner in 2006, is a spatial iteration of Web 2.0 in which the old professionalism associated with map-making disappears as the practice becomes widely accessible to untrained users. This profound democratization of mapping and geovisualization affects conceptualization and expectations of an emerging GIScience as all online mapping venues are expected to include interactions (Sui and Goodchild 2011). Indeed, exchange of information with attendant ability to interact, exchange data, and download “shareware” has become routine. In this, GIS follows all social media. It is this enactment of GIScience as media that is the basis for volunteered geographic information (VGI), location-based services (LBS), spatial big data, and attendant privacy concerns.

Leszczynski recently alerted us to the dangers of distinguishing “neogeography” from plain old GIS and thus exempting its many dimensions from the scrutiny of critical GIScience (Leszczynski 2014). Never has this counsel been more apt as critical GIScience scholars begin to grapple with the implications of unimaginably large collections of geographically referenced data on the web. These include critical examinations of VGI, LBS, and big data, all of which are the basis for an emerging *new critical GIScience* that encompasses the many implications of Web 2.0 and neogeography.

VGI was coined (like the appellation GIScience) by the pre- eminent GIS scholar Michael Goodchild (Goodchild 2007). He recognized very early that mobile devices and persuasive computing were the basis for users to contribute widely and frequently to “citizen science” efforts. Indeed, VGI is the basis for populating spatial databases of many stripes. He
used the example of the forest fires that raged across southern California in 1997. Previously, government officials were charged with warning potentially affected homeowners when they should evacuate. Residents, for the first time, were using Flickr *en masse* to report on the fires’ extent. Homeowners could go onto Flickr and see “where” the fire was. Geotagged photos were far superior reporters of the geographic coverage of the fires than any government official, who could, after all, not be everywhere at the same time (Goodchild 2007). During a subsequent fire, volunteers used geotagged information to create online maps of fire extent that received hundreds of thousands of hits (Goodchild and Glennon 2010). Web-based geotagged information, if reported by enough people, was everywhere at once.

VGI is both a boon and challenge to governments around the world. After all, anyone can report data through geovisualization and maps. Urban planners are now faced with multiple possible neighborhood futures and must seek ways to acknowledge points of view that may have been unsolicited. Legal concerns shadow VGI as well. Liability, ownership, and reliability often remain unknowable (Haklay 2010). The proliferation of VGI also destabilizes spatial data infrastructures that were painstakingly erected and controlled by national governments (Elwood and Leszczynski 2011).

The once fanciful idea that the world is populated by a pervasive army of potential reporters on a wide range of social and scientific phenomena is now a reality. But trenchant critics of GIS have pointed out that VGI is not in fact reported by all, or even a cross-section, of the population. Instead, it remains the domain of mostly male, prosperous first-world citizens – and only a slim portion of those (Lesczynski and Elwood 2015; Haklay 2013). This reminds us that all technology (and data) is socially embedded. And the data that they report on reflect this. There are many classifications of bars and pubs reported in some cities by VGI contributors but none for child care (Stephens 2013). This raises a question central to the *new critical GIS*: Whose data is reported and for what purpose?

This single question is the basis for emerging scholarship that links critical GIS to the geoweb. For instance, VGI is the basis for populating the brave new world of independent maps and software owned by “the people.” But when the “V” in VGI is absent, the data falls into the domain of LBS. Contributors to LBS (e.g., most of us sporting smartphones) are also unwitting data volunteers for corporations keen to sweep up any crumbs of personal information that could result in more persuasive advertising and greater consumption. Any example of VGI as a positive scientific contribution (e.g., ubiquitous temperature reporting in the interests of monitoring global climate change) can be matched with a more sinister one linked to LBS, such as “stalker” apps that report users’ locations to potential predators, often without their knowledge or consent (Leszczynski and Elwood 2015).

When VGI does occasionally sport a dark side, there are almost always LBS involved. For example, locationally aware mobile devices reported girls’ locations back to a central server, which distributed spatial data on proximate girls to subscribers of the service Where the ladies at, mapping the locations of concentrations of women (based on public Foursquare check-ins) as “hotspots” or densities. While this particular LBS has been discontinued, the potential for ethically suspect use of locational data is enormous. Critical GIS scholars are alerting us to ethical dimensions of LBS (Wilson 2012). Perhaps the most striking is the uptake of LBS by corporations largely enhanced through mass participation in social media.
But it is our devices themselves – unrelated to social media – that perhaps offer the greatest technological advances with attendant increases in privacy violations. Since the introduction of Apple iOS 8, iPhones and iPads have been using iBeacon, a Bluetooth-enabled service that allows retailers to determine exactly where potential customers are located (McFarland 2014). Using triangulation, iBeacon can pinpoint in which aisle of a grocery store someone is standing or which painting they are in front of in a museum (a more benign example). In a retail environment, a coupon could be sent to the customer as they view pizzas or big screen TVs in front of them. In a museum or other public setting, a person could sign up for a guided tour of the facility. Proponents will argue that these “intrusions” are agreed upon by the customer through a consent process. However, when money is involved, consent can be a dubious concept.

These small spatial incursions are multiplying. Since the Mac OS called Yosemite was released in 2014, just opening the search function called Spotlight triggers the OS to send a precise location to Apple (Soltani 2014). Tweets, Facebook entries, Instagram photos, and other forms of self-publication on social media contribute to an emerging profile of each of us. It is the linking together of these various bits of personal information (much of it spatial) that we all seed on the web that forms the behemoth that we now refer to as big data.

Big data is, in effect, all the little data crumbs that each of us leave as we cruise the web. Increasingly corporations have harvested these crumbs and developed individual profiles of each of us in the interests of promoting consumption (Leszczynski 2014). The ability to cross-reference these data from various sources to build detailed profiles of individuals as they move through their lives both horizontally and vertically requires significant algorithmic and processing power. Corporations around the globe have stepped up to the task.

While these incursions into our most private lives may seem minor when considered individually, they are significant in the aggregate. The New York Times started to take notice in 2012 that companies were using marketing information that they both collect and purchase (which often is scraped from social media and linked to email addresses) to do “predictive analytics.” Data is not just about what we buy and where, but about how we live. Insurance companies are compiling rates and restrictions based on our lifestyle choices. Whether you are a deer hunter, an avid runner, or a slothful pizza consumer, all of these attributes are linked to life and other insurance applications. These infiltrations are becoming more pervasive as they are linked to scraps we leave on social media. Facebook is at the forefront as it harvests postings of personal activities and combines these with data they purchase from other data scrapers to create custom ads for individual users. Google takes the stakes higher as it created educational apps aimed at college students and then mined their email addresses to link to other activities. That almost all of these data acquisition forays contain valuable spatial data seems self-evident. But when Nordstrom put up signs divulging that they were tracking customers as they roamed department stores, customers were nonplussed and decidedly unhappy.

Perhaps this is because most big data profiling is conducted stealthily and in North America people have chosen to be relatively complacent (in contrast to Europe, which supports greater consumer vigilance). As scholars, we have also been complacent, having paid relatively little attention to spatial aspects of big data. This is changing as scholars from many disciplines wake up to the social implications of pervasive and ubiquitous data collection. Our attention is also stretched
thinly as data collection is not confined to corporations but eagerly pursued by governments. Governments are increasingly the most thorough gatherers of Internet data about individuals. The Snowden leaks in the United States are perhaps only a glimmer of the future in which data (including geographical data) on individuals are assembled en masse. In Canada, in January of 2014, the government was found to have collected travel pattern data on individuals using Wi-Fi at major airports. Sentinel to both examples is not just the collection of data but its use to follow individuals as they move around the globe – far outside the jurisdiction of the governments tracking them. And big data transactions are (or should be) the purview of new critical GIScience scholars and citizens concerned with democratic concepts of liberty.

Digital divide

Some of the potential problems associated with neogeography are first-world problems. As Graham (2012) enumerates, high-speed Internet access is very unevenly distributed across the planet (Graham 2012). Indeed, variable web access reinforces existing divides between the privileged and underprivileged across all the familiar categories, including education, income, and social capital, not just in low- and middle-income countries but in Europe and North America. Just fixing the problem of income inequality will not necessarily close the digital divide. Digital inequality in access to computing equipment and in skills to operate is only a symptom of existing inequities.

Long ago, Haraway reported on the danger of allowing a patriarchal computing world to emerge (Haraway 1991). Rather than chastise men for their role in the evolving “cyborg,” she urged women to become more active in its architecture. Only by learning to program, and engaging with the waking beast, could women and feminist objectives be woven into the construction of the web. The contemporary artifact is the geoweb and its character.

A number of critical GIS scholars have reported on ways that gender relations are reinforced rather than reforged as the geoweb emerges (Leszczynski 2011; Leszczynski and Elwood 2015; Stephens 2013). However, there are many openings for women to shape and be shaped by emerging technologies (Schuurman 2002). Perhaps the largest barrier to this aspect of the digital divide is our own epistemological programming. Pavlovskaya (2009) urges us to use the opportunities of the geoweb to forge new epistemologies and, as a result, allow new ontological categories to emerge in GIS. Cope and Elwood (2009) literally open the door for this development in their book Qualitative GIS, in which they provide many road maps for these categories to emerge from qualitative data that was historically not considered suitable for GIS.

If traditional GIScience and the geoweb have reinforced a quantitative masculinity, they also open the door for new modes of expression, including an acknowledgment of the role of emotion in human expression – whether digital or in person (Kwan and Guoxiang 2008). LBS are freely utilized in this contemporary expansion of expression as men and women broadcast their preferences (along with location) in what Wilson (2012) brands conspicuous mobility. Ironically, the openings that women seek in virtual worlds are frequently those that make them physically vulnerable as well as corporate prey as data is harvested on their every preference and move (Leszczynski and Elwood 2015).
Arguably the antecedents to critical GIS began in the 1980s as STS gained a foothold in the social sciences. A highly distilled account of the messages of STS might be: to understand science, examine its social context. This lesson, like so many from STS, is especially pertinent as critical GIScience remakes itself in the wake of Web 2.0 and the geoweb. Dawn Wright (2012) expressed the value of critical GIS in this context articulately: as GIS becomes inseparable from the web of devices and data that surround our earth, there is an increasingly urgent need for critical evaluation of their effects on geographical scale, proximity, society, and surveillance (Wright 2012).

In our delight over the wonder and possibilities of a newly configured geoweb, we can lose track of the fact that corporations evince a parallel delight in ubiquitous spatial data (Leszczynski 2014). Governments likewise have jumped on the data collection bandwagon with egregious incursions into personal lives in the name of security (Lyon 2014).

As forecast long ago, we have become digital personae (Poster 1996), lightly sketched holograms made of data bits scavenged without our permission but willingly donated to corporate profiles as we virtually cavort through the playgrounds of social media. The cookies we leave on the web, along with our email addresses and other personal identifiers, are being woven into our profiles. It is these implications of the Brave New World of VGI, LBS, and other aspects of web mapping and spatial analysis that form the basis for an emerging new critical GIScience over the coming decade(s).

Critical spatial thinking

Diana S. Sinton
Cornell University, USA

Background and overview

Critical spatial thinking incorporates spatial concepts and geographic principles to guide and inform reasoning. A critical spatial thinker wisely and appropriately uses geographic information to understand problems, derive solutions, and communicate effectively about the process and its outcomes. Thus, he or she is following the regular practices of critical thinking within a context or situation involving geographic information, whether he or she is the producer or consumer of such information. In its simplest form, critical spatial thinking blends habits and processes of both critical thinking and spatial thinking.

The practice of critical thinking itself involves careful and deliberate consideration of the factors and variables that contribute to a situation or problem, and a subsequent analysis or synthesis that leads to a well-reasoned conclusion. As Facione (1990) stated, “the ideal critical thinker is habitually inquisitive, well-informed, trustful of reason, open-minded, flexible, fair-minded in evaluation, honest in facing personal biases, prudent in making judgments, willing to reconsider, clear about issues, orderly in complex matters, diligent in seeking relevant information, reasonable in the selection of criteria, focused in inquiry, and persistent in seeking results which are as precise as the subject and the circumstances of inquiry permit.”

Critical thinking is not a skill that necessarily occurs developmentally, or develops automatically. As an approach to knowledge acquisition and reasoning about the world, it can become a habit, and thus easier and more automatic over time and through persistent effort (Thomson 2008). Habituated actions that build upon constructivist cycles of knowledge production, application, interpretation, assessment, and re-production may be driven by an intellectual commitment to regularly use these thinking skills to guide behavior.

Spatial thinking is an ability to visualize and interpret location, position, distance, direction, relationships, movement, and change through space and over time (Sinton et al. 2013). This broad and inclusive definition is designed to cover subgroups of spatial thinking, such as the skills and abilities often associated with spatial cognition. A location or position that is being visualized and interpreted can be something in geographic space, such as a bend in a river; or something in the space of indoor human activity, such as the corner where two walls meet a ceiling; or something in abstract or digital space, such as the top of a stack of blocks being projected on a computer screen. Although the scales and environments vary, in each of these situations our cognitive spatial thinking processes rely on our capacity to visually comprehend and discern factors, such as the location or position of the phenomena and the distances, directions, angles, and orientations of how all things fit together in their respective contexts. Factors such as these determine how the where of the world is perceived and appreciated. Combining critical thinking with spatial thinking brings together the tenets of these two cognitive approaches to bear on tasks of
reasoning and decision-making. Scale, location, distance, and spatial dependence are among the factors that will affect how someone interprets a situation in a critical and informed manner.

Scale

Scale is of central importance to spatial thinking. At a personal or human scale, spatial thinking and cognition are often of interest to psychologists as they assess the ways in which individuals and groups of people are able to mentally rotate 3-D objects, or visualize objects from folded papers. But at an environmental or landscape scale, spatial thinking is consistent with geographical thinking, as the patterns and processes of the natural and social world are considered.

During the process of spatial thinking, scale interacts with location in terms of measuring and describing space. For example, the location of a point somewhere on the Earth’s surface can be identified by many different spatial reference or coordinate systems, all referring to the same place. Computers rely on these reference systems to store locations relative to the surface of the Earth, but the coordinates are also relative to a scale. For example, on a map of a particular scale, the Eiffel Tower in Paris, France, can be depicted as a single point. A computer may store the coordinate location of this zero-dimensional point with as many as 8–10 decimal places, specifying a location down to the atomic level. Yet on the ground, the actual structure has additional dimensions of height, length, and width that are not associated with the zero-dimensional single point. Without having previously recorded the 3-D data, the computer can only reference the single point location.

Thus, critical spatial thinkers need to become aware of how scale affects measurements, how scale can limit graphic representations, and how computers are capable of storing and displaying location data. Computers are capable of recording and storing coordinate data with a high degree of precision, but this is often out of alignment with both tools for measuring geographic locations and the very nature of a location in geographic space. Appreciating these characteristics of location, and how its measurements aid in assessing and evaluating evidence, is part of the practice of critical thinking. Becoming aware of the ways in which this knowledge affects the correct and informed usage of geographic information systems (GIS) is one way to develop expertise as a spatially literate geographic information scientist (GIScientist) (Sinton and Schultz 2008).

Scale has different connotations within geographical and spatial thinking, and all of these meanings affect how an individual reasons with and through space. Cartographic map scale is the mathematical relationship between units of distance on the map and the same units of distance at the place being mapped. Scale also references the resolution of geographic data in its raster and vector digital form. Lastly, scale is used to describe the extent of a study area. In the process of thinking critically about space, all of these meanings would be understood and applied appropriately and correctly in context. With this knowledge in place, an individual is ready to understand processes and patterns as they cross scales, such as interpreting hierarchies, networks, and fractals.

Location

Location is a nuanced idea that can be both relative and absolute. Any object or structure, such as a single park bench, can have its location described by coordinates and placed on a map of the Earth, based on those coordinates. Critical spatial thinking then involves knowing how that particular locale is situated within countless
other physical, environmental, and social frames of reference. How a bench in an urban center differs from a bench along a beach path, or how the same one in a city could be a different place at 11:00 a.m. versus 11:00 p.m., means appreciating the spatial and temporal context of a location. No geographic location exists within a vacuum; the setting of a location provides extensive other information to critically understand a place.

Appreciating the broader context of location is essential for critical spatial thinking. Location becomes an explanatory variable in a model. Physical, environmental, and social data are all interrelated. A location can be understood by what is taking place upwind, upstream, or uphill of it, and how, in turn, it is affecting the downwind, downstream, or downhill locations. This perspective enables scaling of the pattern and process, those ideas of hierarchies, networks, and fractals, mentioned earlier.

Location varies in its descriptions and measurements as a function of scale. Information about a location or place is collected at and appropriate for a particular scale or level of aggregation. For example, data collected about the city of New York only as a whole, with one set of values covering all of its five boroughs, cannot later be divided to provide details only about Manhattan or the Bronx. However, the data from the individual boroughs can be combined upwards, or to a coarser, larger scale. So this scaling property is unidirectional.

Furthermore, data that were collected about residents living within the same single zip code area cannot readily be compared to data aggregated at a different areal unit, such as voting precincts or school district boundaries. Because the data are not uniformly distributed throughout these areas, they cannot be divided by their areal values and it be assumed the proportions remain consistent. These situations invoke the modifiable areal unit problem (MAUP) and issues of ecological fallacy. Data and modeled relationships are ideally suited only for the scale at which they were originally collected. This truth is a challenging one under which to operate consistently, and it is one that is often violated by individuals not thinking critically about geographic data.

Distance

Like location, distance has both relative and absolute properties, and is a complex notion associated with any space comprised of more than one object (Gatrell 1983). Distances between locations within Euclidean or Cartesian space can be measured with standardized units, and by applying known conversion formulas such distances can be converted across reference systems. But distance can also be subjective and relative when considered in the context to other variables, such as topography or currents. Running a shorter distance uphill and into the wind can be a more formidable task than a running a greater measured distance downhill and with the wind from behind. Distance and rates of travel also have a temporal component. For example, during rush hour it will take more time to travel the same distance as it would another time of the day.

Being savvy about distance informs critical spatial thinking by providing a means to evaluate variables and their expected relationships. This means matching or aligning approaches to measuring distance with particular situations is the best strategy for making the wisest decisions. For example, knowing when to consider absolute or relative measures of distance, or selecting between Euclidian (as-the-crow-flies) and network routing methods, is desirable or possible for modeling movement or flow.
CRITICAL SPATIAL THINKING

Spatial dependence

Distance also underlies the fundamental principle of spatial organization, that everything is related to everything else, but near things are more related than far things (Tobler 1970). This “first law of geography” drives spatial autocorrelation, the likelihood of similar characteristics and values being present in close phenomena. It also affects how geographic patterns can be interpreted through statistics, because the samples of phenomena are not independent from one another, a result of the underlying variables that contribute to their location or placement. Critical spatial thinkers anticipate these spatially dependent patterns and are in the habit of expecting them to occur. That helps them build comparisons, envision patterns, and extrapolate to analogs, other practices of spatial thinkers. Moreover, the habit of expecting spatial dependence facilitates the identification of outliers and anomalies when they do arise. Identifying and investigating these would, in turn, be a practice of critical thinkers as they assess and evaluate interrelated variables.

Error and uncertainty in critical spatial thinking

There are no spatial data that are 100% perfect or absolutely complete for all situations, over all scales and time frames. Gaps, inconsistencies, and unknowns are inherent in the knowledge of this field. Recognizing the existence of uncertainty and being able to address and mitigate it are hallmarks of effective critical spatial thinking. First, important distinctions exist between uncertainty and error, which affect critical spatial thinking in different ways. Error is an inaccuracy known objectively; it is the measured deviation of a value from truth. Error as it is thus defined has its groundings in mathematics, logic, and the law, among other disciplines. Uncertainty, on the other hand, is a facet of our imperfect and inexact knowledge of the world. It is a measure of the difference between the data and the meaning attached to the data by the current user (Zhang and Goodchild 2002). Uncertainty is a result of error, ambiguity, or the lack of information. Errors can be deviations from objective standards, and identifying, quantifying, or documenting them may be possible. Thus, it may be possible to disclose and share the source, amount, and extent of errors. In contrast, uncertainty is more challenging to characterize and easily address, especially in any automated manner.

Both error and uncertainty are likely to be associated with geographic data and spatial analyses, and the existence of uncertainty within spatial analyses is inevitable. Because the complexity of the world cannot be modeled perfectly, and all natural and social phenomena vary over space, all digital data used within GIS-based analyses, for example, are subject to these multiple types of uncertainty. Ways in which the certainty of geographic data can vary include their accuracy, precision, completeness, consistency, lineage, currency, credibility, subjectivity, and interrelatedness (Buttenfield 1993). Through categorizations like these that help people appreciate how diverse and extensive uncertainty can be, particular types can be recognized, better understood, and then addressed.

This is the key connection between uncertainty and critical spatial thinking. Eliminating uncertainty may be an impossible task but acknowledging and understanding it are essential, especially in terms of its broader impacts. For example, products derived from GIS-based analyses are often used in decision-making by people who do not have knowledge or understanding of how the data were collected, generated, or processed. They are unaware of the many ways that uncertainty can affect the nature of the final
product. This undermines and compromises the likelihood of their making optimal choices.

Critical spatial thinking and geographic information systems

Establishing explicit connections between critical spatial thinking and the use of GIS is a goal that is both desirable and elusive. The digital platform allows users to overlay and analyze datasets that were derived at different scales and levels of aggregation, with different projections, and years apart in provenance, among many other distinguishing features. The software can provide “answers” to queries and analyses that violate basic premises of physical, social, and statistical understanding. Posing those queries and executing those analyses requires no knowledge other than pressing buttons in a particular sequence. Critical spatial thinking is neither a prerequisite nor an automatic outcome, but it is a practice that can be modeled and demonstrated effectively and efficiently with the use of a GIS. Understanding problems is as important a recognized outcome as attempting to solve them. Many of the issues and situations addressed with a GIS do not have one single correct solution but may have explanations and better choices that can be informed by critical spatial thinking and abductive reasoning.

Critical spatial thinking requires that both producers and consumers of geographic information be aware of how their information is shared and how they increasingly rely on data that are shared by others. Incorporating a reflexive component into one’s critical spatial thinking habits is one step toward becoming a spatially informed citizen (Gryl and Jekel 2012). The “geographic sense of self” is evolving very rapidly (Downs 2014), and successful critical spatial thinkers will keep aligned with and adapt to new digital technologies and applications while still following the long-recognized tenets of critical thinking and reasoning.

Critical spatial thinking and map interpretation

Another stage at which critical spatial thinking is relevant within decision-making is anticipating how others are going to perceive geographic data and its representations. There can be a false sense of credibility applied to computer-generated graphics of geographic information, via traditional maps or other graphic representations. Though many more people are now making simple maps online of point data, it is still a very uncommon practice for someone in the public sphere to use a GIS to generate a map. Thus, most people are unfamiliar with the process and do not appreciate how simple it may be to manipulate and distort the information and its depiction.

Maps convey multiple messages, whether the author and designer intended so or not. This can be attributed to the map projection that was used, a decision that results in distorted shapes, sizes, distances, or angles and bearings of the phenomena being mapped. Other map elements that can yield particular messages to map-readers include the title, the colors used, and the graphics in the map’s marginalia. One of the most common and effective ways to manipulate a map’s message is to modify its data classification scheme. This is particularly easy to do when quantitative information is being displayed via a GIS. Owing in part to the notion of inherently trusting a map, many map-readers are not adequately attentive to a map’s legend and discerning of its values. Using the GIS, the map-maker can readily modify the range of numerical values to have very unequal “bins” of values, emphasizing particular values,
Critical spatial thinking

locations, or patterns. When using a single color, it has become a convention to have light hues represent lower values (concentrations, densities, etc.) of an attribute and darker hues represent higher values. By reversing these, the map-maker also risks confusing map-readers who only take a cursory, brief interpretive glance at the image. Choosing color schemes that are mismatched with a particular type of data, or a range of data values, is a sure way to obfuscate.

Effective map interpretation habits of a critical spatial thinker include careful review of a map’s title, its legend, its scale, its projection, its data sources, its design and color schemes, and any other information that conveys messages. This becomes a deep reading of a map, rather than a blanket acceptance of the medium’s message. Such a reading of a map is the same practice that a critical thinker applies to other media: images, graphics, tables, figures, and text. Critical thinking means evaluating arguments and suppositions, and a map itself is included among these. This is linked with the skills of twenty-first century media literacy, habits developed for careful consideration of all of the forms of media used to communicate information. Often less visually evident but perhaps no less significant are the messages and intentions behind the medium itself. Comprehensive map interpretation extends to evaluating the intentions behind the map, the agenda of the cartographer or the objectives of the organization producing the data. This may invoke the guiding principles of critical GIS when digital information is being considered.

Critical map interpretation is one specific form of critical image interpretation, a foundational practice of both media literacy and visual literacy. Understanding, producing, and using images to communicate requires knowledge about representations themselves as well as a cultural perspective to be able to anticipate how others will perceive and interpret the information. This sense of perception distinguishes between whether one person her- or himself may be a clever and effective spatial thinker and how well that person may be able to teach critical spatial thinking skills to others, or help others make decisions informed by critical spatial thinking. People with natural capacities and abilities for spatial thinking are not necessarily effective instructors of these skills. The expert-to-novice barrier can be significant.

Critical spatial thinking in decision-making

The capacity to make, and help others make, informed decisions involving geographic data and situations is one of the most important outcomes of critical spatial thinking. The decision can be trivial and mundane, such as where to park one’s car to ensure continued shading, or of a significant, global nature, such as how to design and plan for protected landscape and seascape areas. The magnitude and degree of influence may vary but all such decisions still involve their own respective issues of location, direction, scale, and spatial dependence, among other spatial variables.

Critical spatial thinking may take place at different stages of decision-making processes. As mentioned earlier, a user of geospatial digital data has opportunities to think critically about data throughout its life cycle: how it was collected, at what scale or level of aggregation, how its location is recorded and with what accuracy and precision, how are its attributes defined, and so on. By being a savvy critical thinker, someone can be both proactive in taking steps to minimize error and uncertainty at the beginning of the process and reactive to error and uncertainty later.
CRITICAL SPATIAL THINKING

on. Meanwhile, certain disciplinary fields, such as planning and supply chain management, may demand critical spatial thinking as a continuous facet of a workflow, rather than an episodic one.

Multiple forms of and approaches to reasoning are engaged during a critical spatial thinking instance. In a deductive framework, there are certain theories, principles, and truths that inform hypotheses about geographic processes. That water flows downhill, and that the elevation value of one locale is likely to be similar to its immediate neighbors, informs our understanding of how to model hydrologic processes. Likewise, that a set of watersheds can be nested is also applied knowledge involving scale, distance, and spatial dependence. Expecting certain processes to occur or scale differently on the basis of their relative position within nested watersheds is an example of critical spatial thinking informed by deductive reasoning.

At the same time, initial observations – rather than predictive theories – also inform understanding about spatial processes. Inductive reasoning draws from observations and measurements to ascertain how phenomena might have been affected by their position in the landscape and their subsequent interactions with variables at different scales, for instance.

Drawing conclusions from observed patterns is a type of informal inferential reasoning that is common with geographic information, especially that which is displayed via a GIS. GIS facilitates the symbolization and concurrent display of co-located datasets that may be diverse and completely unrelated to one another. In the absence of critical spatial thinking, merely displaying spatially coincident datasets concurrently can suggest to viewers that a relationship exists between the datasets. Hence, the use of some geographic data during decision-making processes may unintentionally contribute to misguided informal inferential reasoning. Critical spatial thinking reduces the risk, but cannot eliminate it.

Geographically based decisions frequently involve information derived at many spatial scales, from diverse sources, and often in an incomplete state. Thus, another approach to reasoning in the geographic realm is often an abductive one. Abductive reasoning relies on prior knowledge to qualify observations when drawing a conclusion or making a decision, and may mean making a “best guess” or taking an intellectual leap. Often associated with design processes, abductive reasoning can contribute important insights to creative problem-solving. For these reasons, and its accommodation of uncertain data, abductive reasoning fits naturally with critical spatial thinking. Making wise inferences from geographic situations typically requires this more-flexible but informed approach to understanding the world.

Critical spatial thinking in everyday life

Today’s geo-enabled society relies on location to seek and share information, and this has created another benefit to critical spatial thinking. Cell phones and other digital devices are capable of receiving and transmitting location coordinates, whether the device’s owner is aware of it or not. This information may be deliberately used by someone to help locate him- or herself on a digital map if lost, or to find goods, services, or people that are located nearby. Such technologies have spawned microtargeted advertising possibilities, such as a coffee shop being able to text a coffee coupon as a person is approaching the store. Overall, the use of global navigation satellite systems (GNSS) such as the global positioning system (GPS) have enabled and
empowered many people to travel with much greater confidence and competence.

However, there are downsides to the ubiquitous use of location information. Critical spatial thinkers keep themselves in control of how and with whom they share and leverage such data, to be able to benefit and protect themselves concurrently (Gryll and Jekel 2012). For example, cellular devices can have their location services turned on or off, based on the circumstances and applications. The sharing of location information should be done with awareness of the digital geographic footprint that may result. Nefarious individuals are able to create a comprehensive profile of a person based on when and where they travel throughout the week. Critical spatial thinkers need not become paranoid of sharing or using location information, but they can do so with forethought and intention.

One basic reason why using location to share, access, and distribute information has become widespread is that a “map” is a familiar template for organizing any type of information. Graphic displays of information are effective whether the data reside in geographic space with coordinates from the Earth’s surface, or in abstract space on the back of an envelope. Basic gestalt principles are invoked to group data or differentiate between what is near or far. This geography of our physical and intellectual spaces relies on our inherent capacity for spatial thinking as a way that our understanding of knowledge and the phenomena of the natural and social world are organized. This links our production of mental, internal representations and maps with the custom of generating and using external representations as well. Sketching a simple diagram, graph, or flowchart to communicate with others is a prime example. When these acts become familiar practices, the act of critical spatial thinking becomes a more regular habit.

Critical spatial thinking examples from the world around us

In March 2014, a Malaysian jet airliner disappeared from radar during a flight from Kuala Lumpur to Beijing. To try to locate the missing plane, hundreds of people from many different countries have interpreted vast quantities of digital audio files, satellite imagery, and other types of recorded information. Through a careful and critical process, the researchers attempted to separate the signal from the noise, enabling them to narrow the search area. From the very beginning, this task relied on critical spatial thinking to estimate flight ranges, triangulate radar pings, and design underwater search expeditions across steep, deep, and irregular bathymetric terrain.

Public health and disease monitoring are other places where critical spatial thinking is evident. Tracking the spread of contagions and infected individuals requires careful attention to both social and geographical networks of travel and communication. Being able to interpret patterns of distances, associations, and clusters contributed to quarantine protocols for the 2014 outbreak of Ebola.

Analyzing political dynamics is another activity that involves critical spatial thinking. For example, there are ecological and social principles that operate at different scales, from the global to the local. Certain political institutional forms of governance may be consistent across nations, but there is also truth in “all politics being local.” These ideas of global versus local analyses have informed the development of new spatial statistical techniques over the last few decades, producing computational methods to measure both global and local patterns of spatial autocorrelation, for instance. Global measures indicate the presence of spatial clustering or dispersion patterns somewhere across the whole
Critical Spatial Thinking

study area, and local measures can pinpoint these locales. Application of these analytical methods help political scientists understand the past, present, and possible future patterns of countries in political turmoil, such as Syria, Argentina, and the Ukraine.

Similarly, economists have argued that globalization has created a flat world in which geographical distinctions mean less and less for economics and commerce. A counterpoint argument, that place will always matter, has been put forth by geographers who maintain that human and environment interactions are paramount, whether they are historical ones that shaped society and culture or future ones that will inform resource use and trade. These are both valid points and their conclusions are not mutually exclusive. Scale and context make the difference; thinking critically and spatially means that both perspectives can be appreciated.

Description and purpose

The Croatian Geographical Society was founded to encourage the dissemination of geographic research and knowledge, to cooperate with other similar societies in Croatia and abroad, and to generally popularize geography. Improving geographic education and professionalization is among its major goals especially after World War II. Its members are mainly teachers, researchers, and students as well as alumni employed in business, government, and nonprofit organizations in the Republic of Croatia.

The society accomplishes its goals through its journals, one scientific and one professional/popular; occasional monographs/special editions; national congresses and other scientific meetings; lifelong learning programs; national and international school geography competitions; web geography education; and popularization. In order to achieve many of its goals, the society cooperates with the Ministry of Science, Education and Sports, government educational agencies, university geographical institutions, and regional geographic societies.

Journals or major publication series

Hrvatski geografski glasnik/Croatian Geographical Bulletin http://hrcack.srce.hr/hrvatski-geografski-glasnik

Current activities or projects

The society publishes Hrvatski Geografski Glasnik (since 1929, currently 2 issues annually) and Geografski Horizont (since 1955, currently 2 issues annually). It also organizes the Croatian Geographical Congress (every 4 years, sixth congress in 2015), the Geographic Monday Public Lectures (a dozen annually, since 1947), the Winter Seminar for geography teachers (annually since 1955), the Summer Seminar for geography teachers (annually since 1951), the geography teachers workshops, the national school geography competition (annually since 1994) with participation in the IGEO – International Geography Olympiad (participation since 2009), the web programs e-school for young scientists, and the educative portal www.geografija.hr.

Brief history

The Croatian Geographical Society was founded in Zagreb in 1897 by a group of academics initiated by the first geography professor in Croatia, Petar Matković, and lead by geographer Hinko Hranilović and biologist Alfonz Heinz. In 1899 the society joined the Croatian Natural Science Society as its first independent section and was very active until World War I. Professor Artur Gavazzi revived the society activities and in 1929 launched its scientific publication, the Hrvatski
geografski glasnik (Croatian Geographic Bulletin). After World War II the society was registered under the new political dispensation in 1947 and led by Professor Josip Roglić. The new statute defined as its mayor goals the cooperation with education authorities, including concern for teachers and their lifelong education, improvement of geography teaching practice, and so forth. To accomplish them many now activities where created, such as Geographic Monday Public Lectures (a dozen annually, since 1947), the Summer Seminars (annually since 1951), and the Winter Seminars (annually since 1955) for geography teachers. Since 1955 the society publishes a professional publication named Geografski Horizont, mainly serving geography teachers. Its active speleological section was created in 1956. The Croatian Geographic Society continued its scientific activity in the postwar period when it organized the First Congress of Geographers of Yugoslavia in 1949 and building on this first congress, organized the Seventh Congress of Geographers of Yugoslavia in 1964.

As Croatia gained its independency, the Croatian Geographic Society organized the First Croatian Geographical Congress in 1995 and continues to do so every 4 years along with organizing other scientific meetings. The society has remained the umbrella organization for all its geographers, though independent regional geographic societies are also active. The society furthered its cooperation with the Ministry of Science, Education and Sports and with educational agencies and worked on geography curriculum questions, state high school graduation exams, and organized many geography teachers workshops, school geography competition on national and international levels, and so on. The future mission of the Croatian Geographic Society is to remain on the path of advancement of geography education and of validation of geography as a modern science which, in dealing with functional organization of geospatial systems, can provide many answers to questions of our sustainable development.

Cross-border, transnational, and interregional cooperation

James W. Scott
University of Eastern Finland

For several decades, subnational processes of cooperation across state borders have enjoyed considerable research attention within social and economic geography. Interest in these areas has been spurred by political and economic changes of global dimensions that have unfolded since the end of World War II and that have accelerated since the final demise in 1991 of the Cold War order. An inclusive but yet concise definition of cross-border cooperation is that of a political project carried out at subnational levels by public, private, and civil society actors with the express goal of extracting benefit from joint initiatives in various fields. Generally speaking, there are three distinct but often interconnected levels: cooperation within local and contiguous cross-border spaces; cooperation between regions beyond local border contexts; and transnational networks that can involve cities or groups of cities.

The transnational is the most flexible and least spatially fixed of these cooperation contexts; it basically involves the project-oriented networking of actors (e.g., cities, nongovernmental organization (NGOs), economic groups). Conceptualized as an example of “subnational paradiplomacy,” transnational cooperation networks have largely been a focus of international relations and scholars of globalization theory. Research in this area was especially plentiful during the 1990s when putative “postsoverign” transformations of nation-states were understood to produce a new global patchwork of social and political relations between substate actors (Aldecoa and Keating 1999). Examples of transnational cooperation actors include Pacific Rim cities such as Vancouver, Canada, and have sought to intensify relations with Chinese counterparts, and regions such as Quebec which have developed working relationships with other francophone regions around the world. More recently, the concept of transnational cooperation has been appropriated by the European Union within its regional policies; in this case it refers to flexible international networks between national, regional, and local actors in dealing with specific development issues (see Figure 1). The interregional level of cooperation is more specifically European as it emerged out of EU attempts to decentralize, denationalize, and “Europeanize” structural policies. The European Union’s Interreg program – dedicated to cross-border cooperation – provides a platform for development projects between regions within member states.

Finally, the local level of cooperation, which will be referred to here generally as cross-border cooperation (CBC), is the most intensive as it generally involves multiple networks of public, private, and civil society actors that work in close geographical proximity. For historical reasons, it was in continental Europe’s economic core that cross-border cooperation, as it is understood today, began to take root. Here, the confluence of local interests, spurred by the momentum of European economic recovery and prospects of integration, promoted the development of new forums for dialogue and conflict resolution.
The inauguration of a trinationally focused Regio Basiliensis, for example, was driven by a need for the Swiss city of Basle to compete with Zürich and to seek alternatives to the parochialism of national politics, dependent as it was (and still is) not only on its immediate French and German neighbors, but on the greater European context as well (Briner 1986).

While all three cooperation contexts are significant, it is the latter level, that of cooperation between contiguous border areas, that has received most research attention within human geography. One reason for this has been the subject itself – border cities have been a long-standing subject of geographical inquiry, and the investigation of the functional relationships within cross-border urban areas presaged considerations of direct political cooperation. Larry Herzog’s (1990) study of the San Diego–Tijuana urban region on the US–Mexican border and Claude Raffestin’s (1974) analysis of the Geneva functional region between Switzerland and France are important examples of such research. Another major reason for the development of cross-border cooperation as a research field in its own right can be attributed to attempts at creating zones of free trade and continental integration in North America and Europe. These processes brought into focus many of the issues and problems involved in the elimination of barriers to social, economic, and political interaction. European integration in particular was instrumental in enhancing the status and visibility of local CBC.

Social geography deals with cross-border cooperation in all its forms as it has been associated with state–society paradigms that suggest that new forms of politically relevant action increasingly take place beyond the seemingly inflexible territoriality of the state. Similarly, research has been driven by a concern with the consequences of state–society transformations for economic, political, social, and cultural life. The putative significance of CBC is that it provides new political spaces within which to address locally issues that include social affairs, economic development, minority rights, cross-border employment and trade, the environment. Furthermore, through such territorially flexible forms of political and economic interaction – both institutional and informal – it has been suggested that greater cost-effectiveness in public investment can be achieved, economic complementarities exploited, the scope for strategic planning widened, and environmental problems more directly and effectively addressed. While such cooperation initiatives have proliferated in Europe and North America, they have also developed in Asia and elsewhere, lending credence to the notion that CBC is a global phenomenon.

Comparative analysis of local CBC processes has emphasized their contextual nature and, in general, research has indicated that CBC outcomes are subject to (geo)political agendas as well as cultural and structural factors that can enable as well as constrain cross-border cooperation (Scott 1999). In other words, basic differences between regional situations with respect to international integration logics, the conditioning role of states, local cooperation contexts, and different modes of supporting cross-border cooperation explain much of the variation in CBC experiences.

As Figures 1 and 2 indicate, the European Union has developed a comprehensive policy of supporting cross-border interaction at the three different levels discussed earlier. These maps suggest a highly networked European Union that is more complex than a political community of sovereign states. With regard to transnational networks in Europe, numerous programs and initiatives have been launched with the specific goal of opening new spatial

CROSS-BORDER, TRANSNATIONAL, AND INTERREGIONAL COOPERATION

perspectives for cooperation between cities and regions in various areas of economic development and regional policy. These are generally targeted at specific development concerns that are at once national and regional but that serve to link very different regional spaces within the European Union. Providing incentives for the creation of new communities of interest within and between nation-states was intended not only to instill a sense of European identity, but also to diffuse innovations in economic promotion, job creation schemes, and revitalization strategies, among other areas.

In the case of the US–Mexican border, local and regional cross-border trade, as well as the development of export-oriented industrial complexes (maquiladoras), helped fuel the growth of binational urban economies and development problems out of which developed the cross-border cooperation institutions now in place. One indicator of the intensity of interaction is the development of binational coalitions and advocacy groups that have striven to maintain and/or improve conditions for bilateral trade investment but also environmental sustainability. Similarly, a plethora of business development initiatives (including innovative schemes for industrial incubators) have materialized in US–Mexican border cities during the 1980s and 1990s (Peña 2007). In contrast to the European situation, the North American Free Trade Area (NAFTA) project has pursued a logic of limited integration that recognizes, for example, the functional interdependence of border cities and regions but that does not envisage a “borderless” North America nor a comprehensive policymaking process at the supranational level – at least not within the foreseeable future. The reasons for this reflect basic differences between European and North American approaches to interstate integration. Perhaps most importantly, while sovereignty issues appear to have lost much of their divisiveness in Europe, they continue to block attempts at broader political and sociocultural cooperation in the North American context. Fears of losing local and regional decision-making abilities as a result of the adoption of supranational regulations regarding commerce, trade, and environmental protection remain one of the largest sources of resistance to further integration within the Americas. Furthermore, fears of undocumented immigration and drugs trafficking, as well as terrorist threats, have made the US–Mexican border a defensive, heavily guarded demarcation line. Since the September 11 attacks of 2001, CBC along both the US–Mexican and the US–Canadian border has, unfortunately, lost considerable impetus as well as research attention.

Development of the field

The research field of CBC has expanded rapidly since the 1980s and the focus has shifted since the 1980s from empirical research on transnational urban networks and their cooperation mechanisms to the study of local and regional forms of policy-relevant cross-border interaction. In addition, since the 1990s CBC research has expanded to other areas of the world. African, Asian, and Latin American examples give evidence of interest in local and regional forms of cross-border planning coordination, development, and rapprochement. The African Union Border Programme (AUBP), for example, has attempted to provide a policy instrument that encourages CBC and in this way transcend barriers created by colonial borders (Asiwaju 2005). However, while border studies is genuinely international, the principal focus of CBC research – at least in human geography – has shifted to Europe since the 1990s. For this reason, this research has been conditioned by
CROSS-BORDER, TRANSNATIONAL, AND INTERREGIONAL COOPERATION

the experiences of European integration and of EU policy contexts. There is thus, admittedly, a strong Eurocentric character to CBC research which might limit its international comparability.

As the research field has developed and expanded, so have the theoretical approaches that characterize it. This is in part a result of the development of associated research fields, border studies in particular. The focus on local cross-border cooperation processes has become more differentiated thanks to tensions between, but also to an interlinking of, structural, normative-functional, and contextual understandings of CBC. To begin with, a structural perspective on CBC assumes that changes in territorial politics are a result of changes in underlying economic relationships within the world-system. CBC is thus a logical outcome of globalization pressures on states, regions, and local communities. With advanced capitalism and neoliberal ideologies weakening the role of the state and its redistributive policies, CBC follows the path of entrepreneurial local development already broken by cities and regions more generally. Normative and functionally oriented perspectives generally operate from the assumption that, while structural conditions are the principal driver of political change, permeable borders emerge from a rationality that is conditioned by a need to manage sociopolitical problems. CBC is thus inevitable and its relative performance is of central importance. The significance of transnational regionalism is determined, in other words, by governance and addressing in a politically meaningful way local and regional concerns that transcend traditional national problem-solving capacities. Building on the conceptual foundations of subnational paradiplomacy, the normative-functional view offers a specific focus on cross-border policy integration as a form of multilevel governance (Perkmann 2007). Prospects for transboundary region building are thus defined by the outcomes of a gradual and complex process of institutional innovation and capacity building at national, state, and local levels (Scott 2000).

CBC can indeed be interpreted as a form of place-making or region building in which borders are used as strategic resources. However, one major weakness in understanding CBC as a new border-spanning form of governance is a frequent neglect of sociopolitical and historical contexts. CBC experience indicates that induced and institutionally thick Euroregions cannot by themselves lead to a transcending of borders; historical experience and memories of past conflicts continue to affect cooperation outcomes, as the examples of the German–Czech and German–Polish border regions testify (Balogh 2014; Mirwaldt 2010). Partly as a response to the limitations of the governance approach, borders scholars, especially since the turn of the millennium, have elaborated constructivist understandings of CBC as a contested regional development project. Indeed, the normative political language of integration often contrasts with local realities. Rather than represent a new governance ideal, cross-border cooperation often reflects competing territorial logics at the supranational (e.g., EU), national, regional, and local levels and conflicting attitudes toward more open borders (Popescu 2008).

Links to border studies

Research on cross-border cooperation has been closely linked to the study of borders themselves. If the initial phase of de-bordering euphoria that had already begun in the 1980s tended to de-emphasize the actual sociopolitical significance of borders, CBC research – with its close ties to border studies and political geography,
has since developed a more contextually sensitive understanding of the nature of borders themselves. In common understanding, borders result from sociopolitical processes of ordering. Borders, however, also reflect the cultural and symbolic construction of societies at a more general level and as such play an important role in framing and regulating social relations, as well as setting conditions for local and regional development. As a result, borders have been used as explicit symbols of European integration, political community, shared values, and hence identity by very different actors (Perkmann 2007; Popescu 2008). CBC has thus been related to not only the functions but also the symbolism of state borders as a spatial organization of difference.

Similarly, local CBC has been closely linked to the concept of borderland. In traditional academic debate, the term “borderlands” has generally referred to a space of transition between (national) societies (Rumley and Minghi 1991). The processes that contribute to borderland formation operate at different levels and involve a dialectic relationship between local societies and territorial spaces defined by borders. On this view, processes of CBC are not merely a result of more porous borders but are themselves active creators of borderlands and thus of transitions, both physical and cognitive, between different political spaces. Borderlands are formed through processes of cross-border regionalization at different levels and in different realms of agency: cross-border cooperation and political projects of place-making, as well as everyday economic, social, family, and cultural practices of transnationalism. Unlike classical notions of frontier as a regional situation that precedes the consolidation of state territoriability within formal borders, a borderland can also describe an area that closely reflects the physical, political, and social impacts of state borders.

CBC and European integration

CBC research is also linked to the analysis of European integration and cohesion. CBC, understood in terms of cross-border local and regional development, forms part of a rescaling of state–local relationships and the political geography of the state that has been set in motion by EU policies. As mentioned earlier, CBC began as a subnational political project in Europe in the 1950s. Since 1989 it has burgeoned as a result of both local initiatives and orchestrated networking strategies supported by EU programs. According to O’Dowd (2002), CBC has developed in Europe as a function of shifting state formations and changing border regimes. O’Dowd has also indicated that, as part of integration and enlargement logics, European borders have been being reframed in terms of their (often conflicting) significance as barriers, bridges, resources, and symbols of identity, and how these reconfigurations relate to the project of European integration and enlargement.

Here as well, the borderlands concept has served to conceptualize the sociospatial changes generated by European integration. This is most clearly the case with Euroregions, which were pioneered and developed as locally based cooperation initiatives in Dutch–German border regions as early as the 1960s (Perkmann 2007). The Euregio, formally established as the first Euroregion in 1965, was the product of postwar rapprochement between Dutch and German municipalities. Since then, Euroregions have become a part of complex regional policy networks, particularly in west European contexts. Indeed, the Dutch–German Euregio, a Euro-region with its own local council and close ties to German and Dutch state agencies, has served as a model of sorts for the development of border region associations. Having thus graduated from local and/or grassroots beginnings to the level of
a more or less coherent policy area in the late 1980s, transboundary cooperation and border regions development are now largely determined by attempts to promote the goal of political and economic cohesion.

The European Union has also had an important impact on the nature of cross-border relations in Eastern and Central Europe (Zhurzhenko 2010; Scott 2006). In preparing Central and East European countries for membership, the European Union adopted a strategy based on institutionalized CBC and aimed at a gradual lessening of the barrier function of national borders. These policies have also been aimed at integrating previously divided border regions in order to build a more cohesive European space. Nevertheless, Gabriel Popescu (2011) has argued that this normative political language of Europeanization (e.g., as a process of de-bordering regional development) often contrasts with local realities where CBC reflects competing territorial logics at the EU, national, regional, and local levels, and conflicting attitudes toward more open borders.

Current major emphases

Contemporary research on CBC focuses on cross-border cooperation as a form of contingent territorial politics which reflects different and often conflicting uses of borders. On the one hand, CBC has been assessed as a regional development project that utilizes borders as resources, primarily through creating synergetic working relationships between public and private actors. On the other hand, however, CBC has also been investigated with a view to border management and securitization policies that openly challenge cooperation agendas.

Exhaustive appraisals of the results of cross-border cooperation in Europe are difficult due to the vast number of border region initiatives either completed or in realization. However, even if the promotion of a sense of cross-border regionality through common institutions has received ample support, in practice institutionalization patterns have been uneven – both in terms of governance capacities and in their performance of actual cooperation. In well-organized border regions (e.g., the Dutch–German Euroregions), public sector and NGO cooperation has been productive in many areas, especially in relation to environmental protection, local services, and cultural activities. In less successful cases, such as the Hungarian–Slovakian border, cross-border projects have often merely served to enhance local budgets without stimulating true cooperation. Generally speaking, it has also been very difficult to stimulate private sector investments as part of cross-border regional development projects. Rarely has CBC produced rapid results in terms of economic growth and regional development. It is a process that can only produce long-term results in these areas. On the other hand, CBC is of considerable symbolic significance as a de-bordering and trust-building exercise, and it has also contributed to the participation of local governments in EU policy implementation processes.

In a more critical vein, contemporary research on CBC has drawn attention to problems of reconciling border security prerogatives with the aim of cross-border cooperation. Since the terrorist attacks of 2001 in the United States, and of 2004 and 2005 in Spain and the United Kingdom, respectively, it has become difficult to discuss CBC without considering border management issues. Contemporary border studies, for example, focus both on border management (as control and confirmation) and border crossing (as cooperation, contestation, and transcendence) as parallel and simultaneous processes. The crossing and control of borders
CROSS-BORDER, TRANSNATIONAL, AND INTERREGIONAL COOPERATION

compete with each other for hegemony: open and more flexible borders are vital for economic reasons, while tighter and more closed borders are seen as important security measures. It is a delicate balance which, in recent years, has in favor of the securitization proponents because of the emphasis on issues such as personal and physical safety against cross-border threats. The securitization of borders (i.e., the simultaneous erection of administrative and physical obstacles to control migrations) is an attempt not to close space and territories but to filter and sort transnational flows according to their degree of desirability (Jones 2012).

Security issues have seriously curtailed attempts at local CBC in the North American context. However, we are also witnessing a strong dose of political realism creeping into European discussion of borders and cross-border cooperation. Hardening external borders and an increasing EU emphasis on the territoriality of political community are challenging the spirit and raison d’être of CBC. Borders as expressed by visa regimes, citizenship, residence rights, and new forms of physical control of the European Union’s internal and external frontiers gives evidence of the creation of new categories of sociocultural distinction – and thus of contested and partly dividing borders. Furthermore, while the European Union expresses a desire to avoid recreating political divisions, new visa regimes and other restrictions of cross-border interaction threaten to exacerbate development gaps between the European Union and its neighbors.

Future perspectives

Transcending boundaries – at least rhetorically – remains a leitmotif of a postnational understanding of political agency. And yet, more than two decades after the end of the Cold War, borders themselves often remain an obstacle to greater political and social interaction even if the defensive character of many international borders has diminished. What CBC research has often neglected in the past is the changing nature of the power of borders. If anything has become clear in comparing different attempts at cross-border region building, it is that these forms of cooperation are inherently a process of sociopolitical construction and cultural negotiation. Borders not only have different meanings for different actors but are a manifestation of power relations within and between societies at different scales. Contextual and sociocultural issues will therefore most likely dominate future CBC research agendas. Along with a need to further explore the possibilities for creating postnational political spaces, ethical aspects of borders require greater research attention. Finally, a major challenge will lie in attenuating the dominant eurocentrism of CBC research through more inclusive international comparisons.

Cross-cultural research

Tracey Skelton
National University of Singapore

Human geographers have a particular focus on people, space, place, and spatiality. Some geographers, not all of them self-defined as cultural geographers, conduct research projects with people that focus on their cultural identities, practices, and meanings. These identities and practices are located in places and spaces, but they are fluid and dynamic, not necessarily bounded and fixed within those locales. Many geographers conduct research in locations different from those of their own cultural milieu and across spatial boundaries. This is defined as conducting cross-cultural research.

Since the 1990s, books on research methodologies in human geography have usually included a chapter that engages with cross-cultural research. Geographers have produced academic papers that either name cross-cultural research as their explicit theme or imply it through terms such as difference and diversity, insider/outsider positionalities, ethical approaches toward “others,” cultures of knowledge production, crossing boundaries. So there is apparently more cross-cultural geographical research taking place than is declared as such. A definitive definition of cross-cultural research can, therefore, be difficult to pin down. Nevertheless, as the body of work on cross-cultural research expands, albeit more slowly in the past decade than in the 1990s and early 2000s, it has become possible to filter out key elements of what geographers consider to be cross-cultural research (more details below). This expansion also allows us insight into the complexities and considerations of this kind of research.

In the early 1980s, observations were made and concerns raised about human geography continuing to pursue positivist research methods, attempting to emulate the physical sciences in research design and the use of particular methodological approaches, notably quantitative methods. Human geographers argued that unless human geography’s dissidents challenged the discipline’s foundational assumptions and normativities there could not be a re-examination and change of research methodologies (Hodge and Lester 2006). Such changes were necessary if the complex, messy, and dynamic geographies of people’s everyday lives were to be central in human geography research. Post-1980 challenges within geography began to examine and change processes and procedures of research. Key elements of the challenges and pushes for change were found in feminist geography, debates about ethics in geography, arguments over quantitative versus qualitative methodologies, and research in cross-cultural contexts. So from the early 1980s onwards, cross-cultural researchers have been working to challenge normative and positivist research methodologies and practices and move toward more inclusive, participatory, holistic, and decolonized approaches. Within this collective, feminist geographers and geographers working with indigenous people have been very influential in pushing the boundaries of inclusive, open, and equitable research adopting reflexivity and coproducing knowledge. Using culture
as a means to designate the value accorded to difference, meaning, and particularity has been a tactic of cross-cultural geographers to disturb and question notions of objectivity that have been embedded in geography’s interpretations of fieldwork or quantitative methods (Barnett 1998).

While there are complex issues at play in geography as to the meaning and theoretical and conceptual value of the term “culture,” there are geographers committed to practicing and working through the complex and often difficult processes of cross-cultural research. Such research, at a general level, is designed to challenge the power relations embedded in research projects, tackle the difficulties posed by crossing cultures, and work to create research which is more than the value of its publishing status. Most cross-cultural geographers aim to produce warranted and rigorous scholarship but also something that has value and meaning for the people they work with. Cross-cultural researchers face many dilemmas and one of them is the issue of representation and what outputs are produced by the research. Cross-cultural research and its advocates ask important questions of the academy and about the production of academic work, such as what is the value of the research and for whom.

This entry addresses both the processes and practices of cross-cultural research, specifically the methodological doing of this type of research. It also examines the range of dilemmas researchers and their co-researchers/participants have to work through in order to achieve effective, equitable, and empowering research. First, this entry considers what cross-cultural research is and some of the theoretical and political challenges involved. Second, it examines the more specific and practical aspects of research approaches and the methods used. Third, the entry explores the politics, tensions, and rewards of representation and research outputs.

What is cross-cultural research?

An academic journal, called Cross-Cultural Research, publishes articles that describe cross-cultural and comparative studies in all human sciences (geography is not listed). It supports and encourages interdisciplinary comparative research with the objective of establishing scientifically derived generalizations about human behavior. This is not the type of cross-cultural research conducted by geographers and indeed could be one of the reasons why many geographers who conduct cross-cultural research do not call themselves cross-cultural researchers. For them their research is about understanding and interpreting details and specifics of a particular group or set of cultural practices, not establishing generalizations. The cross-cultural element is more about a way of doing research than establishing comparative generalizations on human behavior. Geographers’ cross-cultural research also has to consider epistemological and theoretical challenges, such as the definition of culture.

Don Mitchell’s 1995 publication stated that there is no such thing as culture in order to call for a reconceptualization of culture within “new cultural geography.” He argued that cultural geography reified culture and accorded it an ontological and explanatory status that it did not warrant. For Mitchell, the most important aspect of culture for geographers was the material development of the idea of culture and how that idea of culture was used to explain material differences, social order, and relations of power. He also argued that culture is used to “order, control and define ‘others’ in the name of power or profit” (Mitchell 1995, 104). His argument is complex, compelling, and controversial and this entry cannot do it full justice. However, it highlights one of the theoretical complexities that have to be considered as part of the context of cross-cultural research. If there is no such
thing as culture, then what are we crossing in our research?

If we consider the situation of indigenous people in many countries of the world then we can see that defining them as a cultural group was part of the mechanics of their marginalization, exclusion, and denigration in relation to wider non-indigenous societies. Parceling groups of people up into distinct cultures then proves that cultures exist, the concept of culture is made real and we believe in those differences between people (of course this holds echoes with the negative power relations of racial classification and differentiation). Historically such cultural categorizations have been dangerous and established power relations of “us” and “them/others.” Researchers became classified as insiders or outsiders; most of them “entering a culture” in order to study and, in the past, classify and categorize it. However, at the same time, for indigenous groups and other people who define themselves as having a cultural identity, the notion of distinctive cultures can be used in resistive ways as it has political potential to challenge negative power relations and cultural subordination. For Welsh-speaking people the assertion that their language was an essential part of their culture allowed them to bid for funding from the UK government and the European Union in order to “save” their linguistic cultural identity. In the context of Australian Aboriginal people and Torres Strait islanders, assertions of tribal cultural ancestry and traditional practices have accorded them some rights in relation to land access, caretaking, and consultation on development and planning initiatives. These rights have been hard won and there are many battles still being fought; not only the implementation of these legal rights, but also the designation of a cultural identity and its link to particular spaces and places have been very important to their struggles.

Hence, on the one hand we have an academic argument that there is no such thing as culture, and it is a strong, theoretically and politically important intervention. On the other hand we have considerable evidence that in practice people believe that they belong to a culture and that this often has a geographically defined spatiality. Cross-cultural researchers work with this latter formation of “culture,” but there are caveats. Most cross-cultural researchers do not see cultures as fixed, unchanging, and spatially bound. They do not consider their co-researchers or project participants as “others” but as knowledge producers. They recognize that they are culturally laden and that, for many, their Western culture means they construct their worlds, their identities, meanings, and practices in different ways to the people they work with. Cross-cultural research is designed to be reflective and the researcher’s positionality vis-à-vis the research participants is interrogated and made explicit. Although the value of some aspects of positionality has been challenged by arguments to attend more to how personality affects field research and the production of knowledge (Moser 2008). Cross-cultural researchers place substantial emphasis on field-based research that involves respectful attention, listening and engaging with co-researchers, and on choosing or devising methods that allow such research engagements to take place.

Cross-cultural researchers are therefore aware that they are working with a problematic (intellectually and politically) concept and that culture does quite literally mean different things to different people. Yet, it remains a concept to be worked with and through and certainly has a valence for many people in the world, often those most marginalized economically, politically, socially, and additionally culturally categorized in powerful but negative ways. A key political project for cross-cultural researchers linked with
the notion of cultural politics is to challenge the traditional modes of engagement as practiced in the past by geographers and anthropologists. Such approaches have been termed “colonial research,” which was the dominant mode of research in cross-cultural research in geography, and subsequent approaches that resist these highly problematic and questionable research practices are known as postcolonial and decolonizing research (Howitt and Stevens 2005).

Colonial research approaches to cross-cultural fieldwork embody power relations with “others” that reinforce the domination and exploitation of such groups. It tends to dismiss researched subjects’ own cultural and traditional knowledge and practices and uses intrusive top-down research methods (note that the present tense is used here because there are many examples of this kind of field research still being conducted). Postcolonial approaches act in reaction against and rejection of the above negative practices and work toward the self-determination and welfare of the research participants. This is done through the use of methodologies that enable the production of research findings that value the particular cultural community/ies involved in the research. Their rights, knowledge, perspectives, concerns, and aspirations are recognized, determined as valid, and, where possible, supported by the research. Decolonizing research pushes the politics of openness and equality further as the actual research processes and practices are designed to interrogate and deconstruct cross-cultural “discourses, asymmetrical power relationships, representations, and political, economic, and social structures through which colonialism and neo-colonialism are constructed and maintained” (Howitt and Stevens 2005, 32). Decolonizing researchers (who are often heavily influenced by feminist geography critiques of research practice) will consider their research participants to be co-researchers as all cross-cultural research is in effect a coproduction of knowledge (see Maclean 2015 for an excellent example of decolonized coproduction of knowledge in Australia). Most geographers working cross-culturally pursue one of these three research approaches with, increasingly, the last two or a combination of both in the ascendency.

Practicing cross-cultural research

Human geographers’ writings and debates about practicing cross-cultural research demonstrate a wide range of themes to be considered. Many of these are also shared with other research practices and methods, but they are often more visible and demand more care and attention in cross-cultural research. On an everyday basis the researcher and the cultural group they are working with may have different conceptualizations of reciprocity, personal space, time, socially acceptable behavior and speech, gift giving, hospitality, privacy, bodily comportment, and so forth. These are frustrating but intriguing and part of the co-learning that takes place in open, inclusive, and decolonizing research. Researchers often describe the ways in which they had to learn and present a different way of being, adapt their research processes in situ to make sure they worked effectively and inclusively, and adopt new ways of engaging with people. For example, first and subsequent meeting protocols, what is said and done when and how, can be very intricate in different cultures.

Ethical practices are relevant to all research with human participants. Many argue that they are particularly important in cross-cultural contexts, especially if trying to practice decolonized research. Ethics should be integrated at all stages of the research: planning, design, implementation, and production. Ethics are culturally constructed. Ethical protocols for cross-cultural
Cross-cultural research are more culturally aligned with the researcher than with the project participants. What is defined as ethical practice in one culture and place may not be so ethical or appropriate in another. Often an immediate problematic appears in relation to written participant information sheets and the collection of signed consent forms. This happens when a researcher is working with illiterate people or with people for whom signing a form is an anathema of human interaction or has been a tool of deceit in the past as people signed away land or rights without understanding the consequences. Here the meaning and sentiment of ethical practice comes to the fore and other culturally appropriate mechanisms of informed consent should be used. A key ethical principle in Western research protocols is privacy and confidentiality. Interviews should be conducted in private, away from family, the household, or the community. In some cultures, particularly those based on collective principles, such behavior is considered rude or suspicious. Such “strange” behavior can serve to reinforce notions of a researcher being potentially dangerous, unpredictable, and self-centered in relation to their own research project rather than working collaboratively with their participants. Cross-cultural researchers therefore have to tread carefully (sometimes literally in the context of sacred spaces) to learn from those they work with as to what is ethically acceptable for them and their community. Knowing and understanding as much as possible about the cultural, ethical, and appropriate ways to behave, communicate, and interact with different communities is extremely important. A key ethical principle increasingly demanded by groups that find themselves the “object” of research is how and in what way the project will benefit them and their communities. What is the value in it for them? Who benefits most and least once the project is completed? In decolonized, ethically practiced research the community needs to be met and cross-cultural geographers have to work to build ethical and equitable relationships with them. This is particularly true in working with indigenous people who have frequently been exploited, denigrated, and damaged by Western-style colonial research projects (Louis 2007).

Discussions of cross-cultural research are linked with a presumed binary of researcher status, that is, insider/outsider. In fact, researchers report that they are often in some slippery, interstitial space between the two; the term “betweenness” is often used as researchers differentially connect or disconnect with members of the community. Such relationships also vary across time – first encounters can often mean and feel very different from final partings, and possibly future returns; many cross-cultural researchers participate in longitudinal research and the insider/outside binary becomes meaningless. However, being perceived as an outsider can lead to very rich research as participants provide more information to ensure the researcher really understands the community well and there is no presumption of prior knowledge. Additionally, in communities where gossip is a key aspect of social control, especially of women, then an outsider (female) researcher may be tested, trusted, and, subsequently, given extremely valuable information not usually shared with an “insider” researcher (Skelton 2001). On the other hand, “insider” researchers may be seen as more empathetic, trustworthy, and having the best interests of the community in mind throughout the research.

Cross-cultural researchers discuss a second binary that relates closely to the identity, positionality, and personality of the researcher. This is the concept and practice of same-ness/difference. This is more about the interrelationships that are established between research participants/co-researchers and the researcher/s than about the association or...
CROSS-CULTURAL RESEARCH

disassociation between these two parties. It links to cross-cultural methodology where researchers consciously acknowledge the differences between themselves and co-researchers, consider the consequences of it, and incorporate it into their research practice. Interpreters and/or locally based researchers may be employed to establish some linkage of sameness. Researchers might emphasize their “difference” in order to connect with participants as someone who genuinely wants to learn and understand and work through and beyond the differences. The last approach is often used as a technique when working with elites and people in authority. More usual though is the work that researchers do to find a basis of sameness and commonality with the people they work with. There might be a connectivity found that transcends difference that allows the co-creation of an affinity or alliance which smooths cultural and research exchanges. Feminist geographers have reported using gender, motherhood, and sexuality as points of connection. These elements of sameness may counterbalance differences that cannot be connected to so easily or effectively such as “race,” religious affiliation, or age. However, sameness and difference are not fixed: as part of culture they are fluid and dynamic. Different researchers will find different points of connection and over time differences can be overcome as the actors in the research project spend time and communicate together. What researchers and co-researchers involved in decolonized and feminist influenced approaches often report is that there are reciprocal exchanges taking place in the search for commonalities that allow for shared spaces of similarity from which meanings and understandings can emerge.

An important facet of cross-cultural research practice is interpretation and translation. All forms of cross-cultural research require some degree of interpretation in order to be able to research and talk across differences. Indeed, feminist geographers have discussed the need for interpretation within the academy and across worlds, questioning whether it is possible to talk in meaningful ways about research and publishing in different parts of the world based on their actual cross-cultural research experiences (Dyck, Lynam, and Anderson 1995; Raju 2002; Staeheli and Nagar 2002). In terms of the practices of research, often written tools of research have to be translated; for example, questionnaires have to maintain the same meaning in different cultural contexts. Carefully translated research questions are essential in the early stages of the research, ideally in situ so there can be a discussion about the most appropriate terms that capture the essence of what the research is about. A project on the meaning of “wealth” for a community will provide completely different data if that is translated as “money.” Interpreters and translators (hereafter just called interpreters) hold interesting and complex positions within a research project and can be both insider and outsider. They may differ from the community because of education and social class but have an affinity through family connections. For geographers working cross-culturally there are examples where interpreters have been indispensable to the research project and have enhanced all manner of data collection. Effective processes of translation/interpretation create new spaces of exchange and learning where all research actors develop a cross-cultural relationship around the subject area of the research. New meanings can be created as “in-between” forms of understanding. However, there are also incidents of problems and major clashes with interpreters who will not take the time to work through the finer nuances of linguistic meaning, summarize questions rather than ask them in full, lead participants into particular answers because they “know” what the researcher is
“looking for,” and convey their own prejudices into the research, such as refusing to interpret between a researcher and lower class/different caste/migrant people (Twyman, Morrison, and Sporton 1999). Cross-cultural researchers have to accept that there will always be areas of incomprehensibility, knowledges kept hidden and not shared, and elements that can never be translated.

Politics, tensions, and rewards of representation and research production

Some aspects of politics in cross-cultural research have been discussed above. This final section considers the political power of questioning established forms of authority in the production of knowledge combined with a discussion of the power and politics of representation.

If cross-cultural researchers adopt the decolonizing approach then rich, new, and constructive knowledges will emerge that may counter perceived prejudices, stereotypes, and existing power–knowledge relations. It is important to examine the power relations, inequalities, and injustices at play in communities and to explore the ways in which cross-cultural research can challenge these and bring about change. Such approaches are influenced by feminism and postcolonialism. There must always be questions about the impacts of the research project on those involved, what the research is for, and what will be the value for the research participants. Knowledge production for the sake of knowledge production is no longer considered a valid approach and nor is the presumption that it is the researcher/academic that produces the knowledge. All research is coproducive and cross-cultural research in particular has to acknowledge this in order to empower and fairly collaborate with their “co-researchers.”

Methodologies have to be used which integrate co-researchers’ voices and knowledge. Renee Louis (2007, 131) makes a very explicit call for the use of indigenous methodologies which state that research in indigenous communities is conducted respectfully, from an indigenous point of view, and contributes in some way to the betterment of the community. Such political and methodological approaches within cross-cultural research can establish conversations, connections, and knowledge sharing that is equitable and reciprocal and works to not reinforce Western/northern/colonial authority. Through such culturally and politically aware approaches, spaces and discourses of progressive politics can be established. Such methodological approaches and the ensuing research production (reports, papers, presentations, datasets, advocacy, testimonials) can challenge academic authority and make space for cross-cultural and spatial differences to establish alternative interpretations of practices and power.

In academic research and production there are always tensions. Cross-cultural researchers have wrangled with difficult issues of representation, in particular misrepresentation that emerges from misunderstanding and mistranslation. Careful thinking through of how research findings are produced and reported is essential because much is at stake when a group of people or a place is researched, spoken, and written about. Researchers are part of the production of people and spaces and can be responsible for misrepresentation. It is important that they do not appropriate coproduced knowledge as their own. Continual questioning about what is produced, for whom it is produced, and how the knowledge can be best represented is required. In order to follow through the ethical research practice of “do no harm,” researchers have to avoid and actively counter the reinforcement and perpetuation of certain cultural stereotypes.
CROSS-CULTURAL RESEARCH

(misrepresentations) – this must be done at all stages of the research from interim reports to final publications.

Geographers working with indigenous people provide some of the best examples of this kind of political sensitivity, avoidance of misrepresentation, and recognition of the coproduction of knowledge. Kirsten Maclean and the Bara Yarralji Bubu Incorporation conducted a collaborative research project that enabled an indigenous group in Australia to articulate their knowledge and expertise of water governance on their traditional country. Government engagement with indigenous people is often not very successful mostly because of culturally inappropriate approaches combined with negative stereotypes about the indigenous groups. Through sympathetically and scientifically “crossing boundaries” all researchers in the project demonstrated their learned and practiced knowledge and produced a research report. The co-authors call this a “boundary object” because the report can translate indigenous people’s knowledge, values, and management interests in a form that maintains their cultural integrity and is easily accessed and interpreted by non-indigenous planners and scientists (Maclean 2015, 144).

Future directions

It appears to becoming less common to identify geographers’ work specifically as “cross-cultural,” and there are indeed questions being raised about the value of such a term. In a highly mobile and globalized world it is questionable if there are still distinct cultures to cross into. Cross-cultural researchers would argue not, because no cultures are fixed, completely distinct, or bounded. However, these are important questions to raise and to keep on raising. Cross-cultural researchers have been grappling with the complexities, tensions, and frustrations of working across cultures in ways that have changed for the better: decolonial rather than colonial, reflective, based on principles of coproduction, equitable, rigorous, and effective for researchers and participants. Geographers crossing boundaries are producing “boundary objects” that are transparent and produce legitimate information. All stakeholders (those within or without a research project) can access and understand the information. Researchers acting as “boundary agents” help to communicate the knowledge such objects carry, guarantee their validity, and ensure the recognition of coproduction.

In 1999 Linda Tuhiwai Smith published Decolonizing Methodologies: Research and Indigenous People. While she was focusing on indigenous people her work is highly relevant for all groups of people who have experienced colonization, injustice, and marginalization on the basis of their culture. Her book is a critique of previous colonial research practices and a presentation of indigenous methodologies. She stated: “The spaces within the [dominant] research domain through which indigenous research can operate are small spaces on shifting ground. Negotiating and transforming institutional practices and research frameworks is as significant as the carrying out of the actual research programmes” (Tuhiwai Smith 1999, 140). More than 15 years on many cross-cultural researchers and geographers crossing boundaries are still working on such transformations, challenging institutional practices, reorienting research approaches, and coproducing knowledge that is meaningful for the co-researchers and the communities – step by respectful step.

The frozen realm of the cryosphere consists of snow, sea ice, mountain glaciers, ice sheets, and perennially and seasonally frozen ground. From the polar regions to the tropical mountains, cryospheric elements are found in any location where there are prolonged freezing temperatures and frozen water. The cryosphere plays a fundamental role in Earth’s climate as it responds to changes in temperature and precipitation. Through its influence on Earth’s energy budget, the cryosphere itself drives changes in climate from local to hemispheric spatial scales and from weekly to millennial time scales. Due to the vast and remote expanses covered with snow and ice, the direct measurements needed to characterize cryosphere changes are not attainable. Satellite and airborne remote sensing platforms are, therefore, indispensable tools for mapping, characterizing, and monitoring the cryosphere in all parts of the globe.

Satellite remote sensing of the cryosphere dates back to the early 1960s when US photographic reconnaissance satellites (such as CORONA) used high-definition photography to image regions around the globe, including the Greenland and Antarctic ice sheets, permafrost and sea ice regions in the Arctic. Declassified in 1995, data from the 1960–1972 CORONA satellite missions has been used for cryosphere studies involving change detection (Bindschadler and Vornberger 1998). Unclassified, near–real-time orbital imagery became available starting in 1966 with Nimbus-2, allowing researchers to map snow cover and sea ice extent by examining spatial differences in visible band reflectance. That year also began the start of one of the longest remote sensing time series: snow cover extent. The National Oceanic and Atmospheric Administration (NOAA) used manual interpretation of visible imagery to produce weekly charts of snow extent and produced these weekly charts until 1999. It subsequently turned to an automated daily mapping system that used multiple sensors including passive microwave data, which can map the surface even in darkness and beneath clouds. Active microwave remote sensing of snow and ice began with the 1978 launch of SEASAT-SAR, the first synthetic aperture radar (SAR) instrument. Passive microwave remote sensing of snow began in 1978 with data from the scanning multichannel microwave radiometer (SMMR) on board the Nimbus-7 satellite. The earliest sea ice mapping began with the Nimbus-5 electrically scanning microwave radiometer (ESMR) from 1972 to 1976. Daily polar sea ice mapping with space-borne passive microwave began in 1978 and continues today. These satellite measurements of snow and sea ice are the longest cryospheric environmental data records.

### Electromagnetic radiation and definition of key terms

Before proceeding with an overview of remote sensing of the cryosphere, it is helpful to cover some of the basic, relevant remote sensing terminology.
Remote sensing measures the interaction of energy with materials. There are three basic ways that energy can interact with matter: absorption, emission, and scattering. Absorption and scattering represent attenuation of energy by either conversion to thermal energy (such as with absorption of sunlight) or redirection of refracted/reflected energy (such as with scattering of sunlight or microwave radiation). Terms that are commonly encountered in remote sensing of the cryosphere include:

- **Albedo**: the albedo of a material is the amount of energy reflected relative to the energy incident upon it. Albedo can be a spectral quantity (spanning a narrow range of wavelengths) or a broadband quantity (spanning a wide range of wavelengths, usually across the solar spectrum from about 0.3 μm to 5.0 μm). Albedo and reflectance are not the same quantity. Reflectance, or, more specifically, the bidirectional reflectance, is what is measured by space-borne instruments. Reflectance depends on measurement geometry whereas albedo is independent of viewing geometry.

- **Brightness temperature**: in the microwave portion of the spectrum, satellite-observed brightness temperature ($T_B$) is linearly related to the emitted radiance of a material. Through a simplified relationship, $T_B$ can be defined as the product of the spectral emissivity of the material ($\varepsilon_\lambda$) and its thermodynamic temperature ($T$): $T_B = \varepsilon_\lambda T$.

- **Dielectric constant**: in the thermal and microwave portions of the spectrum, the dielectric constant is used to describe how energy interacts with snow. The dielectric constant, $\varepsilon$, is sometimes called the “relative permittivity.” Permittivity is a measure of a material’s ability to transmit an electric field and $\varepsilon$ is the ratio of the permittivity of the material to that of a vacuum. At 0°C, the dielectric constants of snow constituents are: air $\varepsilon_a = 1.0$, ice $\varepsilon_i = 3.2$, liquid water $\varepsilon_w = 81$.

- **Emissivity**: the ability of a material to emit energy. Materials that are good emitters are poor reflectors and vice versa. Emissivity is a function of the dielectric properties of the material and the shape and geometry of their arrangement. Dry snow has a very low emissivity whereas wet snow has high emissivity.

- **Radiometric resolution**: the quantization of brightness levels expressed as $2^n$-bits where $n$ is an integer (e.g., 8-bit resolution = $2^8 = 256$ brightness levels).

- **Spatial resolution**: the number of spectral bands and their spectral width.

- **Spectral resolution**: the minimum size of an object that can be detected and/or distinguished from another object in an image.

- **Temporal resolution**: the frequency with which remotely sensed data are acquired over an area.

In the following sections, the remote sensing capabilities are described for snow, ice sheets and glaciers, sea ice, and permafrost and frozen ground.

### Remote sensing of snow

Snowpack quantities that can be derived from remote sensing include snow-covered area (SCA), albedo, effective grain size/specific surface area, depth, snow water equivalent (SWE), and melt-thaw status. For each of these properties there are limitations, sometimes significant, in terms of measurement accuracy, spatial/temporal resolution, detectability, and length of data record.
Snow covered area

The unique spectral properties of snow in the visible and near-infrared wavelengths (Figure 1) make it readily distinguishable from other land cover types. Thus, SCA can be readily mapped using the difference between visible and near-infrared snow reflectance.

The normalized difference snow index (NDSI, equation 1) is the basis for the binary (snow/no snow) SCA product from the moderate resolution imaging spectroradiometer (MODIS).

\[
\text{NDSI} = \frac{\text{band 4} - \text{band 6}}{\text{band 4} + \text{band 6}} \quad (1)
\]

where MODIS band 4 corresponds to a wavelength of 0.55 μm and MODIS band 6 corresponds to a wavelength of 1.6 μm. Remote sensing of snow in vegetated areas is challenging and the MODIS snow product accounts for vegetation by adjusting the snow/no snow threshold using a vegetation index. This approach works well for a sparse-to-moderately dense canopy, although there is no algorithm that can map snow under dense forest canopy.

Fractional SCA (fSCA), is the proportion of snow cover in a pixel and is another widely used metric for snow-covered area. Highly accurate estimates of fSCA are possible using a spectral mixture analysis method that decomposes the pixel reflectance into the individual reflectance values of its components (e.g., snow, vegetation, soil/rock). Compared with binary snow mapping methods, fractional snow mapping works very well at times when snow cover is patchy, such as during the melt season.

Snow albedo

Snow albedo can be computed from multispectral measurements of spectral reflectance that are converted to spectrally integrated broadband albedo using regression coefficients derived from measurements. The spectral albedo of clean snow is controlled by grain size (Figure 1), with
coarse-grained snow having a lower albedo than fine-grained snow in the near-infrared wavelengths. Thus, grain size (also referred to as the optically-equivalent grain size or the specific surface area) can be derived from multispectral and hyperspectral remotely sensed data in the near-infrared wavelengths. Snow grain size can be used as input to a radiative transfer model from which snow albedo can be computed, assuming the snow is clean. However, for snow containing dust or soot particles, the visible albedo will be decreased by as much as half.

Snow depth

To date, accurate remote sensing of snow depth has only been accomplished with airborne and ground-based instruments (Figure 2). LiDAR remote sensing of snow depth uses a differential approach in which snow-free elevations are subtracted from snow-covered elevations (Deems, Painter, and Finnegan 2013). Positional accuracy is critical, especially in mountainous terrain where slight shifts in the x-y position can yield large snow depth discrepancies, especially on steep slopes. Thus, kinematic GPS is required to provide ground control points for horizontal and vertical accuracy and to orthorectify the resulting elevation surfaces. For example, NASA’s Airborne Snow Observatory (ASO) uses LiDAR and a hyperspectral sensor to retrieve snow depth, fractional snow covered area, snow albedo, and dust content as part of an
operational approach to improve water resources management in the California Sierra Nevada.

Ground-based LiDAR, also known as terrestrial laser scanning (TLS) uses 360° scanning laser instruments with distance ranges up to 4 km to compute watershed-scale snow depths with a spatial resolution and vertical accuracy of about 5 m and 10 cm, respectively. For maximum efficacy, TLS requires permanent reflectors at multiple locations in the study area and minimal obstruction by vegetation and topography.

Snowpack depth can also be inferred from frequency modulated continuous wave (FMCW) radar, but such measurements require ground-based or helicopter deployments and measurements need to be calibrated with field observations. This active microwave technique holds promise for mapping and characterizing snowpack stratigraphy, as the radar returns respond to grain size and density of individual snow layers.

**Snow water equivalent and melt status**

The natural microwave emissivity from the snow-free ground is attenuated by snow cover and this serves as the basis for passive microwave estimation of snow water equivalent. Passive microwave radiometers have been used to estimate SWE for nearly four decades. However, this measurement has relied on a simplistic empirical relationship between microwave brightness temperature at 19 GHz and 37 GHz with adjustments for the effects of forest cover, differences in snow density, and the presence of tundra lakes below the snowpack. The passive microwave signal reaches an asymptote at about 150 mm of SWE. Passive microwave measurements require a very large footprint because the signal is relatively weak. Determinations of SWE using passive microwave techniques are limited to dry snow because when liquid water is present in the snowpack, the snow itself becomes a strong microwave emitter and it is no longer possible to distinguish snow from snow-free areas. However, this snow property also means that passive microwave can be used to identify the onset of snowmelt.

Passive microwave snow observations have been a valuable addition to model-derived SWE. GlobSnow, from the European Space Agency, is a modeled SWE product that uses passive microwave and ground-based weather station data for the period 1979–2013. SnowDAS, from the NOAA National Weather Service’s National Operational Hydrologic Remote Sensing Center, is a gridded daily snow product (including SWE) derived from a data assimilation model that incorporates passive microwave and optical satellite data, airborne gamma surveys, and ground-based data.

In airborne campaigns, dual frequency Ku-band (12–18 GHz) radar has been moderately successful in measuring SWE (Yueh et al. 2009). As SWE increases, so does radar backscatter due to the larger path length and greater number of scattering elements in the snow volume. Both grain size and SWE affect radar backscatter but these can be solved independently with two Ku-band frequencies. However, the relationship between other snow properties and radar backscatter is complicated. For dry snow, factors that affect radar backscatter include snow grain size, snow density, and snowpack stratigraphy (layering, especially ice lenses and depth hoar). As with passive microwave, wet snow significantly modifies the radar backscatter signal. In limited cases, radar has been used to retrieve the liquid water content of the snowpack.

**Remote sensing of ice sheets and glaciers**

Glaciers and ice sheets store most of the fresh water on our planet. The ice sheets of Greenland and Antarctica are extensive glacial ice masses,
CRYOSPHERE: REMOTE SENSING

exceeding 50,000 km². Ice caps are smaller than ice sheets and consist of multiple, coalesced glaciers, such as Iceland’s Vatnajökull ice cap. Other types of glaciers include mountain glaciers (such as the Arolla glacier, in Switzerland), piedmont glaciers (such as the Malaspina glacier, in Alaska), ice fields (such as the Juneau ice field, in Alaska), and others. Key questions that can be answered using remote sensing include: How thick are the glaciers and ice sheets? What are their surface properties? Are they increasing or decreasing in mass? How fast are the glaciers moving?

Ice sheet surface properties

As with snow albedo, the albedo of the glaciers and ice sheets is critical for estimating surface energy balance. On both Greenland and Antarctica, albedo has been measured and monitored using multispectral sensors such as MODIS. Low contrast between ice and clouds makes cloud detection a major challenge over the bright, large expanses of Greenland and Antarctica. Atmospheric correction of cloud-free imagery can also be a challenge at high latitudes due to low sun angles limiting the applicability of atmospheric correction models. At the high elevation portions of the Greenland ice sheet, the dry snow zone, the broadband albedo typically exceeds 0.85. Albedo decreases to about 0.70 in the wet snow zone and in the bare ice zone exposed firn and bare ice have albedo values of about 0.40. Along the Greenland ice sheet margins, dark algae growing on the snow/ice surface during the summer season can lead to very low albedo – about 0.10–0.20.

Melt extent on the Greenland ice sheet has been mapped using gridded brightness temperatures from passive microwave sensors such as SMMR, the special sensor microwave/imager (SSM/I), and the special sensor microwave imager/sounder (SSMIS). Horizontally polarized 37 GHz brightness temperatures are used to discriminate nonmelting from melting snow in each 25-km gridded image (Figure 3).

Glacier zones such as the dry snow, wet snow, percolation, and bare ice zones have been mapped using albedo and surface roughness. Surface roughness is an expression of surface–atmosphere interactions as winds redistribute snowfall and carve patterns into the surface creating dunes, sastrugi, and wind crusts at scales from millimeters to several kilometers. Roughness is also affected by subglacial topography, creating large-scale (1–100 km) surface features, and by glacier flow, expressed in 1–100 m scale features such as crevasses. Roughness increases radar backscatter and SAR sensors with spatial resolutions of about 3–100 m (depending on scan mode) can detect fine scale surface features. Multi-angular visible reflectance from the multi-angle imaging spectroradiometer (MISR) has also been effective at mapping roughness at scales from 0.1 to 10 m.

Ice thickness

To quantify ice sheet and glacier thickness, scientists have developed airborne coherent radar depth sounding systems that transmit a radar pulse through the ice and measure its return time and characteristics. The pulse delay time has been empirically related to ice thickness to an accuracy of about 2%. Longer than usual radar wavelengths, radio frequencies at 50–500 MHz can penetrate several kilometers of ice and can also provide information on internal layers needed for ice flow modeling. Cryospheric scientists have also used ground-based and airborne radar depth sounding to map the ice–bedrock interface, identifying subglacial channels and preglacial topographic features.
Glacier velocity

Using interferometric synthetic aperture radar (InSAR), studies have been carried out to map ice surface velocity on ice streams and outlet glaciers. After removing the effects of topography, it is possible to compute the phase difference between two SAR images to map surface motion along the line of sight of the radar:

\[
\phi = \phi_1 - \phi_2 = \frac{4\pi}{\lambda} (R_1 - R_2)
\]

where, \(\phi_1, \phi_2\) are the radar phase of each of the two images, \(R_1\) and \(R_2\) are the range from the radar instrument to the ground element and \(\lambda\) is the wavelength. Ice motion must be relatively slow to prevent phase decorrelation between images. Ice velocities for the Greenland ice sheet have been mapped using InSAR data from RADARSAT-1 and the advanced land observation satellite (ALOS) and TerraSAR-X (Joughin et al. 2010). Combining ice velocity with ice thickness gives an estimate of the mass flux of water from ice sheet to ocean. A second method to determine ice surface motion involves cross-correlating glacier features that move with the ice (such as crevasses) and that

---

**Figure 3** Greenland melt from passive microwave brightness temperature. Reproduced from National Snow and Ice Data Center.
are visible in images from one acquisition time to another. This technique requires adequate spatial resolution and feature contrast for effective image-to-image cross-correlation. Landsat thematic mapper (TM) has been used for this purpose, measuring ice velocity on Antarctic ice streams and mountain glaciers.

Surface elevation and mass balance

Radar altimetry and laser altimetry measure the surface elevation of glaciers and ice sheets using the known altitude of the spacecraft and a range measurement from the instrument to the surface. Elevation changes, when combined with density estimates can be translated into changes in ice mass balance. Radar altimeters are nadir-pointing sensors that send a radar pulse to the surface below and measure its round-trip travel time and the returned waveform. Using the satellite altitude and applying corrections for water vapor and ionization, the time estimate is converted to an altimetric surface height. The footprint of space-borne radar altimeters is about 2 km, although this increases over rough surfaces due to increased travel time for the return waveform. Early radar altimeters such as SEASAT-ALT were not designed for ice altimetry but CryoSat-2, launched in 2010, is specific to polar ice surfaces with a high inclination orbit and is augmented by InSAR capabilities to map elevations of sloping and rough ice sheet surfaces. On board NASA’s ice, cloud, elevation satellite (ICESat) the geosciences laser altimeter system (GLAS) was a space-borne near-infrared (1.04 μm) laser altimeter that measured ice sheet elevation. With it 70-m footprint and 170-m spacing, GLAS measured elevations of ice sheet and ice shelf features with detail not previously available from satellite. Due to laser failures, the ICESat was decommissioned in 2010. In its stead, Operation IceBridge, a multi-instrument airborne science program is providing extraordinary 3-D perspectives on the polar regions in more detail than ever before.

One of the most innovative approaches to remote sensing of ice sheets is the gravity recovery and climate experiment (GRACE). Since 2002, GRACE has measured monthly changes in Earth’s gravitational field to estimate regional changes in mass over the ice sheets and large glacier regions (Luthke et al. 2006).

Glacier extent, terminus position, and snowline

With their steep elevation gradients, alpine glaciers are especially sensitive to changes in climate and have also been significant contributors to sea level rise in recent decades. As such, satellite remote sensing has been an important means of tracking glacier characteristics that can be used to estimate changes in glacier mass balance or used as a proxy for climate change. Glaciologists have developed automated approaches to map glacier extent and terminus position using multispectral imagery from sensors such as Landsat TM, enhanced thematic mapper (ETM+) and the advanced space-borne thermal emission and reflection radiometer (ASTER). In the near-infrared wavelengths such as 1.6 μm (ASTER band 3 or TM band 5), ice is very dark compared with non-ice features, including most clouds. In the visible wavelengths ice is very bright. Simple ratios using near-infrared-to-visible spectral combinations or the NDSI (equation 1) are effective for glacier mapping using either TM or ASTER. Combined with a digital elevation model, changes in glacier extent can also be used to estimate changes in glacier mass balance. Using satellite-derived glacier outlines, the global land ice measurements from space (GLIMS) program and the Randolph glacier inventory have mapped hundreds of
thousands of glaciers globally, providing new capabilities for monitoring glacier change. Debris cover on glaciers obscures the contrast between ice and surrounding bedrock and moraines, confounding glacier extent estimates. Limited research has shown that InSAR can map the motion of debris-covered glaciers though to date, there has not been a robust method for their regular mapping and monitoring.

Remote sensing of sea ice

Sea ice forms on the sea surface when the water is sufficiently cold to freeze. The complex atmospheric and ocean circulation processes that characterize the polar regions control its seasonal development and motion.

Sea ice area, extent, and concentration

Sea ice area is the total area of sea ice greater than about 15% concentration in a pixel. Extent is the geographic extent demarcated by the ice margin. Concentration is the fraction of sea ice in each remote sensing grid cell. Optical sensors can readily distinguish open water from sea ice but cloud cover and the dark of polar winter inhibit their views. Passive microwave remote sensing has an advantage of being able to monitor sea ice during periods of darkness and cloudiness. The brightness temperature of open ocean is low compared with that of sea ice, so microwave instruments can map sea ice concentration and extent with high accuracy. Although the passive microwave spatial resolution is coarse (the footprint size is roughly 28 × 37 km for SSM/I and 14 × 8 km for NASA’s advanced microwave scanning radiometer-Earth observing system, AMSR–E), the concentration of sea ice in each grid cell can be determined using a linear mixture analysis approach. This requires an estimate of brightness temperature for sea ice and open water and assumes that the overall pixel brightness temperature is a linear mixture of the brightness temperatures and amounts of each component in the pixel. The accuracy of this method depends on the ice types and other components present, how well they can be distinguished, and their complex spatial arrangement.

Regular, operational monitoring of sea ice started with SMMR in 1979 followed by SSM/I in 1987. Data from these instruments have been processed to create a time series of daily sea ice concentration and extent at a grid resolution of 25 km (Figure 4). This time series continues to the present with the special sensor microwave imager/sounder (SSMIS) sensor and has been augmented with 12.5 km resolution data from the AMSR–E sensor for the period 2002–2011.

Sea ice thickness

Since 2010, CryoSat–2 has been successfully mapping and characterizing sea ice conditions, including sea ice freeboard (the thickness of sea ice above the ocean surface) and sea ice thickness. Cryosat–2 uses an algorithm that determines the optimal fit between the measured waveform and a modeled waveform for a given sea ice freeboard (Laxon et al. 2013). The algorithm requires ancillary data such as the depth of the snow layer on the sea ice and a measurement of sea ice concentration, as ice thickness retrievals are only performed for grid cells having greater than 70% ice concentration. Assuming hydrostatic balance, ice thickness is then computed based on the snow depth and retrieved freeboard.

The GLAS sensor also derived estimates of sea ice freeboard and sea ice thickness. These laser altimeter measurements are limited to cloud-free periods during the 15 periods when the lasers were functioning from February 2003
Figure 4  Sea ice concentrations shown for the Arctic, September 2012. This was the lowest sea ice extent on record. The magenta line shows the historical average extent (1981–2002). Reproduced from National Snow and Ice Data Center.

to October 2008. Since the end of GLAS on the ICESat mission, Operation IceBridge has measured sea ice freeboard and snow depth using a combination of airborne laser altimeters and a snow radar, respectively. Below the ice, declassified upward-looking sonar data from United States and British Naval submarines have provided measurements of ice thickness along their Arctic traverses. US submarine data for the period 1958–2000 combined with the GLAS measurements, create a 42-year time series showing accelerating declines in sea ice thickness over much of the Arctic.

Sea ice type

When first forming, sea ice can be smooth and as thin as a few centimeters; over time, it grows...
thicker and more extensive with characteristic rough pressure ridges and cracks (known as “leads”). “First year” sea ice forms during the polar winter and melts in summer, but when it persists beyond one melt season it is called “multiyear” sea ice and can be 2–3 m thick.

Radars such as SEASAT-SAR, ERS1,2, and JERS-1 demonstrated the immense value of SAR for mapping sea ice characteristics. Classification of multiyear versus first year sea ice works with SAR because multiyear sea ice has more air bubbles (since the bubbles’ briny contents have drained out over time), so it has higher backscatter than first year ice. RADARSAT-1,2, operated by the Canadian Space Agency, have been used operationally to differentiate ice types and for daily ice charts. Such information has been critical for navigation through pack ice in polar regions. SAR’s improved spatial resolution over passive microwave allows mapping of leads and polynyas. Intermittently since 1978, scatterometers such as SEASAT-A, ESCAT, NSCAT, and SeaWinds have measured radar backscatter and have been used to characterize sea ice surface roughness. Scatterometer spatial resolution is comparable to that of passive microwave (e.g., SeaWinds spatial resolution is 25 km) due to the need to average radar backscatter over large areas to achieve adequate response. CryoSat-2 derives sea ice surface roughness from pulse-broadened waveform, which assumes a Gaussian distribution of roughness elements within the radar footprint.

**Sea ice motion**

Sea ice motion is computed by automated tracking of identifiable features from one image to another. This approach uses repeat temporal coverage from satellite data and has been extensively used with optical data (e.g., advanced very high resolution radiometer, AVHRR), passive microwave (e.g., SMMR and SSM/I), and SAR (e.g., RADARSAT-1,2). Using tie-points, image correlation algorithms record the pixel-by-pixel displacement of sea ice features. Sea ice motion tracking is performed on daily to weekly time scales and provides estimates of ice export in the Arctic and for sea ice conditions essential for polar navigation.

**Remote sensing of permafrost and frozen ground**

Soil, sediment, or rock that has remained at a temperature of 0°C or colder for more than two years is defined as permafrost or perennially frozen ground. Permafrost is typically overlain by an active layer, which freezes in the winter and thaws each summer. Seasonally frozen ground is that which freezes during the cold season and thaws during the warm season and it may exist in the absence of permafrost. Key properties include permafrost spatial extent, soil freeze–thaw status, active layer thickness, and thermokarst detection. Remotely sensing permafrost properties is challenging because most sensors only respond to the top few millimeters of the soil surface. Therefore, most methods measure permafrost-related variables or combine remote sensing measurements with models.

**Permafrost/frozen ground extent**

Because freezing is the hallmark of permafrost and seasonally frozen ground, land surface temperature (LST) is a key measurement for sensing the extent and freeze–thaw state of these soils. Satellite measurements of LST have been made using thermal band data from AVHRR and MODIS with spatial resolution of about 1 km. Land surface temperature is also derived from passive microwave brightness temperatures, such
CRYOSPHERE: REMOTE SENSING

as from SSM/I and AMSR-E, at spatial resolutions of 25 and 12.5 km, respectively. Although LST may not be an exact predictor of soil or rock temperatures at tens of centimeters below the surface, these data are valuable input to models that predict the spatial and temporal distributions of permafrost and seasonally frozen ground.

Soil freeze–thaw status

There is a fundamental difference in the dielectric properties of frozen and thawed soils. The bulk dielectric constant of soil is governed by that of water, as the liquid water dielectric constant is an order of magnitude greater than that of ice and soil minerals. Thus, passive and active microwave sensors respond to the freeze–thaw status of soils. Radar backscatter from a thawed soil increases by about 2–9 dB depending on variations in moisture content and surface properties. The 37 GHz vertical polarization passive microwave data have been used to map soil freeze–thaw status on a daily basis from 1979–2012 using SMMR-SSM/I-SSMIS and AMSR-E data (Figure 5). Because of their coarse spatial resolution, passive microwave brightness temperatures are influenced by subpixel tundra lakes, so soil freeze–thaw estimates need to be adjusted based on total lake area. Snow cover is another challenge for passive microwave measurements of frozen ground, as snow obscures the soil and some frozen soil detection algorithms use the same brightness temperature difference (with 37 and 19 GHz frequency) as used for snow mapping. When snow cover is present, an energy balance model must be used to ascertain the thermal state of the soil.

The ESA’s soil moisture and ocean salinity (SMOS) uses an L-band passive microwave radiometer to monitor seasonally frozen ground. The long wavelength of this instrument (21 cm) can provide information on soil freeze–thaw for depths up to 35 cm (depending on soil type and vegetation cover) though at a coarse spatial

![Figure 5](image-url)  Daily soil freeze–thaw status at 25 km from AMSR-E for April 10, 2010; a composite of morning (a.m.) and afternoon (p.m.) satellite overpasses. FR = frozen, NF = nonfrozen, TR = transitional (a.m. frozen, p.m. thawed), INV-TR = inverse transitional (a.m. thawed, p.m. frozen). Kim et al. 2014. Reproduced from the National Snow and Ice Data Center DOI:10.5067/MEASURES/CRYOSPHERE/nsidc-0477.003.
resolution of 35 km. NASA’s soil moisture active passive (SMAP) mission uses an L-band SAR to monitor soil freeze–thaw state. With a temporal resolution of 2–3 days and spatial resolution of 3 km, the SAR instrument on SMAP can capture spatial patterns not evident with passive microwave, although not necessarily the heterogeneous landscape processes that affect seasonally frozen ground.

Active layer thickness

Active layer thickness (ALT) is the maximum depth of seasonally thawed ground that overlies permafrost. Surface-based ground penetrating radar is effective for mapping ALT though only over small areas. InSAR provides an indirect method of estimating ALT by measuring the subsidence that accompanies soil thaw during the warm season. Promising new approaches with greater soil penetration depth and less influence of vegetation include the airborne P-band SAR (e.g., AirMOSS) and kilohertz frequency data (airborne electromagnetic method, AEM) can retrieve active layer thickness.

Surface expressions of permafrost and thermokarst

In regions where permafrost is thawing, the loss of ground ice is a spatially heterogeneous process that leads to localized frost heaving, surface deformation, and subsidence known as thermokarst. Thermokarst landscapes are typically hummocky and include numerous small lakes that form in melt depressions, mounds that remain when ice-rich polygonal ground thaws, and thermo-erosional gullies that form when massive ground ice melts along a slope. These features are readily observed in fine resolution optical satellite imagery with spatial resolutions of 0.5–4 m (e.g., IKONOS, QuickBird, GeoEye-1, WorldView-1,2,3, and Pléiades commercial satellites). Repeat measurements with active sensors such as airborne LiDAR and space-borne InSAR map surface deformation due to frost heave and subsidence.

Beginnings

The cryosphere consists of all terrestrial forms of snow and ice—snow cover, floating ice, glaciers, ice sheets, frozen ground, and permafrost. It is a critical element of the climate system because of its high reflectivity, its insulating effects on the land and ocean, and its storage of water on short and long timescales.

Recognition of the past existence of more extensive Alpine glaciers during ice age conditions came in 1837 with the work of Louis Agassiz in Switzerland. However, the first glacier sketch map dates from 1601 for the Vernagtferner in the Austrian Tyrol. The earliest research on glaciers was carried out in Iceland by S. Pálsson in the 1790s, in studies that were only translated into English in 2004. He made a sketch map of the Vatnajökull glaciers.

Most scientific study of the different components of the cryosphere—snow cover, glaciers, ice sheets, freshwater ice, and sea ice—began around 1890–1900, whereas the study of permafrost and ground ice started in the Soviet Union in the 1920s but did not begin until World War II in the West.

The first definition of the cryosphere and its components was made by A.B. Dobrowolski (1923) in a massive treatise written in Polish, but the term was not widely adopted until the 1990s. Most writings treated single components until the publication of *The Global Cryosphere: Past, Present and Future* by Barry and Gan (2011) and *The Cryosphere* by Marshall (2011).

**Land components**

**Land ice**

Data on glacier fluctuations, from 1881 onward, were published in 1895, and the annual records have been maintained in the series “Fluctuations of Glaciers” published at five-year intervals by the World Glacier Monitoring Service (WGMS) in Zurich. Mass balance data were first collected on the Rhône glacier in 1874 and then continuously on Claridenfirn in Switzerland from 1914–1915. Other programs operated in the 1920s to the 1940s, but continuous annual measurements of glacier-wide mass balance began on the Storglaciären, Sweden, in 1945–1946 and expanded to other mountain ranges only in the 1950s. The WGMS currently lists annual data on terminus locations for 1967 glaciers and on mass balance for 266 glaciers, but most are small and not globally representative. There is now a nearly complete global glacier inventory (the Randolph Glacier Inventory), which contains 170,000 glacier outlines and a global ice area of 737,000 square kilometers. However, details about many of the glaciers remain incomplete. Consequently, the global area and volume of ice remain uncertain.

Theoretical work on glacier flow and snow mechanics began in Britain and the Alps in the late 1930s and resumed after World War II. Extensive fieldwork on glaciers in the USSR began during the International Geophysical
year (IGY; July 1957 to December 1958), and continued through the early 1990s. In Canada and Alaska such work mainly began during the International Hydrological Decade (1965–1974).

High-resolution remote sensing, which began with Landsat in 1972, has greatly expanded the information available on world glacier distribution and characteristics. The Global Land Ice Measurement from Space (GLIMS) program uses the Advanced Spaceborne Thermal Emission and Reflection Radiometer (ASTER) instrument, aboard the Terra satellite, and the Landsat Enhanced Thematic Mapper Plus (ETM+). The GLIMS database has 116,000 glacier outlines. Interferometric synthetic aperture radar (InSAR) mapping has been used to determine motion on selected glaciers since the 1990s.

Ice sheets

Expeditions to the Greenland ice sheet were undertaken in the 1880s and 1890s, but the first substantial work was performed in 1930–1931 by the British Arctic Air Route Expedition of Lauge Koch and Gino Watkins at Watkins’s ice cap station (2440 m) and Alfred Wegener’s Greenland Expedition to Eismitte (3100 m). In 1946–1948 P.-E. Victor led the Expedition Glaciologique Internationale au Groenland (EGIG), which established a survey line across the ice sheet. Summit station (3216 m) has operated continuously since 1989.

Antarctic scientific expeditions began in 1899 with the first overwintering on the continent, but some of the earliest glaciological research was conducted by the Norwegian–British–Swedish expedition of 1946–1947 in Queen Maud Land. During the IGY 12 nations established over 60 stations in Antarctica including South Pole and Vostok on the East Antarctic plateau.

Ice core research began in Greenland during the IGY when 300–400 m cores were extracted and analyzed by C. Langway Jr. Cores to bedrock were drilled at Thule, Greenland, in 1966 and at Byrd station, Antarctica, in 1968. W.C. Dansgaard laid the foundations of paleoclimatic research using ice core data in 1969. The longest climate record to date was recovered from the European Project for Ice Coring in Antarctica (EPICA). The 3,139 m of core so far analyzed spans 740 ka and covers eight glacial-interglacial cycles.

Ice thickness surveys using airborne radio-echo sounding began in Antarctica in the 1960s. During the 1990s and 2000s ice sheet altitudes were mapped by satellite radar and lidar surveys, and melt extent on Greenland has been mapped from passive microwave data. Since 2002, volume change estimates have been derived from the Gravity Recovery and Climate Experiment (GRACE) satellite.

Snow cover

Snow surveys began in California in 1906 and soon expanded to most western US states. These were generally made at monthly intervals in late winter and spring as the basis for streamflow estimates. Snow depths are recorded daily at weather stations but the data are not exchanged internationally.

Hemispheric analysis of snow cover began in the United States in October 1966 from the polar orbiting Very High Resolution Radiometer (VHRR). Initially weekly, maps became daily in February 1997. These were complemented by maps from the 500 m resolution Moderate Resolution Imaging Spectroradiometer (MODIS) on Terra (2000) and Aqua (2002). Snow water equivalent has been determined from passive microwave remote sensing for the northern hemisphere since 1979, although forest cover and melt layers limit the accuracy of the products.
Freshwater ice

There are records of ice on Lake Constance dating from 875 CE and on Lake Suwa, Japan, from 1443 CE. Observations of river ice breakup started in Finland on the river Tornionjok in 1693, and on lakes Kallavesi and Näsijärvi in 1833 and 1836. Ice conditions on the river Danube were studied in 1848 following two years of flooding and in the late nineteenth century on the St. Lawrence River in Canada. Canada maintained an extensive network of around 240 lake observing sites from the 1940s to the 1990s, but almost all of these have since been terminated. In 1995 the Canadian Ice Service began a program of monitoring ice extent on small lakes using high-resolution satellite imagery. The amount of ice on each lake is determined weekly by visual inspection of Advanced Very High Resolution Radiometer (AVHRR) and RADARSAT images. The program had expanded to 118 lakes by 1998.

Trends in lake ice formation and breakup were studied in Finland in the 1940s and 1980s, and subsequently for other regions across the northern hemisphere.

Permafrost and frozen ground

The existence of frozen ground was first noted in 1577 in Baffin Island and then again in 1642 in Siberia. The earliest scientific recognition of frozen ground is attributed to Karl von Baer in 1838. The first maps of permafrost in Russia were published in 1872 and 1899. M.I. Sumgin published the first book on perennially frozen soils in Russian in 1927. The first English text was not published until 1947 by S.W. Muller. Permafrost research in China started in the 1950s. A circum-Arctic map of permafrost distribution and ground ice content was prepared by the International Permafrost Association and published in 1997 by J. Brown and others.

Monitoring of the active layer thickness in the circum-Arctic began in 1991.

Marine components

Sea ice

There is an index of East Greenland ice off the coasts of Iceland from 1150 CE, although some authorities consider it to be unreliable before 1600. Ice edge positions were first documented in the Nordic seas in the 1550s and in the North Atlantic in the 1890s.

In the Antarctic there are whaling ship records from the 1930s to 1950s. Regular aircraft reconnaissance of Arctic ice off Eurasia began in the USSR in 1933 and continued until 1992. Summer ice patrols began in the Canadian Arctic in 1957 and continued through the 2000s. Satellite mapping of ice extent and concentration began in the mid-1960s, with all-weather global passive microwave data available from 1979 and high-resolution radar data from 1991. Ice draft in the Arctic was first measured in 1958 using submarine upward-looking sonar. Sonar data continued to be collected from 1971 through the 2000s, but from 2003 to 2009 the ICES at laser altimeter enabled the direct measurement of sea ice freeboard. In 2010 CryoSat 2 was launched with interferometric radar for the same task.

William Scoresby Jr., an English whaling captain, published a notable book on ice and ocean conditions in the Greenland Sea in 1820. F. Nansen performed the epic drift across the eastern Arctic Ocean in the Fram during 1893–1896. The first book on the physics of sea ice was written by F. Malmgren in 1927 based on observations made during the Norwegian ship Maud's north polar expedition, 1918–1925.
CRYOSPHERE STUDIES: HISTORY

Ice shelves and icebergs

Ice shelves consist of grounded and floating land ice. They exist mostly around the Antarctic ice sheet. The eastern part of the Filchner–Ronne shelf was first explored by W. Filchner in 1911–1912. The western part was photographed from the air in 1947. Bases were set up on the Ross ice shelf from 1929 to the IGY. Major scientific work began in the 1960s and 1970s.

Iceberg calving and ice shelf breakup have been monitored by satellites from the 1970s. Icebergs in the northwestern North Atlantic were documented annually from 1912, after the Titanic disaster.

Organization of cryospheric science

The first organization concerned with the cryosphere was the International Glacier Commission, established in 1894, which documented glacier changes, initially in the Alps. This became the Commission on Glaciers and Snow of the International Association of Scientific Hydrology (IASH) in 1939, which in 1948 was renamed the International Commission on Snow and Ice (ICSI). During the 1990s ICSI members increasingly felt constrained by the restricted scope of their activities under their parent organization, the International Association of Hydrological Sciences (IAHS). Between 2001 and 2004, Gerry Jones, the president of ICSI, decided to push for the establishment of an association of cryospheric sciences as part of the International Union of Geophysics and Geodesics (IUGG). A committee (Roger Barry, Jan Hagen, and Wilfred Haberli) documented the case for the new association and in 2007 the International Association of Cryospheric Sciences (IACS) was approved at Perugia, Italy, as the eighth association of the IUGG. It held a successful first meeting in Davos (DACA-13) in July 2013.

The International Glaciological Society (IGS) was founded as the Association for the Study of Snow and Ice in 1936. It became the British Glaciological Society in 1945 and changed its name and scope in 1971. The International Permafrost Association (IPA) was founded in 1983, and in 1989 it became an affiliate of the International Union of Geological Sciences. In 2000 the World Climate Research Programme (WCRP) established the Climate and Cryosphere (CliC) project to coordinate international research efforts in this field.

Cultural capital

Louise C. Johnson
Deakin University, Australia

The elaboration of a term like “capital” beyond its financial confines has occurred through the work of economists, labor market analysts, and sociologists. Unpacking or extending the term into the various forms that capital can take occurred in the second part of the twentieth century as scholars acknowledged the limitations of neoclassical and Marxist economics. The result has been discussions of “human capital,” the ability of people to create value through their labor and related actions; “natural capital,” or environmental resource endowments; and various forms of capital relating to human values and social positions, via “symbolic capital” and “cultural capital.” The latter term has been particularly important to sociologists, educationists, economists, and geographers as they have theorized the rising importance of consumption over production as well as culture in the constitution of identities and contemporary economies. Fundamental to this reorientation was the work of the French sociologist Pierre Bourdieu who, in his classic 1984 text, Distinction, put status and the quest for social distinction at the center of his analysis of the French class system. This entry considers the nature of cultural capital and related terms developed by Bourdieu before focusing on the main ways in which geographers have utilized the term to analyze the cultural industries and related transformations of economic and social space.

Definitions

The French sociologist Pierre Bourdieu derived and used the notion of cultural capital to analyze and explain the high failure rate of working-class children in the French school system. It was later extended to detail and socially situate the tastes of the bourgeoisie and the ways in which particular cultural forms acquired value. He argued that “culture” has the effect of reinforcing and legitimizing middle-class power at the expense of lower-class taste, status, and power (Bourdieu 1984).

In contrast to a social model that prioritized disembodied class relations or an economic one that privileged rational behavior, Bourdieu admitted human values, taste, and the quest for status into his sociological analysis. Cultural capital thereby describes the possession of knowledge, accomplishments, and formal and informal qualifications – all of which are embodied by individuals and used by them to negotiate their social position. A person’s socialization via family upbringing, formative peer groups, and formal education endows them with stocks of generalized cultural capital that are expressed as habitual tendencies and generative predispositions, forming a habitus. Acquired primarily through formal education, cultural capital is subsequently expressed through consumption practices, which tend to reproduce
socioeconomically based status distinctions. The status of a given type of cultural capital is thereby set by the values, interests, and tastes of the dominant social class factions. In Bourdieu’s analysis, although it does not necessarily match the distribution of economic and social capital, cultural capital tends to reinforce the unequal class order of late twentieth-century France (Bourdieu 1986).

Bourdieu argues that when consumers accumulate new forms of cultural capital they are making an investment in particular constellations of skills, knowledge, and aptitudes. The status value of these stocks of cultural capital lies in their conversion rate – into additional forms of cultural capital but also into social capital (advantageous social connections), economic capital (via occupational opportunities), and symbolic capital (social recognition and respect). The conversion rate is related to the social field in which it is deployed and to the underlying relations of socioeconomic advantage and disadvantage that structure the distribution of social and economic resources among social fields.

If cultural capital is held (or embodied) by individuals as a consequence of their family background, education, and placement in the class system, the cultural object – or objectified cultural capital – intersects with the schema to attain its value through its position in a field of cultural production (Johnson 2009). Within each artistic field, for Bourdieu, there are objective qualities which govern success, and these include price, awards, or grants. These fields have aesthetic, symbolic, and historical value. Each field is the consequence of forces and struggles between key arbiters of taste; institutionalized interests; those who gaze on, value, and purchase the artistic products; and the political context in which transactions occur. As a result, changes in literary or artistic possibilities result from alterations in the power relations, which constitute the positions and dispositions by those involved in defining art and its value: bureaucrats, patrons, critics, producers, arts managers, viewers, and consumers (Bourdieu 1996). It is the intersection of embodied and objectified output with artistic institutions that thereby gives any art object or activity its value. In his detailed analysis of particular art forms Bourdieu thereby linked artistic objects and activity to class, power, politics, and taste.

Uses of cultural capital

Bourdieu’s notion of cultural capital – as a set of acquired markers of social distinction as well as a means of unpacking the value of cultural objects – arose from his sociological investigation of the role of the French school system in reproducing class relations. It is therefore not surprising that much of the work utilizing this concept and comparable methodologies has occurred in education as researchers have charted the ways in which class is either reproduced or modified through schooling. There has also been a use of the concept in literary studies, to unpack the establishment of a literary canon or national identity, and in sociology, with numerous studies of the quantity and quality of cultural capital held by particular social groups.

If such work has built directly on that of Pierre Bourdieu, the notion of cultural capital has been usefully extended by those who have focused on the apparent shift toward creativity in the economic system. Notions such as the cultural industries, the creative class, and the creative city have thereby emerged (see Hesmondhalgh 2002). Key to this conceptual shift, in addition to those prefigured by postmodernism and post-Fordism, was the work of Richard Florida.

In an enormously influential book on The Rise of the Creative Class (2002) Florida argues...
that the various economic, technological, and social transformations that have made the media and communications industries vitally important have also engendered other changes. Beginning with the geography of regional growth across the United States, Florida isolates a number of common characteristics which for him explain the emergence of cities like Washington, DC, Boston, Austin, Chicago, and San Francisco as centers of rapid population growth. He argues that their growth did not arise from firms moving into these areas but rather from creative people seeking out and making these urban environments their own. These cities in turn become centers of innovation and high-technology industry. What they have in common, Florida argues, is “technology, talent and tolerance” (2003, 10). Technology involves the mobilization of capital and innovation to create new things, processes, and industries by those with talent. These talented individuals, in turn, Florida argues, are attracted to places that have a social milieu that fosters and supports their creativity and associated work and lifestyles (Florida 2002; 2003).

Florida’s analysis has proliferated across the globe and has inspired major policy shifts toward the arts and the cultural industries, and political tolerance in a range of places. While it is criticized for being tautological (i.e., if you have a broad definition of a growth class you will necessarily get growth regions), somewhat instrumental, empirically flawed, and overly optimistic, Florida’s work has catapulted the notion of the cultural industries and of cultural capital (a city focused on the development of its creative class and culture) to the top of many urban political agendas. The work that has impacted the most on geography has engaged with the role of the creative arts in the establishment of class taste and power within the city as well as in the growth of the cultural and creative industries which offer new jobs and vehicles for urban and regional regeneration.

**Uses in geography**

Few geographers use Bourdieu’s framework without significant modification, as a result of their application in other disciplines and the very different questions posed and because the world is a different place from 1970s France, when his research was done. Its use can be linked to the revitalization of cultural geography in the 1980s. Thus, the “new cultural geography” is concerned with how landscapes and dominant meanings are produced through the interplay of social relations and texts. Now a vast subfield covering everything from urban images and agricultural landscapes to marginalized social groups, the new cultural geography has focused on cultural and symbolic capital.

In a vital early study of loft living in New York, Sharon Zukin (1982) wrote of the many costs and problems associated with the “symbolic economy,” an intertwining of cultural symbols with entrepreneurial capital. For her the symbolic economy in action was corrupt, as the association with entrepreneurial capital devalued the artistic product, compromised creative people, and imposed exploitative social relations on all those involved. But, in her analysis, Zukin (1995) connected the creation of cultural symbols to urban transformations, materializing the arts into a transformative political urban economy.

In his study of gentrification in Toronto, David Ley (2003) invokes the notion of cultural capital more explicitly as a vital component in changing the value and class character of particular parts of the city. He charts how previously run-down areas with few economic resources have been reclaimed by social groups (artists, academics, intellectuals) with large amounts of cultural
CULTURAL CAPITAL

capital but limited economic capital. In this process, there is a shift as the areas are injected with labor and value to become sites of both cultural and economic capital, in other words, gentrified. It is a powerful argument and demonstration of the power of Bourdieu’s concept in understanding the changing nature of the western city.

If cultural capital has been used to understand the process of gentrification, the notion has also been connected to emerging economic sectors. Allen Scott (2000) has analyzed the importance and specific character of the “cultural products industries.” In addition there have been geographical studies of particular cultural industries, such as the film industry, fashion design and retailing, and the manufacture of surf boards, as industries that basically combine rich concentrations of cultural capital with artisanal production methods to ensure the transformation of cultural to economic capital.

The role of the cultural industries and concentrations of cultural capital in urban and regional regeneration formed the basis of an entire European Union-sponsored program of naming cities as and elevating them to centers of culture or “cultural capitals” (see Landry and Bianchini 1995). The first of these – Glasgow – best illustrates the challenges and benefits of such a designation as this declining manufacturing city was reimagined and rebuilt around its pre-existing cultural assets but also a well-funded and supported program of art, physical regeneration, and programs to grow its cultural industries (Johnson 2009). Directed by the subsequent theorizing by Florida, Landry, and others, this program has been replicated across Europe, North America, and Australasia so that the mobilization of cultural capital has become synonymous with urban regeneration, social animation, and reimagining.

If these examples have taken notions of cultural capital and either applied them directly or merged them into studies of the cultural industries and cities, there have also been geographers who have reformulated their theoretical premises. In their analysis of emerging forms of cultural capital in Europe, Prieur and Savage argue that the types and social relations underpinning its theorization in Distinction need to be updated because of the decline in “high-brow” culture and the emergence of what they argue is a cosmopolitan cultural capital within a European field of a well-educated professional and managerial class. They further argue that, as popular cultural objects become aestheticized and as elite objects become popular, the objective form of cultural capital is supplanted by the embodied form, with the upper classes now more wide-ranging and discerning in their cultural practices (Prieur and Savage 2013).

Cultural capital, therefore, has been used directly and indirectly by a number of geographers to analyze existing phenomena such as gentrification, to understand emerging economic sectors (the cultural or creative industries), and to form the basis of new policy agendas for urban, regional, and social regeneration. In this exercise they have both used the concepts developed by Bourdieu and modified them in the light of Bourdieu and modified them in the light of contemporary economies or their analytical purpose.

Cultural diffusion

Victor Roger Savage
National University of Singapore

The first use of “cultural diffusion” goes back to the American anthropologist Alfred Kroeber’s (1944) influential paper on “stimulus diffusion” or transcultural diffusion. Since then, the concept of diffusion has been used across many disciplines. For geographers, the concept is used to map the travel of both tangible and intangible culture over space. The Swedish geographer Torsten Hagerstrand (1952) has contributed most to an understanding of spatial diffusion processes. Many of the conceptual paradigms of diffusion come from the Swedish school of spatial diffusion. Four of these diffusion processes are often cited in the literature: expansion diffusion (spatial expansion of cultural ideas/artifacts from one of multiple sources); relocation diffusion (implant of a culture in a different place and time); hierarchical diffusion (movement of culture from larger entities to smaller places); and contagious diffusion (how ideas move rapidly through societies/communities through personal communication). The Marxist geographer Jim Blaut (1993) is critical about conceptualizations of diffusion, arguing that on a world scale “diffusionist ideas” are often biased, Eurocentric, and based on single belief systems.

All cultural diffusion needs to be understood as a product of three intertwining factors: (i) culture must have an origin(s), or cultural hearth(s); (ii) it must be transported in time or across space and society; and (iii) it must find expression in a new time, place, and community. Cultural diffusion is as old as the first Homo sapiens seeking effective ways of ensuring survival in varying ecosystems.

Much has been written about cultural diffusion between civilizations and cultural hearths around the world. Academic debates continue to persist about the transference of scientific knowledge, the idea of democracy, and the beginnings of capitalism especially between East and West. For example, while Fernand Braudel, Immanuel Wallerstein, and Eric Wolf state that capitalism originated in Europe and spread to the rest of the world, Janet Abu-Lughod, Jim Blaut, and Andre Gunner Frank posit that capitalism originated in the East and spread westward.

Cultural diffusion has been most widespread when there are institutional forms of cultural transference and indoctrination. Three institutional forms of cultural diffusion may be identified: colonialism, religion, and education.

Throughout history, developed states and civilizations often engaged in conquest and colonization processes, which in turn have given rise to forced cultural diffusion. For example, for over 1000 years China ruled over what is now Vietnam, which it converted into one of its provinces, thereby leading to the diffusion of Chinese culture to the Vietnamese. Edward Said (1994) offers an interpretation of how Western colonialism was not only a colonization of land but an ideological enterprise of the mental subjugation of indigenous peoples. Benedict Anderson (1991) identified three specific ways of achieving this colonial enterprise: the use of mapping to define the colonial state; the development of museums to provide the historical narrative of the colonial state; and the introduction of population census to survey the
CULTURAL DIFFUSION

extent and character of colonial subjects – all current instruments of modern states.

Religious and spiritual beliefs are pervasive across many communities around the world. These include world religions such as Christianity, Islam, Buddhism, and Hinduism, but also an increasing range of spiritual beliefs such as Wiccanism and esotericism. An explicit form of active cultural diffusion is evident in the proselytizing of religions by missionaries. The spread of religion is often accompanied by the diffusion of religious rituals and taboos such as an absence of pork consumption among Muslims or avoidance of beef by Hindus.

The adoption of public and mass education in nearly every state around the world has led to cultural diffusion in two ways. On the one hand, all state public education attempts to inculcate in students a sense of the “national history and culture.” On the other hand, education has also been responsible for the most enduring diffusion of cultural ideas, from those of science and technology, through the social sciences and humanities.

Despite Huntington’s “clash of civilizations,” which remains anchored in Cold War, East–West polemics, the world is becoming more integrated with new technologies (Huntington 1996). The Jesuit priest Teilhard de Chardin’s idea of noosphere (sphere of knowledge) as the repository of global human knowledge is now becoming a pragmatic reality with cyberspace, through blogs, activity streams, event streams, Wikipedia, Internet, Twitter news streams, knowledge, and ideas for a global community. Larry Sanger, cofounder of Wikipedia, argues that Wikipedia is a new industrial revolution, a product of collaboration and the democratization of knowledge, ideas, innovations, news, and information. Such democratization necessarily relies on the rapid cultural diffusion that is facilitated by the new technologies.

Cultural economy

Andy C. Pratt
City University of London, UK

The cultural industries comprise publishing, film, TV, music, theater in both their recorded and their live forms. There has been a focus on the economic reproduction of these cultural forms and, usually separately, of the artists who feature in them. Less common has been a concern with the various technicians and support staff. Accordingly, a more comprehensive framework has sought to include both the objects and texts, as well as labor: the system of production and reproduction of cultural forms, or a cultural field. With such a dynamic topic there is ongoing disputation of its boundaries and value; this illustrates the relational nature of both the circulation of cultural meaning and its constitution.

There is a range of socially and politically privileged cultures and practices, and others that are merely tolerated or even censored. The role of cultural governance is also important within any institution, and specifically within state institutions. Historically, state support for culture has been legitimated through a welfare economics discourse: that culture was subject to market failure, but society regarded it as a merit good, hence it was supported by the state. Historically, culture in this sense is restricted to immaterial and material cultural heritage and the fine arts. In recent years this state-legitimated culture has been placed in tension with the mainly commercial cultural industries. This tension was the primary concern of Adorno (Horkheimer and Adorno 2002/1947), who coined the term “culture industry” as representing a disparaging negative mirror image of “real” culture. The tensions between the mass-produced and craft, and authenticity and its other, have a resilience in public debate. The old tension between the economic and the cultural has been given new force with the pincer movement of, on the one hand, austerity-driven cuts in state budgets or simply neoliberal small-state initiatives, and, on the other hand, the profitability and economic driving force of some aspects of the cultural field.

Another body of work that has used the term “cultural economy” in recent years is that of cultural, economic, and social geographies of the economy (Amin and Thrift 2004). These are a response to the “cultural turn” in geography and seek to apply the tools of cultural analysis to the object of economic action. It is interesting to note that, thus far, none of these analyses has taken the cultural economy (as outlined in the current entry) as an object of analysis.

Terminology

As noted earlier, the originating term was “culture industry,” an object defined by its negative relationship to real culture. By the 1960s the scope of what was and was not culture had been widened, and French communications scholars sought to deploy a new terminology that would reflect the field as a serious area of research. They
also wanted to point to the differences within the field, so they used the term “cultural industries” (Garnham 2005). This term proved helpful in drawing to attention the expansion of related activities under the “cultural” umbrella, both state-supported and commercial. Recognizing the social and economic importance, and registering its purchase on politics, the cultural industries became a topic of policy concern; however, such concern was separate from the traditional focus on cultural policy. In most cases the cultural industries were the responsibility of business and industry departments, while culture came under the remit of heritage. As the cultural industries climbed the political agenda, there was scope for tension with cultural policymaking.

In 1997 the UK government, initiating a re-focus of its governance of the cultural field, took the bold step of placing both concerns within one department, linked to communications. Similar strategies had been adopted by Australia, Canada, and New Zealand. It focused on the commercial cultural industries by renaming them the “creative industries,” oriented to those industries that generate value through intellectual property rights (DCMS 1998). In political terms, this turn made significant overtures to the “knowledge society.” The notion of the creative industries has often been elided with the discussion of the creative class by Florida (2002), which itself conflates with the notion of the creative city.

In order to avoid the fragmentation of a fast-developing field, academics and policymakers began to use the term “creative economy,” taking “creative” from the identification with the “creative industries,” and “economy” from a pre-seventeenth-century usage as a general management of resources. This latter inflection was important in that it sought to loosen the boundaries between for-profit and not-for-profit and formal and informal that clearly united the field in practice. Countries with a very strong public tradition of public funding for the high arts used the term “cultural and creative industries” as it allowed them to speak of the commercial and the cultural at the same time. The narrowing confines of the “creative” modifier have been a source of concern, potentially focusing in an idealist romantic version of “creativity” and genius, as opposed to the social process of cultural reproduction. Recently, the policy community has adopted the term “cultural economy,” thus avoiding the reduction to “creativity” and foregrounding the socially situated constitution of “culture.”

### Long-term change

How and why has the cultural economy come to such prominence? The concept of the separation of culture from other parts of life rose in prominence in eighteenth-century Europe, with an increasing concern with the perfection or beauty deriving from a deity. Humanism and romanticism were woven into a powerful conception of the artist as author and interpreter of the world. These sensibilities were the basis of decisions about which cultural forms were to be supported and cultivated. That they were not “economic” but “merit” goods (goods that the market would not value correctly) gave the state – if it valued these goods – a justification and obligation to support culture (Throsby 2001). Of course, culture also has an ideological role, which is critical in nation building.

There are two aspects to the transformation of economies in the Northern Hemisphere from an industrial to a postindustrial mode of organization. First, in general, people had more money to spend on consumption and so cultural consumption grew. Moreover, participation
CULTURAL ECONOMY

in higher education and extended years of compulsory education created a new consumer power: the teenager. Second, the balance of the economy has shifted to the postindustrial—or service—sector, termed the “knowledge economy.” It has been claimed that the creative, or cultural, economy is at the breaking edge of this new wave of economic change. Such a dual rationale places the cultural economy in a conceptually strategic position to lead growth.

Empirical measures of the cultural economy have since the mid-2000s showed that such anticipated transformation and growth are already a reality (UNCTAD 2010). The growth rates of employment, gross value added (GVA), and trade in the cultural economy have outstripped most other sectors; moreover, they have maintained positive growth through the recession. In distributional terms, much of this growth is concentrated in major cities (highlighting a quite different dimension to the instrumental and consumption-based creative cities agenda); indeed in many Northern cities the cultural economy is in the top five industries. While cultural employment and trade are concentrated in the Global North, rates of growth are higher in the Global South, indicating that the cultural economy is of growing international significance.

Concepts and measures

The notion of the cultural economy is a contested one, and steps to find reliable measures have been hard-won. There is a simple reason. The analytical and statistical framework that constitutes our understanding of the economy is founded (taxonomically) on an early twentieth-century snapshot. Many high-growth and transformative industries of the late twentieth and twenty-first centuries did not exist previously, or were so small as not to be considered worth a taxonomic category. The industries that had grown out of others, such as chemicals, engineering, and pharmaceuticals, were captured by incremental change and the modification of taxonomies. Others, the ones that were not “industries” (such as public cultural forms, orchestras, theaters, etc.) were not recorded or were bundled up with other activities that did not fit the taxonomies. Economically speaking, this was not of great concern, as they were merit, or nonmarket, goods that were not expected to enter into the price system. Of course, as such divisions have dissolved, state bodies have struggled to keep apart the cultural sector and the creative industries, administratively, as they were governed under different logics (indeed, in Adorno’s initial conception, the two categories are corrosive of one another and hence must be separate). So, gross activity in the economy may be measured, but any attempt to find out how many are involved in the computer games industry would draw a blank. As indicated previously, around the end of the twentieth century a number of countries began to experiment with measures for (what they believed to be) a growing cultural economy. The United Kingdom coined the term “creative industries” and included a list of 13 industries selected on the basis of pragmatism (i.e., that they could measure) rather than a rigorous attempt to delimit the field (Box 1). However imperfect it was, the DCMS (1998) “mapping document” proved to be a much replicated template.

National statisticians like good time series, and are wary of making changes to taxonomies lest the time series be broken. The emergence of a new “industry” thus presents a problem. Accordingly, a compromise was adopted: simply, the method was to go back to the basic statistical
Box 1 The DCMS’s 13 creative industries.

The DCMS introduced the notion of the *creative industries* in 1998 defined as “those industries which have their origin in individual creativity, skill and talent and which have a potential for wealth and job creation through the generation and exploitation of intellectual property.”

Taxonomies for industries and occupations at their most disaggregated and then to reconstruct an artificial new taxonomy that included all the activities of the cultural economy. Normally employment statistics on the economy show a breakdown at a one- or two-digit level. The one digit gives descriptors such as agriculture, mining, and manufacture. The two digit gives types of industries, for example car-making, chemicals. The job of taxonomic reconstruction involves going to the four- or five-digit level analyses. When the new “codes” are combined, data can be associated with them to construct a “creative economy” category. Two measures are commonly used: those of employment and of economic output. Researchers have approached the employment measures in three ways: an analysis based on occupations (Markusen et al. 2008) or one based on industry (Pratt 1997), or a combination of the two systems. Clearly, this is not an ideal state of affairs, but, until the whole international statistical taxonomic system is revised, a satisfactory historical record cannot be constructed. Measures of cultural trade are even more problematic. Trade is normally measured in weight, and trade in “invisibles” is underrecorded (UNCTAD 2010). Therefore, although much effort has been put into this task, it significantly underrecords the economic value of culture (let alone the noneconomic value).

The logic for selecting particular occupation or employment categories and excluding others has been the subject of considerable debate; however, work from a conceptual foundation has provided a more comprehensive underpinning for future taxonomies and mapping exercises. In general, the difference between these approaches is that the occupational and opportunistic approaches rest on a quasi-romantic conception of “pure” culture/creativity which, like a ripple in a pond, becomes less and less creative or cultural until one reaches the rest of the economy (Throsby 2001). Such a model places artists at the core and technicians on the periphery. There is also no principle as to where to draw the line between culture or creativity and the rest of the economy. An alternative approach takes the notion of a production system that describes the set of activities and skills necessary to produce a given cultural output. Here there is the concept of a codependency of multiple

processes on a final product, what we normally understand by an industry (Pratt 1997). It is this latter approach that underpins the UNESCO (2009) framework for cultural statistics. This approach has advantages in that it is neutral as to whether the activity is state- or privately funded, high or low culture: it captures comprehensive processes. These approaches have yielded insightful geographical analysis that foregrounds the flows of people and ideas in the construction of cultural value (see Figure 1).

Organization

The analytical challenges of the cultural economy do not end with the collection of quantitative data; qualitative dimensions present additional problems. As noted earlier, the immaterial aspects and the novel (not previously measured) highlight the cultural economy’s outputs, with differentiations based on causal processes rather than appearance or social value systems. From a normative perspective, industries of the cultural economy appear chaotic, or at least quite different. Such criticisms are sometimes used to reinforce popular prejudices about the economic utility of culture, the management abilities of artists, and the “inefficiencies” of the state-subsidized sector. Extensive and detailed analyses of the industries of the cultural economy are relatively new; however, they indicate a variety of novel organizational modes, and disclose rationalities that are not always anticipated by normative approaches. These organizational forms show five common characteristics.

First, the organizational structure of the cultural economy has been characterized as one with a “missing middle,” meaning that mid-sized organizations are underrepresented and small and microenterprises overrepresented. This depiction creates an organizational problem, one that can be solved broadly in two ways: internalize all activities in a larger corporation, or hope for intermediaries to emerge. This echoes a trend of outsourcing that has characterized much of the economy; it has been argued that the cultural economy was a leader in such changes: post-Fordist avant la lettre. Currently the cultural economy is characterized by many freelance and self-employed people, by those in microenterprises (smaller than small), and by a small number of transnational corporations. The articulation of the two organizational forms generates both risk and opportunity.

The second is project working. Smaller enterprises that are able to mediate are formed as short-term projects. These are temporary groupings (firms) of workers and microenterprises to deliver a project (such as a film or a TV series). At the end of the project, the team disperses. The advantages of this form are that unique skill combinations can be managed at short notice. The disadvantages are that workers are in a constant state of impermanence. Such short-termism militates against training and knowledge transfer within organizations. It often
CULTURAL ECONOMY

means that learning, training, and knowledge transfer happen between or outside companies in what has been termed the wider ecosystem of the cultural economy.

The third characteristic is risk. The risk of not having a sustainable job, which is a consequence of project working, is amplified by the nature of the cultural market place. In all markets some products succeed and others fail, but the spikiness is notorious in the cultural economy; it produces a phenomenon that has been termed “winner takes all” markets. Moreover, the uncertainty as to which product will win in the market is extreme. It is a commonly cited rule that the ratio of success to failure is 1:10. The only way to hope to survive the law of averages is to produce at least 10 potentially winning products; if one is fortunate a single product out of the 10 will succeed. This may sound extreme, but it is common in other high-risk industries such as financial services, where it is termed portfolio management.

The fourth is turnover. One of the reasons that stakes are so high is that cultural value is hard to predict and changes quickly. So, even if a product is successful, it may be superseded by another in a short space of time. This places significant pressure on companies to be innovative. While a car company may introduce a new model every two years, clothing fashions change by the month. In an indication of the speeding up of turnover, fashion used to have a seasonal turnover; fast fashion seeks to have a constant renewal. The prime example is the music company, which releases many songs a week, and those that are hits may be so for only a week.

The fifth is boundary spanning. Cultural innovation happens in all parts of the economy and society; some are planned but others are not. Cultural practices take place in the formal and informal economy; the public and private; and in both for-profit and not-for-profit realms. Cultural practitioners tend to work across these boundaries in part in order to put together jobs that may constitute a sustainable strategy; but also to gain new experiences and skills. The mobility of cultural workers can be an embodied form of knowledge transfer; however, it can be sustained only within a cultural ecosystem.

Work

Work is an important theme in research on the cultural economy, and represents the move away from the idealization of culture and artists that commonly precluded them from the lens of cultural analysis. First, the organization of cultural work exhibits a complex ecosystem of firms (commonly with 1–10 workers) and freelance workers, organized around short-term projects. Second, this temporary work engagement leads to precarious employment conditions for most, and the reconception of what a career is. Third, cultural labor includes physical tasks and mental labor, but is to some extent driven by a passion for a particular cultural practice. For some commentators, this raises new issues of “immaterial labor” and to what extent the “self” is sold or is over- and self-exploited. Fourth, and related, is the interest in affective labor and the presentation of self in cultural work. As noted, this affective turn characterizes the cultural economy for many geographers.

Place/space

In the analog age, culture and expression were commonly associated with the places in which they were practiced as if the soil itself gave rise to culture. This tendency was countered by “high” or transcendent culture, which was “out of place.” While craft production and the
limited distribution of cultural goods or service took place, they were not economically significant (except in the trade of goods comprising high-value components, e.g., jewelry). With the mass reproduction of cultural goods huge returns to scale, and in many cases monopolistic market forms, were possible: music, broadcasting, newspapers, and film are all good examples. Cultural production is reliant on large markets, and therefore global cities are popular. Moreover, the association with power and taste-making means that curatorial and fashion trends are found in cities.

It was expected by many that digitization would free producers, especially cultural producers (who were the archetypical symbolic analysts), from the constraints of place, as their work could be done anywhere. The “death-of-distance” hypothesis was much discussed, but geographers discovered in practice that digital producers like to be in close proximity, even though they did not need to be, in terms of the physical transfer of goods (Pratt 2000). As has been suggested, a well-populated and diverse cultural ecosystem is valued by the cultural industries and their workers; moreover, these ecosystems are rooted (but not exclusively located) in places. Cultural industry clusters have increasingly been a topic of analysis of economic geographers concerned with networking and knowledge exchange (Bathelt and Gluckler 2011). The attraction to place is associated with the social and economic reproduction of labor (people have to live and work in a place), but also with the local cultural discussions. Significantly, a taste community is a valuable asset in minimizing risk regarding new products. Quite simply, the notion of a “scene,” which is a community of practice and a social institution, has led to the clustering of cultural producers in cities, often within one or two streets, a hypercluster. Such clusters are stereotypically urban in the sense that the agora of the city, the in-betweenness, is the material and social manifestation of the ecosystem.

The cultural economy has a distinct geography, one that is clustered in cities and in the Global North. The reason for the North/South division is not cultural; rather, it is the global organization of cultural production that is dominated (but not exclusively) by major corporations based in the North which control intellectual property rights. Thus culture has some similarities to global commodity chains, which span the globe but filter control and value added to a small number of actors. It is particularly challenging in the South that colonial and imperial trade and distribution systems provided a first-mover advantage for the North – one that is echoed by the expertise in intellectual property control. These legal issues (access to markets and protection of property) are a significant challenge today.

Governance

Since the mid-1990s, the issue of governance of the cultural economy has grown in economic as well as social and cultural significance, and the modalities of its exercise have become more complex. Previously, the field was occupied by cultural policy and the regulation of culture. The former was usually associated with the public provision of merit goods, or the conservation of heritage, a function that is now increasingly associated with tourism and with national identity. Regulation was exercised through the control of monopolies (economic and of communication) and censorship.

In the 1990s, an instrumentalization of culture took place in many jurisdictions. Culture was mobilized to fulfill social and economic ends, examples of which range from improved mental health to community cohesion to urban regeneration. Previous iterations of cultural policy were
instrumental in terms of nation-state politics and cohesion, but this new wave explicitly used culture for specific ends. The objective was not cultural excellence or even participation; these objectives were held by core cultural policy. Governments lost faith in the justification of art for art’s sake or for the public good, and instead justified it by their other contributions. In this sense, “creative city” policies sought to achieve instrumental aims (Florida 2002) with what they hoped would be politically popular means. As many examples have shown, the investment in opera houses and art galleries to attract foreign direct investment did not benefit the whole population, especially the poor.

In the 2000s debate began about how policy could address the intrinsic value of the cultural economy in either its economic or its cultural value dimension, that is, create jobs in the cultural economy and supporting businesses and/or those sustaining local cultural value systems and communities of practice. The how of this new governance continues to be a challenge for the reasons set out earlier in terms of information about the sector and an understanding of its organization and processes. The emergent concerns are threefold: how to support and sustain cultural intermediaries; how to achieve local capacity building (education, training, archiving, and institution building); and how to gain foresight and information so that practitioners and policymakers can develop and manage strategy. Alongside these new approaches, however, more traditional instrumental approaches still obtain: regulation of monopolies; use of cultural attractions to facilitate foreign direct investment in financial services; and traditional public good policies.

The Great Recession of 2008 which impacted Europe and North America particularly was used by most governments to justify further cuts in public expenditure; these hit the cultural sector, already under pressure, with full force. Thus, in terms of finance and justification, the mid-twentieth-century settlement on culture as a public good managed by welfarist state economic logic has more or less ended. In its place is a complex pattern of governance of the cultural field, a field that has grown significantly and that has, in some cases, become a major player in local economies. The challenge to understand this delicate balance of relationships that constitute cultural ecosystems will continue to be an important field for social scientific research.

Further reading

Marked by several distinct theoretical and methodological positions, cultural geography is often recognized as one of the most vibrant as well as contested subfields in human geography. Indeed, it is not an overstatement to say that cultural geography, with its widespread popularity, has frequently been accorded equal footing with human geography as a whole. That cultural geography has come to represent human geography in its entirety should come as no surprise, especially in the eyes of nonacademic audiences who tend to equate the study of human geography with learning about geographically differentiated and often exotic cultural traits. Such close alignment between cultural and human geography is also evident in titles of popular textbooks that often place “human” and “cultural” geography side by side. Even cognate subfields such as social geography are sometimes seen to be subsumed within cultural geography as their research agenda and theoretical approaches become increasingly indistinguishable to the point that the two sub-disciplines are often referred to conjointly as “social-cultural” geography.

Yet it is also interesting to note that there is no single and unequivocal definition of “cultural geography,” so much so that its flagship journal (formerly *Ecumene*) was suitably renamed *Cultural Geographies* in the plural to reflect the diversity and polyvocal nature of the subfield. There are also multiple competing views on what is deemed appropriate for the study of cultural geography in terms of its scope and method of inquiry. In fact, cultural geography means quite different things to different people depending on their specific encounters and subdisciplinary convergences (Longhurst 2007). From postcolonial and ethnic studies to research on feminism and the consumption of popular cultures and new media, cultural geography has left its imprint on both theoretical and methodological debates. It is thus not an exaggeration to say that the intellectual reach of cultural geography has clearly gone beyond human geography per se and has indeed crossed over to the academic terrains of a wide range of disciplines in the social sciences and humanities.

Notwithstanding its vibrant diversity, it will be surprising to many that the subfield has recently been said to be undergoing something of an intellectual crisis, with skeptics readily pointing to the growing disenchantment with the contemporary relevance and value of cultural geography for the wider society. Indeed, contemporary cultural geography has often been criticized for being too fragmented and diffused, while for others it is derided for being narrowly microscopic and “navel-gazing” in its orientation. Whether justified or not, such critiques actually reflect the inherent ideological tensions and schisms between what might be termed “old” versus “new” cultural geographies (more on this later). Arguably, the fragmented and diffused nature of the subfield has also been seen by some practitioners as having forestalled the potential development and contribution of cultural geography at the turn of the century. Not
least, for Jane Jacobs (2006, 1), the unfulfilled promise of cultural geography has led her to question its continued existence. As she notes:

A mere decade ago cultural geography was seen as an analytical frame that could promise not only a productive, but also a necessary, reshaping of geographical scholarship. Now it seems we can’t decide if we want this subfield to be dead or alive!

If indeed cultural geography is undergoing an existential crisis and disciplinary anxiety (Nash 2002), part of the problem may be traced back to the vexed old question of what constitutes “culture” and what work culture accomplishes. As Don Mitchell (2000) has usefully pointed out, we need first to understand what culture is and what it isn’t, or if it even exists in the first place! Beyond challenging the ontological presupposition and the often taken-for-granted view of culture, we need to unpack the conceptual black box of culture to examine “how what gets called culture is itself socially constructed through all manners of contests and cooperations over the materials – places, jobs, pictures, foods, art, histories, ethnicities, sexualities, etc. – that make up our lives” (Mitchell 2000, 12).

Revisiting the question of culture

Often said to be one of the most complicated words to define in the English language, the notion of culture has been keenly debated by geographers and cultural theorists alike. From Clifford Geertz to Raymond Williams, culture has been given various intellectual interpretations from the purely idealist and phenomenological to the staunchly materialist. Taken at face value, culture is often used to represent a whole litany of ideas and behavioral traits, and may refer to many things including cultural beliefs, value systems, lifestyle practices, and even material artifacts. In more popular conceptions, culture can be used to signify “high culture” expressed through the fine arts that are consumed by the upper class, but it also has a more democratic notion that refers to the quotidian way of life of ordinary groups of people. In fact, it is not overstating the case to say that the definition of culture can be an intellectual muddle and can indeed mean all things to all people.

Nonetheless, cultural geographers have attempted to come to terms with the complex usage of the concept of culture by providing a working definition that is appropriate for the study of cultural geography. Several thematic distinctions have been invoked to describe culture as the spatial distribution of things, as a way of life, as symbolic meaning, as a form of practice, and also as the manifestation of power relations. More importantly for cultural geographers, the fundamental concern is how we think “spatially about culture” while also thinking “culturally about spaces” (Anderson et al. 2003).

Despite the myriad ways that culture has been defined and used, cultural geographers have all underscored the importance of “taking culture seriously” in geographical analysis. At the same time, some geographers have also warned against using “culture” too loosely or simply treating it as a shorthand for describing place specificities and cultural variations seen on the ground. Undeniably, the call to put culture at the forefront of intellectual or geographical enquiry has also precipitated the rise of the “cultural turn” in human geography and the social sciences and humanities more broadly. To the extent that culture is now everywhere (and yet nowhere), the cultural turn has attracted both supporters and detractors. In particular, it has been argued by many scholars that, with the permeation of the cultural agenda into practically every sphere of research and
everyday life, cultural geography as a subfield has been hollowed out and has become something of an empty signifier for *all things cultural*. To put it more bluntly, it may be said that cultural analysis and the mobilization of “culture” as the unit of analysis can no longer be the preserve of cultural geographers alone given that everyone now has a stake in culture as a *researchable* object.

If cultural geographers have no proprietary claim over the use of the concept of culture, and given its diffused and fragmented nature, the corollary to this assertion is what distinct contributions cultural geography can offer as a unique subdiscipline. More pointedly, can cultural geography as an academic enterprise stand on its own? Rather than being consumed by attempts to (re)claim the concept of culture, or even attempt to provide an unequivocal definition of culture or cultural geography, it may be more fruitful to focus on the diverse practices of doing cultural geography on the ground. After all, as Shurmer-Smith (2002, 3) argues compellingly, “culture is practiced and not owned” and we should think of it as “adverbial” – that is, “what people do, not what they have, and they keep doing different things in different ways, with different other people all of the time.”

We can perhaps make an epistemological distinction here between culture as a practical idea as opposed to its being a static category of analysis. This distinction is an important one especially when the meaning of culture is so protean and polymorphous that it makes little sense to try to pin it down in a definitive and substantive manner. To the extent that culture can be seen as a practical category or a conceptual toolkit that can be mobilized to work on a number of different geographical problems and issues, it is timely to review the different approaches and methods that have been deployed over the years. Before proceeding further, it is important to qualify at the outset that these different approaches should not be seen as radical breaks or as moving in a linear trajectory but as coevolving. It should also be noted that, while it is often difficult to neatly divide the contemporary development of cultural geography according to distinct chronological time frames, a historiographic narrative is nevertheless useful to provide some broad sketches of the evolution of the subfield since the twentieth century. And, as with any historiographic accounts, they constitute the collective memories (however contested) and self-scripted narratives that together help to shape the evolving identities of the subdiscipline.

### Cultural geography in action: paradigm shifts and turns

Contemporary cultural geography in the anglophone academic world traces its origin to Carl Sauer and the Berkeley School. Similar to the Vidalian tradition of the French regional studies, a key intellectual hallmark of the Berkeley School was its strong advocacy for an interdisciplinary perspective that combines insights from anthropology, history, and natural science, as well as a general disdain for positivistic social science. With an emphasis on cultural ecology and humans’ role in transforming the physical environment, Sauer’s Berkeley School sought to bring culture squarely into the agenda of geography’s intellectual project and also to provide a corrective to the prevailing paradigm of environmental determinism that was dominant in the early part of the twentieth century. If there is an emblematic work that represents the Berkeley School, it has to be Sauer’s landmark publication “The Morphology of Landscape,” in which he argues for the study of cultural landscape as an entity that is forged from a natural landscape by a culture group (Sauer
CULTURAL GEOGRAPHY

For Sauer, the agency of culture is often imprinted on land which acts as the natural medium; the resultant "cultural landscape" is often thought to be the end product that bears testament to the agentic forces of culture acting on a natural area.

Insofar as the Berkeley School of cultural geography shares several similarities with the French regional school (although Sauer himself was influenced more by the German intellectual tradition, especially the works of Herder and Hettner), the Sauerian-inspired approach has also been criticized for its analytical fixation on empirically oriented studies that focus on historical material artifacts and a tendency to reify the cultures of dominant groups. By the late twentieth century, however, what is deemed the traditional Berkeley School of cultural geography was roundly challenged by an emerging group of "new" cultural geographers led by geographers such as Peter Jackson, Denis Cosgrove, and James Duncan. Expressing dissatisfaction with the conservative conception of culture as representing the values of dominant groups in society, proponents of the new cultural geography were vociferous in their attack on Sauer's alleged treatment of culture as a "superorganic" entity, among many other objections. Unlike Sauer, whose main concern was to discover (in a more formal sense) the culture of particular social groups in the form of their unique customs, arts, antiquarian lifestyle, and so on, the new cultural geographers were more concerned with how culture is implicated in struggles over social differences such as class, ethnicity or "race," and gender. To the extent that the Berkeley School is often criticized for its static mapping of cultural artifacts, the new cultural geography may be described as a self-conscious response to the upwelling of cultural politics within contemporary social life in many globalized Western cities that have witnessed the surge in diverse population groups marked by class, gender, and ethnic differences.

If Carl Sauer's (1925) "The Morphology of Landscape" sought to place the role of human culture at the forefront of (cultural) geography's intellectual project, Peter Jackson's (1987) Maps of Meaning represents an attempt to revitalize cultural geography and to retheorize the field. At the core of the new cultural geography is an attempt to displace the traditional (Sauerian) "unitary view of Culture" in favor of "a plurality of cultures, each of which is time- and place-specific" (Cosgrove and Jackson 1987, 99). The new cultural geography argues for a new spatial constitution of culture which is best encapsulated in the following programmatic statement: "Culture is not a residual category, the surface variation left unaccounted for by more powerful economic analyses; it is the very medium through which social change is experienced, contested and constituted" (Cosgrove and Jackson 1987, 95).

In tandem with the retheorizing of culture as such, the idea of cultural landscape has also been reworked to recognize it as "a sophisticated cultural construction: a particular way of composing, structuring and giving meaning to an external world whose history has to be understood in relation to the material appropriation of land" (Cosgrove and Jackson 1987, 96). In a nutshell, the cultural ecology of landscape and human–environment interaction soon gave way to ideas on the contested representation and symbolic meaning of landscapes that soon became the new buzzwords in cultural geography.

It is equally important to point out that the critiques leveled at the Berkeley School are highly partial, resting on the selective targeting and oversimplified reading of certain programmatic statements while ignoring the broader remit and influence of the Berkeley School. The challenges of new cultural geography in many
ways point to the ideological clashes between Sauer and Jackson. As Olwig (2010, 177) noted: “Sauer and Jackson were like oil and water, they didn’t mix, and this, unfortunately worked to polarize cultural geography.”

To the extent that such “orthodox” narratives that pit “traditional” against “new” cultural geography have become almost the hegemonic account of the subdiscipline, we risk ignoring other significant parallel developments in the field. Since the 1970s, humanism as a philosophy had also found its way to a receptive pool of audience among human and cultural geographers who were disenchanted with the economic determinism and dehumanizing logic of the “quantitative revolution” which was steadily gaining ground during that time. For these groups of scholars, the humanistic movement is seen to both endorse as well as challenge existing paradigms in cultural geography. While the humanistic approach is critically aligned with the new cultural geography in that they both reject the superorganic conception of culture in favor of the view of culture as actively constructed by individuals, historically inflected forms of humanistic scholarship were, at the same time, also seen as compatible with the more traditional forms of cultural geography with its focus on antiquarian cultures and civilization histories and origins. In particular, humanism, broadly speaking, has provided cultural geography with the academic license to place the study of people at center stage, with an emphasis on their distinctively human agency, meanings, values, and purposes.

If humanism has laid the important foundations for a revitalized cultural geography, cognate humanist philosophies such as idealism, phenomenology, existentialism, and pragmatism have further animated cultural and humanistic geographical research, giving rise to themes such as “sense of place” (Tuan 1977) and “lifeworld” (Buttimer 1976) and at the same time injected new epistemological as well as methodological innovations through studies on landscape iconography, mental maps, environmental perception, and everyday geographies. It may be observed that a key idea driving humanistic research for many cultural geographers is how diverse human experiences and conditions are being shaped by the spaces that people inhabit, and in turn how humans transform the geographical world through various place-making endeavors.

It must, however, be noted that, despite the close association between humanist geographers such as Yi-Fu Tuan with the Berkeley tradition, humanistic work, strictly speaking, did not set out to reform cultural geography at the outset. As is often pointed out, both humanistic and cultural geography could be said to be united in their response to a common ideological adversary—quantitative spatial analysis in the 1960s and 1970s.

Nonetheless, if humanism provided the much needed intellectual booster for cultural geography on both sides of the Atlantic by the 1980s, the Marxist critical approach also served to further invigorate and “radicalize” cultural geography. As is laid bare in his “call-to-arms” manifesto “Towards a Radical Cultural Geography,” Cosgrove (1983, 1) averred that “Both Marxism and cultural geography commence at the same ontological point.” Arguing for a synthesis between Marxist theory and cultural geography, Cosgrove drew on the works of Raymond Williams and E.P. Thompson among others to push for a rapprochement between historical materialism and cultural analysis. Applying such historical materialist understanding to cultural concepts such as landscape, Cosgrove (1984, 2), in his book *Social Formation and Symbolic Landscape*, further argued that

the landscape idea does not emerge unprompted from the minds of the individuals or human
CULTURAL GEOGRAPHY

groups ... historically and theoretically it is unsatisfactory to treat the landscape way of seeing in a vacuum outside the context of a real historical world of productive human relations.

Needless to say, Cosgrove was not alone in this endeavor, given that David Harvey had earlier argued for culture to be understood as inseparable from capital production and circulation itself. While it does not reduce culture wholly to the circulation of capital, a radical cultural geography approach takes on the uneasy relationship between culture and economy by questioning how culture is spatially produced and whose interests and benefits it represents. Eschewing a totalizing “cultural explanation” for a more concretely political economic approach, Marxist cultural geographers stress that cultural analysis is best operationalized by foregrounding the unequal social structures that shape the production of meanings in social life. To put it more starkly, “culture is politics by another name” (Mitchell 2000, 294).

A whole generation of critically minded cultural geographers responded to the call to radicalize cultural geography by embarking on various projects that interrogate the structural imperatives and power relations behind the production of spectacular landscape and the urban built environment. From schools, religious institutions, ethnic enclaves, iconic skyscrapers, to shopping malls, power politics and “culture wars” are read into the production of these “landscapes of power” (although it has to be noted that few of these works are strictly Marxist in orientation). In other words, radical cultural geography went beyond a strictly Marxist mandate to engage more broadly with critical cultural studies that drew inspiration from neo-Marxist social theories such as those emerging from the Frankfurt School. Revisiting the work of Theodor Adorno and Max Horkheimer, many cultural geographers also critically examined the roles of the cultural industries and commodities in contemporary society, which are seen as bearers of cultural codes that mediate the production and consumption of everyday life. On the latter, researchers have stressed that cultural resistance is as much a part of everyday life and that people are not “passive dupes” who uncritically internalize the hegemonic meanings encoded in the landscape. A typical research strategy with such an approach is to uncover how ideologically charged landscapes are being read, decoded, and appropriated or even subverted by the masses. Searching for “slippages” and “contradictions” in the landscapes became the dominant leitmotifs that characterized the research agenda of cultural geography in the 1990s, although it should be pointed out that “geographies of resistance” rarely ever correspond neatly to “geographies of domination,” and vice versa.

If there is a concept that distinguished the new cultural geography from its predecessors, the idea of landscape as text is a strong contender. In both epistemological and methodological terms, the textual metaphor of the landscape, developed with insight from poststructural linguistic and literary theories, cannot be more different from that of the Berkeley School. Whereas landscape in the traditional sense was often seen as reflecting the cultures of social groups which could be readily apprehended through empirical observation, the “textual turn” saw landscape itself as constitutive of culture through a signifying system that helps to reproduce power relations in society. The latter suggests that different textual communities are at work to mobilize their own readings and interpretations of the landscape or text, and that struggles over different textual interpretations can have real material consequences (see Duncan 1990). Notably, the notion of landscape as text not only opened a novel perspective to landscape studies that combines Marxist cultural materialism with different ways of seeing,
but it also provided a common vocabulary for cultural geographers, literary theorists, and others to engage in critical discursive analysis of landscape representation and cultural politics.

Another observation that could be made about the new cultural geography was the shift in empirical focus from farms and villages to cities and urban places. Arguably, if traditional cultural geography has an unmistakably rural bias, then the new cultural geography from the late 1980s onward has become urbanized, with much of the research output dedicated to the interrogation of urban cultural politics. This period also coincided with the rise of entrepreneurial urban regimes in many Anglo-American cities that provided fodder for research, with topics ranging from urban place marketing to the interrogation of urban cultural politics. This period also coincided with the rise of entrepreneurial urban regimes in many Anglo-American cities that provided fodder for research, with topics ranging from urban place marketing to the contested cultural and spatial logic of postindustrial cities.

Beyond urban cultural politics, another strand of critical cultural geography work has been the focus on the “hidden” labor that goes into the production of landscape and commodities. Don Mitchell (2003), for example, in his penetrating analysis of the political economy of California’s agricultural landscape, argues that the bucolic scenery of the rolling fields and strawberry farms is sustained by the “dead labor” that is embodied in the production of commodities such as the strawberry, as well as the spatial injustices that (re)produce both the visible and the hidden landscapes around us. Fundamentally, both the real and the symbolic meanings of the landscape are seen as a function of who has the power to represent that landscape.

Since the 1980s, interdisciplinary inspiration from a wide range of thinkers such as Michel Foucault, Michel de Certeau, Bruno Latour, as well as Gilles Deleuze and Felix Guattari, have provided cultural geographical scholarship with a further “radical turn” through the postmodern challenge. Responding to the challenges of postmodernism requires cultural geographers to problematize the use of discrete and bounded ideas such as cultural hearths, landscapes, or regions and to attempt to deconstruct these taken-for-granted spatial concepts by interrogating their internal diversity and heterogeneities. Such a radical turn in postmodernizing cultural geography also extends to demanding a new attitude and sensibility toward multiple forms of otherness, including marginalized social groups and communities based on ethnic minority status, sexual deviance, or disabilities, as well as disenfranchised groups of working-class, urban poor, migrant workers and also women, elderly people, and young children. Collectively, these diverse groups of people are often absent in research programs or are seen as a lesser counterpart to the dominant white middle-class heteronormative (Western) society that frames academic discourse and analysis.

In other words, if new cultural geography sought to displace the uniform view of culture of dominant groups, the postmodern turn went further to give voices to diverse subaltern groups, including feminists, those who are disabled, ethnic minorities, postcolonial subjects, and to entrench cultural politics at the forefront of cultural geography’s research agenda. Indeed, the “politicization” of new cultural geography has practically become a quintessential feature in almost every research program spanning the period. What unites such critically informed cultural geography research seems to be the commitment to the rather formulaic conception that cultural politics is ubiquitous since nothing is politically neutral, and that the cultural landscape we inhabit must necessarily reflect and manifest the contestation of cultures even in the most mundane and unremarkable of settings such as the home, school, workplace, shopping mall, theme park, and so on.

Nonetheless, while the new cultural geography, with its postmodern critical inflections, had
CULTURAL GEOGRAPHY

become academically fashionable by the end of the twentieth century, its novelty soon wore out and before long even new cultural geography itself had fallen out of fashion and ceased to function as anything more than a convenient descriptor for demarcating what was seen as the “old” and the “new,” or as merely a marketing tagline for academic publishers. While criticism and misgivings over new cultural geography have been well documented, it is worth pointing out that a major disgruntlement lies with an overemphasis on the politics of representation. Many cultural geographers, for example, were concerned that the knowledge generated in cultural analysis is no longer capable of doing anything productive apart from just dabbling with the discursive politics of representation. To put it more bluntly, as Neil Smith (2000, 27) charged: “cultural geography, perhaps human geography in general, has downgraded the importance of fieldwork and has too often come to think of empirical research as a question of perusing texts – magazines, adverts, movies, landscapes – for representations of this or that.”

For the harshest critics, the whole enterprise of cultural geography in the 1980s and its revival was largely built on an intellectually stultifying preoccupation with the politics of representation that valorizes the symbolic and rhetorical at the expense of actual practice and expressive life.

In response to what has been termed the “death of representation,” a body of work rallying around “non-representational geographies” (Thrift 1996) has emerged to place the multisensory practices and experiences of the everyday life at the forefront of geographical analysis over its abstract representation. For this group of scholars, new cultural geography and the cultural turn is seen as overly theoretical, contemplative, and even too culturalist. Indeed, if traditional cultural geography was criticized for its super-organic conception of culture, new cultural geography is similarly seen as locked in a totalizing view of culture and its endless representation.

Nonrepresentational scholars, instead of representing the world through abstract language and theories, make a conscious and deliberate attempt to focus on the performative aspects of the multisensuous corporeal world that is lived and experienced through bodily spatial practices. Strategically speaking, focusing on the creative and performative aspects of cultural geography has also been a way to elevate the relatively low public profile of the subdiscipline as it begins to make inroads into more popular public art forms such as photography, videos, dance, and creative writing. All in all, more-than-representational scholarship may be characterized as an approach to the study of the “restless” cultural world, which is primarily concerned with meanings that are produced and enacted through mobile activities (walking, dancing, climbing, cycling, driving, etc.). In essence, movement and the mobile structuring of everyday life are seen as the core of what constitutes being purposive human agents.

Another contribution of the more-than-representation work has been to draw attention to the “mobility turn” and the “new mobilities paradigm.” While geographers have always been interested in the study of people and things on the move, new mobilities studies see mobility as more than just an empirically observable brute fact out there, (i.e., the movement from point to point) – as an embodied spatial practice that is socially produced and conveyed through a diverse array of representational strategies that endow it with social-political meanings (Cresswell 2006). In particular, the new mobilities paradigm makes the case for paying close attention to the bodily practices and performance of mobility, and makes mobile embodied practices central to how cultural geographers study and experience the world. Mobile practices such as walking,
running, and flying, and the spaces they traverse, are often inflected by complex geographies and histories, and are seen as embroiled in a whole range of processes from political-economic to cultural and ethical concerns. By highlighting the diverse variety of mobile experiences that characterize a world in motion, the new mobilities paradigm can also be credited with building connections between cultural geography and other subdisciplines such as in transport studies, as well as tourism and migration research.

Insofar as nonrepresentational theory has shone a spotlight on mobile spatial practices and the materiality of social life, Sarah Whatmore (2006) further argues for cultural geography’s “materialist recuperation” and calls on geographers to attend to the more-than-human geographies we inhabit. This entails several analytical shifts that redirect our mode of inquiry from discourse to practice, from meaning to affect, from the politics of identity to the politics of knowledge (Whatmore 2006, 603–604). But, more importantly, the more-than-human call challenges geographers to venture beyond the indifferent stuff of a world “out there” and to signal a return to the “livingness of the world” that is articulated through the corporeality and materiality of the human existence. To be sure, while this commitment to a more-than-human cultural geography has been to steer away from a purely anthropocentric position, it does not exclude humans at the same time and instead views humans/animals and technological devices as agents provocateurs in the “co-fabrication of the socio-material worlds” (Whatmore 2006, 604).

Beyond the purely anthropocentric concerns, the more-than-human approach also resonates with Wolch, Emel, and Wilbert’s (2003) call to “reanimate cultural geography” by bringing the “animal question” back to the forefront of geographical research agenda. This is not entirely a new research endeavor given that human–environment and human–animal interaction has long intellectual roots in geography from pre-Darwinian zoogeography to Carl Sauer’s pioneering work on the role of animal domestication and the evolution of cultural landscapes, to Yi-Fu Tuan’s study of the dominance and affection that underscores the power relationship in pet-keeping. Drawing inspiration from social theory and responding to new cultural geography, contemporary study of animal geographies departs from earlier approaches by radically reconceptualizing culture, nature, and animal subjectivity as well as having a strong commitment to environmental ethics and the role of animals in the moral landscape.

In tandem with the focus on embodied practices and materiality, cultural geographers have also called attention to the role of affect and emotion in mediating the spatiality and temporality of everyday life. Beseeching geographers to pay greater attention to how the geographical world is at once being constructed and experienced through human emotions of pain, anger, happiness, feelings of affection, and so on, Anderson and Smith (2001) have led the call for an “emotional turn” in geography that recognizes the complex range of human emotions and sensations (anger, grief, happiness, affection, etc.) as important and valid ways of knowing, being, and constructing the geographical world; however, the apparent lack of attention to emotions by cultural geographers needs to be qualified. After all, the geographical literature is already replete with emotionally laden concepts such as sense of place, topophilia, or place alienation. Nevertheless, it is true that, at least on the surface, the discipline of geography as it has been represented historically tended to be portrayed as a rational and emotionally detached science that eschews any unquantifiable objects of analysis such as the human emotions. In many respects, such a scientific view of the geographical academic
CULTURAL GEOGRAPHY

discipline is largely a product of the Western Enlightenment tradition, rooted in Cartesian and Stoic philosophies that are often suspicious of the ineffable nature of fickle human emotions. But if, indeed, emotions do matter in geography, the emotional turn will demand an epistemological shift to take human emotions into account in the production of geographical knowledges beyond their usual visual or textual registers.

In many ways, the focus on emotions and bodies has paid intellectual dividends by reinvigorating and widening the scope of cultural geography, which has previously been seen as being more interested in landscape interpretation and textual analysis than in real people. Arguably, this shift from the purely representational to the messy materiality of bodies, emotions, and sexual differences offers a new discursive space for feminist geographers, who have erstwhile been apprehensive about being aligned with cultural geography per se.

Clearly, this call for emotions to be taken seriously in human/cultural geography has not gone unheeded, judging by the burgeoning literature on affectual and emotional geography, although Pile (2010, 17) has rightly cautioned against the uncritical importation of “an ever-expanding shopping list of expressed emotions,” and of taking “an increasingly cognition-centred, humanistic and romantic view of expressed emotions,” without ever reflecting on why and how emotional geographies matter in the first place.

New cultural geographies, new methodologies?

The new cultural geography has opened up a fresh intellectual terrain and even brought about several paradigm shifts and turns, but several geographers have pointed out that much of its contribution seems to be theoretically driven and offers little serious consideration to the issues of methodology and fieldwork innovation beyond the narrow range of qualitative techniques of interpreting and decoding landscapes. More seriously, Thrift (2000, 3) has lamented the lack of methodological innovation and the conservative approaches that cultural geographers bring to the table: “how wedded they still are to the notion of bringing back the ‘data,’ and then re-presenting it (nicely packaged up as a few supposedly illustrative quotations), and the narrow range of sensate life they register.”

There is no doubt that, as cultural geographers move forward with a renewed cultural geography, it is crucial (for the subdiscipline) to be more explicit and articulate about methodological choices and assumptions. Furthermore, if contemporary cultural geography is often observed to be searching relentlessly for new terrains of research from mobilities to human emotions, such vigor also has to be equally matched by bolder methodological innovations. Not least, nonrepresentational currents of thought in geography have already challenged much of the conventional methodological toolkit available for geographical fieldwork – in particular, participant observations, in-depth interviews, and focus groups – which are seen to accentuate the contemplative and discursive aspects of geographical fieldwork and inquiry.

Recently, practitioners of cultural geography have lobbied for greater methodological pluralism by juxtaposing traditional qualitative research methods that rely mainly on discourses and textual representation with more experimental practices such “go-along ethnography,” walking, participant photography, and so on in order to augment the multisensory embodied experience and the expressive modality of the research subject at hand. Thrift (2000, 4–5), in particular, has called for greater openness as well as “cultural and practical generosity” in
learning from practice found in street theater, dance and music therapy, performative writing, and creative storytelling, which help to “co-produce the geographical world that we live in.” As Jacobs (2006) warns, however, such innovation and experimentation should not detract from the foundational methodological commitments of cultural geography, which in her view means attending to the relationalities between material and immaterial, small and big, mundane and exceptional, or global and local (Jacobs 2006, 22). Using the modernist skyscraper as an example, Jacobs demonstrates how cultural geographers can profit by avoiding the fixation on representational geographies and to take on board a “semiotics of materiality” that pays attention to the “relational assemblages of human and non-human that work to ‘make’ a building event” (Jacobs 2006, 2).

Also, while nonrepresentational theory tends to privilege prediscursive and noncognitive practices, it “does not seem to allow room for considering visual and textual forms of representation as practices themselves,” and appears to “offer more theoretical guidance for considering practices over representations rather than strategies for bringing them together” (Nash 2000, 662). For Nash, it is vital that proponents of nonrepresentational theory do not totally abandon the study of representation and texts, which make up the core tradition within cultural geography. As she notes, “Exploring practices, performances, texts, objects and images together rather than abandoning the knowable for the unknowable may be less theoretically ambitious than ‘nonrepresentational theory’ but it is also more politically effective” (Nash 2000, 661).

Contemporary cultural geography has certainly come a long way, and has precipitated various paradigm shifts and conceptual turns within the subfield, but much of these intellectual developments remain firmly entrenched in the anglophone academia, bypassing much of the non-English-speaking world. Such omission of non-anglophone voices is particularly jarring if we are to take seriously contemporary cultural geography’s mission to “decolonize” and “decenter” Western academic discourses. Many of the earliest work in cultural geography can actually be traced to non-anglophone traditions in Greco-Roman as well as Chinese and Muslim scholarship. Indeed, as many scholars observe, it would not be surprising to find cultural geographers (or their equivalents) as part of the intelligentsia of expansionist empires of the ancient world such as the Greek and Roman civilizations, the Tang dynasty, or the Ottoman empire.

In recent years, criticism of “faux-cosmopolitanism” in Anglo-American geography (Smith 2000, 27) has led some scholars to reflect on their disciplinary practices, and in particular on the role of language. Several geographers have begun to challenge what they perceive as linguistic hegemony, which is often evident in anglophone publications. It has been pointed out that challenging the dominance of English in everyday academic discourse and publication is an urgent task if cultural geographers (in the anglophone world) are serious about transgressing the linguistic boundaries that they have been advocating. If subverting the dominant lingua franca of academia seems to be a way to disrupt and destabilize Anglo-American geography, a wider implication here is to examine how different ways of doing and practicing (cultural) geography on a daily basis – including how we formulate research ideas and theories as well as conduct scholarly activities such as publishing and attending conferences – can all be modified to open up the discipline to a plurality of non-Anglo-American voices as well as “alternative ways of valuing forms of geographical enterprise” (Kitchin 2005, 2).
If the country reports in the flagship journal *Social & Cultural Geography* are anything to go by, the hegemonic status of Anglo-American geography (whether real or perceived) has warranted great concern among geographers. It has been pointed out that anglophone-centric geographical literature has a tendency to reinforce its own dominance through the use of English language as the de facto lingua franca of academia. Nevertheless, as Kitchin (2003, 253) notes, the country reports that appear in the journal hope to serve as both an *intellectual* and a *political* project that “seeks to disrupt and destabilize the prevalent trend towards English and Anglo-American hegemony in the international production of geographic knowledge.”

Attempts to bring social and cultural geographers from around the world into dialogue should not be conceived as an attempt to bring the work of “geographers at the margins” to the Anglo-American center, or worse, to co-opt non-Anglo-American geographers into the fold of “Anglo-American ways of knowing, interpreting and writing” (Kitchin 2003, 253).

For that purpose, the commissioned country reports on social and cultural geography in the respective regions are published in both English and the contributor’s native language. Indeed, such a practice is now widely adopted in many major geographical journals such as *Area, Annals of the Association of American Geographers, and Transactions of the Institute of British Geographers*, where article abstracts often appear in more than one language, although the main manuscript remains published solely in the English language. While such a linguistic gesture toward including “native” languages in the journal abstracts is certainly a welcome addition that gives the journals an “international” appeal, it remains to be seen how far such endeavors go in terms of bridging the gaps between (non-)anglophone academic worlds.

Part of the difficulties in engaging with non-anglophone scholars goes beyond simply the linguistic divide. As various country reports in *Social & Cultural Geography* seem to suggest, the dearth of social and cultural geography works that engage with an international (English) audience can equally be attributed to the exclusiveness of non-anglophone academic communities and their general mistrust and/or disdain of foreign influences, and to Western intellectual trends that are often perceived as threats to the integrity of local traditional scholarship. Even in France, despite the popularity of works by French theorists such as Lefebvre and Foucault in Anglo-American geography, much of French social and cultural geography literature remains rather insular and patchy. A huge intellectual gulf remains between English-language geography and French geography. Indeed, part of the reason for the deficit in cultural geography in some places hints at much broader structural conditions and the state’s role in shaping geography as an academic discipline. This role is especially pronounced in countries such as China which have experienced massive social and political transformations in recent decades. Against the changing political and ideological backdrop in China, several commentators have shown how cultural geography (alongside various subfields in human geography such as political and social geography) had been under severe state sanctions owing to their perceived Western bourgeois influences and became forbidden areas of research in the 1960s and 1970s. It was not until after the economic reforms in the late 1970s and early 1980s, with the gradual opening up of the country, that Chinese human geographers began to engage with Western geographical theories and to apply them to understanding many pressing contemporary concerns in China, ranging from
globalization, tourism development, and urban growth politics to environmental protection and sustainable development.

Clearly, there are regional differences as well as internal heterogeneity in how cultural geography takes root and develops in different parts of the world which reflect not only different institutional norms and state practices but also the underlying diverse geohistorical contexts. For instance, social and cultural geography in the fledgling nation-states of Southeast Asia after the postwar period, in the 1950s and 1960s, often focus on the politics and challenges of postcolonial nation-building and globalization (see, e.g., Bunnell, Kong, and Law 2005). While cultural geography in different places has developed and evolved in quite different ways from the Anglo-American pathways, there are also signs of convergences which are often spearheaded by significant individuals who often act as agents of change. In Japan, for instance, several globally oriented scholars initiated contact with anglophone, French, and Italian geography, and also translated key publications from English and French authors, including David Harvey, Paul Claval, Ron Johnston, Jacqueline Burgess, and John Gold. Notably, the *Jim bun Chiri* (*Japanese Journal of Human Geography*), published by the Human Geographical Society of Japan, has recently translated several Japanese articles into the English language to facilitate the cross-fertilization of ideas across linguistic divides. In a similar vein, translations of key cultural geography texts such as Anderson et al.’s (2003) *Handbook of Cultural Geography* have also found a receptive audience among Chinese scholars in contemporary China.

While it is encouraging to see such signs of the bridging of different linguistic divides, we should question if such changes can ultimately disrupt and destabilize dominant anglophone geographical scholarship, or if they merely signal the “reeling in” of native geographers into the fold of “Anglo-American ways of knowing, interpreting and writing” (Kitchin 2003, 253). Kong (2010, 601), in particular, has issued the challenge that the study of China’s cultural geography should avoid becoming just “another case study” illustrating the theoretical logics established in “Western” settings. In this sense, local knowledge production is crucial and “could lead to exciting, perhaps even revolutionary, new theoretical insights, representing a welcome opportunity to unsettle Anglo-American scholarly hegemony.”

As a theoretical rejoinder to dominant Western narratives, a fairly typical response by scholars working in the Global South has been to underscore the uniqueness and particularities of their respective local case studies as a way to speak back to dominant Anglo-American theories. By highlighting the different local contexts, it is often hoped that such nuanced local knowledge and contextual differences might translate into different ways of knowing and theorizing places. To be sure, the production of idiogetic and locally specific knowledge does not preclude the production of more generalizable nomothetic theories. Indeed, the production of close-grained empirical scholarship which has a rich tradition in much non-Anglo-American academic geography is often valued as a starting point to engage with more abstract theoretical work. Yet it would be naive to think that empirically based work can somehow be unproblematically grafted onto existing (Western) theoretical frameworks. Nor should such projects be driven by a self-gratifying need to theorize for theory’s sake.

While cultural geography in the Anglo-American context has evolved from a distinctly Western philosophical tradition, cultural geography in many non-anglophone contexts has developed from a vastly different intellectual environment and genealogy. It is critical to
CULTURAL GEOGRAPHY

Reflect on how non-anglophone cultural geographers can venture beyond merely engaging nominally with international academic literature by being active agents in the production of geographical knowledge and theories within their own intellectual lineage and tradition. For example, we might ask how humanism, which has a long-standing tradition in Asian philosophical thought, can shape contemporary debates in cultural geography. What are the alternative forms of (non-Western) modernities that ground the cultural experiences of the Global South?

There is also a danger of falling into the “Orientalism” trap by mistaking such endeavor as an attempt to recover the lost “authentic” history of non-anglophone intellectual traditions. Rather, the impetus here is to draw on local intellectual resources and scholarly imaginations in order to engage in theorization from within. Necessarily, such an intellectual project will entail going beyond the translation of Western ideas and concepts into native languages, to represent a concerted attempt to provide an alternative epistemological and even ontological framework for understanding the complexities of the geographical world that is invigorated by different positions and views from elsewhere. Arguably, if past decades have seen how “the intermingling of American and British geographers has helped to create sensitivity to the subtle differences in what is understood by culture in both places” (Olwig 2010, 178), it will be interesting to see how the increasing interaction with non-anglophone cultural geographers will further deepen and broaden intellectual dialogue.

Looking to the future

The agenda that was championed by (cultural) geographers in the 1980s is now widely accepted and has even become a hegemonic project to some extent. It is not surprising nowadays to find geographers specializing in political, economic, historical, or even transport geography who consider themselves nominally as cultural geographers. Such a paradoxical situation points ironically to the success of a renewed cultural geography enterprise and its “crisis of overproduction” (Nash 2002). But, more fundamentally, the disciplinary anxieties expressed earlier also reflect the different ways that cultural geographies have been written about, valued, learned, and practiced over past decades, both old and new, traditional and avant-garde, conservative and radical.

While the old versus new divide has often been used to frame the historiography of cultural geography, being overly fixated with such dichotomous representation can lead to a dangerously oversimplified view of the complex evolution of intellectual ideas and to promoting a falsely heroic worldview of (mostly male) academic movers and shakers associated with different schools of thought and the dramatic paradigm shifts that they have engineered. Such highly partial and even sensational accounts also tend to exaggerate the internal unity and coherence of different ideological camps and, further, to encourage antagonistic caricaturing of their respective research programs at the expense of providing a nuanced appreciation of the historical continuities of different intellectual lineages and traditions. Indeed, such historical continuities are already evident in the recent resurgence of interest in human–environment interaction and environmental history, echoing the Sauerian tradition as a result of widespread environmental concerns.

While the cultural turn has revitalized the discipline as a whole and given cultural geography a new identity by shaking off its “old nerdy image,” it has also generated tensions with other subfields and been duly accused of
eclipsing and marginalizing “social” geography (Valentine 2001). What matters here is not only that boundaries between subfields are porous and fluid, but also that developments within cultural geography have unintended spillover effects on other cognate subfields. For Valentine (2001, 170), a real practical concern about the cultural turn “is not so much with the evacuation of the social but rather with the depoliticization of social geography.”

Indeed the lack of an explicitly political agenda is also a critical issue that confronts contemporary cultural geography, with its preoccupation with meaning, identities, and representation at the expense of giving due emphasis to class inequality and even social environmental justice. While geographers have been quick to embrace the latest styles offered by intellectual fashion houses in France, many such “cutting-edge” and “avant-garde” works are jargon-ridden and have little relevance for public policy. Even when such academic works do attempt to speak to important social and economic issues of the day, they are often written in such a convoluted manner that they are difficult to translate into policy-friendly language that can be digested by policymakers and planners.

For the detractors and critics who are eager to take a potshot at cultural geography, the subfield is often an easy target for ridicule because of the increasingly inaccessible corpus of work that is riddled with complex jargon, abstract metaphors, and pompous language which produce quixotic forms of scholarship catering only to insular intellectual peer groups. Whether such accusations are justified or not, Don Mitchell (2014) has warned against what he calls the “complicated fetish” in geography whereby intellectual premium seems to be accorded to ever more complex ways of framing understandings and explanations of the world. To be sure, such critiques are not meant to express anti-intellectual sentiments or, worse, to advocate the dumbing down of geographical scholarship. On the contrary, it is precisely because the geographical world is infinitely complex that researchers and scholars need all the more to make such “hard-won knowledge” more accessible to people rather than forestalling greater understanding and action through unnecessary jargon-laden rhetoric (Mitchell 2014, 126).

As cultural geography progresses into the future, it is also imperative that the subdiscipline continues to demonstrate critical relevance in its scholarship in terms of both the production and the dissemination of knowledge. This is not, of course, to suggest that cultural geographers working in the earlier tradition have been uncritical in their work. Without denying or ignoring the historical specificity of any approach to critical geography, what counts as critical is often itself a product of its time. Any number of approaches in the longue durée of geography’s intellectual development from environmental determinism in the late twentieth century, through Sauer’s cultural ecology, the quantitative revolution of the postwar years, and the humanist and postmodernist movements in the 1980s and 1990s, can rightly be labeled as “critical” geography of its time. They all offer a critique and challenge to dominant approaches and ideologies. An important issue confronting contemporary cultural geographers is how the conditions for the realization of critical geographical praxis have changed in the context of an increasingly globalized and neoliberal (academic) world. Indeed, many cultural geographers now count themselves active members of critical geography groups and online communities, and journals have appeared such as *ACME: An International E-Journal for Critical Geographies*, but just what does being critical mean and who gets to say and define what constitutes being critical in the contemporary age? We also need
to question not just what cultural geographers are being critical of but also what are they being critical for. What higher purpose and goals does critical scholarship serve beyond being a rallying point for motley groups of self-proclaimed leftist/radical/anarchist scholars? Too often, being critical in academic writing takes the rather well-trodden, even formulaic, route of citing the fashionable critical theory of the month or celebrity authors rather than genuinely engaging with an honest critique of hegemonic ideologies, social inequality, and spatial injustices on the ground.

On the whole, the intellectual project of cultural geography is still an unfinished business, as noted by several commentators, and is best characterized as an ongoing project of critical self-reflection, ideological disagreement, and intellectual commitment. It is certainly premature to sound the death knell on cultural geography. It will remain, in the foreseeable future, as a vibrant subfield, albeit one that is confronted with the critical challenges of being innovative while staying socially relevant.

Heritage definitions and classifications

Heritage may be defined as anything of value inherited from the past, to be used at the present and to be passed on to future generations. This simple definition, however, belies the complexities that often attend the heritage selection, interpretation, and presentation process. In multicultural and multiethnic societies, conflicts emerge when questions about whose heritage and who decides what is heritage are asked. In multifunctional and multiuser sites populated by residents, migrants, and tourists, questions about what heritage is and who benefits from it further compound the complexities of heritage definition and utilization.

Heritage may be classified as either natural or cultural. Natural heritage includes physical environments and biological features such as unique geological landscapes, national parks, and coastlines, as well as historic gardens and archaeological sites. The habitats of threatened species of animals and plants, and natural areas of outstanding scientific or aesthetic value, are also included. Cultural heritage refers to the handiwork of humans deemed worthy of preservation and may be either tangible or intangible. Tangible cultural heritage includes buildings, monuments, artifacts, and historic places. Also known as built heritage, it ranges in size from a single monument or museum to an urban district or an entire historic city. Such built heritage is often significant to the archaeology, architecture, science, or technology of a specific culture.

Intangible heritage, also known as living heritage, refers to the practices, representations, expressions, and skill sets and knowledge of communities, which include oral traditions, performing arts, customs, and rituals, and traditional crafts and skills. As these intangibles are passed from one generation to the next, they are constantly adapted to suit changing needs, values, and technological standards of society. Although mutable, intangible heritage nevertheless provides communities with a sense of history, continuity, and identity, bonding them as a unique people.

The 1970s may be regarded as a pivotal period when heritage came to general public awareness. Two key initiatives were responsible, the first being the 1972 World Heritage Convention where proposals on nature conservation and the preservation of cultural properties were brought together in a single document that was agreed on by member states of the United Nations. The convention document was adopted by the United Nations Educational, Scientific, and Cultural Organization (UNESCO) and came to define the World Heritage List. In 2014 the list comprised 981 properties: 759 cultural and 193 natural sites, and 29 mixed properties, spread across 160 countries (the website at http://whc.unesco.org/offers information on World Heritage Sites and their classification).

Another significant milestone was the designation of particular years to celebrate heritages. For example, the European Architectural Heritage Year (1975) was highly successful in promoting public awareness in and pride among European residents of their shared urban heritage. Interest
among tourists and increased conservation practices across the continent inspired further designations such as the European Campaign for an Urban Renaissance (1981), the European Year of the Environment (1989), and subsequently the European City of Culture designations and the millennial project of European Capitals of Culture. Such campaigns not only raised heritage consciousness but also drew attention to the role of heritage as a tourism resource and unifying political tool.

**Geography of heritage**

It has been argued that a “geography of heritage” exists. The study of heritage may be approached from various geographical perspectives, for example, through an understanding of location (where heritage is sited and who it belongs to) or distribution (why heritage is found in a particular site or region and not another). Scale is another dimension in heritage studies. Heritage may be individually owned (e.g., a family heirloom) or take the form of a single site on a national scale (e.g., a monument or historic city) (Graham, Ashworth, and Tunbridge 2000). Heritage is most often conceived at the national scale because national heritage is a critical component for nation-states in consolidating a sense of belonging while differentiating themselves from other territories.

It is also possible to think of heritage at a global scale, particularly with respect to UNESCO’s World Heritage Sites. Such sites are recognized as possessing outstanding universal value from an aesthetic or scientific point of view. They are also bound by international codes on conservation and management practices as defined by UNESCO and its subsidiary organization ICOMOS (International Council on Monuments and Sites). Access to a world reserve of professional expertise consisting of architects, archaeologists, historians, geographers, engineers, and town planners is also available (see the section on “Heritage management and sustainability” later in this entry).

Geographers of different subdisciplines are interested in heritage issues for different reasons. While historical geographers are concerned with unraveling the facts and meanings of places through heritage landscapes, urban geographers focus on conservation efforts and the effects on residents, land uses, and place images. Cultural geographers have explored how heritage is linked to wider debates on representation and identity, while economic and tourism geographers have studied how heritage may be used in the planning and regeneration of towns, cities, and regions.

Finally, some geographers have argued that heritage planning cannot be divorced from the agencies that own the land on which heritage is sited and whose plans inevitably affect the geography of the land. Conservation trusts and development agencies are viewed as geographic agents of change and a worthy aspect of heritage geography research. The works of agencies like the National Trust in England, Wales, and Northern Ireland (established in 1895), Heritage Canada (1973), and the Urban Redevelopment Authority of Singapore (1964) impact not only the physical character of cities and the countryside but also the functional and social character of places. The agencies’ roles in place conservation and change management are well aligned with geography’s concern with the environment and human impacts on it.

**Commodification and the heritage industry**

Beginning with museums and heritage centers in the late nineteenth century, which first
charged visitors entrance fees to today’s historic theme parks, the heritage industry emerged as an outcome of commodification. The term “commodification” denotes the appraisal of heritage as a commodity to be manufactured, marketed, and sold to a paying consumer. While some view commodification as an offshoot of tourism, others see it as a way to stave off declines in the manufacturing sector while boosting pride in national history. Robert Hewison’s (1987) *The Heritage Industry*, for example, attributes Britain’s obsession with heritage in the 1970s and 1980s to the frustrations associated with modern life, including inner city unemployment, coalminers’ strikes, and the ugliness of modernist architecture. Moments of economic decline are often critical in triggering people’s nostalgic impulses and the emergence of a heritage sector.

There exist many forms of heritage commodification. The most common are museums, castles, palaces, historical relics, and national parks, where entrance fees are levied on visitors. Free access contemporary sites may also be regarded as examples of commodification, especially when heritage is deployed for commercial ends. These include mega shopping malls where aspects of the past are recreated (e.g., West Edmonton Mall in Edmonton, Canada, and its replica of Columbus’s Santa Maria), as well as restored waterfronts and festival marketplaces that adaptively reuse historic buildings for contemporary needs (e.g., Singapore’s Clarke Quay, which features retail, leisure, and office uses housed in previously defunct warehouses). Whether heritage is celebrated or commercially exploited is debatable.

Critics of commodification charge that the heritage industry reduces historical sites and cultural resources to trivialities appreciated only for their photogenic qualities. The primary function is usually commercial, while the historical and cultural significance recedes into the background. Supporters, on the other hand, claim that new uses for historic sites and resources ensure their continued existence and greater access to members of the public. Without contemporary uses, old buildings and architecture would have a much slimmer chance of survival. The pros and cons of commoditization are points of debate not only among researchers but among policymakers too.

While it is easy to dismiss commodification outright, the economic benefits of a heritage industry should not be underestimated. Employment brought about by tourism (both quantitative increase in numbers and qualitative changes in the types of jobs created), spin-offs in such sectors as retail, convention, and construction, infrastructural improvements that benefit local residents, and the upgrading of human capital are positive outcomes of the industry. Whether economic benefits outweigh the cultural drawbacks of heritage commodification, and what local residents and other stakeholders feel about the tradeoff, should be considered in heritage planning and development.

**Heritage tourism and authenticity**

Heritage tourism is any form of tourism where the focus is on historical resources. It involves tourists visiting sites of cultural and natural relics, and the industry’s attempt to cater to this demand. With the rush to develop historical resources for tourists, the authenticity of the heritage product and experience is often questioned.

The concept of authenticity assumes a verifiable authentic past to which the contemporary heritage product may be compared. Such a comparison can take different forms, one example being the contrast between handicrafts and trades. Tourists usually purchase handicrafts or souvenirs because of their cultural link to
CULTURAL HERITAGE

Cultural heritage refers to the collective memory of a particular place or people. Handicrafts are created specifically for the tourist market and are often mass-produced. By comparison, trades refer to methods and techniques by a workforce operating independently of the tourism industry. The authenticity of trade items are thus contrasted to the inauthenticity of tourist handicrafts (Urry 1990).

Another area of comparison revolves around preservation and conservation. While preservation entails wholesale restoration with an emphasis on historical accuracy and unchanging customs, conservation refers to adaptive and selective reuse of old buildings and practices in order to cater to contemporary needs. Under conservation, historical sites are rendered accessible and tourist-friendly, with modern amenities including toilets, souvenir shops, restaurants, and staged performances. Under preservation, minimal intervention is permitted and the outcome is usually an unchanged environment or cultural form that is traditionally authentic, even if slightly inaccessible to tourists.

How the past is presented to tourists is the result of interpretation. Often, state authorities and commercial enterprises decide on what aspects of history or culture to offer, and how the heritage product is to be communicated and marketed. Such interpretations are criticized for being highly selective and overly aligned to commercial agendas. For this reason, nongovernmental organizations and heritage interest groups have increasingly asserted their inputs. In what has been described as “histories from below,” alternative interpretations that do not always reinforce dominant political or commercial interests are also being heard (Hardy 1988). Answers to questions of whose history and what heritage are broadened beyond the scope of the elite, allowing a greater range of opinions and a more encompassing view of conservation to emerge.

Heritage, identity, and nation building

The interpretation of heritage goes beyond tourism and is often part of the political process of nation building. Nation-states foster a sense of identity and shared bonds by harking back to a common heritage. Promoting the glories of past regimes, emphasizing shared ancestry of land, language, customs, and values, as well as censoring select aspects of history that are detrimental to the nation’s image are all integral aspects of interpretation and nation building. Defining a national heritage can also help to neutralize competing claims by fractious groups or regions within the nation while differentiating it from other territories.

The search for a common heritage may also be a response to external threats. In an era of globalization, many nations face the threat of cultural homogenization and loss of identity. Without a bedrock of shared history, customs, and traditions, communities run the risk of becoming rootless and soulless. In Singapore, for example, a Committee on Heritage in 1988 defined heritage as offering a social and psychological defense to the nation. As citizens become more westernized, it is feared that many will forget their common ancestry as Asian immigrants and the customs and traditions that bind them as a people. Through conserving historic landscapes and designating national monuments, architecture, and even food and music, heritage is rendered in explicit material form that can hopefully bind citizens as a community and also as a nation (Kong and Yeoh 2002).

As nations evolve, how heritage is interpreted changes too. In countries such as Australia, Canada, New Zealand, and the United States, traditionally Western conceptions of heritage have been increasingly challenged by indigenous and migrant communities offering alternative interpretations of history, culture, and beliefs.
In newly independent countries, heritage reinterpretations also provide opportunities to forge new coalitions and a sense of belonging. For example, before apartheid ended in April 1994, heritage in South Africa had followed an elite Western interpretation consisting mainly of colonial architecture, battlefields, and archaeological sites. In the postapartheid era, new preservation laws were passed that added heritage sites and practices that were deemed important to the indigenous people. Such “new heritage” includes places of spiritual significance, sites associated with the history of slavery and the independence movement, graves, cemeteries, and apartheid-era prisons, as well as artifacts associated with tribal oral traditions (Green 2011). Such inclusions play a necessary role in forging a new sense of identity for the evolving nation.

Beyond the nation, heritage can also play a role in fostering transnational identities. In the run-up to the formation of the European Union in 1993, for example, much of the discussion on creating a pan-European identity revolved around the need for a shared heritage. Quintessential European achievements and heritage such as the Renaissance and the Enlightenment, and certain innovations in the arts, architecture, science, and technology, were identified, endorsed, and celebrated as pinnacles of European history and experience (Graham et al. 2000). For a “new Europe” to emerge, history had to be reinterpreted and a “new past” or “new heritage” devised (Ashworth and Larkham 1994).

There are many challenges in co-opting heritage for nation-building purposes. The term “heritage dissonance” describes discord whenever people have conflicting views about heritage and what best represents a nation and its people. Apart from the obvious differences across citizens and migrants, the views of citizens may also differ along the lines of age, gender, class, ethnicity, and political affiliation. State-sanctioned heritage adds another dimension on top of already complex pre-existing layers of identity, further complicating questions of what heritage is and who decides. As much as heritage has a cohesive potential, it also has a separatist or divisive tendency that must be addressed if nation-building projects are not to go awry.

Heritage management and sustainability

The importance of cultural and natural heritage necessitates long-term care and administration. Heritage management involves resource restoration and protection, as well as management of resource conflicts. Such conflicts arise when different groups or countries contest each other by asserting exclusive claims on or use of particular resources.

A central tenet in heritage planning and management is cultural resource management (CRM). CRM entails a multifaceted approach, beginning with a holistic view of resource selection, a thorough consideration of how heritage is affected when it is being developed, vigilant control of looting, and systematic archiving of resource documentation and conservation practices. In addition to taking care of heritage sites physically, it is also important to manage sites socially. This involves active management of people’s behavior, particularly in locations that are popular with tourists, and public education programs targeting locals, visitors, and resource owners.

Heritage management is also deeply concerned with the issue of integrity. Heritage integrity is defined as the intactness of a particular resource and its attributes. All the elements of a heritage must be present in order for its outstanding universal value to be expressed (Gullino and Larcher 2013). To ensure integrity, management plans must be long-term and holistically conceived.
CULTURAL HERITAGE

Local participation is crucial and entails involvement by stakeholders such as local site managers, communities, local and regional governments, heritage interest groups, and nongovernmental organizations (NGOs) (Landorf 2009). A cycle of continuous action that involves planning, implementation, monitoring, evaluation, and feedback must also be put in place. While all this is feasible in theory, the reality is that the execution of management plans is fraught with difficulties, particularly in the developing world. The lack of political will and administrative resources, as well as heavy financial costs, frustrate the implementation of plans.

For UNESCO World Heritage Sites, management is easier to enforce and monitor. Formal nomination entails commitment on the part of owners and country governments to protect heritage through a detailed plan, which includes long-term legislative, regulatory, and institutional provisions. Heritage sites also have access to grants and technical assistance from the World Heritage Fund. World Heritage Site listing may also be withdrawn if management guidelines are not adhered to. Such sites are first placed on a “World Heritage in Danger” list by the World Heritage Committee and negotiations are undertaken with local authorities on remedial strategies. Two natural heritage sites have so far been delisted – one in Oman and another in Germany – because of developments near the sites that were regarded as detrimental to their scenic qualities and their flora and fauna. Such delistings are unfavorable for countries not only because of the loss of funding opportunities but also because of the embarrassment to local authorities. One of the guidelines for World Heritage listing is advanced recognition of threats in the form of development, pollution, tourism, and agriculture. Management strategies must also be identified to alleviate these threats.

It should be clear that heritage management is about not only the physical care and protection of sites, but also the management of people's behavior and the provision of information to the public. While the former contributes to physical sustainability, the latter concerns social sustainability. Each heritage site is conceived as having both a physical and a social carrying capacity. If the physical carrying capacity is breached, heritage sites will experience wear and tear, resulting in destruction, denudation, and the loss of tangible artifacts. In the case of social carrying capacity, poor management results in the loss of local traditions, skills, and customs, particularly in sites that are overwhelmed with tourists. Resentment of tourists requires monitoring and, where needed, mitigation through schemes that benefit local residents. These include free access to heritage sites or discounted membership for cultural programs. Both dimensions of physical and social control must be acknowledged if management is to be holistic and sustainable.

The future of heritage

Although heritage consists of relics from the past, it is crucial to think about its future. Heritage evolves over time in both a quantitative and a qualitative sense. In a quantitative sense, the sum total of what is regarded as heritage changes as “new” heritage is added to the sum or when existing heritage is lost because of environmental problems. In a qualitative sense, what constitutes heritage will also change as societies, politics, and technologies evolve.

The most immediate cause of heritage change is the threat of physical destruction brought about by climate fluctuations. Over time, an increase in global temperatures resulting from the emission of greenhouse gases has led to the demise of natural and cultural heritage. Changes
in water temperature have caused coral bleaching and loss of marine biodiversity. The Great Barrier Reef, for example, experienced severe bleaching in the late 1990s and early 2000s, which led to about 5% of its reefs being stripped of 50–90% of corals (UNESCO 2007). Global temperature rise also affects snow and ice cover, depleting upland glaciers and leading to severe consequences for lowland rivers. Cultural heritage is not spared either. Increased urban floods affect historic buildings, many of which were built with materials not accustomed to excessive ground moisture. Changing soil conditions also affect archaeological sites, while rising sea levels impact historic coastal areas. How much heritage survives into the future depends on the severity of environmental problems and the effectiveness of mitigation measures.

Qualitative changes also take place and such changes refer to how heritage is defined. The World Heritage List is a good example. It is only since 1992 that new categories have been added to the list which, at that time, was made up of mainly religious, cultural, and archaeological heritage. Since then, recognition has been given to commercial industrial heritage (such as railways and factories), buildings of local architectural vernacular, rural cultural sites, and pilgrimage and migration routes. Such reappraisals take place because of changing values and what people consider as historically or culturally important. Likewise, today as the composition of society changes, new constructs of identity, authenticity, and belonging emerge. In many cities and countries, the contributions of migrant ethnic communities are acknowledged and their cultures recognized as part of a collective heritage. South Asians in London and Chinese in Toronto and Vancouver are examples of migrant communities whose heritage have been accepted as part of the historical and cultural fabric of their host societies.

Another change lies in the area of tourism. The mass tourism of the past has given way to segmented groups of travelers characterized by specific interests. What was earlier identified as heritage tourism may be more accurately recognized today as comprising niche groups such as culinary, education, or architecture tourism. Tourists are no longer satisfied with the passive observation of heritage but demand active participation and immersion too. For example, culinary tourists no longer desire only good food but also wish to visit local markets, interact with chefs, and engage in cooking and food preparation. A deeper appreciation of heritage is possible through active engagement. Tourism planners and service providers must ensure that, as new forms of heritage are made available, the exchange between guests and local hosts is mutually beneficial.

Finally, new media and communication technologies are presenting innovative ways for heritage to be archived, publicized, marketed, and consumed. In the twenty-first century, many heritage boards, trusts, and museums have turned to digital and web technologies to change the way heritage is communicated to the public. Artworks, museum pieces, and heritage sites are showcased on different web platforms for virtual visitors to enjoy. Technology has also allowed three-dimensional “up close and personal” viewing in a way that reality cannot or will not permit. The archiving of oral histories in digital format and immediacy of access have also brought intangible heritage closer to people. Feedback from the public on any aspect of heritage can also be instantaneously channeled to managers and administrators.

As debate continues over whether virtual tourism can ever substitute for actual visits to heritage sites, there remains considerable interest in heritage and increasingly novel ways of presenting it to the public are found. Sensitive
CULTURAL HERITAGE

management of heritage and sustainable ways of communicating it are essential if heritage is to live up to its definition as something precious to be protected and passed onto future generations.

Cultural politics

Orlando Woods
Independent scholar

Cultural politics stems from the fact that we are all – to varying degrees and in various ways – conditioned by culture. Our cultural identities automatically (and often unknowingly) create a taxonomy of understanding that deeply influences how we see ourselves (and people like us) and how we see others (or people not like us). Such taxonomies are often deeply rooted, as societies traditionally have formed, developed, and strengthened along the lines of cultural similitude and spatial segregation. Less than a century ago, it would not be uncommon to find communities that were more or less culturally homogeneous. Since then, shifts in global politics and economics, and advances in technology, have caused the mixing and dilution of cultural norms, and the creation of new cultural forms. Such shifts and advances have facilitated processes of migration and the development of global communications networks. In turn, these processes and developments have shaped the sociocultural landscapes of the modern world in ways that are unprecedented in scale and effect. Most noticeable is the fact that they have resulted in the constant and largely unavoidable blending of people, ideas, symbols, and values, and ever-greater assertions and contestations of power. The relative safety of cultural homogeneity has given way to the uncertainty of cultural heterogeneity, and with it a whole raft of questions and concerns about cultural difference have emerged.

Cultural differences create power asymmetries, which are enshrined in a number of oppositional pairings. Such pairings – power and resistance, dominance and subordination, sameness and difference, inclusion and exclusion, insider and outsider – form the lexicon of cultural politics. Each pair reveals the different standpoints and tensions of different cultural stakeholders. Such standpoints also play a central role in the ordering, classification, and use of space, and the politics contained therein. Indeed, space and place can both reflect and enforce the cultural politics of a given community or area, and have helped shape the research agendas and theoretical contributions of cultural geographers since the 1980s. Such agendas and contributions have engaged with debates in the broader social sciences to show how cultural politics not only come from within (i.e., how culture dictates the framing of self and other), but from without as well (i.e., how culture is studied, understood, and interpreted by scholars and public discourses that seek to advance specific interests, or a specific idea of “culture”). “From within” and “from without” are two approaches to understanding cultural politics.

The politics of cultural knowledge production

The new cultural geography of the 1980s sought to dismantle existing frameworks of cultural understanding, and to replace them with a new focus on cultural practices and processes, and their relations to power. Doing so has, among other things, led to a scholarly focus on understanding the power relations that are
CULTURAL POLITICS

inherent to cultural knowledge production. This has resulted in the interrogation of academic knowledge production itself, with a particular emphasis on exposing and reconciling epistemological norms and biases. Cultural knowledge production has, as a result, evolved from being the identification of ontological “fact,” to a more situated and subjective – and inherently contestable – interpretation of culture instead. Accordingly, it is now widely accepted that there can be multiple constructions and interpretations of the same cultural form; however, not all constructions and interpretations are shared and accepted in an equitable manner. As Tim Cresswell (2004, 124) puts it:

The study of culture is … closely connected with the study of power. A dominant group will seek to establish its own experience of the world, its own taken-for-granted assumptions, as the objective and valid culture of all people. Power is expressed and sustained in the reproduction of culture.

Any form of cultural production reflects a struggle between dominant powers, orders, or understandings, and those that seek to resist such dominance. Efforts have been made to bridge the gap between forms of knowledge production from above (i.e., codified, universalist, hegemonic) and from below (i.e., tacit, locally sensitive, emancipatory). Doing so has led to the acceptance and interrogation of culture as an idea (i.e., something constructed and understood by different people in different ways), rather than something that is inherent in people and place.

Such efforts have been strongly influenced by a variety of epistemological developments associated with postmodernism, all of which have led to a rethinking of the power relations associated with cultural knowledge production. Two developments in particular have helped to unravel and to understand (and, in some respects, to further) cultural politics: postcolonialism and postructuralism. Each contributes significantly to the politics of cultural knowledge production that is imposed by constructors on the constructed – a cultural politics from without.

Postcolonialism

Since the Enlightenment thinkers of the seventeenth and eighteenth centuries, cultural knowledge production has served to develop a sense of European (more recently, Western) superiority and civilization, the aim being to further justify and expand European power in the colonies. Cultural knowledge production is intimately bound with geography. Creating the geography of the world (and the discipline itself) coincided with the global spread of capitalism, imperialism, and modern scientific discourse; the mapping of the world and of nation-states in accordance with pre-existing ideas of superiority and inferiority; and the production of cultural knowledge in the colonies. Indeed, the very premise of cultural knowledge production during the colonial epoch was to understand hitherto unknown people and places in order to extend and enforce control over them. To the extent that the political apparatus of colonialism has since been dismantled, so too has postcolonial thought striven to dismantle the construction of culture as the intellectual products of a Western elite who observed, wrote about, and claimed to represent the cultures of non-Western peoples. And yet, as Audrey Kobayashi (2004, 242) rightly claims, “it would be difficult, indeed hypocritical, to avoid the fact that the discipline of geography is dominated by Northern, Western, white scholars whose lives and careers have been constructed out of the very colonial systems that produced them.” This sort of awareness has led to critical self-reflection among cultural knowledge producers, their aim being to bring about the decolonization not
just of territory and people, but of thought and knowledge as well.

Drawing in particular on the work of cultural theorists such as Edward Said, new cultural geographers have attempted to unravel the politics of knowledge production and representation. Said’s (1979) book *Orientalism* has gained notoriety for revealing how Western cultural representations served to legitimize the physical structures of colonial rule. Such representations often served to demean and dominate non-Western peoples and places through language and knowledge. As Dan Clayton (2004, 450) put it:

> the momentum of western power is now deemed to lie as much in the “cultures of imperialism and colonialism” – in language and knowledge, texts and discourses, images and representations, and the iconography of power – as in the political economy of imperial expansion and colonial incursion.

As a result, culture has been rethought in more relational terms. Culture is always produced in relation to the producer, meaning that critical interrogation of the production of culture itself can reveal unequal (or inequitable) patterns of cultural representation and acceptance. Processes of postcolonialism have, in other words, necessitated a focus on who is writing about culture, and the politics of (mis)representation that are inherent in the production of culture.

This development has had a number of tangible effects on the academy. Not only has the recognition of researcher positionality – and associated assumptions and biases – come to the fore, but the study of the subcultures of marginal groups has been elevated to a level that is almost on a par with that of dominant or “official” cultures. Greater physical intermingling of dominant and marginal cultural groups has, without doubt, contributed to such an elevation. Indeed, the formation of subaltern studies – a disciplinary collective that seeks to uncover and legitimize the cultural productions of ostensibly “hidden” (or subaltern) groups – is a clear reflection of the growing prominence of the marginal in mainstream discourses. Some scholars have even been accused of expressing a preoccupation with marginality, to the extent that they have been accused of “fetishizing” the other. Whichever way it is presented, it is clear that the processes of postcolonization have contributed to the devolution of cultural knowledge production, and a relentless scrutiny of who is producing culture and for what purpose.

**Poststructuralism**

The emergence of a new cultural geography in the 1980s marked a point of departure from structuralism. As the predominant organizing principle of much Western academic thought, structuralism classified the world according to oppositional binaries of us versus them, self versus other, center versus periphery, modernity versus tradition. Since the 1980s, however, poststructuralism has largely supplanted structuralism in academic discourses. An important contribution of poststructuralist thinking has been the effort made to overcome these binaries, which establish figurative lines of difference that set people and places apart. In a globalized world where people are increasingly interconnected and cultural symbols increasingly shared, such binaries have become as fallacious as they are redundant. There is no such thing as an all-encompassing “self,” as it is likely that most of us will share one or more facets of cultural identity with the “other.” To this point, one of the most pervasive legacies of poststructuralist thought has been the work of Michel Foucault (1977) and his rethinking of the cultural “subject.” Such rethinking has witnessed an evolution from understandings that are coherent
CULTURAL POLITICS

and bounded to those that are more fragmented and multifaceted.

The pervasive influence of Foucault’s work has caused the cultural to become a more subjective, fluid, and complex frame of understanding. The intellectual hallmark of poststructuralism – and part of Foucault’s enduring legacy in the social sciences – is social constructionism, and the associated belief that knowledge is not inherent nor predetermined by biology but constructed (or invented) by humans advancing specific interests and viewpoints. Female characteristics such as being more passive, dependent, and emotional than males are now believed to be the result of ascription by one person or group to another, rather than an intrinsic characteristic that is unique to women. This has brought about a scholarly focus on the power relations that are enmeshed within the practices of everyday life, and which contribute to the production of identities and the boundaries that demarcate difference. Geographers in particular have since focused on the “messy and inherently spatialized entanglements of domination/resistance, as always energized and traversed by the machinations and effects of power” (Sharp et al. 2000, 2). Feminists, for example, have rallied against the effects of patriarchy on society, and the creation of spaces that serve both a constraining and an enabling role for women.

The politics of cultural identity

Cultural identities are not homogeneous, nor are they coherent. Poststructuralist thought stipulates that identities are multifaceted, fluid, relationally constituted, and sometimes contradictory; they are not essential. Identity grants acceptance into some cultural groups but not others, just as it enables access to some spaces and not others. Above all else, the cultural politics of identity are concerned with diversity, and with the inclusion or exclusion of cultural minorities in the dominant sociospatial order. That is, power is not held and yielded unilaterally by one group. As much as institutional power is enforced from above, it is also complemented, challenged, and sometimes nullified by power (or resistance) from below. The gaps that arise in the difference between the yield and effect of power from above and below are what drive the politics of cultural identity – a cultural politics from within. The following subsections explore the cultural politics of the group, the cultural politics of the individual, and the cultural politics of landscape. While the first two subsections focus specifically on the operation and effect of society in space, the third focuses on the effect of space on society.

The cultural politics of the group

Social groups tend to draw on one or more facets of cultural sameness in order to bind themselves together. The power of the group lies in its ability to define itself in relation to others, and in so doing to establish and enforce ideas of sameness and difference. Importantly for geographers, it is also able to impose conditions or restrictions on the access to, and behaviors within, the spaces that it claims, owns, and occupies. Groups that draw on deeply rooted (and often immutable) cultural traditions are typically more conservative in nature, and share an often idealized understanding of cultural values and legacies. They can be oppressive in their willingness to protect and maintain the prevailing sociocultural order. As Iris Young (1990, 303) reminds us, they are typically intolerant of difference and are defined by the pursuit of “the same social wholeness and identification that underlies racism and ethnic chauvinism on the one hand and political sectarianism on the other.” Dominant groups often strive to keep minorities apart – and, by doing
so, enforce social and spatial division rather than diversity – while minority groups often seek to resist and subvert dominant groups in the bid for institutional acceptance and to express their own cultural identities. Invariably, therefore, majority and minority cultural groups often exist in a state of tension, with each trying to control, suppress, or undermine the other.

Nationalism is the most territorially specific form of cultural identification, and also one of the most potent drivers of identity politics around the world. Majority cultural groups that share common ethnic, linguistic, and/or religious traditions may form a national union that claims the sovereign right to a given territory. Given its implicit numerical dominance, such groups are often closely aligned with the state. This alignment (in the form of the nation-state) serves to strengthen the cause of nationalism while encouraging the intolerance of cultural minorities. Such intolerance typically involves the marginalization – even persecution – of minority groups, or culturally distinct migrant communities with whom a common territory or citizenship may be shared. Minority groups may resist by campaigning for greater autonomy or even liberation from the restrictive or controlling influence of the dominant group. In its most extreme form, the cultural politics of the group can lead to secessionist war or even genocide, as witnessed in the Holocaust against the Jews from 1941 until 1945, the mass slaughter of Tutsis in Rwanda in 1994, and the civil war between Sinhalese and Tamils in Sri Lanka that played out over two and a half decades from 1983 until 2009.

The cultural politics of the individual

Every individual is a cultural being, and cultural identity is an embodied phenomenon. Every body has a set of physiological characteristics that reveal the building blocks of a person’s cultural identity. Physiology makes visible a person’s sex and race, but it is the different interpretations of – and expectations associated with – these identifiers that often drive the cultural politics of the individual. As such, there are socially constructed – and socially accepted – ways of being male or female. While the physiology of the body cannot (without invasive surgery) be changed, the way the body is dressed, decorated, and adorned by the cut and color of hair, the style of clothes, the presence of tattoos, piercings or makeup, the accessorizing with jewelry – not to mention the style of speech, mannerisms, attitudes, and behaviors – gives the individual unlimited freedom to interpret and represent their cultural identity as they wish. In other words, while it is nearly impossible to escape the biological entrapments of cultural belonging, everybody has the power to use their body in a way that can enforce or challenge predetermined cultural stereotypes.

Cultural geographers have explored how space can dictate and control the movement of bodies and, specifically, how cultural norms and expectations can restrict mobility. For example, gendered dress codes in office spaces – narrow skirts and high-heeled shoes – have resulted in the inability of women to walk quickly and assertively. In some instances, the evolution and expansion of cultural identifiers has resulted in the clearer demarcation of social space. Class, for example, was once a descriptive term that referred to income, status, occupation, or consumption habits, but has since developed into a more meaningful term that can be simultaneously exploitative, judgmental, and spatially restrictive. Gated communities have developed as spaces that do not welcome – or permit the entry of – working-class bodies without due reason, while working-class council estates are spaces wherein the bodies of the affluent may
CULTURAL POLITICS

feel threatened and vulnerable to attack. While the cultural identifiers of the body can grant and restrict access to various spaces, they can also dictate behaviors in space as well. For example, the movement and freedom of Muslim women in public spaces can be controlled through dress (having to wear the burka or hijab) and prescriptions on behavior (in Saudi Arabia, for example, Muslim women are banned from driving cars; in many Western contexts, however, restrictions on the freedom to wear Muslim dress are often depicted as violations of human rights). Transgressing such conditions of movement can lead to a range of outcomes, from emancipation to social outcasting and persecution.

The cultural politics of landscape

Cultural landscapes are at once a reflection and a manifestation of the dominant cultural order. Such landscapes are most commonly associated with public spaces, and can be divisive insofar as they help to instill and enforce feelings of cultural inclusion and alterity. While public spaces typically refer to the built environment, they also include other mainstream spaces associated with the media, education, politics, and housing. As David Chidester and Edward Linenthal (1995, 17) state with regard to religious spaces—a maxim that has wider-ranging application beyond religion—the cultural landscape can reflect and establish “hierarchical power relations of domination and subordination, inclusion and exclusion, appropriation and dispossession.” The presence of cultural minorities and the associated alteration of the cultural landscape can be a cause of much resentment and resistance, and can lead to greater expressions of cultural diversity on the one hand, and be a source of bitter intercultural conflict (and the more stringent regulation and surveillance of public spaces) on the other. Accordingly, the spaces of cultural minorities—also referred to as subcultural spaces—often function as spaces of resistance to a dominant cultural order. Clearly, cultural landscapes provide some of the most tangible and visible evidence of cultural politics, and are one of the most long-standing areas of inquiry among cultural geographers.

In many Western contexts, public spaces have traditionally been associated with masculinity, heterosexuality, and able-bodiedness, and imprinted by the dominant racial, religious, and linguistic group of a territory. Neighborhoods and housing are typically segregated along the lines of class or ethnicity, whereas public spaces have traditionally—whether intentionally or not—enforced various stereotypes associated with gender and sexuality. While feminists have shown a preoccupation with overthrowing—or at least moderating—the patriarchy associated with mainstream culture, scholars of queer studies have sought to do the same with the assumptions of heterosexuality that permeate everyday cultural symbols found in advertising, film, and TV storylines, and in residential and educational spaces. For example, the Stonewall Inn (a gay bar in New York City) has been credited with marking the beginning of the modern struggle for gay and lesbian rights after its patrons defiantly resisted a raid by a homophobic police force in 1969. For other groups, private spaces are where resistance to the prevailing cultural order can be realized and fomented. House churches in communist China and Buddhist-majority Sri Lanka have been shown to enable the proliferation of Christianity in cultural contexts where public displays of religious presence and growth are discouraged via a variety of formal and informal means. Indeed, it is almost to be expected that, wherever a cultural landscape reflects the ideals of a dominant group at the expense of
minorities, it will encounter some form of resistance.

The politics of cultural representation

Finally, as part of the emancipatory agenda of the new cultural geography, debates around the different forms of cultural representation have come to the fore. In particular, a rift between the scholarly foci on texts, theories, and things (or representations of culture), and experiences, practices, and feelings (or fleeting and often more performative representations of culture), has caused a rethinking of how culture is studied and understood. Cultural representation has, in other words, expanded and become more nuanced as researchers grapple with different – and often unthinking – ways of studying, understanding, and replicating cultural symbols and property. Nonrepresentational theory attempts to provide recompense to the belief that normative representations of culture have become increasingly decoupled from experience, leaving behind a representational void that is filled by nonrepresentational forms of cultural transmission. As such, nonrepresentational cultural geography focuses primarily on the performative aspects of culture, such as music, dance, art, and other forms of sensory-affective experience. In many respects, the politics of representation come from the same root as the politics of cultural knowledge production – that is, how the cultural world is understood, interpreted, and (re)produced.

Pioneered by Nigel Thrift in the mid-1990s, nonrepresentational theory aims to celebrate the everyday workings of culture – through creativity, imagination, and play – and how such workings are used to undermine systems of power (see Thrift 2007). The argument is that academics do culture a disservice by losing the contextual nuances of culture by writing about it in academic books and journals. In a bid to alleviate this problem, nonrepresentational theory seeks to present culture not as a post hoc event, but in the moment of creation. Doing so has seen a methodological shift toward more in situ methods such as filming, and asking research participants to document their lives through photography, film, and journaling in a bid to create real-time data. Indeed, alongside the growing sensitivity toward cultural politics, there has also been growing interest among geographers in not just studying cultural politics, but also addressing and attempting to alleviate its effects as well. Participation has ranged from charitable and volunteer work to the embracement of participatory methods and, in its most persuasive form, political activism and lobbying.

Nonrepresentation is not, however, without criticism. Just as nonrepresentational forms of cultural study attempt to break away from representation, they cannot, ultimately, disconnect from representation entirely. Representational forms of communication are needed to translate the nonrepresentational into something that can be shared and understood by a wider academic community. While it has been criticized for promoting a sort of intellectual circuitousness – one obsessed with linguistic games and the decoding of meanings – nonrepresentational theory has nonetheless helped to provide another approach to the study and understanding of cultural politics. In doing so, it serves to further highlight that cultural politics is an inherent part of cultural study, and pervades every aspect of cultural production, identity, and representation.

Massey University, New Zealand

Cultural studies is a critical interdisciplinary (and sometimes antidisciplinary) field that studies cultural dynamics, forms, struggles, and transformations. Defining cultural studies is difficult as the field has always resisted disciplinary codification and closure. It draws on various strands of Marxism, feminism, semiotics, and poststructuralism to examine culture as it is lived, experienced, performed, contested, and transformed. Culture is understood as a site of struggle through which meanings, pleasures, discourses, representations, identities, and practices are fashioned and reworked. Its proponents are interested in how relations of power and oppressions of class, race, gender, and sexuality are reproduced and can be subverted, and they see everyday cultural practices as important sites for such reproduction and subversion. Cultural studies unsettled established academic disciplines because it dealt with cultural forms and practices that were not traditionally studied or taken seriously within universities, including ordinary and popular cultures of everyday life in contemporary societies such as working class tastes, youth subcultures, and women’s cultures. It focuses on the structural constraints within which these cultures come into being, but also on the forms of agency, pleasure, and resistance that enable ordinary and subordinated people to generate meanings, creative practices, and forms of struggle. Cultural studies famously refused to view contemporary cultural consumers as “cultural dopes” (Hall 2005, 67).

While there are some standalone departments and programs of cultural studies, scholars who identify with the label are widely dispersed throughout the humanities and social sciences. Cultural studies has inspired, and been inspired by, many other disciplines, including English, sociology, anthropology, geography, and education. It also interacts heavily with and informs many interdisciplinary fields, such as American studies, media studies, postcolonial studies, science and technology studies, and gender studies. Cultural studies as a field of study is now thoroughly institutionalized and is visible in universities, conferences, academic societies, and publications throughout the world, and its intellectual contributions have been fundamental and decisive. Its defiance and critique of traditional disciplinarity, and its engagement with subject matter historically disregarded by the academic establishment, have reshaped how many fields and established disciplines operate. Nevertheless, in the age of the increasingly corporatized university, cultural studies often occupies a contested and sometimes precarious position. While cultural studies work has been and continues to be highly influential throughout the world, the field’s radical interdisciplinary and, arguably, increasingly amorphous identity have rendered it vulnerable in the context of neoliberal universities’ cost-cutting, restructuring, and deepening audit cultures. Indeed,
cultural studies was hastily eliminated at the University of Birmingham in 2002 after a research assessment exercise result that fell one point below expectations.

The question of what constitutes the boundaries of cultural studies is a complex and contested one. While a spirit of theoretical experimentation and radical interdisciplinarity has long been central to cultural studies’ ethos and its practitioners have struggled against the calcification of the field into an orthodoxy, it has also been apparent from the start that “cultural studies” must be more than a synonym for any and all studies of culture. Those who edit the field’s journals, organize its conferences, and run its degree programs necessarily encounter a recurring need to articulate the boundaries of cultural studies, however provisional, expansive, and permeable they may be. Hence the present, future, and even the past of cultural studies have been matters of ongoing debate since the field’s earliest days.

Emergence of cultural studies

While there have been politicized analyses of contemporary culture throughout much of the twentieth century and the world, cultural studies as a specific field of intellectual enquiry came into being in the United Kingdom via an initial creative blending of critical pedagogy, adult education, and Marxist analysis, joined later by semiotics, structuralism, feminism, ethnography, and poststructuralism. Richard Hoggart’s *The Uses of Literacy* (1957), Raymond Williams’s *Culture and Society* (1958), and E.P. Thompson’s *The Making of the English Working Class* (1964) are often described as key texts for the emergence of British cultural studies. While quite different from each other, these works are united in taking working class culture seriously and emphasizing, albeit to varying degrees, the agency and capacities of ordinary people to make their own culture.

The naming and institutionalization of cultural studies began with the creation of the Centre for Contemporary Cultural Studies (CCCS) at the University of Birmingham in 1964. Richard Hoggart, who had worked as an adult educator before joining the university in 1962, was the center’s first director. He was succeeded in 1968 by Stuart Hall, a Jamaican-born leftist. Hall’s thinking was more theoretically inclined than Hoggart’s, and under his leadership the center engaged closely with Marxism, structuralism, and semiotics. While Althusserian and Barthesian approaches enabled those at CCCS to develop sophisticated analyses of contemporary media culture, by the end of the 1970s the center had turned decisively to Gramsci, whose theory of hegemony offered a way to rethink the functionalism increasingly associated with Althusser’s account of ideological state apparatuses (ISAs) and subjects, and thus more effectively to identify sites of hegemonic contestation and possibilities for political transformation across contemporary cultural landscapes.

Those who worked at the center described it as a theoretically productive and experimental space, full of tensions and vibrant debates. During the 1970s, CCCS scholars produced pathbreaking analyses of working-class lads, popular music subcultures, and television news and its audiences. In the mid-1970s, in the midst of second-wave feminism, a number of female graduate students, including Angela McRobbie, Chris Weedon, Charlotte Brunsdon, and Janice Winship, took the faculty to task for their lack of attention to gendered power and to the cultures of women and girls. In 1978 they published *Women Take Issue: Aspects of Women’s Subordination*, which combined theoretical analysis with case studies such as women’s magazines, teenage girls’ cultures, and the home lives of...
working-class women. This initiative paved the way for the development of feminist cultural studies that explored things like soap operas, romance novels, and the cultures of women’s and girls’ everyday lives. Hall (1992, 282) wrote that like a “thief in the night,” feminism “broke in, interrupted, made an unseemly noise, seized the time, crapped on the table of cultural studies.” Similarly, there were important interruptions and redirections of the Birmingham project’s original focus on class as an object of analysis with the attention given to race in one of the center’s most celebrated publications, *Policing the Crisis: Mugging, the State, and Law and Order* (1978), and in *The Empire Strikes Back: Race and Racism in 70s Britain* (1982).

Stuart Hall: meaning, discourse, and ideology

The turn to Gramsci at the center in the 1970s facilitated analyses of the ways in which subordinated social groups negotiate the social circulation of meanings and ideologies in contemporary culture. Among cultural studies’ primary targets were various reductionisms (economic as well as textual) that too readily presume the effects of the “culture industries” in securing the domination of the power-bloc. As Hall (2005, 71) writes, popular culture is best understood in much more contingent, dynamic, and processual terms as a site where the struggle “for and against a culture of the powerful is engaged.” Hence, although “it is partly where hegemony arises, and where it is secured,” it is at one and the same time, for Hall (and for cultural studies), a thoroughly contradictory terrain where competing perspectives, discourses, and interests – top–down as well as bottom–up – clash and compete, and where “the people” might be constituted as “a popular-democratic cultural force.”

Hall encouraged us to think of cultural productivity and agency in terms of articulation, understood as both a contingent link that can be broken and a process for putting into meaning or “language-ing” (see Grossberg 1996). Meaning is thus understood as a product of contingent linkages between different discourses, sub-discourses, and other signifying elements that may, though need not necessarily, be conjoined within larger ideological formations. The meanings that result from such breakable connections can be shifted through practices of disarticulation and rearticulation; the conjunction of previously disjoined discourses necessarily brings new meanings into social circulation. Hall’s self-styled “post-Marxist” approach to this issue thereby evades long-standing problems of reductionism and essentialism in Marxist thought concerning the relationships between economic practices and subjectivity/consciousness (or other cultural products). Hall replaces the notion of pregiven social formations (such as classes or races) and of fixed ideological ones (e.g., “dominant ideology,” revolutionary consciousness) with a more flexible and contingent set of concepts that nevertheless remain anchored in a materialist epistemology and politics.

Within this framework, when the subelements of an existing discourse are negotiated, broken up, rearranged, and articulated to subelements of other discourses, new subject positions emerge that generate fresh ways of making sense and of engendering social crises and mobilizations. Such newly rearticulated discourses and subject positions might then become part of emergent social identities and movements, which are themselves understood as the products of these ongoing negotiations and articulatory practices (rather than being understood as preexisting “classes” waiting to be activated into consciousness). Hall’s
presumption that there are no pregiven, fixed identities prior to the negotiation and cultural articulation of meanings is not a form of idealism (e.g., “everything is discourse,” “anything can be articulated with anything else”), but rather a rejection of essentialism and excessive determinism.

Hall gives the example of Jamaican Rastafarians, who came to political consciousness and to social and cultural activism by rearticulating the subelements of preexisting discourses from the text of the Bible into a thoroughly modern and wholly new set of expressive practices. As Hall writes of the Rastafarians, because the Bible was a text that “did not belong to them,” they had to rearrange and invert it to produce meanings “that fit their experience. But in turning the text upside-down they remade themselves; they positioned themselves differently as new political subjects; they reconstructed themselves as blacks in the new world: they became what they are. And, positioning themselves in that way, they learned to speak a new language” (Grossberg 1996, 143). Condensed into this highly dialectical example are key ingredients of a nonreductive, nondeterministic mode of cultural studies thinking: cultural innovation comes not from whole cloth but rather from a materially anchored and socially motivated reworking of existing sense-making resources for new purposes. In this reworking, the cultural agency of subordinated peoples is neither unconstrained nor fully subordinated to the control of centralized administrative bureaucracies or conglomerated capitalist enterprises; rather, it exists within a field of continuous and ongoing contestation over the disposition and mobilization of signifying resources: a site of semiotic struggle or a terrain characterized by conflict in terms of a politics of meaning that is fully enmeshed within and articulated to lived conditions of material existence wherein significant stakes hang in the balance.

**Internationalization of cultural studies**

Throughout the 1980s, cultural studies increasingly went global and started to become a much more diverse and variegated set of enterprises. Key practitioners moved from Britain to Australia at the onset of Thatcherism and helped generate a very significant cultural studies scene down under. Meanwhile, cultural studies took hold in the United States as an alternative to both economistic and more pessimistic modes of Marxist analysis. During the same decade, cultural studies began its extended engagements with poststructuralism, post-Marxism, and postmodernism. The first two of these, particularly in the guise of Michel Foucault and Michel de Certeau, would lead to even further complication of cultural studies’ theories of power and subjectivity. To a significant degree, the third formation, postmodernism, began giving way to the conceptual problematic of globalization as a source of theoretical energy and terrain of struggle in cultural studies from the 1990s onward.

Throughout the period of cultural studies’ internationalization, the field has multiplied its issues and perspectives, engaging with an ever-expanding range of theorists and objects of analysis. In recent decades, scholarship in cultural studies has dealt with contemporary media; popular audiences and fandom; critical pedagogies; genders and sexualities; race, ethnicity, and nations/nationalities; subjectivities, identifications, and identity politics; urban life and cultures; postcolonialism and decoloniality; cultural policy; globalization and transnational flows; science and technology studies; surveillance; human–animal relations; cultures of environmentalism; satellites and remote sensing; bodies and bioethics; new social movements; human rights and citizenships; the War on Terror and securitization; neoliberalization; and consumption.
While the Birmingham School is central to the development of cultural studies as an intellectual field, it is important to recognize the diverse sites in which cultural studies emerged and continues to proliferate. The cultural studies project has been taken up around the world in a variety of ways (see Ríos, Trigo, and Del Sarto 2004; Abbas and Erni 2005). Today, cultural studies has many regional formations that extend far beyond the United Kingdom into Asia, Oceania, the Americas, Africa, and continental Europe. While some cultural studies formations recognizably build on the intellectual foundations developed by Stuart Hall and others in the United Kingdom, it is important to observe that they also draw on other regional cultural histories, theoretical underpinnings, and intellectual trajectories. Latin American cultural studies, for example, is influenced less by Raymond Williams and Richard Hoggart than by José Martí, José Carlos Mariátegui, Angel Rama, and Darcy Ribeiro, and this work in turn influences Latin American geographers. A recognition of and engagement with such diverse genealogies has led to the indigenization, decolonization, and de-Westernization of cultural studies and to productive comparative debates across geographical difference. For instance, there is a body of literature emerging from Latin American cultural studies, termed the modernity/coloniality/decoloniality (MCD) paradigm, which draws on earlier decolonizing historical events and scholarship, and on indigenous and popular knowledges from América. As John Frow (2005) has noted, cultural studies’ intellectual, theoretical, and institutional history is highly contested and heterogeneous; there is no singular trajectory that can be neatly mapped, but there are important theoretical detours, key theorists, and debates that vary depending partly on where one practices cultural studies. While there are many ongoing arguments about the strengths and weaknesses of cultural studies, the field’s sense of radical experimentation persists and has tended to prevent its congealment into a fixed disciplinary identity.

One strain of cultural studies work that has been both influential and controversial in recent years has developed around the expansion of participatory digital media and the emergence of what Jenkins (2008) calls “convergence culture.” In the new media environment, where audiences, citizens, and fans can produce, circulate, remix, refashion, vote on, and comment about all manner of cultural events, products, and figures, spaces are opened for the participatory negotiation and rearticulation of significant political issues (Cupples and Glynn 2013). In the digital media ecology, people develop and hone skills that lend themselves to the production of new modes of participation, creativity, and collective intelligence, new forms of political and transcultural engagement, decreased dependence on official expertise, and enhanced capacities for collaborative problem-solving (Jenkins 2008).

Cultural studies and geography

In many ways and for various reasons, cultural studies set out deliberately to disrupt established modes of disciplinary thinking and practice. The intellectual debates engendered by the work of the Birmingham School had a profound effect on disciplines such as sociology, mass communication, and geography, all of which underwent a “cultural turn.” Geography, for example, was reworked in the 1980s and 1990s as practitioners drew on intellectual sources and developments taking place elsewhere, including in cultural studies. This reworking has given us a significantly expanded terrain of geographic subject matter in the form of the new cultural geography.
A seminal text that explicitly brought cultural studies into dialog with human geography was Peter Jackson’s *Maps of Meaning* (1989). This book drew on the work of the Birmingham School (and other theoretical influences) to give questions of race and racialization a distinctly spatial inflection and thus to demonstrate that both racisms and struggles against them have their own specific geographies (see also Jackson 1987). In the process, Jackson developed a critical and materialist cultural geography that moved beyond the rigidity and structuralism of classical Marxism. Without denying that ordinary people in Thatcher’s Britain operated under structural constraints, Jackson emphasized the spaces for agency and resistance they created through their uses of cultural resources available to them. Since the publication of *Maps of Meaning*, scholars such as Tim Cresswell, David Morley, Kevin Robins, Nick Couldry, Lynn Spigel, Clive Barnett, Jason Dittmer, and others have produced work explicitly positioned at the intersection of human geography and cultural studies.

Meanwhile, cultural studies has undergone something of a spatial turn, which has proven to be highly compatible with the field’s commitments to conjunctural and contextual analysis. For example, significant work has explored the micropolitics of living rooms as places where TVs and digital media are both embedded within and constitutive of (particularly gendered and generational) relations of meaning and power. An important recent collaboration at the intersection of human geography and cultural studies, the Kilburn Manifesto (http://www.lwbooks.co.uk/journals/soundings/manifesto.html), seeks to intervene in widespread processes of neoliberalization. This initiative, led by Stuart Hall, Doreen Massey, and Michael Rustin, is a series of publications that attempt to stimulate the generation of alternatives to neoliberalism by radically rethinking the current economic order in terms that are missing from many contemporary political debates. Geography’s cultural turn and cultural studies’ spatial turn have made it difficult to distinguish categorically between contemporary cultural geography and cultural studies.

Cultural turn

Clayton Rosati
Bowling Green State University, USA

The cultural turn describes a broad set of shifts in the social sciences and humanities, which blossomed from the 1970s to the early 2000s. This shift moved geography’s object of study from economic logics, the direct exercise of power (in geopolitics), the quantitative and positivist geography of the early 1970s, and the morphology of landscape, to questions of shared meaning, representation, and the politics of language and consent. Especially in critical geography, modes of explanation shifted from political economy to culture. Culture became an object of study not just in its traditional home of cultural geography but across the gamut of human geography, from economic geography to critical geopolitics to urban geography.

Coinciding with and building on emergent critiques of positivism, universalism, determinism, essentialism, patriarchy, heteronormativity, racism, and Eurocentrism, this shift incorporated many theories and methods, including feminism, phenomenology, poststructuralism, postcolonial studies, black studies, ethnic studies, queer studies, linguistics, symbolic interactionism, and qualitative methodologies. One might see the roots of the cultural turn developing with Italian communist leader Antonio Gramsci’s interwar critiques of the “vulgar” Marxism – particularly forms of economism, ignoring especially political struggle, intentionality, and intraclass difference – that dominated the Second International after Marx’s death. Just as importantly, the 1950s’ seemingly permanent postwar prosperity in the “first world” demanded further reconsideration of traditional Marxist critiques of impoverishment and crisis, provoking instead critical theories of social management and mental freedom. The English translation and subsequent popularity of Gramsci in the 1970s found utility in an analogous tension between determinism (“structuralism”) and theories of difference (“culturalism”) in the 1960s and 1970s, identified most commonly in E.P. Thompson’s critique of Louis Althusser (Thompson 1978) (although Thompson’s postscript to The Poverty of Theory rejects the idea that he is a culturalist, e.g., pp. 297–298). The interventions of poststructuralists like Derrida and Barthes, and critics of modernity – and Marxist complicity with capitalist modernity – like Foucault, Baudrillard, and Lyotard, struggled to push critical and radical thought beyond the limited horizons of Hegelian grand narratives of history and structuralist fixity in meaning and language.

All of these influences converged in the work by Hall, Gilroy, and others from the Centre for Contemporary Cultural Studies at the University of Birmingham, beginning in the early 1960s, which became crucial for mainstreaming critical scholarship on culture and a central resource for critical geographers. Ultimately, after the failures of the 1960s revolutions worldwide, the cultural turn also came to focus on micropolitics and a rejection of parties, grand strategies, and revolution, in general. With the rise of Thatcher, Reagan, and neoliberalism’s popularity among the Anglo-American working classes in the 1980s, the “natural majorities” and assumed alliances among social movements had to be rejected and, instead, fought for (e.g., Hall
1988). “Culture” became a way of describing the terrain of that struggle, drawing heavily on Gramsci’s theories of building class alliances and winning consent for dominant social norms in “civil society” before they take hold in the state. Here, Barthes and Derrida’s influential work on language was equally important. On the one hand, culture was that which is determined by shared “maps of meanings,” discourse, ideology, and forms of “common sense.” And, on the other hand, it became that which is constantly differentiated, local, historically and geographically specific, and made contingent through use. The cultural turn, thus, embodied a paradox and a continuation of old tensions.

In geography, the cultural turn’s impact was felt widely and drew heavily on these shifts, impacting – among others – contemporary cultural geography, including landscape studies; economic geographies of labor, regulation, innovation, agglomeration, culture industries, urban economic geography, and studies of the capitalist state; and geopolitics involving Gramscian and Foucauldian international relations, scale and activism, development, and neoliberalism; however, culture and the cultural have invited critique. Within geography, the latter part of the 1990s wrestled with the concept after its critique by Mitchell (1995) for reifying culture into a thing, sphere, or realm, making culture a causal force, and ignoring the power of culture industries in producing ideas of difference, if not difference itself. Beyond this, the sensibilities of the cultural turn’s Gramscian emphasis on meaning and representation, and its tendency toward valorizing individual autonomy, are increasingly under critique by non-Gramscian currents in affect theory, actor-network theory, and other variants of new materialism.

Contemporary cultural geography, including landscape studies – where geography’s cultural turn had its principal and most resounding impact – begins in the early twentieth century with the rejection of environmental determinism and social Darwinism, which led to the adoption of an anthropological model whereby the diffusion of particular cultures determined the morphology of vernacular landscape. This, now, “old cultural geography,” in the 1970s came to focus increasingly on the ordinary and everyday aspects of landscape as society’s “unwitting autobiography” (Lewis 1979). With the growing dominance of concepts from cultural studies, however, a “new cultural geography” developed, which rejected the structuring determination of life implied in this old school of thought. Duncan’s (1980) thorough critique of the “superorganic” – Hegelian–like cultural entities above human beings, which determine their actions and works – in cultural geography emphasized the internal differences, choices, conflicts, and struggles that were erased in this old model. The so-called new cultural geographers of the late 1980s and the 1990s engaged emergent theories of difference and linguistic understandings of use and practice (see an influential collection of papers from the 1991 Royal Geographical Society–Institute of British Geographers conference edited by Chris Philo). Landscape, as with the old cultural geography, was still a text to be read. But, with the new incorporation of semiology’s emphasis on the relationship between sign, signifier, and signified, reading landscape also involved reading social attitudes and the maps of meaning produced in interactions with not just landscape morphologies, but also previous meanings associated with them. Drawing also from cultural studies, the status of particular meanings and types of morphological forms themselves varies, understood as dominant, residual, or emergent. Landscape is, thus, seen as part of the constituent process of hegemony – life lived under dominance, not as force but as given conditions and
assumptions beyond which life is difficult to imagine. Work on landscape and urban design also eventually extended this through more Nietzschean critiques of truth into Baudrillardian notions of the hyperreal and simulacra, of signs referring only to other signs.

In economic geography, the cultural turn had several impacts, mostly in branching away from strict and deterministic understandings of capitalist accumulation and of industrial firm location. The impact of French regulationism on economic geography is significant in its engagement with transitions away from economism and versions of ahistorical capitalist logic. Here, as in cultural geography, the inclusion of factors like contingent and historically specific systems of social meaning and social agency in labor geography, capitalist accumulation, and studies of the capitalist state tempered more determined understandings of economic systems and structures. So-called cultures of production, and shared differences between firms’ production practices, were studied as means of developing competitive advantages. “Innovation” became another associated way of understanding the “cultural” or forms of difference in production practices. If culture was conceptually inserted into terms of the practice of production, cultural artifacts by corporations – small and large – also became an object of study for economic geography. With some key exceptions, these studies generally were not critical or did not engage with the content of those artifacts. Rather, as critics have noticed, they were interested mostly in the economic behavior and success of capitalist firms. Importantly, decades after Raymond Williams (1977) imploded the overbaked base–superstructure relationship, economic geographers began to engage with meaning, symbols, and differing social practice as a constitutive part of the foundation of economic and capitalist production. Ultimately, by the mid-2000s, the distinctions – more so there than in cultural geography – between the “cultural” and “economic” aspects of social life were reconceptualized and described as the cultural economy.

Critical work on urban economic geography and on the capitalist state pulled important lessons from Foucauldian and feminist understandings of biopower and discourse. Likewise, urban and economically oriented work on critical race studies and the prison industrial complex (e.g., Ruth Gilmore’s work) were central contributions to the critical side of geography’s cultural turn. Some of the most controversial work from economic geography’s cultural turn is on diverse economies and the epistemological politics of capitalism (e.g., J.K. Gibson-Graham’s work), which aims to subvert conceptualizations of the “organic totality” of global capitalism toward envisioning and enacting “new class futures.” They claim that the power, scale, and coherence of capitalism are determined by our discourses, which ascribe it those characteristics. While knowledge and systems of meaning are foundational to understandings of economic power, the question of what kinds of epistemological politics are appropriate for which kinds of capitalist subjection remains open, if hotly contested. Here, the post-1968 political question of how to avoid reproducing what is being fought is central to ongoing critiques of capitalism. But, particularly after the 2007 world financial crisis, the macro-conditions – even if produced through myriad micropractices – of the capitalist mode of production still demand to be studied. Though much work from the 1990s and 2000s focuses on critiques of neoliberalism, perhaps to this end, they have tended to sidestep the questions “What is capitalism?” (of which neoliberalism is a specific articulation) and “How do we transform it?”
CULTURAL TURN

In geopolitics, the cultural turn brought Foucauldian knowledge/power and Gramscian hegemony into the study of relations between states as relations based on more than the direct exercise of force. Toal’s (1996) Foucauldian engagement with the principles of geopolitics and Agnew’s (1998) Gramscian utilization of hegemony pushed discussions about American geopolitical power beyond notions of simple dominance. Although raw military force remains important, the development of American international power has to do with a foundation of institutional, philanthropic, corporate, and other agents of building consent for American leadership. With this came research into the internationalization of the nation-state as a mechanism for building and maintaining hegemonic leadership in geopolitics. Here as well, the Washington Consensus, which aimed at liberalization and fiscal discipline, and at neoliberalism more broadly, became the framework for understanding forms of consensus in international development and economic policy, enacted within various governmental and nongovernmental institutional pressures. Scholarly engagements with protests at the disruptive nature of these projects and resistance to development projects more broadly also incorporated lessons from Gramsci. By focusing on the construction of class alliances and social movement tactics that would help scale up a social movement’s reach and impact, these movements engaged in Gramscian “wars of position” over accepted ideas and appropriate questions to ask so as to eventually capture elements of state power and policy. Some recent work on this has questioned the effectiveness of traditional movement tactics involving large urban protest spectacle, especially on the use of media for jumping scale, due to the increased police control over permissible public spaces for protest.

Many critiques of culturalist approaches exist, some from within and others from without the broad cultural turn. Mitchell’s famous and still controversial 1995 critique from within, “There’s no such thing as culture,” challenged the very notion of culture as either a causal object or as a sphere or realm distinct from other aspects of social life. While the theories and methods of new cultural geographers rejected economic reductionism, Mitchell’s critique suggested that in doing so they reified culture in these separations. Drawing on work by James Clifford and echoed by critics like Terry Eagleton, the idea of culture became increasingly disenchanted in geography. Culture, it seemed, either as systems of meanings or as localized diverse uses, constantly deferred the questions of social power, politics, and how it was produced. Further, and more to the crux of the matter, since the 1970s, “culture” had become the most fashionable means among policymakers to blame the poor for their impoverishment, rather than looking to exogenous, economic factors. Here, in policy debates about the so-called culture of poverty/welfare/entitlements is where the seeming arcane debates about culture’s ontological status have clear political force and implications. Beyond critique, Mitchell’s work on culture, more importantly, aimed to reconstruct the object of study in cultural analysis and the bases of culture’s production within the limits, pressures, and material social power of political economy. But in Mitchell’s critique, unlike others, the production and politics of meaning remain crucial to the mission of critical geography.

By the mid-2000s, a number of new theoretical directions – drawing from environmental/ecological crisis, quantum physics, biological and neurosciences – had taken root in human geography and in cultural studies, which challenged several of the foundations of
the cultural turn. Affect studies, actor-network theory (ANT), a set of loosely confederated “new” (non-Marxian) materialisms, and a broad engagement with Deleuze and Guattari, directly disputed humancentric orientations, meaning in social exchange, and historical processes. Like an echo of earlier determinisms, affect studies and so-called nonrepresentational theories push previous understandings of biopower beyond the discourses of norms and bodies into the direct modulation of feeling and affective response, which happen before and thus determine meaning and choice. From that vantage, the political struggles around Gramscian hegemony seem defunct on ontological grounds, since meaning, language, and representation are no longer presumed to be the operative mechanism of political life. Debates commenced, subsequently, about “posthegemon” theory. Further, the insistence of ANT and theorists of “vibrant” matter on the equality of humans and nonhumans as agents or social actors, and on human consciousness as a kind of determined effect, is like the metastasization of Althusser’s antihumanism, against which Thompson wrote so pointedly. Many of these approaches minimize or outright reject systems (e.g., capitalism), history, material fixity, and other concepts that would either extend beyond locally observable phenomena or determine a world seen as radically immanent and contingent.

In the contemporary period, the tensions and paradoxes subsumed within the cultural turn have been extended and pushed to their limited conclusions. Gramsci and systems of meaning, which determine the production and use of material life, are still important in human geography but exist in contention with these recent challenges more so than they did in previous decades, during the flourishing of the cultural turn.

To the extent that they have affected radical politics, these new challenges have left them even more constrained – resistance confined often to the accidental and social meaning subordinated to the agency of inanimate objects. The extension of micropolitics and intensification of antielectoral political tendencies, however, is unreflective as a rejection of previous (pre-1968) failures, in its lack of comparative engagement with other potential strategic paths and with subsequent failures and incongruities. As such, the insurgent view of Gramsci’s irrelevance increasingly limits the question of where Gramsci and, for example, the affective may overlap or where meaning and mindfulness may intercede in or perhaps overcome the determining attempts at affective control. Again, the post-2008 global financial collapse demands a reconsideration of economic systems and history, not to mention a re-engagement with notions of a world public and global political organization. Even further, the focus on objects and the agency of matter misses many of the determining – real limits and pressures of inheritance, profit and interest, and so forth – and particular meaning-related processes that produce the objects in our social world, one of the key principles in landscape studies, for instance. The cultural turn’s critique of positivism’s or empiricism’s lack of skepticism of the world as it appears is implicit here. When it is incapable of addressing these, the new materialism of geography requires a cultural re-turn but one that further engages the materiality of meaning and struggles for consent and studies the production of systems of meaning through political economic force and the technological composition of that force.

Further reading

Culture is a central concern of geography, for its perceived role in shaping spatial variations in social relations and human–environment interactions. There is also great diversity in how culture is defined and used in the production of geographical knowledge. It can be simultaneously a verb and a noun, a category and a quality.

Defining the term literally, as a verb, links culture to practices of cultivation – to grow, extend, feed, or rear – as in agriculture, horticulture, or viticulture. To culture is to steward or produce material objects and artifacts in particular places and times. This is one of the older interpretations of culture in geographical thought, and is commonly found also in cognate disciplines such as anthropology and archaeology, where the study of material culture (artifacts, crafts, objects) is common. Indeed, in the colonial period culture was pivotal to European understandings of what it was to be human, distinguishing Homo sapiens from nonhuman species. Charles Darwin (1871, 122) himself famously argued that “The highest possible stage in moral culture is when we recognize that we ought to control our thoughts.” Cultivated practices distinguished humans from other nonhuman nature. A capacity for cultivation enabled humans to secure food production in ways that are seemingly beyond “natural” laws and ecological limits. Such antecedents set in train a linguistic and ontological binary dualism between “culture” and “nature” (the latter positioned as antonymic to the former) which would later come under fire from critical geographical scholars.

Other nuances of meaning in the term also derive from the colonial era. Caught up in the Enlightenment pursuit of scientific knowledge, geographers were important public intellectuals mapping regions hitherto unknown to Europeans, observing difference and attempting to theorize extant variation. Culture, understood as practices of cultivation, was a central part of this context. The dominant thinking was that geographical variants in aspects of nonhuman nature (including the distribution of soil, landform, climate, and geological types) determined agricultural practices and differences. Nature explained observed variations in the geography and manner of human social, economic, and political development. Human culture and its geographical diversity were, in essence, thought of as manifestations of underlying physical biophysical variability. Such ideas would later be heavily critiqued within geography for their reliance on environmental determinism at the expense of human agency and contingency.

Throughout the same period, culture slipped into usage as a noun, denoting a quality, something possessed by a society that has progressed or “civilized” to the point of developing a set of shared norms, behaviors, and rationalities. This explains the related term “cultured.” Such a meaning was absorbed into European ways of thinking and acting hierarchically. Deeming themselves “cultured,” Europeans claimed technological and intellectual superiority. Such claims fused with prevailing imperial and social Darwinistic thinking, whereby humans were classified into different cultural types (e.g., “races”), and their humanity ranked (e.g., as...
CULTURE

“less human” savages, or as “children” who are in a stage of civilizing development). At its apex, such thinking linked culture as an achieved human quality with technological and imperial might, at a time when biological or organic theories of geopolitical expansion were manifest in the extreme fascism of Nazi Germany.

Related to this colonial legacy, but without its violent overtones, culture has often been used as a synonym to describe, often in a hierarchical manner, the creative expressions, and intellectual and aesthetic achievements of talented people within particular societies. People who understand and value intellectual and creative expressions are often positioned as critics, agents, and managers – arbiters of taste responsible for differentiating between what is considered “high” art (the domain of “cultured” people) and “common,” popular culture, such as pop songs and television shows. Influenced by French theorist Pierre Bourdieu, as well as the Birmingham School of Cultural Studies in the late twentieth century, such thinking was critiqued for its links to a politics of class division and tension. Nevertheless, such distinctions linger on, in for instance demarcated cultural precincts within cities (which typically feature an art gallery, museum, civic library, theater, or performing arts center) and in preferential government financial support for the “fine” arts as part of their nation-building and place-branding efforts.

Perhaps the most common definition of culture is as an identifiable way of life. In this definition, culture is understood as a set of shared values and beliefs based on language, religion, customs, or ethnicity. These cultural traits are expressed in material cultures, including crafted products, clothing, foods, buildings, and occupations, as well as in collective tendencies, political predilections, and behaviors. Such notions of culture are understood as “superorganic,” in that they suggest that culture is an independent, active force working on or through people and possessing casual power beyond that of the individual. Culture could be deployed to make generalized claims about all people within a particular geographically bounded area, termed a cultural realm or region.

In geography, culture as a way of life remained a dominant and largely uncontested meaning for over six decades from the 1920s to the 1980s. It was especially pervasive in the United States, where the influence of Carl Sauer, professor of geography at the University of California, Berkeley, was profound. Sauer sought to reinstate humans as active agents in the production of landscapes. In “The Morphology of Landscape,” Sauer argued that humans possess the unique capacity to modify landscapes (Sauer 1925). The Berkeley School of Cultural Geography, led by Sauer and his disciples, became more interested in the diffusion of culture traits (rather than in evolutionist generalizations of their origins), the identification of culture regions (in both material and nonmaterial terms), and the role of culture in conditioning human perceptions of nature and the environment.

Since the 1980s, however, the successive influences of poststructuralist, feminist, multicultural, queer, and more-than-human thinking on contemporary geography have challenged the primacy of viewing culture as a superorganic force. Drawn to contest categories and to reveal them as contingent and unstable rather than fixed, many contemporary cultural geographers resist any attempt to approach culture as a cause or to define culture as a thing, type, or even subdisciplinary field. Don Mitchell (1995) famously quipped that “There is no such thing as culture,” implying that culture is a fabricated category, a construct of ideology made to perform the work of power relations, without any real material existence.
Such arguments have meant that culture now occupies an ambivalent position in contemporary geographical thinking and research. Prevalent nowadays is an interpretation informed by a less everyday sense of the cultural: culture as knowledge production. In philosophical terms: What exists in the world? And how do we know what we know about the world? Such questions encourage researchers to identify links between knowledge production, power, practices, behaviors, and possibilities for change and transformation. Culture as a way of thinking and knowing is informed by a concern to examine how particular ideas are established, circulated, maintained, and challenged.

But even this sense is being superseded by a push from within the discipline to rematerialize culture in analysis. The previous emphasis on cerebral discourses, ideas, knowledges, and representations has been at the expense of acknowledging embodied interactions and the materiality of everyday life. It has also privileged human cognition and agency over the experiences and capacities of nonhuman others. Culture is more than mere ideas, and involves humans and nonhumans struggling for survival and meaning amid ongoing, unfolding, and emergent relationships – be they fleeting or more permanent – between animals, plants, material things, and bodies. At the vanguard, culture has almost slipped from the geographical lexicon, because of its deeply problematic association with a stable and fixed category of the human as cognitively superior and ontologically distinct.

What remains, then, is a highly variegated landscape of thinking and writing about culture across geography. How culture is adopted and used itself varies geographically within academic research – influenced by the degree of adherence to regional, national, and/or linguistic traditions. In the United States, where the legacy of Sauer remains strongest, culture as way of life is still a common understanding. In the United Kingdom, where the “cultural turn” of the 1980s was more thorough, waves of poststructuralist, relational-materialist, and posthumanist interpretations have seemingly distanced questions of culture from the superorganic, regional tradition. Elsewhere are hybrids of influences, blending global theories with endogenous factors and traditions (including language itself – an imprint of culture that has shaped, for instance, distinct French and German geographical traditions). In Singapore, China, and much of Asia culture in geographical research intersects with questions about national and religious identities and is therefore as much a topic of political geography as of cultural geography. In Canada, Australia, and New Zealand questions of culture in geography also bring to the fore their anxieties as settler-colonial nations still struggling with colonial injustices toward indigenous peoples and seeking to accommodate indigenous rights, practices, and traditions. In such circumstances, culture signifies not just a way of life or a sphere of meaning and identity, but a deeply politicized area of struggle for recognition and respect.

Cultures of nature

Lesley Head
University of Melbourne, Australia

Culture and nature

Geography has a long-standing indeed foundational interest in the relationships between culture and nature (and their parallel distinctions “society and nature,” “people and environment”). Study of how such relationships have varied over time and space has been a fundamental part of the discipline, and for many people it is embedded in the division of the discipline into human and physical geography. Both sides of the discipline (and the sciences generally) have approached such relationships within a humanist tradition, which assumes fundamental differences between humans and the rest of nature, whether living or nonliving. Phenomena such as imagination, conscience, ideology, worldview, and planning do not have their direct counterparts in other living organisms. So plants, animals, earth, water, and climate were approached in physical geography using the observational tools of the natural sciences.

The term “cultures of nature” refers to scholarship over the last two to three decades in which those categories and divisions became not so self-evident, largely due to human geographers taking on subject matter traditionally understood as the preserve of physical geography. The history of this research effort is often traced to Margaret Fitzsimmons’s (1989) call for human geographers to pay more attention to the idea of nature and to social natures. Various authors seen as part of the “cultural turn” in geography, influentially Kay Anderson, Sarah Whatmore, and Bruce Braun, drew attention to the implications of culturally variable understandings and perceptions of nature (e.g., Anderson 2003). In particular they argued that the clear binary or dualism between culture and nature was neither empirically nor ontologically valid. The cultural turn was also influenced by parallel trends in the sciences that systematically deconstructed the notion of humans having a special or distinct place in nature. The nature of human difference and similarity from other organisms became an open empirical question, not one to be approached with assumptions of essence.

Since then there has been a great flourishing of work across a number of disciplines, but particularly cultural geography, seeking to analyze and deconstruct the separation of culture and nature and think about it differently. Emphasis is placed on relations rather than essences; phenomena are seen to develop their characteristics in relation with a host of others. Alternative concepts advocated at different times by different authors include hybridity, actor-network theory, assemblages, and posthumanism influenced by key thinkers outside geography including Donna Haraway, Bruno Latour, John Law, and Annemarie Mol.

Components of “nature,” and its companion concepts

Nature in these debates is generally understood to encompass a wide variety of nonhumans. A
particularly strong body of work emerged under the umbrella term of animal geographies (Wolch and Emel 1998). Human interactions with many different species, including fish and birds, were studied, connected to a broad variety of topics. Many stemmed from animal welfare concerns, including in the context of farming and eating, and the consequent ethical debates. These deal with issues of subjectivity closely associated with concepts of mind and consciousness – how might we understand animals against the norm of the human subject? Hence geographic approaches drew in new work in philosophy and animal biology. The spatial context of many studies was urban – encompassing both pets and non-domesticated animals – helping to break down the parallel binary of cities as places of culture and rural areas as places of nature. Studies in protected area contexts included fraught issues such as the reintroduction of wolves in North America and northern Europe.

New approaches to organisms somewhat more different from the human emerged more slowly but have flourished in recent years. An influential work on trees (Jones and Cloke 2002) led plant approaches, which now encompass gardens, food, and invasive plants as well as more conceptual work. Fungi, microbes, and bacteria have been the subjects of recent critical study. While many animal geographic studies are framed by the similarities and commonalities between humans and other animals, work on bacteria or weeds has to start with the question of difference. Such work is no less relational, but it has forced different kinds of thinking about subjectivity and agency, which have then to be discussed without recourse to human or at least mammalian concepts such as mind and consciousness. This is more difficult but also opens up exciting new possibilities.

At the boundary between living and nonliving (a divide itself open to critique in the natural sciences) is a set of works that include among their nonhumans water, air pollution, weather, seawater, and the indifferent earth itself (e.g., Clark 2011). Clark has stimulated important discussions about what constitutes the political in inhuman nature. Now increasingly referred to as the “geological turn” in human geography, it remains to be seen whether this provides a basis for reforging links with physical geographers.

If the nature/culture binary was to be challenged, so was a set of companion concepts which assume their distinction. Foremost among these were wilderness and the wild, built out of long-standing but complex intellectual Western traditions of pristine nature. Indeed empirical challenge to the concept of pristine wilderness, founded on archaeological, indigenous, historical, and paleoecological evidence and picked up in a number of human geography studies, constituted one of the earliest contributions of cultures of nature scholarship. There are strong spatial contexts and applications in these debates, for example, when an understanding of national parks as pure nature is manifested in maps, texts, and images, thus drawing a line on the ground between natural space inside to be protected from cultural space outside. Boundaries, borders, and belonging are common themes in the literature. For example, vociferous debate over the appropriate places for native plants and animals, compared with invasive or feral species, shows how concepts related to nature (e.g., nativeness, alien, feral) have material outcomes with implications for which organisms are privileged over others in different spatial contexts.

**Cultural variability**

Broadly speaking, “cultures of nature” research has built an extensive body of work in which the culturally variable engagements with that
which is understood as nature are documented. Culture was here understood in vernacular and everyday terms, not just as “high” or elite culture. It is understood to be very dynamic and to pervade and be part of discourses, practices, and beliefs. Comparative studies of indigenous and settler engagements with land were a fundamental building block in Australia, New Zealand, Canada, and the United States of America; influenced by the rising consciousness of indigenous land rights and associated political struggles in the last several decades of the twentieth century. This work had purchase partly because of its very clear relevance to debates that were happening around world heritage sites, biodiversity protection, protected area conservation – it became clear, albeit contested, that mainstream settler land management processes were not themselves self-evident but had a cultural dimension and a number of embedded assumptions.

Indigenous environmental knowledge and modes of environmental interaction are not only interesting for their own sake, as an important dimension of cultural variability. Rather, there are also conceptual challenges attendant on taking seriously indigenous understandings, for example, how they help identify capacity deficits in existing natural resource management institutions and practices. Indigenous and other non-Western ontologies offer a range of cultural resources in the necessary reframing of relationships between humans and their environment. The Australian indigenous concept translated as “Country” provides an important example (Suchet-Pearson et al. 2013).

A flourishing body of work proceeded to analyze the gender, age, class, and religious dimensions of human interaction with the nonhuman world. Studies from the affluent West dominated much Anglo-American cultural geographical discourse with considerable geographical variation in how the issues have been dealt with. There were productive interactions with urban studies, for example, Kong’s (2000) work on children growing up in mostly apartment contexts in Singapore. As seen also in the examples of animal studies and gardens, cultures of nature research in urban contexts (often referred to as urban natures) helped challenge a further binary, that between the urban and the rural. An emerging feature of research in settler societies and those Western societies with high migration is greater attention to the role of ethnicity, and in particular nonwhite ethnicity and nature (Buijs, Elands, and Langers 2009).

In needing to maintain a very dynamic view of culture, researchers had to consider the intersections of different influences, and also consider cultural change over time. For example, Australian anthropologists discuss the ways Christianity has been absorbed into traditional Aboriginal worldviews as an outcome of the colonial experience and the implications of this for landscape attachment and understandings of country.

Methods

People make and remake culture as individuals, communities, and in institutions and academic disciplines. They do it in everyday practices and over both long and short periods of time. It follows that to understand environmental cultures or cultures of nature we need fine-grained methodologies that enable understanding of motivations, behaviors, contradictions, tradition, change, and flexibility in requisite depth. Cultural research pays a lot of attention to that which is taken for granted and understood to be common sense. It also follows that cultural research methods can be applied to the examination of how large-scale institutions, economies, and structures of meaning are created and maintained, and how different understandings of
nature are embedded in organizations charged with land and natural resource management on the ground.

In keeping with the diversity of the subject matter, a wide variety of methods are used in research on cultures of nature. Most common are qualitative methods in the ethnographic tradition where there is overlap between cultural geography and anthropological methods. In-depth interviews and participant observation are frequently undertaken with different cultural groups, for example, with indigenous groups in their own country. Many studies have undertaken media and textual analysis as a means of understanding the cultural discourses around nature and their power within society. Recent work focuses particularly on embodied practices such as walking. Quantitative approaches include surveys and photo-elicitation approaches, in which broad trends are established, for example, exploring which groups of people prefer which landscapes. Other researchers have used geographic information systems to map places where people feel most connected to nature.

Extending traditional qualitative methods more recently are various forms of embodied and performative work, which pay attention to the emotions and affective dimensions through careful examination of processes of walking, looking, listening, and touching. Angelo’s (2013) research on relationships between people and birds provides an instructive example. Working with both birdwatchers and ornithologists, in a context that included conflict over the killing of birds for taxidermy, she shows clearly how “experience makes nature, differently for different people and over time” (Angelo 2013, 367).

A controversial extension of the methodological challenges in going beyond the human–nature binary is the idea of multispecies ethnography (Kirksey and Helmreich 2010), which seeks to bring animals, plants, fungi, and microbes into the conversation as subjects, rather than as the traditional objects of ethnobiological approaches. This is prompting much discussion of the extent to which ethnography is an inescapably human-centered (anthropocentric) method.

New ontologies, yet persistent dualisms

A paradoxical contribution of cultures of nature scholarship is to challenge if not undermine the value of its two constitutive concepts. New traditions, sometimes referred to as posthumanist, argue that the binary between humans and environment, or society and nature, is ontologically impossible to sustain. Posthumanist perspectives critique “the human” as an essentialized and unified category, and further emphasize relational approaches, whereby the characteristics of phenomena are constituted in the process of their relationships with other phenomena. Important contributions in this area have come from materialist approaches that illustrate the fundamental material basis of life. A further implication of the materialist approach is that the distinction between living and nonliving matter seems to disappear, so technology and materials become part of the debate. Particularly rich contributions in this vein are seen in work on biosecurity, quarantine, and genetically modified (GM) foods, which draw in science, disease, laboratories, and public fears to the concerns of some cultures of nature research.

Castree (2014) makes a strong argument that the culture–nature dualism cannot be wished away, because it is deeply embedded in social and mental structures. It is in some ways an inescapable dilemma: “Our life condition appears to be ‘both/and’ rather than ‘either/or,’ obliging us to use the contradictory ideas of nature as ‘external’ and ‘universal’ when discussing ourselves” (Castree 2014, 29). His argument is that scholars need to keep paying attention to how
the concept and notion of nature is mobilized in many different ways in modern society. It will not disappear just because criticized within academia.

Davison (2008) illustrated the complex interdependence of dualistic and nondualistic understandings of nature within a study of urban environmentalists: “ideas of untouched nature exist in complex interdependence with non-dualistic understandings of the seamlessness of social and natural existence in the lives of many environmentalists.” The latter particularly relate to their suburban existence and everyday rhythms of

Walking and weeding in nearby bushland, growing and preserving food, sharing homes with companion animals, observing suburban wildlife, reading the moods of suburban mountains and coastlines, finding peace and privacy in suburban gardens: such everyday engagements revealed often subtle navigation of socionatural complexity. (Davison 2008, 1294)

Davison thus identifies untapped potential in these liminal understandings and experiences – not fully recognized by the environmentalists themselves. There are ongoing ontological and practical challenges in this complexity.

The “so what?” question

The point is not necessarily to resolve the tensions elucidated by Davison, but to recognize and use them. Research and scholarship going under the umbrella of cultures of nature often faces the “so what?” question. It often comes from physical geographers and natural scientists who ask how such research makes a difference on the ground. Embedded within that question is often a taken-for-granted view of the world and how things are, but the questioner is rarely likely to be sympathetic to deconstruction and critique for its own sake. It also comes from more politically attuned parts of the discipline, such as political ecology, where there is justifiable concern about insufficient attention to unequal relations of power in some connected or networked descriptions.

Critique makes an important contribution in its own right, and history already shows cultures of nature scholarship to have had a profound influence in some key environmental and land management debates. Understanding diverse perspectives provides a basis for clarifying and potentially resolving conflicts, for example, between environmentalists, miners, forestry interests, and hunters, all of whom have been studied within this tradition. This scholarship has also shown how concepts and categories of nature, and of culture, become embedded in societal structures, and how these concepts have power once they are incorporated into legislation, institutions, and public discourse. A notable example is the question of heritage, and the relationships between “natural” and “cultural” heritage used by UNESCO and many member countries. These categories of heritage have required significant revision over the last two decades, in direct response to cultures of nature research.

A further contribution is providing critical and historical analysis of what stands for common sense and normal behavior and how it came to be. Understanding environmental norms and practices helps identify both barriers to and thresholds for change in the context of contemporary sustainability challenges. For example, attention to cultural variability within and between households allows resources for change to emerge from unlikely places, including among older people who explicitly do not identify as “green” but who nevertheless have a number of sustainable practices based on frugality and not wasting.
Further, the influence of this scholarship throughout the discipline can be recognized in seemingly unrelated debates. It is scarcely possible now to discuss key questions in urban geography without explicitly considering nonhuman natures. And there is increasing recognition among scientists and policymakers that sustainability and climate change issues have significant if not easily tractable cultural dimensions.

Despite the persistent dualisms, there are good reasons for pushing forward to better conceptualize relations between humans and the rest of nature. The evidence of the Anthropocene, that humans are embedded in all Earth surface processes, has confirmed that the binary between humans and nature is both empirically and thus ontologically questionable. We have no choice but to think differently. The key contribution of cultures of nature research may yet be that it helps us all to think in such a way that the concepts, and thus the terminology, have been superseded by something better.

Cultures of work

Trevor J. Barnes
University of British Columbia, Canada

A culture of work is a distinct and stable set of shared values, norms, meanings, institutional forms, artifacts, and embodied practices that unifies a group of workers as they labor at a given site of employment. A culture of work is not separate from the labor process; it is not an extra, something that is added. Rather, it is there from the very beginning, joined with the labor process, indissolubly connected to it. It shapes how work is performed; the relation that workers have with one another, including with their bosses; how things are done and by what means; and, even more fundamentally, what counts as work in the first place.

Recognizing a culture of work is important because it demonstrates that work is more than just a bare economic transaction. Orthodox (neoclassical) economics conceives of work as only an economic calculus. In exchange for expending physical effort and/or mental energy to complete tasks set by an employer, the worker receives a wage. The wage is the price of a laborer's work. In neoclassical economics the determination of the wage rate in the labor market is the only interesting fact one needs to know about work. Once the price of labor is determined everything else follows. Such a position is contested by the idea of the culture of work, however. Rather than the wage rate in the labor market determining everything about work, it is everything outside the labor market bearing on work that determines the wage rate. This position is forcefully argued by the French sociologist Pierre Bourdieu (whose work will be discussed further). Orthodox economics begins with an economic relation, the determination of price in the marketplace that then determines all other noneconomic relationships. Bourdieu argues the reverse – that it is the noneconomic that determines the economic. As he puts it, “it is not prices that determine everything but everything that determines prices” (Bourdieu 2005, 77). The culture of work is part of the noneconomic, and gives it central importance.

One more general point: the culture of work is not singular but plural. There is not one culture of work but many. Even at the same geographical site, there can be a multiplicity of work cultures. These cultures may overlap at different points or may be separated; they may be tacit or formally articulated; they may be imposed from above or arise organically from below. However, to be a culture of work it must be shared. A culture of work never pertains to just one individual worker. It must have the capacity of being taken up, learned, transmitted, and imparted to other workers in either the same place or in other places even if they are half a world away. Exactly how that culture is taken up, learned, transmitted, and imparted varies geographically and historically, but the existence of such a capacity is essential.

This entry is divided into two main parts. The first provides a conceptual framework for understanding the culture of work. As an idea, it stems from political economy, but since the 1970s it has increasingly severed those ties, becoming more squarely associated with social and cultural theory. The second provides a set
of illustrative empirical cases drawn mostly from research in economic geography, the discipline within human geography most concerned with work and its culture. As a field it has progressively moved away from orthodox economic analysis to approaches emphasizing the social and the cultural.

Theorizing cultures of work

Workers employed in England’s “dark satanic mills” of nineteenth-century industrial capitalism were generically called “the Hands.” It is a term Charles Dickens memorably satirized in his novel *Hard Times* (1854), set in the ultimate (fictional) gritty industrial city of Coketown. Dickens’s use of the label “Hands” was symptomatic of the cruelty of industrial capitalism, which reduced the wholeness of a worker to only two bodily appendages. That, at least, was how Mr Bounderby, the antihero capitalist at the center of the novel, thought of his workers. But, Dickens suggests, and as illustrated by one of the novel’s characters, Stephen Blackpool, workers were much, much more than merely a pair of hands. Work as Dickens portrayed it was always embedded within a larger setting of cultural sentiment and meaning, that is, within a culture of work.

Karl Marx wrote at the same time as Dickens and in the same city. He too was concerned with the dire and horrific character of work and the fate of workers within English industrial capitalism. But, whereas Dickens’s criticisms were couched in terms of morality and sentiment, Marx’s were framed by a rigorous and stark political-economic logic. Marx believed that logic incontrovertibly proved the unsustainability of industrial capitalism. His analysis consisted of many elements, one of which bore specifically on work, and which he formulated as worker alienation. Alienation occurred because of a disjunction between the nature of workers as fully rounded human beings and their transformation into less than humans under capitalism. At work they were deployed merely as things, as inputs, part of the machinery of production. This was at odds with their real nature as sentient humans. Consequently, they were alienated from their product, from their work, from themselves, and from other workers. Workers lost any culture of work. They were simply grunt laborers, employed as Hands, and for nothing else. Marx’s political project was a restorative one: to eliminate worker alienation by re-establishing a culture of work, which he thought would be possible only through a working-class revolution. It was his analysis that initiated a political-economic approach to the culture of work.

Dickens and Marx, in their different ways, both pointed to the need to provide a wider discussion of work that went beyond simply a description of acts of labor and its remuneration. There was a need to situate work and workers within a larger social and cultural context. Subsequent depictions initially followed the political-economic tradition of Marx, but were later supplemented and then overshadowed by explicitly culturally inflected analyses.

Political economy

Marx and his collaborator Friedrich Engels were concerned primarily with factory workers and their work. In volume 1 of *Capital* (1867), Marx relied on reports completed by factory inspectors to document the appalling conditions under which workers labored. The shocking excesses of the descriptions made it clear that work was never simply an economic calculus. Engels saw those factory working conditions up close in 1842 when his father, part owner of a
textile mill in Manchester, sent the 22-year-old there to learn the business. Apart from allowing Engels to record working conditions, this also gave him the opportunity to document the pitiful and hazardous state of working-class urban life in Manchester. During his time off, Engels roamed the city, writing up his observations as *The Condition of the Working Class in England* (1844).

For there to be a change, Marx and Engels argued, there needed to be a working-class revolution, which would happen in part as a result of the alienation of workers at work: workers would rebel against their horrific treatment. But to mount an effective revolution, workers needed to collaborate, to act collectively, to forge a class consciousness, to become a class for itself. In turn, that required a working-class culture, a culture of work.

That was the thesis at the heart of the British historian E.P. Thompson’s now classic volume, *The Making of the English Working Class* (1963), which documented the rise of an English working-class consciousness in the period 1780–1832 which was intimately tied to the experience of work within early industrial capitalism. Perhaps the most important part of Thompson’s title was the present participle “making.” It signaled a commitment to understanding the working-class consciousness as an ongoing process that, historically and geographically, took variegated forms. How workers came to consciousness at their workplace, and the form and consequences that consciousness took, differed substantially across period and place. As Thompson (1963, 9–10) wrote:

Class-consciousness is the way in which experiences [at work] are handled in cultural terms: embodied in traditions, value-systems, ideas, and institutional forms. If the experience appears as determined, class-consciousness does not. We can see a logic in the responses of similar occupational groups undergoing similar experiences, but we cannot predicate any law. Consciousness of class arises in the same way in different times and places, but never in just the same way.

Thompson was concerned with the emergence of class consciousness, and its equivalent the culture of work, during early forms of capitalism. Those forms were in continual flux, however, often undergoing radical transformation. As Marx and Engels (2010/1848, 16) put it, “all that is solid melts into air.” Capitalism was always changing its spots, and as it did so new cultures of work appeared. The “machinofacture” that Marx, Engels, and Dickens described, in which work consisted of feeding inputs into machines, had given way by the first part of the twentieth century to a new form, Fordism, in which workers in effect became part of the machinery itself. It was a new culture of work.

The culture was clinically analyzed by Harry Braverman in his book *Labor and Monopoly Capital* (1974). The beginnings of that work culture lay in the late nineteenth-century time and motion experiments carried out by Frederick W. Taylor (1856–1915). Taylor was concerned with designing workplace strategies that would squeeze from workers the greatest amount of work from the least amount of work time. To formulate those strategies, Taylor carried out experiments on workers, varying their work conditions and timing and recording their performances. From the results he developed what he called three principles of scientific management that could be applied to all laborers, and which would maximize efficiency at work. The first was dissociating the labor process from the skills of the laborer. This was what Braverman (1974) later called “deskilling.” Workers were not employed for the manual skills they possessed but for their capacity to carry out a minimal set of repetitive simple tasks that required no skill at all. For Braverman, the deskilling of labor became ever more marked and pervasive.
as capitalism developed historically. The second was the separation of conception from execution. Workers were paid not to think (conception) but only to do (execution). Taylor found from his experiments that thinking took time, producing inefficiencies and requiring elimination. Workers were most efficient when they became part of the machinery, carrying out rote mechanical acts without thought. The third was to use “task cards” to specify exactly what was to be done, how it was to be done, when it was to be done, and how long it should take.

The new culture of work, Taylorism, was perhaps best seen in the factories of mass manufacturing production that emerged in the early twentieth century. It was exemplified by the Rouge automobile plant in Dearborn, Michigan (by 1928 the largest integrated factory in the world), built by Henry Ford, where the production method combined assembly-line techniques with the systematic deployment of principles of scientific management. The culture of work was for workers to stand in place along the assembly line and robotically carry out the same single minimal task over and over and over again. It was culture that was spoofed by Charlie Chaplin in his film *Modern Times* (1936) and (strangely) celebrated by the Marxist Mexican painter Diego Rivera in his Detroit Institute of Arts murals of workers at the Rouge (1932–1933).

Only a few years after it was published, the sociologist Michael Burawoy criticized Braverman’s work. In *Manufacturing Consent* (1979), Burawoy argued that the culture of work under Taylorism was defined less by draconian control enforced by authoritarian scientific managers (Braverman’s view) than by a consensual process in which workers agreed to their own domination. In making this argument Burawoy drew on the idea of cultural hegemony originally put forward by the Italian Marxist Antonio Gramsci (1891–1937). This was the notion that capitalists exerted social control not by strong arm coercive tactics but by winning consent from the larger population. Consent was gained by capitalists seemingly granting the masses what they wanted and meeting their interests. In reality, though, as Gramsci argued, the interests of the proletarian masses were never met. They only appeared to be met. Consent was secured under false pretenses, with the elite the only beneficiaries in the end. Burawoy took Gramsci’s idea and applied it to Taylorist workers. Under a regime of cultural hegemony, Burawoy argued, workers consented to their own oppression and deskilling. They mistakenly believed that Taylorism gave them choice and widened their work experience. That was why they consented. In reality it gave them neither, allowing capitalist employers to exploit and oppress them to an even greater degree.

Cultural hegemony was also central to Paul Willis’s classic ethnography, again written in the late 1970s: *Learning to Labour: How Working Class Kids Get Working Class Jobs* (1977). Willis explored not so much the culture of work as the culture at school that prepared working-class boys for Taylorist jobs in a factory. Conducting interviews with a dozen schoolboys in their last year and a half at a secondary modern school in Britain’s West Midlands (then at the heart of the country’s automobile industry), Willis identified two groups: “the Lads” and the “Ear ’oles.” The Lads did not pay attention at school. They were bored by it. Their main aim was “to have a Laff,” which they did by resisting school authority in various forms (Willis 1977, 14). The “Ear ’oles,” in contrast, paid attention, strove to complete their school work, and respected their teachers. Willis’s argument was that, for the Lads, the cultures of class and masculinity at the school prepared them perfectly for the culture of work in a factory into which they went when they left school. Work, like school, would also be boring and not require their attention,
but it could be endured by having a “Laff” and by circumventing and subverting authority whenever they could. This was a form of cultural hegemony because the Lads consented first at school and then at their workplace to their own domination. Of course, they did not see it in such terms, believing that their acting out provided them with freedom and agency when in reality it only met the interests of capitalists. Working-class kids got working-class jobs, and the larger system of industrial capitalism was smoothly reproduced.

Of course, it wasn’t always so smooth. Even during the golden age of Fordism, there were occasional downturns when it was difficult for working-class kids to get working-class jobs. From the late 1970s, however, there was a tectonic shift in the Global North, when massive deindustrialization and economic restructuring profoundly impacted employment, labor, and work. “Old Father Ford” didn’t immediately die, but he became very poorly, making those 1970s studies, and the masculinist assumptions that underpinned them increasingly redundant as male Taylorist workers themselves were made redundant. This change also brought about a tectonic shift in the literature on the culture of work. Up until the 1970s the culture of work, for the most part, meant men’s work. After the 1970s, however, and in step with the larger structural changes in the economy in the Global North (and for that matter in the Global South too), there was much more emphasis on examining the work of women. The old political-economic perspective, with its emphasis on the male working class, was out of sync with the new times. Instead, a different, more relevant, theoretical perspective was taken up that emphasized the cultural, drew on feminist and poststructural theory, and conceived of class as not only a narrowly economic category.

Cultural theory

Deindustrialization cut a grim swathe across Global Northern manufacturing regions from the 1970s, eliminating an enormous number of relatively high-paying, Taylorist, often unionized manufacturing jobs held by men. Such changed work practices became fodder even for popular culture. For example, the 1997 film *The Full Monty* (1997), later a Broadway and West End musical, featured a group of male Sheffield steel-workers who, when they were made redundant, took off their boilersuits and steel-capped boots and entered the traditionally female service sector occupation of exotic dancing.

While the film may have been a fantasy, it pointed to a fundamental change around work and its culture. The Global North was moving toward a postindustrial, service-based economy, turning upside down older Fordist nostrums of work. Employment now came in two main forms. There were the “McJobs,” which were low-paid and required few skills and little experience. Even in this general category there could be variation, depending on the particular culture of work in the McJob. At the higher end of the job hierarchy was employment in establishments of conspicuous consumption such as boutique cafes and designer clothing stores. At the lower end was flipping burgers in fast-food restaurants or as “associates” working the floor of big-box discount retailers. The other type of service sector employment was in the creative economy, or the new or cultural economy. Workers here were often highly paid, and frequently required skills that were formally credentialed. Work could be in existing sectors that had been reconstituted such as advertising or higher education, or in entirely new sectors like video game or web design. Both kinds of service work – the low end and the high end – required embodied interactions with customers and with other workers, calling for cultural, social, and even
emotional (soft) skills. Unlike in manufacturing, where one worker’s body was like another’s, simply the repository of brawn to be dispensed in the industrial process, in the service sector the body was often a vital part of the product sold. What kind of body made a difference, and how it was dressed, comported itself, spoke, and looked could be crucial. Out-of-the-box Taylorist management principles were still applied, especially to low-end service work. But typically there was scope, which increased as one moved up the service sector job ladder, for conception, even creativity and individuality, as well as execution.

Within this transformed setting the culture of work came to mean something different. It didn’t necessarily lead back to class, and to questions of social revolution, as it did under political economy. Instead issues of cultural identity around gender, race, sexuality, and age were central. And even when class was emphasized it was conceived differently, with a cultural inflexion.

Bourdieu’s work, especially his book *Distinction* (1984), made that clear. Bourdieu argued that economic differences in income and wealth were not the only, indeed were not even the most important, criteria in determining class membership. For Bourdieu class location was set by three kinds of capital that an individual controlled: economic (money), social (networks and contacts), and cultural (aesthetic tastes). The latter was not just an add-on but, for Bourdieu, often the most important determining influence, albeit interacting with the other two factors. Furthermore, Bourdieu argued, while economic and social capital were accumulated over time, cultural capital was learned at an early age, inherited from one’s family. Once one’s tastes were fixed, they were then difficult to change, and as a result ossified class distinctions.

The culture of aesthetic distinction channeled different class members into different jobs. For a number of service sector jobs, such as those in the hospitality sector, recognizing distinction was imperative. How one presented oneself, the clothes one wore, the words one chose, the accent in which they were spoken, and the manners one displayed all made a difference. They were the required culture of labor for that job. But it was a culture that one either had or didn’t have depending on one’s inherited cultural capital. In Yasemin Besen-Cassino’s (2014) study of youth labor in America, the possession of cultural capital mattered even for minimum-wage service jobs. Besen-Cassino researched student workers employed in hip coffee shops in an East Coast city. Although remuneration was minimal, in order to be hired and to keep their jobs students needed to possess the appropriate cultural capital: to like and to be able to judge the correct music, to be able to converse appropriately and on fitting topics, and to look right. The employees may not have had much economic capital, but they possessed cultural capital. Indeed, the economic capital they acquired was quickly turned into what Bourdieu called symbolic goods, commodities whose aesthetic qualities only further demonstrated their good taste, reinforcing their privileged class membership.

The work of the baristas that Besen-Cassino (2014, 40–42) studied was, as she noted, an exercise not only in cultural distinction but also in cultural performance. The dais on which the baristas made their cappuccinos and lattes was their stage, the customer line-up the audience, the physical layout of the cafe and the chairs and tables the scenery, their smart talk the script, their uniforms, theatrical costumes, and their accessories props. Treating cultural and social life as a performance has been discussed by scholars for at least the last half-century. It was found in philosophy in the work of J.L. Austin on “performatives” in sociology in the writings of Harold Garfinkel on “ethnomethodology,” and more recently in feminism in the
texts of Judith Butler (discussed further). The original use of the “dramaturgical” metaphor, as it has been called, was with the Canadian-born sociologist, Erving Goffman, and his book *The Presentation of Self in Everyday Life* (1959). His argument was that, in order not to embarrass ourselves and also to control what others think of us, we put on a performance. We use the stage setting and any appropriate props to conjure a positive image of ourselves, to present ourselves in everyday life as we would like to be rather than as who we really are. Afterward we return backstage, taking off the mask and reverting to our true selves.

Goffman’s dramaturgical metaphor seems especially suited to understanding service sector occupations, in which the culture of work plays such a central part. Besen-Cassino’s case study of college baristas is, of course, one such example. Another is Arlie Hochschild’s (1983) study in her book *The Managed Heart* which examined, among other occupations, female flight attendants. Hochschild introduces the idea that some workers are employed to manage emotions, both of those whom they are serving and their own. In both cases there is a performance of what she terms “emotional labor.” First, the worker tries to cultivate in the customers they are serving the “right” emotions, in the sense that they allow the customers to properly appreciate the service they are purchasing. Second, for this to happen and for it to be authentic, like all good actors, the workers must also induce within themselves the “right” emotional feelings while at the same time suppressing any “wrong” feeling that might disrupt their performance. In the case of female flight attendants, a major task is to quell any emotional fears passengers may have of flying. This is “managed” by the attendants persuading passengers that the flight is an exotic journey, luxurious even. Hence the smiles; the trolley of drinks and tasty snacks; the in-flight entertainment; the jokey, even flirtatious, chit-chat; the short skirts; the tailored uniforms; the coquettish headgear. But there is also the need for the flight attendants to manage their own hearts which, as Hochschild shows, can be difficult. Apart from boorish talk and occasional violent acts by passengers, they have to deal with their treatment by the airlines, which subject them to horrendously long and physically taxing work days; meticulous disciplining of bodies and appearance; and continual surveillance and control – moral, corporeal, and work – both inside the cabin and out.

Hochschild shows the dark underbelly of the culture of work, located within a larger force field of changing relations of power that are sometimes positive, often not. There are also connections to the French social theorist Michel Foucault and his concern with power, surveillance, control, and the body. Foucault’s ideas certainly link to earlier formulations of the culture of work put forward by Frederick Taylor. Taylorist workers are nothing if not controlled, disciplined, and surveyed. But Foucault’s interests apply perhaps even more so to the contemporary service sector and the bodies that perform it. The body is so important to Foucault because it is a site on which so many discourses are inscribed: gender, race, sexuality, disability, age, among others. The consequent cultural identities, in turn, shape what kinds of jobs people undertake, and their experiences at work.

The body as Foucault suggests can also be a site of potential resistance. This is a theme further developed in Judith Butler’s work, especially *Gender Trouble* (1990), which provides a critical feminist reworking of the idea of performance. For Butler gender is always performed. That performance takes the form of repeated iterations, which can mistakenly give the illusion that gender is fixed and natural rather than socially constructed and continually remade. Of course, there...
are immensely powerful regulative discourses that maintain the formative iterations of gender. But, and this is where there is at least the possibility of bodily resistance, one iteration may not be exactly the same as the one before, and raises the possibility of progressive change, however gradual. The idea that performances of the culture of work can produce at least a possibility of progressive change has become a strong theme in the geographical literature, and to which the entry now turns.

Cultures of work in geography

Within human geography, work as a topic has been most often discussed by economic geographers, and linked to discussions of the labor market. Very little has been written explicitly on the culture of work, however. Instead, it needs to be teased out from individual studies, which is the aim of this section.

From its very beginning, economic geography recognized that labor influenced the location of economic activities. Initially, that locational influence was conceptualized (as in, e.g., Alfred Weber’s classic location triangle) in terms of the cost of workers (i.e., wages) and not their culture. The first glimmer that the culture of work might also have a locational effect came with geographical studies of industrial districts undertaken during the 1940s. An industrial district is a tightly bound area within a city specializing in one particular type of industrial production, for example the garment district. The British economist Alfred Marshall, working at the turn of the twentieth century, was the first to recognize the phenomena of industrial districts, explaining them as a consequence of agglomeration economies. He came to realize, though, that this explanation went only so far, and augmented his account with an additional factor, “industrial atmosphere.” Subsequently, Marshall’s “atmosphere” was interpreted as the force of culture – the missing ingredient that explained why industrial production geographically clumped rather than dispersed. Specifically, the culture of work, in this case interpreted as common social ties and institutional affiliation linking similarly skilled workers, was used to explain why particular types of employees cluster in one part of the city, which then functioned as an inducing labor pool for an industrial district.

For the two decades or so after the end of World War II the topic of work mostly disappeared from the agenda of economic geography, and the focus was on labor and final output rather than on work and the production process. This began to change from the early 1970s with the emergence of political economy. David Harvey, the most prominent geographer writing within that tradition, made little of work (and even less of culture) at first. Labor for him was simply the kick-start of value – in his schematic, labor power (LP) – which then began a complex geographical circulation (Harvey’s central preoccupation). This changed in the early 1980s when the topics of work and culture became more prominent, the result partly of the Global North’s firestorm of industrial restructuring and deindustrialization that made work, or the lack of it, so prominent; and partly of the beginnings of feminist geography which started with a discussion about women and work, the so-called domestic labor debate. Those two approaches, political economy and feminism, opened up the culture of work to scrutiny.

The hollowing out of manufacturing led those in the political economy tradition to attend directly to work. This involved in part enumerating the hemorrhage of manufacturing jobs, but also describing changes in the nature of the industrial work that remained. With deindustrialization came industrial restructuring, a move from an older Fordist form of work based on
Taylorism to a new (leaner) post-Fordist form of work based on labor flexibility. Here workers learned the manual, could potentially operate at any workstation, contributed ideas to “quality circles,” could stop the assembly line when they saw flaws (the ultimate no-no under Fordism), and were paid to think as well as to do. It was a new culture of work, and which those from within the political economy tradition began to describe variously as post-Fordism, lean production, or flexible accumulation (Amin 1995).

Doreen Massey’s writings, especially Spatial Divisions of Labour (1984), were particularly important during this period. Massey applied ideas of culture directly to work. An especially potent case study was her analysis of the South Wales economy which, in the late 1970s and early 1980s, shifted away from its historical specialization of heavy industry (coal, iron, and steel) to the assembly of electronic goods. Primarily American and Japanese multinational firms were drawn to South Wales by the prospect of realizing a particular culture of work, which was to be realized not by men, the traditional employed worker in the region, but by women. The corporations wanted an educated, “greenfield,” and female labor market that was geographically trapped, and consequently would be cheap, pliable, and knowledgeable. Massey argued that the culture of South Wales had created just such a workforce. The culture of the male workers of South Wales’s heavy industries had in effect produced a pool of potential female workers who, while they had gone to school, had not generally worked outside the home because of the region’s masculinism and patriarchy. When retrenchment started in heavy industry, female partners went out to perform paid work, although they remained geographically constrained because of demands to continue domestic (household reproduction) duties. The American and Japanese multinationals were waiting for them.

The other strand pushing the culture of work in geography, and again one in which Massey was also central, was feminism. In the early 1980s feminist geographers attracted to political economy followed the larger socialist feminist literature which at the time was preoccupied with the question of female domestic labor and household reproduction. That literature identified the household as a site of (re)production. The household produced workers and future workers (children), ensuring that they were clothed, fed, and sheltered, ready to turn up to work (or school) the next day. But how should the unpaid domestic work of women, and who (re)produced the central commodity of capitalism, labor, be treated conceptually? On the surface it appeared as if the work women did in the home was different from laboring in a factory. It was different culture. Work disappeared. But the classical economistic and functional Marxist interpretation reduced domestic labor, women, and the political ends of feminism only to class position. Culture disappeared.

Partly as a result of this, from the late 1980s and early 1990s there was a break as feminists in economic geography moved away from Marxism toward poststructural theory, which emphasized the cultural. Often the focus was the body, both men’s and women’s, and the various (Foucauldian) social and cultural discursive inscriptions written on it. One of the first studies bearing on work from this new sensibility came from Doreen Massey who shifted her focus from a declining old industrial economic region, South Wales, to a brand new one, the Cambridge high-tech research triangle in England. In both regions, though, there was a distinct culture of work in operation. Massey, along with her co-author David Wield, showed in High-Tech Fantasies (1992) that the culture of work was inextricably linked to the culture at home. The seemingly disembodied discourse of science
CULTURES OF WORK

and rationality practiced by the overwhelmingly male research workers at high-tech companies in the Cambridge research triangle was possible only because of the embodied labor of the overwhelmingly female partners at home and female support staff at work. The culture of work was possible because of the culture of home.

Later works drew especially on Goffman’s dramaturgical metaphor, as well as Butler’s post-structural feminist version, to reveal cultures of work. Philip Crang’s (1994) study of a themed restaurant somewhere in southeast England disclosed that everyone, both workers and customers alike, adhered to a cultural script, dressing up, using the right prop at the right time, and saying their lines when prompted. Especially interesting, Crang observed, was when things went wrong, when people muffed their lines or didn’t follow stage directions, or when the props broke. Such moments were like when the curtain went up prematurely, revealing the backstage. It showed just how the frontstage presentation was pulled off.

A more politically pointed use of performance following Butler and focused on gender and the body was Linda McDowell’s study of merchant bankers in the City of London, Capital Culture (1997). Like other service workers, bankers must not only talk the talk but also walk the walk. They embody the product they sell: they are finance incarnate. McDowell was especially interested in how gender and sexuality were performed as the culture of work. It was done by clothing choice (leather skirt or demure suit); by language (English public school or the street market); and by acts and gestures (a head nod or a flapping arm). McDowell showed how narrowly constrained and vigorously policed such cultural performances were. Transgressive moments were necessarily subtle and fleeting: a grey suit that was just a little too grey, a hand gesture in the trading room that was just a little too enthusiastic. They might not be transgressions that would bring down financial capitalism but they could get you fired. Or they just might, following Butler, redefine an acceptable culture of work in the performance of gender and sexuality.

Another related example is the cultural performance of race at work. Beverley Mullings’s (2012) research about male and female sex-trade workers in the Caribbean showed that, just like gender, race is performed into existence. Sex-trade workers in her study used their bodies to perform that version of race expected of them by their often European (colonial) clients. Race, like gender, then, was pliable, taking on different forms. It was not natural but always a performance, always a response in this case to the larger culture of work in which it is situated.

There is one more form of performance around the culture of work, the performance of academic researchers as they try to change the culture of work that they are investigating. J.K. Gibson-Graham’s The End of Capitalism (as We Knew It) (1996) was pioneering. Gibson-Graham used their workshops, focus groups, and interviews with the female partners of Australian miners working in the Latrobe Valley, Victoria, to perform a different version of what a miner’s partner might be. They tried to create a space for feminist politics that altered not only the culture of home life, but, through the effect on the male partner, the culture of work life as well. Perhaps the end point of this trajectory is when academic research becomes literally a stage performance. Geraldine Pratt’s work on Filipina domestic workers in Vancouver, Canada, has become that. Pratt initially wrote it in standard academic prose but subsequently transformed her research material about Filipina domestic workers into a theatrical script for performance on stage (Families Apart, 2012). That production was a critical exploration of the culture of work of Filipina
nannies in Vancouver. Through influencing its audience, like Gibson-Graham’s project, it aspired to change the current culture of work, to perform a new world of work into being.

Conclusion

The culture of work is an overstuffed term. It seems as though it contains everything interesting that is left out of the standard economic account of the labor market, which is an enormous amount. The theories reviewed in this entry try to give the culture of work a more precise shape and definition. The political economy approach conceives of the culture of work as an addendum to class, which has the potential to be used strategically both to advance class interests (e.g., raising class consciousness) and also to thwart them (e.g., as cultural hegemony). The other approach, cultural and social theory, resists linking the culture of work only to class. Instead it seeks to explore the full spectrum of its elements – gender, race, sexuality, disability, age, and so on. Both approaches have their origins in part in the character of the work to which they have been applied. Crucial here, as suggested, was the profound shift during the 1970s and 1980s in the nature of work in the Global North as it moved from a manufacturing to a service-based economy. It triggered a change in the conception of the culture of work. However, the need to remember that the economy, including work, is always linked to culture is unchanging. Perhaps that is the most important role of all that the idea of the culture of work plays.

CULTURES OF WORK

Economies as self-correcting or self-reinforcing systems

At a very broad level of conceptualization, there have long been two main, and opposing, views of how economies function and develop. The first sees economies as essentially self-correcting systems that inherently and constantly tend toward equilibrium or balance. Theories based on this assumption or ontology regard equilibrium as the “natural” or normal state of affairs, and, if some disruption or event disturbs this state, various mechanisms are automatically set in motion – via the normal functioning of market processes – that act to restore equilibrium. The second view is quite different, and sees economies as systems in which market forces, rather than leading to equilibrium in a self-correcting way, tend instead to lead to disequilibrium and imbalance, and, moreover, operate to reinforce such imbalance. The former view is typically associated with conventional neoclassical and related schools of economic thought, the latter view with new growth theory and heterodox economics, and in particular with the theory of cumulative and circular causation.

These two distinctive worldviews carry equally distinct implications for how the economic landscape is perceived to develop. Under the neoclassical perspective, which assumes constant returns to scale, diminishing returns to labor and capital, the unhindered mobility of the latter, and ubiquitous knowledge, if a development gap opens up between regions or localities, as manifested by differences in per capita output, profitability, (real) incomes, and employment opportunities, then labor and capital movements are triggered such that labor will move to the higher-income, higher-productivity regions while capital will move in the opposite direction to take advantage of cheaper labor and the potential for major productivity advance. These movements act to bring regional per capita (real) incomes and productivity back in line, that is, to restore spatial “equilibrium.” Regions may differ in their particular industrial mixes, but the thrust of this view of regional development is that, over time, per capita (real) incomes should converge across space, or at least converge conditional on irreducible differences in consumer tastes and preferences, technology, or industrial structure. Empirical tests of this proposition for numerous countries have revealed, however, that in most cases the rate of regional convergence is very slow, that in some instances it is nonexistent, or that even in others divergence rather than convergence appears to be dominant.

Under the self-reinforcing or cumulative causation perspective, the fact that regional disparities in economic growth and prosperity may not be self-correcting and convergent but persist or even increase over time, is entirely consistent with how actual market economies function. Leading development theorists, such as Myrdal, Hirschman, and Nurske, were stressing this fact back in the 1950s. Thus Gunnar Myrdal, widely...
regarded as one of the key exponents of cumulative causation theory, argued that “the main idea I want to convey is that the play of the forces in the market normally tends to increase, rather than decrease, the inequalities between regions” (1957, 26). At about the same time, Albert Hirschman similarly claimed that “we may take it for granted that economic progress does not appear everywhere at the same time and that once it has appeared, powerful forces make for a spatial concentration of economic growth around the initial starting point” (1958, 183). For these theorists, uneven regional development is not some self-correcting, equilibrating process, but a self-reinforcing, cumulative one, although possibly subject to various spread effects that might limit the eventual degree of regional disparity.

It was not until the 1970s and early 1980s, however, that the idea of cumulative causation was developed further, primarily by Nicholas Kaldor (1981). Kaldor set the idea within a nonequilibrium theory of export-led manufacturing growth based on increasing returns, and, like Myrdal and Hirschman before him, used the notion to explain regional income disparities. Then, from the early 1990s onward, the notion began to attract wider attention, stimulated by a number of factors: a more general rediscovery by economists of the idea of increasing returns and its incorporation into different aspects of growth theory (Buchanan and Yong 1994), including new endogenous growth theory; the development of path dependence economics (David 1989; Arthur 1999; Setterfield 1997; 2010); and the emergence of the new economic geography (Krugman 1991, 1997), to name but three. Some have gone so far as to argue that the principle of circular and cumulative causation (CCC) provides the foundations of a new nonequilibrium economics (Berger 2009). And, for their part, economic geographers have embraced the concept, elevating it to a key principle for understanding (uneven) regional development:

any attempt to answer the questions posed above [concerning the economic development and specialization of regions] must formulate the problem by reference to a dynamic of cumulative causation whose logic is definable not in terms of some primum mobile or first cause, but in terms of its own historical momentum. (Scott 2006, 85)

All this is not to suggest that there is now a single, coherent, and generally agreed theory or model of CCC. Kaldor (1970; 1981) came close to a synthesis, which Setterfield (1997; 2002) has sought to extend and formalize; but a comprehensive CCC theory linking production, technological change, economic growth, and income distribution, let alone regional development, has yet to be advanced (Toner 1999). Furthermore, CCC theorists themselves often deploy the notion in different ways. Nevertheless, there is consensus about the basic principle of CCC, and about its key mechanisms.

**The principle and mechanisms of circular and cumulative causation**

It was Myrdal who first used the phrase “circular causation of a cumulative process.” As the phrase suggests, it refers to a process in which there is causative feedback between key aspects or features of a system, which feedback serves to reinforce the development of those same features in a cumulative manner. Thus, for example, an initial increase in some variable, X, induces changes in a second variable, Z, which result in a further increase in X, and so on. This interaction continues indefinitely, without leading the system toward a position of equilibrium. Kaldor’s model exemplifies this basic principle (Kaldor 1970; 1989). It posits a circular causal
process that links three basic mechanisms or determinants of regional (and indeed national) growth: trade-driven demand for a region’s exports; increasing returns and externalities; and technological change. To capture these links, the Kaldorian CCC model appeals to Verdoorn’s law, according to which the rate of growth of productivity depends on the rate of growth of output. The Verdoorn law is commonly understood as a dynamic analog of Adam Smith’s original dictum that represents the influence of output growth not just on the extent of specialization in the production process, but also on learning by doing, the propensity to engage in research and development, and firms’ willingness to invest in new physical capital that embodies technological improvements. Rapid growth induces dynamic increasing returns, via Verdoorn’s law, which enhance export competitiveness and hence export growth, so that the circular cumulative causation process takes the form:

\[ \text{High } X_t \rightarrow \text{High } Y_t \rightarrow \text{High } q_{t+1} \rightarrow \text{High } X_{t+1} \]

and so on, where \( X, Y, \) and \( q \) are the rates of growth of exports, output, and productivity respectively.

Given that regions, for the most part, are highly open economies, crucially dependent on the external demand for their products (or services), the model is highly relevant for understanding regional growth and development (Figure 1). The demand for a region’s products (or services) will depend on their price, and the price will depend on the productivity of the region’s industries providing those products (or services), and their prices relative to those for similar goods and services produced elsewhere (in world markets). The higher the productivity of a region’s industries, compared to the wages in those industries relative to those elsewhere, the more competitive the region’s industries will be and the higher will be the demand for its products (or services). The faster the growth of a region’s exports, the faster the growth of regional aggregate output (which includes multiplier effects on industries and services that are not exported but which supply the export sectors or are stimulated by the increases in incomes generated within the export sectors). With increases in output comes greater scope for exploiting increasing returns and externalities. Within the neoclassical system, increasing returns are generally examined at the level of the plant or firm, and via the concept of scale economies, that is, benefits to the plant or firm arising from expanding output, such as indivisibilities in factor inputs, gains from specialization, and the use of superior and more efficient techniques. While CCC theory recognizes these sources of increasing returns, it also puts particular stress on dynamic economies, especially those associated with technical “learning by doing.” Cumulative experience with a production process leads to technological change, which in its turn raises productivity. Growth itself thus stimulates technological change, which in its turn helps to stimulate productivity, and hence competitiveness, which makes a region’s products and services attractive in external markets; this then boosts exports demand and thus regional growth, and so on.

In emphasizing the role of increasing returns in his version of CCC theory, Kaldor (1989) referred explicitly to the importance of geographical agglomeration. Drawing on Alfred Marshall’s account of “industrial localization,” Kaldor argues that one of the most remarkable features of modern industrial development is the spatial concentration of economic activity, especially manufacturing. The spatial concentration of industrial activity is explained largely by the fact that agglomeration confers a variety of benefits or externalities on firms. These advantages go well beyond the economies of large-scale
CUMULATIVE CAUSATION, ENDOGENOUS GROWTH, AND REGIONAL DEVELOPMENT

Figure 1  The process of circular and cumulative regional growth: a Kaldorian-type schema.

operations, such as plant- and enterprise-scale economies. According to Kaldor, the advantages of geographical concentration arise from the local availability of skilled labor, joint production, and the possibilities for ready communication of trade, technical know-how, and management practices. Further, the close proximity associated with spatial agglomeration affords a ready identification of market opportunities for a firm’s products or related products, and for monitoring changing market trends and competitors’ behavior. In his version of CCC theory, geographical agglomeration reinforces the effect of Verdoorn’s law.

But, in addition to these externalities arising from agglomeration, an additional mechanism that is of critical importance for the operation of self-reinforcing cumulative development in a spatial (regional) context is the geographical mobility of capital and labor. As mentioned above, whereas in neoclassical growth theory, such interregional movements are argued to lead to convergent growth paths and to equalize regional incomes over time, in CCC theory they can have the opposite effect. Imagine a national economy composed, geographically, of two regions, north and south, and assume that, for some reason — possibly an accident of history, or some natural or environmental advantage — the...
south gains a lead in economic growth and begins to develop the increasing returns effects and positive externalities associated with the spatial concentration of activity. The prospect of better job opportunities, higher incomes, and greater profits in the south draws in finance capital (investment) and workers from the north (and possibly also from overseas – increasingly important in a globalized world). In effect, these inflows raise the full employment growth ceiling (FEGC) in the south above what it would otherwise be, preventing supply-side constraints from emerging, and thereby enabling further growth to take place, and a yet greater spatial concentration of activity in that region (see Figure 2). To the extent that it will be the more skilled and enterprising workers who move from the north to the south, bringing knowledge and technical expertise with them, this reinforces their positive impact on the south’s productivity, its competitiveness, and hence its growth rate. The outflow of capital and labor from the north has the opposite effect, constraining or even lowering its full employment growth ceiling (FEGC), and hence limiting or even reducing its growth rate, particularly if the workers who

Figure 2  Labor and capital mobility and cumulatively divergent regional growth (adapted from Holland 1976).
migrate from the north to the south are indeed among the more skilled sections of the north’s labor force (see Holland (1976) for a detailed exposition of this sort of model). In addition, the greater the agglomeration of firms in the south, the greater will be the knowledge and technological spillovers encouraged by close proximity, and the faster will growth be in the south compared to the north. In a spatial setting with relatively free movement of capital and labor, but localized technological spillovers, the process of circular and cumulative causation is thus essentially one of combined and uneven (divergent) regional development. As Harvey expresses it thus:

Small pre-existing geographical differences, be it in natural resources or socially constructed endowments, get magnified and consolidated rather than eroded by free market competition. The coercive laws of competition push capitalists to relocate production to more advantageous sites and the special requirements of particular forms of commodity production push capitalists into territorial specialisations … Agglomeration economies (including those achieved through urbanisation) generate a locational dynamic in which new production tends to be drawn to existing production locations … Circular and cumulative causation within the economy then ensures that capital rich regions tend to grow faster while poor regions grow [relatively] poorer. (2006, 98)

Three issues arise in connection with CCC theory. First, how does it relate to the recent rise of endogenous growth theory, given that the latter also allows for increasing returns, and thence for the possibility of divergent regional growth patterns? Second, given that in CCC theory regional growth is endogenous to its past history, how does it relate to path dependency theory, which itself has attracted considerable attention from economic geographers since the mid-2000s as a way of thinking about regional development? And, third, what are the limits to circular and cumulative causation? Since regional growth paths do not necessarily diverge indefinitely, what does this imply for the assumption of continuous self-reinforcing dynamics?

**Endogenous growth and cumulative causation**

The distinctive feature of CCC theory is that growth is viewed as endogenous to the economy, generated entirely from within by recursive causal mechanisms. As Kaldor stated:

it is impossible to assume the constancy of anything over time, such as the supply of labour or capital, the psychological preferences for commodities, the nature and number of commodities, or technical knowledge. All these things are in a continuous process of change but the forces that make for change are endogenous not exogenous to the system. The only truly exogenous factor is whatever exists at a given moment of time, as a heritage of the past. (1989, 61)

This is in stark contrast to standard neoclassical growth theory. The latter identifies the underlying rate of output growth as the sum of exogenous labor force and capital stock increase, and exogenous technical change. Indeed, there is a basic theoretical paradox in neoclassical theory, in that technological change is seen as of fundamental importance for economic growth but is not explained by the theory. Instead, it is simply assumed to occur autonomously outside the economic system, which is hardly a very realistic assumption since it ignores purposive research and development by firms. In CCC theory, technological change is stimulated by growth itself, through the increasing returns and learning effects that growth generates. Further, as numerous empirical analyses have shown, technological change (in the form of research...
and development activity, innovation, patenting, and the like) is not distributed evenly across geographic space but tends to concentrate in particular regions or urban centers, where it is fueled by an endogenous circular process by virtue of the externality and increasing returns effects generated by the dense locational proximity of innovation-oriented firms and workers.

However, recent developments in neoclassical growth theory have sought to endogenize technical change and give due recognition to the role of increasing returns in growth. In general terms there are three main variants of endogenous growth theory: those that attribute technical change (and thence growth) to investment in capital stock (which generates learning by doing); those that stress investment in human capital, via education and intentional research (which also increases spillovers of knowledge); and Schumpeterian versions that allow for purposive and profit-seeking improvements in technology by entrepreneurs (for a detailed overview of endogenous growth models and their implications for regional development, see Martin and Sunley 1998). Essentially, such models seek to endogenize technical change within the standard neoclassical production function model, and allow for increasing returns to capital and labor.

All three variants (and there are also several hybrid forms) can be applied to the analysis of regional growth and development (see Martin and Sunley 1998). Under certain assumptions, for example about the relative mobility of capital and labor, the in situ propensity for local workers to invest in education and skills, and the scope for and extent of local knowledge spillovers, endogenous growth models predict varying degrees of self-reinforcing regional divergence, akin to CCC models (see Skott and Auerbach 1995). Which outcome is predicted depends much on the extent, if any, of interregional spillovers of technology, which work to disperse growth and hence to prevent the continuing accumulation of activity and growth in certain regions at the expense of others.

One particular type of model of the economic landscape that draws on endogenous growth ideas (especially learning by doing, induced technological progress and knowledge spillovers), and which incorporates a version of increasing returns and cumulative causation type mechanisms, is the new economic geography (NEG). The new economic geography literature that emerged in the 1990s sought to formalize certain cumulative causation mechanisms that account for the uneven geographical distribution of economic activity. Depending on assumptions concerning transport costs, initial economic structures, and labor mobility, regions are shown to fall into rich (core) and poor (peripheral) categories as production concentrates where the market is larger. In Krugman’s (1991) seminal contribution – the basis of much of the subsequent development of NEG – the tendency for firms and workers to concentrate in one or more core regions is driven by the interaction of labor migration and transport costs, in the presence of increasing returns effects and external economies. Larger markets attract more firms, which in turn attract more workers. In more recent versions of the model, the agglomeration of industry occurs via cumulative processes triggered by input–output linkages between intermediate (upstream) producers and final goods (downstream) firms. With increasing returns to scale, intermediate producers will have an incentive to concentrate where there is a large final goods industry, in order to produce at a more efficient scale and to take advantage of the possibilities of inventing new combinations. This in turn will make it attractive to final goods producers to locate where there is a large intermediate industry, as the cost of intermediate goods will be cheaper there. The
process is thus a circular one, and may result in large and self-perpetuating uneven geographical configurations. In one extreme variant of the NEG model, all activity will concentrate in just one region (with a “catastrophic” emptying of other regions). In still other versions, the specific spatial equilibrium outcome depends on the strength of dispersion forces, such as market-crowding effects which encourage firms to locate in less highly agglomerated regions.

In his early exposition of NEG, Krugman (1991) briefly acknowledged the influence of Kaldor’s work on the relationship between increasing returns, cumulative causation, and regional agglomeration. And it can be argued that, in certain respects, Kaldor’s work may well have been a prologue to the NEG literature (see Bhattacharjia 2010), as captured in his statement that

The spatial aspects of competition under conditions of cumulative causation constitutes a field that has not been explored yet, but which may call for radical changes in the prevailing views concerning the effects of freedom of trade between different countries or regions. (Kaldor 1989, 34)

However, Kaldor’s dismissal of the relevance of equilibrium – which is a core feature of NEG models – no doubt explains the subsequent lack of reference to his work, and indeed to CCC theory more generally, by NEG theorists. In fact, the process of circular and cumulative causation raises key questions about whether actual regional economies can ever be in a state of equilibrium.

Cumulative causation and path-dependent regional development

With increasing returns, the productive possibilities in an economy in any given period depend crucially on the level of production achieved in the past, since, in the presence of increasing returns, technical possibilities for production today are endogenous to those past levels of production. Cumulative causation is therefore a historical or path-dependent, rather than a conventional equilibrium, process. Again, Kaldor makes this point:

Once however, we allow for increasing returns, the forces making for continuous change are endogenous … And the actual state of the economy during any one period cannot be predicted except as a result of the sequence of events in previous periods which led up to it. (Kaldor 1970, 1244)

The basic idea behind the notion of path dependence is that, once a particular path or pattern of development is initiated – be it a particular technology, industry, or geographical distribution of an industry – various processes emerge that tend to reinforce that path or pattern. Although there are different models of path dependence economics (see David 1989; Arthur 1999; Setterfield 1997; 2002; Martin and Sunley 2006), most invoke some form of increasing returns effects as the mechanism by which a self-reinforcing path or pattern of development assumes momentum.

In Arthur’s (1999) work, for example, it is assumed that the autocatalytic or self-reinforcing mechanisms that generate economic path dependence have a spatial dimension in that, choosing where to locate, firms are attracted by the presence of other firms in a region. In the spin-off version of this model, the path-dependent geographical distribution of industry occurs through a process of local firm spin-offs from existing parent firms. Arthur suggests that this type of cumulative, self-reinforcing process has characterized the geographical concentration of the US electronics and car industries. In the agglomeration economies version, if one region by chance gets off to a good start, its
attractiveness and the probability that it will be chosen by firms will be enhanced; further firms may then choose this region, with the result that it becomes yet more attractive because of the emergence of various agglomeration economies and externalities, and the concentration of firms (and perhaps also particular industries) there becomes self-reinforcing. Arthur refers to three such agglomeration economies or externalities: dynamic learning effects (learning by interaction with other proximate firms – knowledge spillovers); coordination effects (various local network effects, such as local supply chains, specialist intermediaries, and the like); and self-reinforcing expectations (when the increased prevalence of other similar firms doing similar things or making similar products enhances belief and confidence in a local developmental path).

Arthur (1999) suggests that Silicon Valley in the United States is a possible example of this sort of cumulative, self-reinforcing spatial agglomeration of a given industry, in this instance electronics. Certain key people – entrepreneurs like the Hewletts, the Varians, the Shockleys of the industry – happened to set up near Stanford University in the 1940s and 1950s, and the local labor market expertise and interfirm market they helped to create in Santa Clara County made subsequent location extremely advantageous for the thousand or so other firms that followed them. Arthur cites this as a classic example of (almost) unbounded agglomeration economies, which have fueled a cumulative, self-reinforcing, and path-dependent process of clustering. Another example is the high-tech cluster in Cambridge. The origins of this cluster are usually traced back to the establishment of a research consultancy and transfer enterprise (Cambridge Consultants) in 1969, followed soon after (at the beginning of the 1970s) by the construction of a science park just outside the city by Trinity College. These events set off a cumulative, path-dependent process whereby new high-tech firms have been created or attracted into the cluster, which in their turn have promoted the growth of a highly qualified scientific workforce. And, as the cluster has grown, this has stimulated research and innovation, increasingly closer links with scientific research within the university, the emergence of a local circuit of venture capital and business angel finance, and a general climate of entrepreneurship and enterprise formation, all of which have maintained the cluster’s growth momentum. In many respects, then, clusters display the sort of self-reinforcing, path-dependent development that typifies the process of circular and cumulative causation.

The limits to cumulative causation

But, in its basic form, there is an obvious problem or caveat in the cumulative causation model of regional development. Essentially it suggests that success breeds success and failure begets failure indefinitely. The recursive, self-reinforcing nature of cumulative causation means that once a particular pattern and path of regional development is initiated, it simply continues and cumulates as time progresses. It appears, therefore, that an initially faster-growing region will permanently experience faster growth, while its less successful partners will endure slower growth: this is the impression given in Figure 2, for example. Put another way, once the initial relative success or failure of a region is known, then, given the path-dependent nature of cumulative causation, so too is its subsequent history. By the same token, the basic CCC model predicts progressive and unabated regional divergence in per capita incomes.

Yet, from the stylized facts of regional growth, it is known that disparities in regional per capita incomes do not widen indefinitely. Some classic
CUMULATIVE CAUSATION, ENDOGENOUS GROWTH, AND REGIONAL DEVELOPMENT

studies have argued that, as a country develops, so regional disparities widen for a while as economic development agglomerates in certain core regions, but that with time they begin to narrow, as peripheral regions catch up. Both Myrdal and Kaldor recognized this possibility. Myrdal, for example, argued that various “spread” and “backwash” effects – such as induced demand from the core for the products of the periphery, or dispersion of economic activity from the core because of rising costs there – could limit the extent of uneven regional growth caused by cumulative causation-propelled spatial agglomeration. More recently, Leon-Ledesma (2002) has suggested that the diffusion of technology from core growth regions to lagging peripheral ones may allow the latter to catch up. In other words, with time “spread” or “centrifugal” effects can come into effect to limit and counter the agglomerating or “centripetal” pull of the prosperous core region. That is to say, the balance between agglomerating (centripetal) and spreading effects may shift over time in favor of the latter, thereby allowing peripheral or lagging regions to improve their relative growth performance and then to embark on a virtuous circular and cumulative developmental path of their own.

But the stylized facts also indicate that, notwithstanding the possibility of such spread effects, successful regions can lose their inherent relative growth advantage, and subsequently experience periods – often prolonged – of slow growth or relative depression. There are essentially two ways of conceptualizing such eventualities – by invoking an external shock that interrupts the cumulative causation process from without; or by recognizing that various processes or mechanisms may emerge endogenously from within the process of cumulative causation itself. As an example of the former, consider the key role that external (export-led) demand plays in the development and growth of regional and urban economies. In any round of the cumulative causation process, the dynamics of a virtuous regional growth circle depend on sufficient export demand for the region’s products or services being forthcoming, induced by the rise in efficiency brought about by the realization of scale economies and by positive externalities associated with the increased spatial agglomeration of activity in the region in the previous round. But what if the rate of growth of exports is subject to exogenous shocks over time? A major new external competitor may appear, offering far more superior forms of the products or services in question, or at much cheaper prices. A major reduction in the export demand for the region may then occur, and this in turn will disrupt the cumulative growth process, possibly causing it to break down. Economic history is replete with examples of countries, regions, and cities that were once national, even international, leaders in their respective specialisms, but then lost that leadership to the rise of other, more competitive, nations and regions elsewhere, and with it their economic dynamism. For example, since the late 1970s, the rise of cheap labor producers in the BRIC countries, especially China, has undermined the export growth of much of the Western mass production industry. The positive export-led cumulative causation dynamics previously enjoyed by many Western cities and regions has in effect been transferred to certain cities and regions in the BRIC nations, which have enjoyed extraordinary growth rates as a consequence.

Faced with an exogenous shock of this sort, a region’s firms have three main possible responses: to struggle on with declining market share and falling profits, and eventually go under; to restructure and reorganize production via technological and product upgrading (a technological fix), in order to resume competitiveness and hence export demand for their products;
or to shift some or all of their production to cheaper or more dynamic locations elsewhere (a spatial fix).

But a region’s cumulative causation dynamic may break down and be lost as a result not of an external shock but of processes and features that emerge from within the cumulative process itself. The very process of cumulative spatially agglomerated sectoral specialization, though making for cumulative and self-reinforcing growth, or positive path-dependent lock-in, for a certain period, may itself eventually give rise to structural, technological, and institutional rigidities and fixities that then usher in a period of negative path-dependent lock-in which impairs the ability of the region’s economy to realize transformational growth (Setterfield 1997; Thirlwall 2013). The increasing rigidity of the regional economy may occur for various reasons, depending on the structure and organization of that economy. According to the extent to which new types of fixed capital must be accumulated in the pursuit of economies of scale, the ability of a region to realize dynamic increasing returns may be impaired if it suffers from technological interrelatedness, both within local firms and, crucially, across local firms. Because this phenomenon makes technological change a nonmarginal process, it can become highly costly or subject to coordination failures, and this may result in the negative lock-in of the regional industry in question to a previously existing technological regime. The ability of the region to transform its stock of productive assets in a manner in keeping with the realization of increasing returns and with maintaining its export competitiveness may suffer accordingly.

For example, in a regional economy based on an industry with a detailed interfirm horizontal division of labor, with different firms specializing in different stages or aspects of production of a finished export good, the high degree of interrelatedness across firms may come to hinder the introduction of major technological improvements to production. This is particularly likely to occur if the industry in question involves large sunk costs in expensive dedicated machinery or plant. In such a regional production complex, no one firm will invest in new techniques of production unless other firms do so, with the result that none may be willing to risk making the first move. As a consequence, technological inertia may develop and eventually hold back productivity advance. The regional economy then becomes especially vulnerable to the rise of competitors that have switched to the more advanced and more efficient techniques.

A prime example of this situation is the Lancashire cotton textile sector in the United Kingdom. From the late eighteenth century onward, this region enjoyed strong self-reinforcing cumulative, path-dependent, spatially agglomerated growth, involving thousands of local firms linked in a complex interfirm horizontal division of labor in cotton textile production. By the mid-nineteenth century Lancashire had become the world’s largest exporter of cotton textiles, accounting for two-thirds of the world’s exports, and employing over 600,000 workers locally. But, toward the end of the nineteenth century and into the early decades of the twentieth century, the region came under increasing international competition from overseas competitors that had adopted new technologies, including upright automatic looms, while Lancashire’s firms still clung on to the old horizontal looms on which its original productive superiority had been founded. The high degree of interfirm division of labor and technological interrelatedness between Lancashire’s firms, together with an institutionalized self-confidence (some would say overconfidence) born of past success, became sources of negative technological lock-in and
entrepreneurial inertia, which then slowed down the region’s technological upgrading, with devastating consequences. Between the two world wars, several thousand of the region’s textile mills closed down, and the industry never recovered.

More generally, there is evidence that the economic benefits that can accrue through the self-reinforcing spatial agglomeration of industry may themselves follow a sort of life cycle over time, initially rising as the cumulative process gets underway, then reaching a maximum as the regional industry matures, and then declining thereafter (Potter and Watts (2011), find this, for example, in the case of manufacturing industries in the United Kingdom’s Birmingham region). That is to say, agglomeration economies may not increase continuously over time, or even remain unchanged once established, but rise and fall as the industries around which they developed rise and fall. The reality is that regional industrial structures change and evolve over time, and the processes of cumulative causation can be expected to ebb and flow as a consequence. Theorists have as yet given insufficient attention to the endogenous evolutionary dynamics of cumulative causation, yet this would be necessary if the model is to capture the long-run evolutionary paths of regional economies. The issue is akin to the way that the notion of path dependence is typically used in economics, regional studies, and institutional studies, whereby a given path and pattern of economic, technological, and institutional development, once established, is assumed to get locked in and to change only when subjected to an external shock of some kind. In the real world, economies, technologies, and institutions also display differing degrees of ongoing endogenously generated change and adaptation. Both path dependence theory and the CCC model need to incorporate and account for such change and adaptation (Martin 2010).

CUMULATIVE CAUSATION, ENDOGENOUS GROWTH, AND REGIONAL DEVELOPMENT

CyberGIS – defined as GIS (geographic information science and systems) that is based on the development and use of advanced cyberinfrastructure – represents a new modality of GIS in the era of big data; it has emerged during the past several years as a vibrant interdisciplinary field (Wang 2010; Wang, Wilkins-Diehr, and Nyerges 2012; Wang et al. 2013; Wright and Wang 2011). Cyberinfrastructure (sometimes referred to as e-infrastructure and e-science) typically integrates digital environments to support collaborative research, as well as computing- and data-intensive scientific problem-solving. Specifically, cyberinfrastructure consists of computing systems, data storage systems, advanced instruments and data repositories, visualization environments, and people, all linked together by software and high-performance networks to improve research productivity and enable scientific breakthroughs that are not otherwise possible (Wang and Zhu 2008). An initial landmark in the history of cyberinfrastructure is the blue-ribbon panel report titled Revolutionizing Science and Engineering through Cyberinfrastructure that was published by the US National Science Foundation (NSF) (Atkins et al. 2003).

Major advances in cyberGIS as an interdisciplinary field are rooted in multiple research domains including advanced cyberinfrastructure, complexity science, computational and data sciences, distributed computing and systems, GIS, high-performance and parallel computing, spatial analysis and modeling, and a number of domains concerning geospatial questions and problems. Early research on geo-middleware set an important foundation in cyberGIS for integrating high-performance and distributed computing resources and services to enable collaborative and computationally intensive geographic analysis (Wang 2004).

A variety of research related to cyberGIS had been pursued before 2010 (Wang, Wilkins-Diehr, and Nyerges 2012; Yang et al. 2010). For example, Wang and Liu (2009) demonstrated a suite of technical capabilities for establishing an online science gateway to bridge cyberinfrastructure and GIS functions based on a service-oriented architecture and high-performance and distributed computing. The first holistic understanding of cyberGIS, however, was gained by the development of an integration framework for synthesizing cyberinfrastructure, GIS, and spatial analysis and modeling to solve computationally intensive and collaborative geographic problems (Wang 2010). The case study used to demonstrate the application of this cyberGIS framework focused on revealing spatial patterns of the impact of climate change on crop yields in the United States. The computation, data, and collaboration requirements of the study could not be met by conventional GIS approaches based on a monolithic architecture, sequential computing, and single user interfaces.

Several cyberinfrastructure, geospatial, and GIS research communities have been working together to advance the field of cyberGIS. A key community event was the NSF TeraGrid...
Workshop on CyberGIS that took place in conjunction with the University Consortium for Geographic Information Science Winter Meeting in February 2010. The workshop report laid out a compelling cyberGIS roadmap that underpins fundamental issues of cyberGIS for enhancing cyberinfrastructure while contributing to the advancement of the next generation GIS, which will integrate high-performance, distributed, and collaborative capabilities to support geospatial discovery and innovation (Wang, Wilkins-Diehr, and Nyerges 2012). Built on the success of the workshop, a multi-institution and multidisciplinary proposal to NSF was funded in 2010 to begin a five-year $4.43 million project on “CyberGIS Software Integration for Sustained Geospatial Innovation” with the following six major goals (Wang et al. 2013):

1. engage multidisciplinary communities through a participatory approach to evolving cyberGIS software requirements;
2. integrate and sustain a core set of composable, interoperable, manageable, and reusable cyberGIS software elements based on community-driven and open-source strategies;
3. empower high-performance and scalable cyberGIS by exploiting spatial characteristics of data and analytical operations for achieving unprecedented capabilities for geospatial scientific discoveries;
4. enhance an online geospatial problem-solving environment to allow for the contribution, sharing, and learning of cyberGIS software by numerous users, which will foster the development of cross-cutting education, outreach, and training programs with significant broad impacts;
5. deploy and test cyberGIS software by linking with national and international cyberinfrastructure to achieve scalability to significant sizes of geospatial problems, amounts of cyberinfrastructure resources, and number of users;
6. evaluate and improve the cyberGIS framework through domain-science applications and vibrant partnerships to gain better understanding of the complexity of coupled natural and human systems.

This major NSF cyberGIS initiative has established three interrelated pillars of a cutting-edge cyberGIS software environment, including the CyberGIS Gateway, CyberGIS Toolkit, and GISolve middleware.

The CyberGIS Gateway has evolved from the TeraGrid GIScience Gateway (Wang and Liu 2009) and provides an online environment for making cyberGIS capabilities accessible to a large number of users for various research and educational purposes (Wang et al. 2013). The CyberGIS Gateway serves as a platform for a suite of scalable spatial analysis and modeling applications built on GISolve middleware. These applications are broad and diverse, including, for example, assessment of climate change impacts, hydrological information analysis, social media analytics, and spatial econometrics, which are supported by the modular architecture of the CyberGIS Gateway. The computation, analysis, and modeling tasks are conducted using multiple cloud computing environments along with several leading cyberinfrastructure environments, such as the NSF extreme science and engineering discovery environment (XSEDE) and the Open Science Grid. The user interfaces of the CyberGIS Gateway are designed to accommodate specific application characteristics in a user-centric way, so that a large number of users who do not possess in-depth cyberGIS technical knowledge can access complex cyberinfrastructure and cyberGIS workflows.

As a result, the CyberGIS Gateway is able to serve as a learning environment and is also
accessible to the general public. Numerous undergraduate and graduate students have used the CyberGIS Gateway to learn advanced cyberinfrastructure, service-oriented architecture, GIS, high-performance computing, spatial analysis and modeling, and computing- and data-intensive geospatial problem-solving at universities in the United States and beyond.

The CyberGIS Toolkit is composed of loosely coupled geospatial software components, each of which can take advantage of advanced cyberinfrastructure resources (e.g., those provided by XSEDE) in a scalable way. The CyberGIS Toolkit is open source and enables computational and data scientists in various geospatial domains to directly contribute to and benefit from community-driven scalable software and tools. The approach used to build the CyberGIS Toolkit develops and leverages scalable computing strategies that are required to solve computing- and data-intensive geospatial problems, and also exploits high-end cyberinfrastructure resources, such as supercomputers integrated by XSEDE and high-throughput computing resources on the Open Science Grid. A rigorous process of software engineering and computational intensity analysis (Wang and Armstrong 2009) is applied when a software component is incorporated into the CyberGIS Toolkit, including software building, testing, packaging, performance and scalability analysis, and deployment. A selected set of software component examples of the CyberGIS Toolkit include the following.

- Parallel agent-based modeling (PABM) software is for multiscale and spatially explicit agent-based modeling (ABM) of coupled natural and human systems.
- Parallel genetic algorithm (PGA) is used to address computationally intensive spatial optimization problems; it can efficiently scale up to hundreds of thousands of processor cores available on multiple cutting-edge supercomputers.
- Parallel PySAL provides a set of scalable PySAL functions. PySAL is an open source library of spatial analysis functions written in Python. Parallel PySAL uses a multiprocessing Python library.
- pRasterBlaster is a high-performance map reprojection software originally developed by the Center of Excellence for Geospatial Information Science within the US Geological Survey (USGS).
- Terrain analysis using digital elevation models (TauDEM), created by Dr David G. Tarboton at the Utah State University, is enhanced to include a suite of high-performance digital elevation model (DEM) tools for watershed delineation and the extraction and analysis of hydrologic information from topography as represented by DEMs.

GISolve middleware bridges the CyberGIS Gateway and Toolkit by managing the complexity of interactions among heterogeneous and distributed resources and services of advanced cyberinfrastructure (e.g., XSEDE and various cloud computing environments) and providing standard interfaces for the integration of scientific applications into the cyberGIS software environment. GISolve represents the leading middleware approach to integrating advanced computational and data infrastructure with geospatial data and computing capabilities for computationally intensive and collaborative geospatial problem-solving, and is openly accessible via a suite of open service application programming interfaces (APIs) (Wang et al. 2013). These APIs are compatible with community standards such as those facilitated by the Open Geospatial Consortium, and adopt widely used web service protocols such as the representational state transfer (REST) architectural style. Consequently, GISolve supports
interoperability among different cyberGIS software environments. For example, it has been demonstrated that ArcGIS Online and the CyberGIS Gateway can interoperate for applications to take advantage of both environments while accessing advanced cyberinfrastructure based on GISolve APIs.

Previous work shows that scientific problems exhibiting high spatial complexity require holistic approaches to integrating rich spatiotemporal data, analytics, and models to form novel problem-solving approaches enabled by cyberGIS (cf. Wang 2010; Tang et al. 2011). Conventional scientific approaches to solving such complex geospatial problems, however, tend to be fragmented in space and time and are constrained by an inability to take advantage of complex, diverse, and massive geospatial data, which makes extrapolation across large and multiple spatial and temporal scales difficult or infeasible. Researchers from multiple institutions are engaged in research and development activities on the three pillars of the cyberGIS software environment. These investigations span various domains (e.g., bioenergy, emergency management, geography and spatial sciences, and geosciences) as illustrated by the examples given in the next sections.

**Complex geographic problem-solving**

Multiscale simulation of geographic dynamics often uses spatially explicit ABM approaches to study spatiotemporal complexity of coupled natural and human systems (e.g., multiscale disease spread). However, significant computational and data challenges must be resolved when dealing with massive multiscale agent–agent and agent–environment interactions, efficient exploration of alternative individual-level scenarios, and rigorous sensitivity and uncertainty analyses. In a simulation study of disease spread involving billions of individual-level agents, operating across multiple spatial and temporal scales, Shook, Wang, and Tang (2013) identified that variations in spatial and temporal scales had a strong influence in the representation of transmission processes for disease spread dynamics. Such multiscale geospatial simulations often require high-resolution spatiotemporal datasets during and after computation, while producing massive geospatial datasets for representing and examining spatiotemporal dynamics. This type of complex geographic problem-solving is difficult or impossible to pursue without cyberGIS.

Not only does cyberGIS provide a means to resolve computational and data challenges in solving such complex geographic problems, but it also represents a new paradigm for conceptualizing geographic processes based on parallel and distributed computing. Real-world geographic processes take place concurrently and in parallel with interactions across various spatiotemporal scales. But due to the dominance of sequential computing approaches in research and development of GIS, geographic process modeling has been limited by missing theoretical and methodological underpinnings for systematically representing concurrency, parallelism, and related spatiotemporal interactions. CyberGIS is built on parallel and distributed computing; thus, it is well suited to nurture such underpinnings for transforming computational and data-driven research on complex geographic problems.

**Data-intensive knowledge discovery**

Geospatial data have become ubiquitous and are increasingly important in numerous research fields (e.g., ecology, environmental science and engineering, geography and spatial sciences,
geosciences, and social sciences, to name just a few). Such data are instrumental to solving many critical scientific and societal problems (e.g., disaster management and environmental sustainability). With the increasing availability and capability of location-based sensors and devices, the explosive growth in volume and complexity of geospatial data will continue to accelerate in the foreseeable future. For example, it is estimated that the 3-D elevation program (3DEP) of the USGS for acquiring 3-D elevation data using LiDAR will result in data volumes that are of the magnitude of 7–9 petabytes, considering only the point cloud, intensity signals, and bare-earth elevation model for covering the United States. Conventional GIS approaches are ill suited to resolving such big data challenges. The realization of the full potential and benefits of 3DEP, estimated at $1.2–13 billion in new benefits annually by the national enhanced elevation assessment (NEEA) study (Snyder 2012) is dependent on the ability of cyberGIS for management, processing, visualization, and analysis of such massive geospatial data.

Extracting features from such elevation data promises to create new valuable data products (e.g., high-resolution stream network and drainage area) for integration with the USGS national map, which is a collaborative effort among USGS and other federal, state, and local partners to improve and deliver topographic information for the United States. Fine-resolution DEM data have a significant impact on the accuracy and reliability of hydrological modeling. Though tools exist for deriving topographic information from DEM data for hydrological modeling, when such tools are applied to fine-resolution DEM data, the resulting computational burden makes GIS approaches based on sequential computing unfeasible. TauDEM integrated within the cyberGIS software environment promises to resolve this data-intensive challenge.

Through rigorous computational-intensity analysis, the ability of TauDEM to take advantage of advanced cyberinfrastructure resources for data-intensive terrain data analysis is eliminating barriers to desirable computational performance. The enhanced TauDEM software can scale to thousands of processor cores and is able to analyze tens of gigabytes of DEM data within a single analysis, which was not possible on small-scale high-performance computing resources and lies far beyond the capabilities of GIS tools based on sequential computing strategies. With large data volumes of tens to hundreds of terabytes for a single basin, cyberGIS-based scalable data analytics is arguably the only viable approach that will allow effective analysis of 3DEP data to yield valuable geospatial information and enable its sharing with user communities. Meanwhile, tackling the significant computational and data challenges as posed by 3DEP will require development of a rich array of new cyberGIS capabilities and software that will, in turn, drive the frontiers of data-intensive geographic knowledge discovery.

Emergency management

Social media data (e.g., from Twitter) and volunteered geographic information are becoming increasingly useful in emergency management due to widespread use of location-aware mobile devices and near-real-time emergency status updates. Leveraging the cyberGIS software environment, in 2012 a collaborative project called Global Twitter Heartbeat analyzed a real-time stream of 10% of Twitter’s several hundred million daily tweets as they were posted. The entire process from data ingest to analysis to visualization was optimized to be completed
within a few seconds. This project demonstrated the tremendous power of the cyberGIS software environment for resolving the computational and data challenges of processing big data in an efficient and scalable manner. While no other existing tools can simultaneously manage, process, and analyze such massive, semi structured or unstructured, and streaming data in this near-real-time fashion, such cyberGIS capabilities are crucial for emergency management purposes.

Specifically, the project analyzed every tweet to determine its location and sentiment tone values, and then visualized related information in a heat map infographic that combines and displays tweet location, intensity, and tone. The project examined Hurricane Sandy, on which millions of tweets were posted, making cyberGIS a significant platform for communicating what was happening at every moment across a number of spatial scales. The live demonstration of this research outcome was debuted at the 2012 International Conference for High Performance Computing, Networking, Storage and Analysis (SC12) in Salt Lake City, UT.

Geodesign and spatial decision-making

Bioenergy is an important source of renewable energy. Optimal and sustainable management of bioenergy infrastructure, such as its supply chain, is a complex geodesign problem, which requires the collaboration and participation of different types of decision-makers who are usually not experts on cyberinfrastructure, GIS, or spatial analysis and modeling. Normally, a biomass supply chain optimization model is computationally intensive when applied to realistic scenarios across multiple spatiotemporal scales; this computational complexity makes it infeasible for decision-makers to directly interact with pertinent GIS analytics during the duration of a typical meeting. Another challenge for such decision-making processes is related to the data used as input and output for optimization modeling, and the integration of diverse geospatial data types (e.g., crop, land use, soil, transportation, and water).

A computationally intensive optimization model of a biomass supply chain – BioScope – has been integrated into the CyberGIS Gateway to demonstrate that cyberGIS can enable the computation of the model by accessing powerful cyberinfrastructure resources while providing an interactive and simple user interface for decision-makers who are not required to possess any technical knowledge of cyberGIS (Figure 1) (Hu et al. 2015). Decision-making experiments accessible to a large number of users can be conducted at the spatial scale of the contiguous United States, which is difficult or impossible to achieve without cyberGIS.

The four examples (i.e., complex geographic problem-solving, data-intensive knowledge discovery, emergency management, and geodesign and spatial decision-making) described above are not intended to form a complete taxonomy of cyberGIS-enabled research and science. The overarching emphasis is rather placed on demonstrating the role of cyberGIS in supporting important research breakthroughs.

Computational theories and methods

CyberGIS has been advanced through the synergy of critical computational and spatial thinking (Wang and Zhu 2008). For example, the theoretical construct of a spatial computational domain was established to guide the development of generic methods and efficient algorithms for multiscale spatial modeling (Shook, Wang, and Tang 2013) and data-intensive geospatial
Figure 1  CyberGIS-BioScope application user interface.

analytics (Wang 2010; Wang et al. 2013). The formalization of the spatial computational domain addresses the following important questions: How can massive shared cyberinfrastructure resources be harnessed to solve computationally intensive geographic analysis problems? What is the nature of computational intensity of geographic analysis? Why is a spatial perspective needed to address the first two questions? Such theoretical work also involves methodological and empirical investigations that reveal how the spatial characteristics of data and analytical operations affect computational requirements for cyberGIS-based geographic analysis (Wang, Wilkins-Diehr, and Nyerges 2012).

Due to the complexity of evolving cyberinfrastructure and the diversity of geographic analytical approaches, significant scientific and technological challenges must be tackled before generic computational methods can be established for cyberGIS-based geographic problem solving (Wang 2013). Building on the theoretical foundation of the spatial computational domain, a number of computational methods have been developed for solving complex geographic problems such as spatially explicit agent-based
models that simulate the movement of massive numbers of individual agents through space and time (Shook, Wang, and Tang 2013), and data-intensive viewshed analysis (Wang et al. 2013). These methodological advances enable efficient and shared use of massive cyberinfrastructure resources for scalable analysis of geospatial big data and solving computationally intensive geographic problems (Tang et al. 2011; Wang 2013).

A major empirical element of cyberGIS centers on an open and functional process for understanding the nature of computational challenges in various geographic problems and for overcoming these challenges to empower desirable research productivity and progress. This process facilitates the development of scalable computational methods and associated algorithms that are encapsulated into geospatial middleware that manages the complexity of cyberinfrastructure. Previous research on geospatial middleware has provided interoperable geographic analysis services for empowering a large number of users and diverse applications (Wang et al. 2013).

Digital geospatial ecosystems

CyberGIS fulfills an essential role in enabling computing- and data-intensive geospatial research and education across a broad swath of academic disciplines with significant societal impacts. The future realization of cyberGIS’s reach is compelling as the role and complexity of big data continue to challenge the state of the art of collaborative, interactive, and scalable knowledge discovery through the processing and visualizing of complex and massive amounts of geospatial data and performing associated analysis, simulation, and visualization.

CyberGIS-based scientific approaches have already made a significant impact in several research domains (e.g., hydrology and water resources, complex coupled natural and human systems, emergency management, and spatial econometrics). CyberGIS based on critical computational and spatial thinking is needed to combine rich and complex geospatial data, analysis, and models, and is expected to support the effective and timely resolution of many grand geospatial challenges (e.g., energy and environmental sustainability, emergency and disaster management, and health and wellness).

CyberGIS exemplifies and enhances the vision of integrated cyberinfrastructure and, thus, will continue to positively contribute to broad scientific advances. Integrative approaches are required to meet the increasing needs for combining diverse and massive digital resources and services across individuals and organizations, to serve various research and education purposes. To navigate through the extensive digital transformation across science and society, cyberGIS has an important role to play, as it bridges the divide between broad digital and geospatial realms by nurturing sustainable digital geospatial ecosystems. As argued by Wang (2013), the ecosystem metaphor for characterizing cyberGIS emphasizes the notion of systems of systems that are developed and evolved in heterogeneous computing, communication, information, and human environments.

As a recent example of geospatial innovation for cyberGIS hardware and software, in 2014 the CyberGIS Center for Advanced Digital and Spatial Studies at the University of Illinois at Urbana-Champaign received an NSF major research instrumentation grant to establish a national cyberGIS facility. This facility is based on a single tightly integrated instrument – a high-performance computing system optimized to deal with geospatial data and computation, that is equipped with:
• approximately seven petabytes of raw disk storage with high input/output bandwidth;
• solid-state drives for applications demanding high data-access performance;
• advanced graphics processing units for exploiting massive parallelism in geospatial computing;
• interactive visualization supported with a high-speed network and dynamically provisioned cloud computing resources.

CyberGIS software and tools integrate these system components to support a large number of users who are investigating scientific problems in areas as diverse as biosciences, engineering, geosciences, and social sciences.

The design of the cyberGIS facility is driven by requirements posed by these diverse scientific investigations that are critically dependent on scalable spatial data infrastructure and cyberGIS workflows involving interactive steering of simulations, and processing and visualization of large, complex, and heterogeneous geospatial datasets.

The potential of cyberGIS to contribute to broad scientific and technological advances continues to be empowered by rapid developments in digital technology in general, and advanced cyberinfrastructure in particular. It is important to recognize that cyberGIS exhibits significant complexity, as it represents digital geospatial ecosystems embedded within massive evolving systems, dynamic connections, and complex relationships. Management of such complexity while sustaining innovation is a grand challenge for cyberGIS as an interdisciplinary field.

Description and purpose

The main aim of the Czech Geographical Society is to promote geographical research and geography as a scientific discipline. It represents Czech geographers in their contacts with Czech political authorities and with other scientific organizations in the Czech Republic and abroad. It is a base for cooperation among all Czech geographers.

Journals or major publication series

Current activities or projects

Brief history

Czech geography, as a science, was born at the end of the nineteenth century in the Austro-Hungarian Empire when the Germanized old Czech university was divided into a German and a Czech section in 1882. Jan Palacký (1830–1908) was appointed the first Czech professor of geography. The Czech Geographical Society was established in 1894 and between 1920 and 1939 and between 1945 and 1990 it existed as the Czechoslovak Geographical Society. The best time for its activity was the period of coexistence with the Geographical Institute of the Czechoslovak Academy of Science (1962–1993). The most famous director of this institute was the geomorphologist Jaromír Demek (born 1936), who was also the president of the society from 1978 to 1981. Nowadays, Czech geography is predominantly an academic discipline and it is taught at eight universities (Prague, Brno, Ostrava, Olomouc, Plzeň, České Budějovice, Ústí nad Labem, and Liberec) where regional branches of the society have been established. The most renowned one is Charles University in Prague, which is known especially for the Albertov School of Human Geography owing to two theoretically oriented geographers Jaromír Korčák (1895–1989) and Martin Hampl (born 1941).
Soil development: conceptual and theoretical models

Ronald Amundson
University of California at Berkeley, USA

Models and theories

A model implies the creation of a verbal or mathematical representation of how something works. There is considerable inconsistency in the definitions or distinctions between model and theory. However, it is widely agreed that theories provide falsifiable predictions of the phenomenon being examined. For example, a mass balance model of soil on a hillslope that states that the soil thickness is the balance of erosion and soil production provides little in the way of a falsifiable prediction. Yet, such a model that states that rate of soil production is inversely correlated with the soil thickness, and the rates of erosion are positively correlated with soil thickness, is indeed a testable hypothesis, providing a theoretical underpinning to the model. This review of models of soil development focuses on the combined development of both theory and conceptual models in the field of pedology over the past two centuries.

The concept of soil

The science of pedology focuses on the processes that form and distribute soils on the landscape. Pedology is largely a historical and observational science, as opposed to other related branches of soil science that are mainly laboratory based and experimental. Soil is the object of study in pedology. It is sometimes said that “soil means different things to different people.” Yet, for pedology to be a science, there must exist a definition that reflects a theoretical understanding of soil. For most of human history, soil was viewed through the lens of agriculture, or as a construction material. Since about the mid-1800s, however, the definition of soil has had a sound theoretical basis. The Soil Science Society of America’s Glossary of Soil Science Terms provides two definitions of soil.

1. The unconsolidated mineral or organic material on the immediate surface of the Earth that serves as a natural medium for the growth of land plants.
2. The unconsolidated mineral or organic matter on the surface of the Earth that has been subjected to and shows effects of genetic and environmental factors of climate (including water and temperature effects), and macro- and micro-organisms, conditioned by relief, acting on parent material over a period of time. A product-soil differs from the material from which it is derived in many physical, chemical, biological, and morphological properties and characteristics.

The first definition above is purely utilitarian and has no theoretical basis. The second definition is based on a theory, one that began with the work of the Russian scientist Vasily Dokuchaev. By the time of the publication of his treatise Russian Chernozem (Dokuchaev 1883), Dokuchaev had...
SOIL DEVELOPMENT: CONCEPTUAL AND THEORETICAL MODELS

already clearly recognized that soil is a natural body – a segment of nature distinct from other components – that reflects the “a) ground, b) climate, c) vegetation, d) topography, as well as e) the duration of the formation period of the soil” (Dokuchaev 1883; Minasny, McBratney, and Salvador-Blanes 2008). Dokuchaev examined the individual effects of each of these five factors on the soils of the Russian steppe. Most importantly, he recognized that this relationship had predictive power: “it is quite obvious that any two given points emerging simultaneously from under sea level, identical in physicochemical composition and topographic situation, inhabited by identical vegetation and affected by identical climatic conditions must have identical soils” (Dokuchaev 1883). For this reason, Dokuchaev and his colleagues are credited with developing the theoretical and definitional underpinnings of our field.

State factors

Nearly 60 years after Dokuchaev’s Chernozem, Hans Jenny began his book Factors of Soil Formation: A System of Quantitative Pedology with the simple sentence: “As a science grows, its underlying concepts change, but the words remain the same” (Jenny 1941). This concise, spartan prose announced what would be a reworking of Dokuchaev’s concepts into a physical framework amenable to numerical quantification and mathematical representation. A physical chemist by training, Jenny had been hired by the University of California at Berkeley in the 1930s to teach courses on pedology and mineralogy (Amundson 2005). In the course of this effort, Jenny began to view soil as an open physical system (with boundaries chosen by the investigator) whose properties could be defined by a set of external variables (e.g., the factors of soil formation)

(Figure 1). In the case of a starting material like an igneous rock or loess, the parent material is largely isotropic at \( t = 0 \). The fluxes of mass, water, gas, and energy between the atmosphere and the soil (along with biological and physical mixing) create a variously anisotropic system over time. As Jenny knew, the vertical trends in soil properties identify or demark the soil horizons.

These external variables or factors, drawn from Dokuchaev and others, were carefully defined so that they might be quantified and represented numerically in a mathematical framework. Briefly, these are:

- climate \((cl)\): the temperature, rainfall, humidity conditions surrounding the system;
- organisms \((o)\): the potential biota that can inhabit the soil system from the immediate surroundings (e.g., the gene pool of the potential biota). Note that this definition and conception are fundamentally different to the biota existing within the system, which is a system property or dependent variable, as opposed to an independent variable. Jenny (1958) elaborated at length on the nature of the biotic factor. This paper is critical
reading for anyone interested in the state factor model;

- relief or topography (r): the initial geographical configuration of the soil system;

- parent material (p): the initial physical/chemical makeup of the soil system (or the configuration at the beginning of a chosen period of study);

- time (t): the elapsed time since the parent material stabilized or since a period of observation began.

These factors, as defined by Jenny, are commonly independent of the soil system itself. Thus, the change in the soil system (s) itself is due to the combined impacts of each factor on the soil, written in the form of a differential equation (equation 1).

\[
\frac{ds}{dt} = \left( \frac{ds}{dl} \right)_{o,r,p,t} dl + \left( \frac{ds}{do} \right)_{d,r,p,t} do + \left( \frac{ds}{dr} \right)_{d,o,p,t} dr \\
+ \left( \frac{ds}{dp} \right)_{d,o,r,t} dp + \left( \frac{ds}{dt} \right)_{d,o,r,p} + \ldots (1)
\]

Because the nature of the mathematical relations between soil properties and any of the factors (e.g., ds/dl) was only poorly understood at the time, Jenny emphasized that pedologists strive to derive these functions through the observational study of sequences of soils (climosequences, chronosequences, etc.). A sequence of sites (carefully selected such that the other variables are constant) represents a fundamental experimental design that can allow the researcher to determine the nature of the relationship between the soil property and any given factor. In a sequence, four factors are held constant, while one (the one of interest) is allowed to vary. Jenny noted that there are two different ways to hold other factors constant. First, hold the variation in the other variables to zero. For example, if the property being examined has little relation to variations in soil age, then \( ds/dt = 0 \).

The appeal of this fundamentally clear and inherently understandable approach to soils is unmistakable. For this reason, many soils textbooks have been outlined by discussing the role of each factor on soils and soil properties using “sequences” of soils as examples. Indeed, a quick search of the Web of Science using “________sequence” as the keyword reveals hundreds to thousands of papers that use and incorporate these types of “sequence” concepts.

A key component of equation 1 is the ellipses or dots that follow it. They represent additional factors that may be important but are, as yet, undiscovered or unaccounted for. Indeed, Jenny had devoted considerable conceptual development to humans as a separate factor of soil formation, but chose in 1941 to keep them within the biotic factor. In the decades following his book, some noteworthy papers were published articulating the need to make humans an explicit soil-forming factor (Bidwell and Hole 1965; Yaalon and Yaron 1966). However, an advancement of this idea was provided in Amundson and Jenny (1991). In this paper, the authors struggled with the issue of why humans require a designation as a separate soil-forming factor. Briefly, the paper focused on the uniqueness of humans, and one of their qualities that is special relative to probably all other species: culture. Culture, like genes, is malleable and can be affected by “selection” when transferred to new environments (Diamond 2012). Culture contains the tools, technologies, and ethical framework that determine what people do to soil. Amundson and Jenny thus defined the human state factor as \( o_h, c_i \), where \( o_h = \) human genotypes and \( c_i = \) cultural inheritance. These independent (of
the system and of each other) external variables, once emplaced within a soil system, become dependent variables that over time may diverge from the values emplaced in the system at \( t = 0 \).

Another concept that Jenny (1961) elaborated on is what he called the “larger system” (soils + overlying biosphere), which is what is now known as an ecosystem. As Amundson and Jenny (1997) noted, this quantitative, factorial articulation of an ecosystem did not appear to become part of the ecological sciences until possibly the 1990s, as ecosystem ecologists and biogeochemists became increasingly interested in ecosystem and watershed mass balances. As an example of the linkage of Jenny’s (1941) ideas with modern ecology, many ongoing Hawaiian Island chrono/climo gradient studies have been designed using the state factor model (Vitousek 2004).

The state factor model is “phenomenological,” and articulates the relationship of soil properties to factors. Jenny was particularly clear that the soil forming factors “are not forces, causes, or energies, not are they necessarily environment. They have but one feature in common. They are the independent variables that define the soil system.” And, later: “The solutions given in this study are formalistic, as contrasted with mechanistic. In simple words, we endeavor to determine how soil properties vary with soil-forming factors. We exhibit but little curiosity regarding the molecular mechanism of soil formation and thus avoid lengthy excursions into colloid chemistry, microbiology, and so on. Such treatment will be reserved for [a] later occasion.”

Essentially, using this guidance, soil is viewed as a “black box.” A black box, in science, is a system where the workings remain unknown and only the output and the controlling conditions or processes are understood. The factors thus set the boundary conditions for the box; they are relevant to subsequent process-based or mechanistic investigations but do not explain or articulate the actual surficial and pedogenic processes that eventually form the soil. That is why this model is referred to as a factorial model, and not a process-based model.

In the intervening years, other models have been devised, especially to highlight the role of energy in the soil system (Runge 1973). Others have conceived of models that shift the emphasis to pedogenic processes and the resulting impact on the nature of the soil profiles (Simonson 1959; Johnson and Watson-Stegner 1987).

Finally, although the “state factor” approach is generally referred to as a model, it is not mechanistic or subject to simulation like a typical model. Additionally, it provides predictions that can be tested in the field. For example, existing work has shown that soil organic matter in well-drained soils increases with rainfall and decreasing temperature (Jenny 1941), a relationship mechanistically understandable when the processes involved are considered (Jenny, Gessel, and Bingham 1949). Thus, it should be possible to predict the organic matter content of unstudied locations based on climate information. And then, the predictions can be tested by subsequent field study. Taken to its extreme, as Dokuchaev predicted, two soils with the same soil-forming factors must (or, at least, should) be identical. While ultimately the distinction between model and theory may not seem essential, it is important to recognize the intellectual foundations of our science, which in turn impacts or guides other fields.

Factors versus processes: opening the black box

Opening the “box” that is the soil system to process-based research and models essentially occurred simultaneous to other developments
of the state factor approach – and sometimes by the same people. This synergy is to be expected, as one wishes to understand why a functional relationship exists, or how a given set of processes may be distributed across the landscape. However, the study of soil processes also owes its success to the contributions from other sciences; here, some of the key contributors to our understanding of soil dynamics are reviewed.

One overarching model for soils involves mass balance estimations. This approach was perhaps first conceptually developed – in pedology – by Roy Simonson (1959). Simonson’s goal was to recognize that soils, and soil-forming processes, operate as a continuum across the surface of the Earth. To most effectively link these features and processes, a general “balance” model was needed to organize or account for changes via additions, removals, transfers, and transformations to, within, and out of the soil system. This generic framework was deliberately designed to replace or quantitatively understand soil horizon changes due to more vaguely defined processes such as “melanization,” which is really a complex combination of processes resulting in the darkening of soil by organic matter, or rubification, which in general implies soil reddening. As Simonson (1959) articulated, the model can be applied to any number of soil processes. Here, some of the major developments in these specific models that have occurred over the last several decades, focusing on physical, chemical, and biological processes, are examined.

Physical processes

Soil on hillslopes is in constant, slow motion – downslope due to slope and surficial processes, downward due to gravitationally driven processes, and upward due to some forms of pedoturbation. Biological and physical processes mix or move soil particles, and, with the aid of gravity, they move downslope, as well as downward within the profile. This view, while now part of the pedological mainstream, began to develop before the science of pedology existed, and it took many years before it became a widely adopted pedological concept. Let us start at the beginning and trace forward.

James Hutton (1726–1796), the Scottish naturalist and scholar, is viewed as the father of modern geology. And yet, his reputation for this achievement might be based on his even more startling grasp and articulation of a conceptual mass balance model of soil formation. Hutton (1788) began his contemplation of upland soils from what, today, might be considered an unusual starting premise: we inhabit a world designed by God to support life and, in such a world, fertile soils are necessary to support plants. Yet Hutton was well aware that erosion occurred following rainstorms, and simple reasoning suggested to him that without a restorative mechanism of underlying rock being converted to soil, the soil mantle would gradually disappear. This outcome was inconsistent with his view of a habitable Earth. Considering this further, Hutton recognized that although soil erosion and production were inherently slow, together they would eventually wear down and level the landscape, leading to geologic/pedological stagnation. Thus, from his reading of geological strata – and his view of the requirement of a habitable planet – Hutton recognized that geological uplift and recycling must occur to maintain a general planetary steady state. Hutton’s contemplation of the relatively slow rates of soil formation and erosion, when linked to observations of geological strata in an array of rock records, provided “no vestige of a beginning, no prospect for an end.”

Nearly 90 years later, the American geologist G.K. Gilbert participated in the early geological expeditions to the American West. In his work
SOIL DEVELOPMENT: CONCEPTUAL AND THEORETICAL MODELS

Figure 2 A depiction of a hillslope mass balance model. The losses from the soil are due to physical losses (flux out flux in) and chemical erosion. Gains are due to atmospheric deposition and, most importantly, to the conversion of rock or saprolite to mobile soil. From Owen et al. (2010). Reproduced from Elsevier.

on the Henry Mountains of Utah, Gilbert (1877, 105) wrote that “over nearly the whole of the earth’s surface there is a soil.” Yet, unconstrained by Hutton’s starting premise, Gilbert noted that “the general effect of vegetation is to retard erosion; and since the direct effect of rainfall is the acceleration of erosion, it results that its direct and indirect tendencies are in the opposite directions.” Thus, Gilbert suggested that plants are responsible for the maintenance of hillslope soils. Gilbert’s short discussion of hillslope soil processes (Gilbert 1877, 99–108) added a number of testable hypotheses to Hutton’s general hillslope mass balance model. First, Gilbert indicated that erosion is proportional to “declivity” or downward slope gradient. Second, Gilbert hypothesized that the rate at which rock is converted to mobile soil (soil production) is inversely related to soil thickness, down to some critical minimal threshold, beyond which the soil cover no longer is capable of accentuating rock degradation, and the soil mantle disappears (see Figure 2). This model is today commonly referred to as the soil production function (Figure 3). It remained for physical scientists like Carsen and Kirkby (1972) to formalize these concepts and translate them into the language of mathematics:

\[
\frac{dH}{dt} = P - E \tag{2}
\]

where \(H\) = the mobile soil thickness layer (commonly equivalent to the A horizon) (L), \(P\) = soil production (L/T) and \(E\) = erosion (L/T). Some functions that are found to commonly describe \(P\) and \(E\) are:

\[
P = P_0 e^{(-\alpha H)} \tag{3}
\]

\[
E = \partial Q_s = K \nabla^2 z \tag{4}
\]

where \(P_0\) = maximum soil production rate at \(H = 0\) (or some critical depth), \(\alpha = a\) constant \((1/L)\), \(K = a\ constant\ \((L^2/T)\), and \(\nabla^2 z\) = slope curvature \((1/L)\). Once dislodged, soil material is inherently mobile from a geologic perspective, especially on slopes. This model is applied to
convex hillslopes, where curvature is negative. When curvature is negative, slope increases with distance downslope and there is a net removal of soil. When curvature is positive, slope declines and mass is accumulated from upslope from erosion. When curvature is zero, the slope is planar, and no net loss or accumulation occurs via erosion.

In what may be one of the most important papers for pedology in the last 15 years, Heimsath et al. (1997) developed a means of using cosmogenic radionuclides to determine the rate of soil production, or the conversion of rock or saprolite to soil material (e.g., equation 3). In their paper, the authors provided the first empirical test of Gilbert’s (1877) hypothesis that soil production from bedrock should be inversely proportional to the thickness of the overlying soil mantle. This paper in effect launched the present synergy between pedology and geomorphology, and introduced a new set of tools that now stimulate both fields. Subsequent to Heimsath et al.’s (1997) physical mass balance model, Riebe, Kirchner, and Finkel (2003) and Yoo et al. (2007) provided means for quantitatively integrating chemical and physical mass balances on hillslopes. In particular, Yoo et al.’s (2007) numerical framework, when coupled with cosmogenic nuclide derived soil production rates along hillslope transects, allowed soil scientists to determine if the rate of soil erosion is related strictly to slope gradient, or to other parameters such as soil thickness.

Chemical processes in soils

Water is a pervasive solvent of rock, and a mechanism which moves both suspended and dissolved material through the soil profile. Quantifying the chemical alteration of soil is needed to understand weathering rates, the release of plant nutrients, and the role of soils in global biogeochemical cycles. By the late twentieth century, characterization of soil profiles had advanced greatly. Terms and procedures had been standardized for describing and characterizing the physical, chemical, and mineralogical composition of soils. Yet, these measures by and large were selected for their applications to agriculture, soil classification, or other practical uses of soil.

In large part, total chemical analyses of soils – so popular in the early twentieth century – had fallen out of favor during this period. A fortuitous renaissance occurred when Hans Jenny took two Berkeley geoscientists on a field trip to examine a unique groundwater in Spodosol on the northern California coast. One outcome of this trip was the inclusion of this soil as an example in a paper illustrating how total chemical analyses can be used to quantitatively examine mass and volume changes over time. This chemical mass balance approach, which was introduced to soil science by Brimhall and Dietrich (1987), or arguably reintroduced (Merrill 1906), has become one of the most important soil mass balance models in the last 30 years. Applying principles and methods used to study ore body evolution in economic geology, Brimhall and Dietrich (1987) described the use of index elements to quantify gains and losses of elements that had occurred in soils via chemical weathering. A key component of this model is the “tau” (τ) value, the fractional gain or loss of an element in a soil horizon relative to the parent material:

\[
\tau = \frac{R_s}{R_p} - 1
\]

where \(R_s\) and \(R_p\) are ratios of the concentrations of mobile to immobile elements in soil horizons or the parent material. While not explicit on the specific mechanisms involved, the approach...
provided quantitative tools for determining total elemental changes during soil development. This quantification of chemical processes in soil assisted in changing the soil system “from a black box to a grey box,” as suggested by Chadwick, Brimhall, and Hendricks (1990). Minasny, McBrantney, and Salvador-Blanes (2008) also pointed out that the “work by Brimhall and Dietrich (1987) is the cornerstone of the last 20 years of soil formation work by many people.”

This relatively simple, soil chemistry based, mass balance model might be viewed as the foundation on which more process-based modeling is presently based. In particular, White et al. (2009), Brantley and Lebedeva (2011), and Maher (2010) used total soil chemistry, mineralogy, pore water chemistry, and thermodynamic data to understand mineral weathering rates, rates and depth of clay formation, and the limiting factors controlling chemical weathering rates of soils. While these very quantitative models lie outside of the scope of this review, they are representative of the novel directions currently underway in soil modeling (Minasny, McBrantney, and Salvador-Blanes 2008).

Biological processes in soils

The importance of macroscale, biological processes on soil formation have been recognized since the development of the field, yet their quantitative study seems to have waxed and waned over time. Dokuchaev and others clearly understood the role of vegetation in the formation of the dark surface horizons of the Chernozem soils of Russia. Gilbert (1877) recognized the role of biota in stabilizing loose sediment on hillslopes, as well as in their effect on breaking up rock and converting it to loose soil. In a largely unrecognized side note to the development of hillslope geomorphology in the nineteenth century, Darwin (1881) independently arrived at the idea that sediment movement downslope by earthworms is also proportional to slope gradient. In spite of his self-acknowledged weakness in mathematics, Darwin provided data on rates of soil movement across slope contour lines. These data provided scientists the opportunity to calculate a numerical value for a slope-dependent, earthworm-mediated, transport coefficient that is implied in Gilbert’s (1877) discussion (i.e., sediment flux rate = K • (slope)).

However, an additional component of Darwin’s research focused on the effect of earthworms on soil mixing and their direct and indirect movement of large particles/clasts over time. Darwin’s observations of gravel, stones, and artifacts in soils revealed that, over time, fine material brought to the surface by worms eventually led to the downward migration and burial of the larger objects, which the worms (bioturbators) could not move (Figure 4). Thus, these larger objects tended to settle to the maximum depth of their burrowing activities. Although the broader implications of these processes to pedology (by gophers, etc.) seem obvious in hindsight, Darwin’s work remained outside of the pedological mainstream for decades.

In the past few decades, an important addition to the pedological lexicon has been the term biomantle. A biomantle is composed of material that has been mixed and homogenized by plants and burrowing organisms. It usually occupies the uppermost part of the profile (Figure 4). The term first appeared in 1975, but its growth as a key process in pedology is largely due to the efforts of Donald Johnson (1934–2013). Johnson, Domier, and Johnson (2005) suggested that Darwin’s work on earthworms and bioturbation represents a key and ignored pedological paradigm. Although Darwin did study how worms help mix and form A horizons, his focus
was not on soil formation as a phenomena, or on the soil itself.

The biomantle concept also links well with the model of hillslope soils discussed above. Geomorphologists recognize that such a “mobile soil layer” – soil lacking any residual rock or sediment structure – is commonly the soil’s A horizons, and thus the biomantle constitutes a conveyor belt of soil that slowly creeps down many hillslopes. This concept has been elaborated upon and developed in a model of soil and hillslope development called the dynamic denudation

Figure 4 The conceptual stages in the biological mixing of a parent material into a biomantle (Johnson, Domier, and Johnson 2005. Reproduced by permission of Taylor & Francis Ltd., www.tandfonline.com). The mixed, mobile layer is commonly equivalent to the A horizon in many soils.
model (Johnson 1993), which not only helps explain slope processes but also the biomantles and stone lines that commonly underlie them.

Conclusions

Dokuchaev and those that followed provided the academic community with both our central pedological theory and a scientific definition of soil. The theory has been subsequently refined and made more amenable to quantification, and has guided and stimulated research in a number of fields. The conceptualization of soil as an open physical system, in turn stimulated the development of mass balance models, many of which are now quite mathematical and amenable to computer simulations. However, it is the original, conceptual breakthroughs or illuminations that started the process.

Although it might be easy to critique the sometimes vague scope of early conceptual models and breakthroughs – because they do not immediately lend themselves to a particular quantitative application – it is important to consider how they set in motion new ways of seeing things and transforming a field. Theories are the parables of science, allowing us to see and investigate what we otherwise have not seen.

Disturbance in biogeography

Thomas T. Veblen
University of Colorado Boulder, USA

Disturbance defined

Disturbance is an inherent component of all ecosystems affecting both the local and broad-scale spatial and temporal patterns of biota across the Earth. Although definitions of ecological disturbance vary in their nuances, the definition most widely adopted by biogeographers and ecologists is: “a disturbance is any relatively discrete event in time that disrupts ecosystem, community or population structure and changes resources, substrate availability, or the physical environment” (White and Pickett 1985, 7). Understanding the roles of disturbances in different ecosystems is particularly critical to the field of biogeography because it aims to understand how natural processes, as well as human activities, determine biotic patterns across spatial scales from the local to the global and across a range of temporal scales. Although disturbance is an important concept in marine and aquatic sciences, this review will focus on terrestrial ecosystems, given their greater relevance to physical geography.

Intellectual context and societal importance

Ecosystems are shaped by natural disturbances of numerous kinds such as windstorms, fire, flooding, snow avalanches, landslides, herbivory by large mammals as well as by insects, and outbreaks of disease-causing organisms (pathogens). Anthropogenic disturbances such as logging, treading, altering fire activity, or manipulation of grazing animals are also key influences on many ecosystems. The ubiquity of disturbances in all ecosystems, and their importance in shaping ecosystem structure and function, make them a vital component of biogeographical analyses of how and why vegetation patterns vary across the globe.

Disturbances influence plant communities through their direct effects on plant biomass by killing entire plants or removing parts of plants which in turn affect competition, environmental conditions, and the availability of substrate and resources to other plants. When disturbance removes or partially removes a large plant, in many environments the resources released may be used by other plants of the same or of other species. This sets in motion changes in biotic interactions and population dynamics that may significantly alter the composition and structure of the vegetation. Thus, disturbance is a primary cause of spatial heterogeneity in ecosystems. When disturbance affects a single plant or small
DISTURBANCE IN BIOGEOGRAPHY

group of plants (such as a single tree-fall), the result is an alteration of fine-grain patchiness. Coarse-grained patchiness results from larger areas disturbed such as in the case of fire. Thus, in the context of biogeography, given its focus on patterns at all scales, disturbance is a major source of patchiness and heterogeneity in the landscape.

Repeated disturbance is a key process in maintaining biodiversity because species have adapted over evolutionary time to environmental conditions reflecting different frequencies and intensities of disturbance. Following a particular disturbance, some species invade or increase in abundance while others are eliminated or decrease in abundance. Some species are adapted to the environmental conditions that immediately follow a severe disturbance, whereas others thrive only after many decades of biotic and abiotic changes that occur in the absence of a severe disturbance. The former are sometimes termed pioneer, early seral, or colonizing species, and the latter are often called climax, late seral, or late successional species. The co-occurrence of plant species with different adaptations to different frequencies and severities of disturbance is of fundamental importance to the resiliency of plant communities to disturbance. Differences in species traits such as dispersal and competitive ability and the capacity to grow under different levels of resource availability (e.g., light, nutrients) provide mechanisms by which ecosystems recover after disturbances and contribute to overall ecosystem stability.

Appreciating the role of natural disturbances in vegetation dynamics is fundamental for understanding the roles of humans in altering natural communities and in managing resources. This general principle is inherent in land management paradigms such as ecosystem-based management, emulation of natural disturbance, and historical range of variability (Hayward et al. 2012). The idea that ecosystems should be managed in a manner consistent with their historical structure and functioning as related to the disturbances that shaped these ecosystems was proposed in the 1990s as an alternative to management paradigms guided primarily by resource extraction. In the context of land management there is a strong consensus that effective land management of forest and rangeland ecosystems depends on a thorough understanding of the history and effects of disturbances on such ecosystems. Ecological science has demonstrated the importance of natural disturbances in determining ecosystem conditions and trajectories: equilibrium conditions are rare or short-lived in most ecosystems. During the second half of the twentieth century, in ecological science there was a shift away from a previous emphasis on equilibrium (i.e., stasis) toward acceptance of continuous variation in species composition and ecological structure. This resonated in the 1990s with the practical experiences of many land managers in dealing with the effects of changes in fire activity and the consequences of species introductions and extirpations (local extinctions). Research in disturbance ecology is inherently interdisciplinary and is strongly developed in disciplines such as physical geography, ecology, forestry, and range management.

Historical perspective: from Clements’s superorganism to Odum’s strategy of ecosystem development

The modern concept of plant succession was developed largely in North America at the turn of the nineteenth and twentieth centuries, and owes much of its origin to the trend among natural scientists during the nineteenth century to shift away from static views and toward dynamic views of nature. At broad scales, this trend toward acceptance of changes in species distributions and their traits is based on the
development of ideas in evolutionary theory and their applications to explaining plant and animal distributions by Charles Darwin and Alfred Russell Wallace. Key to their viewpoints was an understanding of plant populations changing over time as opposed to creationist views of the Earth and its landscapes which stressed stasis. This shift toward an appreciation of the Earth’s surface as a dynamic phenomenon is also exemplified by the theory of the “geographical cycle” developed by the geologist and geographer William Morris Davis in 1899. Davis’s theory stressed the orderly development of landforms, starting with the uplift of a new erosion surface and culminating in the “peneplain,” a rolling landscape of low relief. The progressive development of the physical landscape was explained by analogy with the development of a human organism by describing a landscape as passing through stages of youth, maturity, and old age. This organismal metaphor, emphasizing change and evolution, was a departure from earlier views that emphasized the stasis of landscapes, and such metaphors were typical of the post-Darwinian nineteenth century. One of the pioneers in the early scientific study of plant succession was Henry C. Cowles, who used a theoretical framework similar to Davis’s geographical cycle to describe and explain changes in the species composition of dune vegetation on the shores of Lake Michigan.

It was Frederick Clements, an American botanist, who in publications during the first two decades of the twentieth century developed the first comprehensive theory of plant succession that included general mechanisms and causal explanations (Glenn-Lewin, Peet, and Veblen 1992). Clements’s theory was based on an order and logic that dominated most research on plant succession for much of the twentieth century and that continues, often unacknowledged, to influence the way land managers and the general public perceive vegetation change. Much of the modern debate about the causes and nature of vegetation change harken back to the issues of predictability, convergence, and equilibrium which were stressed in Clements’s theory of succession. Clements viewed succession as a highly predictable and orderly process in which vegetation change was, in fact, the “life history” of a plant community, thus making an analogy to an organism. He believed that, although initial starting points may differ in environmental conditions and species composition, succession would eventually result in convergence to the same type of mature or climax vegetation over an area of uniform regional climate. In his theory, the climax vegetation was believed to be a highly stable equilibrium condition unlikely to change unless there was a significant change in the regional climate. In modern ecology this viewpoint is termed an equilibrium perspective because it requires the concept of a stable or climax vegetation. Today, it is also regarded as a deterministic model because it postulates such an orderly and predictable series of vegetation changes inexorably culminating in the development of the climax vegetation. In such a deterministic model, the role of randomness is denied, and the model is assumed to always produce the same output from a given set of initial conditions.

Two key early critics of Clements’s succession theory were the American botanist Henry A. Gleason and the English ecologist Arthur G. Tansley (Glenn–Lewin, Peet, and Veblen 1992). As early as the late 1910s, Gleason argued that Clements’s view of a plant community as a highly integrated organic entity, sometimes termed a superorganism, was not consistent with field observations of the individualistic behavior of plant species. Gleason stressed the role of chance events such as availability of bare areas for colonization and unpredictable timing of the arrival of dispersal units (seeds,
DISTURBANCE IN BIOGEOGRAPHY

fruits) of a plant species with overlapping but not identical environmental tolerances. Thus, in Gleason’s view, the combined influences of chance dispersal of propagules and variability in sites over time and space will lead to independent distributions of species as opposed to static combinations of the same species. In his view, plant communities were composed of species with individualistic but overlapping distributions so that broadly similar plant communities actually were unique assemblages of species. While they might be similar in dominant species they were actually different in species composition from place to place. His view became known as the individualistic concept of the plant association.

Tansley, writing mostly in the 1930s, challenged Clements’s assumption that all vegetation in a region of similar climate would ultimately converge in species composition toward a single type of climax vegetation. He argued that other controlling factors, such as unusual geological substrate and topographic position, would result in undisturbed vegetation types quite different from that which might be allowed by climate under more favorable geological and topographic conditions. Thus, he recognized a series of stable vegetation types that might be associated with waterlogged soils induced by topographic position or nutrient-poor soils associated with particular rock types. His viewpoint became known as the polyc climax theory in contrast to Clements’s monoc climax theory. Thus, Tansley and his followers’ critiques of Clements’s view of the climax centered on the degree of convergence to a single type of climax. As discussed later in the entry, this debate has largely become moot as modern ecological studies revealed the importance of repeated disturbances, as well as climate variability and climate trends, in resetting the direction of successional change.

In the early 1950s the American ecologist Robert H. Whittaker merged the key elements of Gleason and Tansley to describe vegetation as varying spatially simply because of the continuous variability of the underlying physical environment. Whittaker’s viewpoint, known as the gradient concept of vegetation, eventually became the predominant theoretical framework for conceptualizing how vegetation varies across space and was illustrated by numerous quantitative studies of plant species distributions along environmental gradients in mountainous environments. Highly similar ideas emerged at approximately the same time in the 1950s based on quantitative studies of species distributions along environmental gradients in less topographically dramatic settings in the upper Midwest of the United States. These studies were led by J.T. Curtis of the University of Wisconsin, and the resulting conceptualization of spatial variability in vegetation was termed the continuum concept of vegetation.

While many aspects of Clements’s theory of plant succession are not supported by modern ecological science, his ideas were important in directing research on the mechanisms by which vegetation changes in response to disturbance. These mechanisms include the dispersal and establishment of plants at a disturbed site, competition and other biotic interactions, and the modification of the abiotic environment by plants in ways that may affect further vegetation change. He particularly stressed the role of reaction as the dominant mechanism resulting in successive changes in plant community composition toward some sort of climax. The aspects of Clements’s theory that are no longer strongly supported include his emphasis on long-lasting stability in the form of a climax vegetation, the high degree of convergence of initial differences toward a uniform climax, and his overall emphasis on predictability. Modern views of vegetation change recognize greater variability in successional pathways and the frequent importance
of stochastic events such as timing of dispersal events, and do not stress long-term stability. In addition, modern viewpoints stress repeated disturbances of varying types and severities that continue to alter vegetation in contrast to the role assigned by Clements to disturbance as simply an initial trigger of progressive vegetation development.

In 1969 Eugene Odum published a highly influential paper entitled “The Strategy of Ecosystem Development” which succinctly summarized numerous trends to be expected in the course of succession. Odum’s synthesis reflected a conventional view of succession as presented in textbooks of the time, and aimed to integrate earlier perspectives on succession with key concepts of the emerging field of ecosystem science. He summarized a number of successional trends in community- and ecosystem-level properties which he postulated result from the tendency of ecosystems to develop toward greater homeostasis or control of the physical environment in the sense of attaining maximum protection from disturbances. He postulated that the strategy of ecosystem development is, in fact, directional change toward greater stability or homeostatic control of the environment by the organisms dependent on that environment. He described succession as an “orderly process of community development that is reasonably directional and, therefore, predictable” (Odum 1969, 262). The mechanism of successional change that he emphasized was the modification of the physical environment in ways that drive species changes in a predictable way. Odum asserted that succession eventually culminates in a stabilized ecosystem in which maximum biomass and self-reinforcing interactions among organisms are attained for that particular physical habitat. Thus, although described in ecosystem parameters not defined until the mid-twentieth century, Odum’s strategy of ecosystem development is highly similar to Clements’s theory of succession. Although Odum’s synthesis was widely accepted at the time, reproduced in textbooks, and cited for its implications for the management of global resources, it was seriously challenged by William Drury and Ian Nisbet in a critique published in 1973. They systematically critiqued the 24 trends identified by Odum, finding that the supporting data were weak, contrary, or nonexistent. Although Drury and Nisbet’s 1973 paper was published in a relatively obscure (at least to ecologists) journal (Journal of the Arnold Arboretum) after apparent rejections from mainstream ecological journals, the questions about the Clements–Odum model raised by this paper triggered a renewal of research interest in succession in the 1970s. The late 1970s to early 1980s saw the publication of numerous empirical and review papers re-evaluating the mechanisms of succession, emergent properties associated with succession, and the relative stability of successional end points (i.e., climax). These studies formed the basis for the development of the modern nonequilibrium paradigm of vegetation dynamics in which repeated disturbances play central roles.

### Disturbance in the context of the modern nonequilibrium approach to vegetation dynamics

The modern nonequilibrium view of vegetation dynamics is a consensus paradigm articulated in numerous publications in 1980s for which Drury and Nisbet’s 1971 and 1973 papers were foundational, regardless of whether they were cited. Drury and Nisbet (1971) insightfully described Odum’s and Clements’s views of succession as developmental theories. In such a developmental theory, succession is viewed
largely as the consequence of relationships and interactions within a community, whereas external influences such as coarse-scale disturbance, climate variability, and the arrival of new species are either held constant or relegated to minor roles. In the developmental theory of succession, it is assumed that the physical site and external influences on biota remain constant for a long period during which there is a progressive development toward a type of ecosystem that maximizes stability. Thus, an inexorable trend toward greater homeostasis in Odum’s model is the deterministic driving force underlying successional trends. In contrast, Drury and Nisbet (1971) proposed that there should be no assumption of long-term site stability (i.e., the absence of disturbance or climate variability), nor should the theory depend on the existence of a stable end point. They termed their ideas a “kinetic” viewpoint of vegetation change that is now more commonly termed a dynamic and nonequilibrium view of vegetation change.

While the nonequilibrium view of vegetation dynamics emerged as the consensus view in the 1980s, it is important to recognize that other ecologists had articulated similar ideas much earlier. Remarkably, as early as 1901 Cowles described succession as “a variable approaching a variable rather than a constant” to emphasize the transience of any predicted climax vegetation (Glenn-Lewin, Peet, and Veblen 1992, 6). Likewise, in work published mostly in the 1930s to 1950s Hugh M. Raup of Harvard Forest pointed out that the time period required for succession from a pioneering community on a bare site to a climax community was so long that the assumption of environmental constancy, especially of climate, was not tenable. In the 1910s to 1930s, with a strong focus on the population mechanisms responsible for temporal change in forest structure and composition, Alexander S. Watt of Cambridge University conducted a series of insightful studies of beech forest dynamics in England that became the basis for modern studies of tree-fall gap dynamics in forests. He lucidly revealed the importance of the role of tree-fall gap-phase processes of tree population dynamics in maintaining the relative stability of species composition at a coarse scale across the entire forest stand. Raup and Watt presaged, mostly through their empirical field observations, the recognition of the lack of constancy in the determinants of vegetation attributes at any particular place in the landscape and, in particular, the importance of variability induced by disturbances of different types, severities, and frequencies.

While Clements recognized the importance of coarse-scale disturbances such as fire and glacial retreat as triggering events of succession, he and his followers focused nearly all their research on how interactions among plants and plant influences on the site (i.e., reaction) would determine the course of succession during long disturbance-free intervals. Modern ecologists also continue to examine the types and relative importance of these plant-centered mechanisms of succession, but today equal attention is devoted to quantifying disturbance regimes and developing frameworks for predicting both disturbances and vegetation responses to disturbances (Turner 2010).

The definition of disturbance by White and Pickett (1985) presented earlier has been widely adopted as a general purpose definition of proven utility in many ecological applications, but it is not meant to be an exclusionary definition. Thus, it easily applies in the common situation where a disturbance event is destructive of biomass and thus releases resources, often creating a relatively bare area or open space. Frequently, a disturbance results in the release of resources, increasing their availability to surviving or newly arriving plants such as in the case of a tree-fall and the resulting understory
response. However, this is not always the case. A disturbance such as an extensive volcanic ash deposit may result in a subsequent reduction in soil-related resources such as available plant nutrients and soil moisture. Although many disturbances, such as fires, can result in relatively discrete patches in the landscape, others, such as herbivory, may be spatially diffuse. Disturbances that occur suddenly are easily perceived, but at some spatial scale some disturbances may not be distinguishable from slow, gradual trends in environmental conditions, sometimes referred to as secular environmental changes. “Disturbance” and “perturbation” are often assumed to be synonyms, but the latter is more commonly applied in experimental situations where variables can be artificially manipulated and equilibria can be perturbed. The term “disturbance” has proven more durable in applications in field ecology and related modeling treatments.

A large amount of definitional and classificatory terminology has developed around the term “disturbance,” most of which is not particularly helpful in understanding disturbance processes or their effects on ecosystems. Sometimes disturbances are classified as endogenous as opposed to exogenous, where the former originate from processes inherent in the plant community (e.g., plant death due to senescence) as opposed to exogenous disturbances that originate independently of the plant community (e.g., volcanic eruptions or earthquakes). However, many disturbances cannot be predicted or their origins understood without considering both factors that are internal and external to a plant community, such as fire which depends on the fuel attributes of a plant community as well as external ignition sources and weather. Analogously, “autogenic” and “allogenic” are somewhat archaic terms used to distinguish between processes controlled by the actions of plants themselves and processes that result from factors independent of the plant community (e.g., drought).

More important than the terminology surrounding the concept of disturbance is a practical way to describe the attributes of disturbances affecting a particular ecosystem which is accomplished with the concept of a disturbance regime. The sum of all the disturbances affecting an ecosystem is known as its disturbance regime. Thus, a disturbance regime is a description of all the disturbances affecting an ecosystem, landscape, or even a larger region. To be useful, a disturbance regime must be explicitly linked to a real place in the landscape and to a defined time period. For example, it is necessary to identify a specific study area (e.g., perhaps a small valley or a larger landscape) and to state the time period for which the disturbance regime applies, which may range from a few years to millennia. Synthesis of descriptions of disturbance regimes for many actual ecosystems and landscapes may allow generalization for these ecosystem types (i.e., classification categories), but it cannot be assumed that superficially similar ecosystem types will have identical disturbance regimes. The key descriptors of a disturbance regime are the type of disturbance, spatial attributes, temporal characteristics, specificity, and interactive components.

An important research goal in modern ecology and biogeography has been to quantitatively describe as many of the potential descriptors of disturbance regimes (Turner 2010) as feasible. The applicability of the various descriptors will vary according to disturbance type, with discrete high-severity fire events probably being the disturbance type for which it is easiest to conceptualize the descriptors. Spatial characteristics include the size of the area disturbed, potentially its shape, and its spatial distribution relative to pertinent environmental settings (e.g., according to slope aspect, steepness, and other topographic variables). Temporal characteristics include, most
DISTURBANCE IN BIOGEOGRAPHY

importantly, frequency (number of events per period of time) which, when combined with data on the area disturbed, can yield an estimate of a rotation period or the time required to disturb an entire study area once given the estimated frequency and areas of disturbance events. Environmental heterogeneity within a large study area often results in multiple fire events (or other disturbance events) in parts of the study area before the first such event occurs elsewhere in the same study area. Thus, rotation periods must be interpreted cautiously in terms of their applicability to a particular point in a large landscape. The same caution applies to a disturbance such as forest blowdown, where turbulence induced by distance from ridges or tree instability associated with topographic differences in soil drainage complicate the computation of a rotation period for a large, topographically complex landscape. Magnitude refers to the intensity of the event (e.g., heat released by a fire) whereas severity refers to the damage done by the disturbance (e.g., size and number of trees killed by a windstorm or by a fire).

Specificity as an element in the description of a disturbance regime describes whether the disturbance is selective according to plant species, which is likely to be an important factor in cases of herbivory or pathogen attack. Specificity by the size or age of the plant may also be important in some cases such as preferential insect attack on only large, old trees or greater susceptibility to wind damage among taller trees. The residual organisms or propagules present after a disturbance event such as a severe fire or blowdown are fundamental in determining potential post-disturbance recovery trajectories. These are also called biological legacies or remnants (Turner 2010) and are particularly important in assessing the effects of human-caused disturbances (e.g., land clearance) on the future viability of patches of vegetation surrounded by intense human land use. The term “synergism” was initially used to describe the potential effects of one disturbance on another, and (as described later in the entry) disturbance interactions constitute a theme of major current research activity.

Current research frontiers

Applications in wildland management

The most common context for research conducted by biogeographers and ecologists on disturbance phenomena and their impacts on vegetation during the late twentieth century has been in the area of management of wildlands. In some cases the land-use context has been commodity production (e.g., timber, livestock), but in most cases the context has been environmental protection and conservation science. Specific research goals have often been to inform land management policies aimed at ecological restoration or mitigation of societal vulnerability to disturbances such as wildfire. Studies of disturbance ecology play a central role in modern research management approaches such as ecosystem-based resource management and emulation of natural disturbance. There is widespread agreement among scientists and managers that disturbance ecology, and in particular understanding of the history and effects of disturbance in the landscape, provides essential insights for decision-making. This consensus is based on the premise, supported by ecological theory and practice, that comprehending the causes and consequences of temporal variability in ecosystems is crucial to successful resource management (Hayward et al. 2012).

Numerous studies in disturbance ecology have been and continue to be conducted because of their direct relevance to wildland management issues such as ecological restoration and fire mitigation. Such studies are solicited by the public
and policymakers because of three key principles (Hayward et al. 2012): (i) knowledge of past natural variation provides an essential reference for evaluating impacts of modern land-use practices such as grazing, fire suppression, and logging on current ecosystem conditions and processes; (ii) past natural disturbances have played key roles in structuring contemporary ecosystems, and will continue to do so in the future; (iii) hypotheses about the drivers and mechanisms of future ecological change driven by climate change must be informed by understanding the roles of past climate-related disturbances on the landscape.

Disturbance interactions

Despite the existence of hundreds of studies of disturbance regimes, there are relatively few which explicitly consider more than a single type of disturbance in the same study area. Thus, most fire history studies consider data only on fire and most tree-fall gap dynamics studies present only data on tree-falls. In many of the study areas targeted by these studies, it is evident that multiple types of disturbances play important roles in shaping the ecosystem structures. For example, many fire history studies recognize that grazing in the same area has probably had an important influence on the vegetation and indirectly on fire through alteration of fuel quantity or fuel type, but rarely are quantitative data available on the grazing component of the disturbance regime. Analogously, there are numerous studies of hurricane impacts on tropical coastal forests in areas where land-use practices (grazing, hunting, burning, and agricultural land abandonment) are known to be important influences on forest composition and structure, yet rarely are quantitative data on land-use practices effectively integrated with temporal and spatial data on blowdowns. Such integration of quantitative data on multiple types of disturbances is one of the current research challenges in disturbance ecology.

In contrast to the past tendency to focus on a single disturbance type, numerous studies of coniferous forests in western North America recently have yielded robust quantifications of disturbance regimes of both fire and lethal insects (typically bark beetles) at landscape scales (e.g., Veblen et al. 1994). Many of these studies have been motivated by questions of whether widespread bark beetle outbreaks will influence subsequent fire frequency, extent, or severity. This emerging research frontier is examining both linked disturbances (in the sense of Simard et al. 2011) and compound disturbances (in the sense of Paine, Tegner, and Johnson 1998). Linked disturbances are disturbances that interact by altering the extent, severity, or probability of occurrence of a subsequent disturbance. Although extensive tree mortality caused by bark beetles intuitively leads to expectations of increased subsequent extent, frequency, and severity of fires, dozens of retrospective field studies and fuel-driven fire behavior simulation studies have failed to demonstrate a clear or consistent pattern of increased wildfire activity. This is currently a subject of intense research activity but, at this date, the consensus is that widespread beetle kill may somewhat alter fire behavior under particular conditions (i.e., pre-beetle kill forest structure, severity and time since beetle kill, and fire weather conditions), but it has not fundamentally altered the wildfire hazard in affected forests. Both beetle kill and wildfire activity are strongly driven by warm, dry weather conditions, and both have increased in extent in western North America in conjunction with climate warming during the late twentieth century. Compound disturbances refer to the occurrence of two disturbances at relatively short intervals so that they have a synergistic effect greater than the effect predicted from the sum
of the individual impacts of the disturbances. For example, two surface fires occurring at short intervals may prevent successful tree regeneration as a result of insufficient time for juveniles to reach a size at which they are fire-resistant. Another example could be a beetle outbreak that selectively removes seed sources of one species so that, when it is followed by a fire, there may be greater success of postfire regeneration of a non-host species such as in the case of beetle-killed conifers and quaking aspen in western North America. Although the potential for disturbances of the same type or different types, occurring in different sequences, to amplify or attenuate the effects of individual disturbances has long been recognized, there are few empirical studies that have quantified these potential effects.

Alternative stable states

A second major area of current research activity in disturbance ecology, which overlaps with the study of disturbance interactions, is the study of how positive feedbacks from disturbances may result in major long-lasting switches in vegetation types, or so-called alternative stable states. Alternative stable states in species assemblages occur when under the same broad-scale environmental conditions (especially regional climate) and a similar biota, dramatically different species assemblages can occur side by side in apparently the same environment. For example, the presence of extensive tropical savannas of sparse populations of small trees and shrubs mixed with tall grasses and juxtaposed with tall tropical forests under the same regional climate has long intrigued biogeographers. Ecologists and biogeographers have documented the role of different fire regimes in maintaining such sharp boundaries. Whereas savannas are easily burned by natural or human-set fires and therefore are subject to frequent grass-fueled fires, forests in the same environment rarely burn because of their less flammable fuel types and their microclimate which is less conducive to fire. Repeated intentional understory burning of forests often associated with exceptional drought can result in microclimatic and fuel-type feedbacks that increase flammability and result in a switch to a savanna.

Alternative stable vegetation states with abrupt boundaries resulting from different fire regimes are also documented in temperate ecosystems where tall forests are replaced by shrublands or mixtures of tall shrubs and small trees. For such vegetation switches to be maintained beyond the life span of the initial postfire occupants of the site requires feedback mechanisms that increase the probability of a subsequent fire to perpetuate the postfire species assemblages. These mechanisms in the pyrogenic plant communities have been documented to include a wide variety of attributes such as greater flammability of individual species due to their physical and chemical properties, spatial arrangements and sizes of fuels, and fire-favoring microclimatic conditions. Some of these pyrogenic traits may also be selected for by the effects of herbivory by introduced wild and domestic mammals. For example, where herbivory prevents the regeneration of obligate seeding trees but allows the resprouting of browse-resistant shrubs with plant architectures that promote the spread of surface fires into shrub canopies, herbivores contribute to the perpetuation of the more flammable shrub alternative stable state. In some ecosystems, rare, severe droughts are required to facilitate fires in forests that otherwise are not easily burned, and to initiate the switch from forest to nonforest. Thus, in the context of climate warming, altered fire regimes and the positive feedbacks from pyrophilic vegetation become the mechanisms for possible large-scale transitions from forest to shrublands or grasslands. Such transitions
often termed “tipping points” because of the accelerated rate of vegetation change in response to climate change. Much research is needed in disturbance ecology to improve our understanding of mechanisms responsible for switches to alternative stable states and their relationships with climate change.

**Invasive plants and animals**

Invasions by alien plants and animals are disturbances per se but may also have synergistic impacts through their alteration of disturbance regimes. In the example mentioned in the previous section, introduced herbivores had a fire-promoting effect through their selective influences on regenerating plant species, but introduced herbivores also often have a dampening effect on fire through removal of fine fuels. Introduced plants may have profound effects on species composition and functioning of native ecosystems by altering edaphic conditions and plant competitive interactions. They can have particularly dramatic effects on native ecosystems by altering fire regimes such as the promotion of fire by the invasive cheatgrass (*Bromus tectorum*) in semiarid environments in the Great Basin region of western North America. In the context of climate change, disturbance ecology research on the effects of climate alterations of disturbance regimes on the success of invasive species, and in turn their influences on disturbance regimes, will continue to be a research priority.

**Future research directions**

Although disturbance ecology has traditionally been dominated by field-based empirical studies conducted at scales ranging from tens to hundreds of hectares, the development of geospatial technologies and remote sensing in the final decades of the twentieth century has provided important opportunities to scale up the study of disturbance processes and effects to large landscapes and regions. Thus, datasets that can be verified through careful field data collection are now available for parameters such as wildfire severity and tree mortality at regional or subcontinental scales. Merging of approaches based on observations across a range of spatial scales is rapidly improving our understanding of the broader scope impacts of disturbances such as fire and beetle kill. In the context of climate change, simulation modeling of climate impacts on future vegetation patterns, and ecosystem function, has long been based on research results on the physiological responses of individual plants (and to a lesser extent of small experimental ecosystems) to altered climate and atmospheric gas concentrations. Currently, however, the rapidly improving capacity to observe and monitor disturbance processes such as fire and tree mortality is allowing the integration of disturbance ecology into regional and global modeling of the effects of climate change on regional and global ecosystem function and the feedbacks to the atmosphere. Research on the potential feedbacks of fire and tree mortality on the atmosphere through carbon dynamics is clearly one of the frontiers in disturbance research (Turner 2010).

Climate scientists agree that the anthropogenic release of greenhouse gases has been and will continue to be the major driver of warming temperatures on Earth for many decades. However, research is needed on the ecological consequences of climate change and to improve understanding of how ecological processes may result in feedbacks that could further accelerate future warming. For example, increased wildfire activity is recognized as a likely consequence of warming, with a potential positive feedback to the atmosphere through the release of carbon dioxide from burning vegetation. To address the
actual impacts of future wildfire activity on the atmosphere and future climate requires an interdisciplinary approach in which disturbance ecology must play a major role. Research in disturbance ecology needs to be integrated with studies of Earth surface processes and studies of land-use change in a broad earth-system science framework. Such a framework views the biosphere and atmosphere as a coupled interacting system in which fire plays a major role. The long history of research on the controls and ecological consequences of wildfires conducted in the context of disturbance ecology and land management provides a strong foundation for addressing the challenge of integrating research on wildfire activity into an earth-system framework.

Large-scale biogeographic responses to climate change, including disturbances such as fire and interactions with land-use practices, incorporate feedback effects of land-cover changes to atmospheric processes through changes in albedo, evapotranspiration, and roughness. Clearly, research in disturbance ecology on the effects of fire and tree mortality (either from insect outbreaks or from the direct effects of warming and drought) is of primary importance in understanding mechanisms that affect regional- and global-scale carbon dynamics. Such research is of vital importance in addressing the efficacy of land-use policies aimed at using carbon sequestration by vegetation to mitigate the effects of burning fossil fuels.

Multiscale research in disturbance ecology is needed on the differential susceptibility of various vegetation types to wildfire and on postfire transitions from one cover type to a different cover type (e.g., from closed canopy forests to shrublands or grasslands), which in turn may further enhance fire potential under a warmer climate. At a global scale, the area burned annually is estimated to have increased in the second half of the twentieth century, but trends are highly variable regionally. Recent increases in wildfire activity in some regions have been linked to changes in climate and land use, operating independently or in combination. However, warming does not necessarily result in increased fire activity in all biomes because decreases in moisture availability can reduce the amounts of biomass for burning in already low-biomass ecosystems. Land-use practices have been shown to have significant influences on wildfire activity at a global scale, based on strong associations of fire activity with human population densities and socioeconomic variables (e.g., gross domestic product per capita and ratio of crop cover to other land covers). However, the relationships of these coarse-scale indicators of socioeconomic variables to wildfire activity need to be more thoroughly examined at regional and local scales to identify actual mechanistic explanations of these relationships.

The development of useful regional- and global-scale dynamic models of future fire-driven vegetation patterns requires a mechanistic understanding of fire determinants such as the amount and flammability of biomass to burn, fire weather, and sources and probability of ignition. At a landscape scale, feedbacks such as time since last fire and land-use impacts on fuels have been demonstrated to be critical to future landscape heterogeneity and the associated potential for fire. Thus, research in disturbance ecology, integrated with studies of land-cover change and land surface–atmosphere interactions will continue to play a major role in the development of regional, and ultimately global, dynamic vegetation models.

Domestic spaces

Irene Cieraad
Delft University of Technology, Netherlands

The term “domestic space” may not have existed before the 1970s, but its function as a household’s living space within an enclosed structure of a house or hut existed for thousands of years, as archaeologists have lavishly demonstrated in their maps of excavated prehistoric settlements. Material remains serve as testimonial to possible functions of the spaces, as traces of a fireplace might indicate the main living space. In this context of the emergence of “domestic space” as a new concept in the 1970s, it also must be noted that the word “space” was not used before the late nineteenth century.

Although archaeologists used the concept “domestic sites,” it was the British social anthropologist Mary Douglas (1972) who introduced the concept of “domestic space” to an audience of archaeologists in 1970. She cautiously presented the anthropological and symbolic interpretation of tribal settlements and the tribal use of domestic space as a possible tool for understanding the symbolic meaning of spatial arrangements in excavated settlements. Her examples illustrated, however, that spatial arrangements and material traces as such were insufficient clues for anthropologists as they depended for their symbolic interpretation on people’s behavior and practices. In other words, she was rather pessimistic about a possible archaeological endeavor of reading the meaning of domestic space from material remains alone.

Despite Douglas’s pessimism, the concept of domestic space was more readily adopted by archaeologists than by fellow anthropologists. With the adoption of the concept of domestic space in the writings of archaeologists, the discipline witnessed a shift of focus from the function to the meaning of spatial divisions in settlements. Nowadays, anthropological studies on symbolic interpretations of tribal spatial arrangements have become a source of inspiration for archaeologists, and so too have sociological studies of behavior in public and private space, providing the availability of written sources as in the case of classical antiquity (Nevett 2010).

In the late 1970s the concept of domestic space gained momentum in opposition to the more familiar concept of public space within the discourse of academic feminists, and contributed to the conceptual framework of the newly initiated women’s studies, which thrived on male/female opposition. Domestic space was interpreted not so much as the living space of a household but as a secluded female domain in which women took care of children and the household, while men spent much time in public space earning a living and socializing with other men. Although the male/female opposition was a common symbolic opposition in tribal spatial arrangements as described by anthropologists, the new domestic/public opposition gave the male/female opposition more of the character of a male conspiracy in secluding women within the home.

In crude feminist interpretations, capitalism was to blame for the economic separation of the domains of consumption and production into separate domains of living and working. The exclusion of women from the domain of
DOMESTIC SPACES

production started within the class of better-off merchants in the seventeenth and eighteenth centuries and gave rise to a spatial segregation of the secluded female home place in opposition to the public male work place. In the nineteenth century the separation was translated into emotional contrasts of the intimate and caring relationships within the domestic domain versus the anonymous and businesslike relationships within the public domain of industry and commerce. Privacy and domesticity became the much praised and near-sacred attributes of the domestic space of the nineteenth-century home where the woman and housewife had to guard and cherish this moral sanctuary from worldly evils.

Although this concept of domestic space did not exist in the seventeenth or eighteenth centuries, it was presented by feminist scholars as part and parcel of the so-called domestication of women in the merchant’s class. Decades of historical research on the position of women have corrected not only the beginning of the domestication process, but also the parallel image of the subjugated homebound housewife. Medieval sources revealed that prosperity was a main incentive for domesticating women as it allowed merchants’ families to imitate the lifestyle of the gentry and aristocracy, whose women led more secluded domestic lives and engaged in recreational needlework (rather than waged needlework).

Also, the defining characteristic of domestic space as a nonproductive domain is corrected in historic research on the productive aspects of housework and the many skills of housewives. Even domestic space as a female-dominated domain is contested by male scholars, like John Tosh (1999), who thinks that the gender contrast is overrated and that the Victorian home was as much a man’s as a woman’s place. As such, Tosh presents the beginning of the modern ideal of domestic space as home, portrayed as a family leisure space and a refuge from the obligations of work and school.

The domestication of women in the merchant class is illustrated by the changed architecture of merchants’ houses in late seventeenth-century Amsterdam, at that time one of the biggest cities of Western Europe. The access to the house changed from an open entrance at street level into raised doorsteps leading to a majestic, but shut, front door. Previously, housewives supervised the open entrance hall while monitoring the public space of the street, but the changed architecture of the merchant’s house mirrored a changed attitude of these upper-class women, who retreated from the public eye of the street into the back zones of the house. In most European cities, however, the domestication of upper-class women and children alike became evident in the nineteenth century (Cieraad 1999).

Twentieth-century historic research revealed that the domestic space of the nineteenth-century gentleman’s house was in fact an intricately zoned hierarchy of spaces, not only the superior domestic spaces of the family with different gradients of domesticity and privacy as opposed to the inferior service spaces of the domestic staff, but also differently decorated domestic spaces for male and female family members and visitors, for children and adults. As such, the plural of “domestic spaces” seems more adequate than the singular.

The more recent use of the plural bears witness to a shift of focus in today’s scholarly literature on domestic space. Initially, the boundary between the domestic space of the house and the public space of the street was of prime importance, especially to feminist scholars. Also, in the traditional anthropological and symbolic interpretation of Mary Douglas, the threshold as the border between the inside and the outside of the house represents an important ritual boundary, which is still obeyed in the old custom of the
groom carrying the bride into the house. With the more recent shift of scholarly attention toward the internal zoning of domestic space according to use, gender, and age, not only has the threshold as the border between inside and outside lost its importance as a ritual boundary but so too have the walls of the house as the confines of the domestic domain.

The domain of present-day domestic spaces most likely extends into the domestic garden, as the popularity of the outdoor kitchen illustrates, or onto the roof, as the popularity of the roof terrace illustrates. Even seasonal influences on these outdoor spaces are countered by all-weather furniture and domestic comforts like fireplaces, heating devices, and awnings. In today’s interpretation of domestic spaces, the traditional interiority of domestic space is not defining anymore, but its domestic usage, in particular of these outdoor spaces, is. Where the garden or the roof terrace is used for food preparation, dining, relaxing, or receiving guests, it becomes one of the many domestic spaces in and around the house. More than anything, the short scholarly history of domestic space illustrates human geography’s concern “that space and place are more than just containers of social processes; they are the social processes” (Short 1999: x).

Domestic workers

Rachel Silvey
University of Toronto, Canada

Domestic workers are paid to carry out household labor. They do paid child care, elder care, house cleaning, laundry, and often cooking and pet care in the homes of families that are not their own. In human geography, feminist geographers spearheaded research interest in domestic work, and the body of scholarship on the topic has burgeoned in recent decades within the discipline, as well as in neighboring fields. The now large body of research on domestic workers is a reflection of the heightened importance accorded to feminist approaches in geography in general, and an indication of substantive shifts in the global organization of domestic work.

Historically and internationally, paid domestic work was and continues to be almost entirely a women’s occupation, cross-cut by class relations, rural/urban divisions, and racial and ethnic distinctions. The numbers of domestic workers have grown with each phase of global capitalism. Geographers have focused primarily on the period after 1970, when the international migration of domestic workers began to grow considerably, and immigrant women began filling the jobs of nannie and maids in rising numbers. Many of the jobs that immigrant domestic workers fill have been newly created in recent decades as a result of expanding middle-class populations and lifestyles, and changing gendered global divisions of labor and their reverberations in the domestic sphere. Research on domestic workers has shed light on the ways in which nationality and citizenship, as well as new and long-standing racialized hierarchies, shape who does the “dirty” work and for whom.

Studies of domestic workers began to gain traction in the discipline in the 1990s when geography was also beginning to register engagements with poststructural, feminist, and postcolonial theories. They have opened up questions about the politics of methodologies and embodiment, the diversity of care migration and social reproduction, the social construction of space and scale, and chains of care work.

While most immigrant domestic workers are now paid for the labor they perform for others, many work under conditions of indentured servitude, and the majority earn incomes at the bottom of the wage scale in their respective countries of work (Romero, Preston, and Giles 2014). They are often faced with the garnishing of their wages, and high levels of debt are common. Indebtedness intensifies dependence on employers and heightens vulnerability to excessive workloads (sometimes reaching 18 hours a day), underpayment and nonpayment of wages, and a wide range of other abuses, including verbal and sexual harassment, violence, and rape (e.g., Yeoh, Huang, and Gonzalez 1999).

Domestic workers have fewer rights than most other workers in most countries. Because their work is carried out in the “private” space of the home, governments have commonly considered it beyond the reach of the law. In locations where laws are in place to protect domestic workers’ rights, such as the United States and the European Union, in practice workers are often unaware of these rights or are afraid to claim them, given their status as contract workers or their liminal citizenship status. Domestic
DOMESTIC WORKERS

workers’ rights intersect with their experiences of civic space, transnational legal abandonment, the micropolitics of households, and national and urban sociolinguistic and racialized hierarchies.

The dividing line between the roles of paid domestic worker and that of unpaid household worker and wife are not always clear-cut. Indeed, some domestic workers seek to marry citizens in their host countries as a pathway to citizenship and to escape repeated short-term labor contracts abroad. In some cases domestic workers who marry local citizens play important roles in remaking their new local communities’ identities and social fields (Faier 2009). Furthermore, domestic workers often also work in other sectors while they are employed as domestics, engaging in various supplemental formal and informal sector income-earning activities. They are frequently misrecognized as victims of human trafficking, and antitrafficking policies have criminalized domestics working without legal documentation.

Sending states play active roles in promoting and managing the overseas migration of domestic workers with an eye toward earning foreign exchange in the form of remittance income. In many parts of the world, migrant domestic workers are required to live in the homes of their employers, an arrangement that contributes to their social isolation and exclusion from the public sphere. Control of the living and working space of domestic workers is conjoined with the control of their bodies. Gender ideologies of sexuality and proper womanhood, religious piety, and place-specific norms about gendered family roles have also shaped the migration and working conditions of domestic workers. They are taught to embody a subservient, desexualized manner by labor brokers who recruit and train them, as well as by their local communities and overseas employers.

The formal and informal conditions under which domestic workers labor differ considerably across countries and remain highly dependent on the whims of individual employers. Nonetheless, the globalization of domestic work has also sparked numerous progressive, creative, and increasingly successful movements for the rights of domestic workers. Meanwhile, scholarship has challenged the representational reduction of domestic workers to either heroes or victims (Gibson, Law, and McKay 2001), and deepened its analyses of domestic workers’ emotions, desires, religions, and sexualities (Silvey 2007).

Domestic work is intimate labor, and when it is carried out by immigrant women it interweaves global, local, and embodied processes. Each of these scales of analysis is shaped by the gendered material and discursive “forces of domesticity,” which persistently position women in the cleaning and caring roles of households, nations, and the global economy. Migrant domestic workers’ contracts tend to require them to leave their children at home, and their sojourns thus usually involve long family separations. Though these patterns take highly diversified forms across specific places, women family members such as sisters or grandmothers, or lower-income women neighbors in the origin countries, pick up the residual local domestic and caretaking roles, and are usually paid low wages drawn from remittances income, which is also expected to cover the everyday needs and education costs of the families left behind. These transfers have been termed “global chains of social reproduction” (Parreñas 2015), such that the labor of migrant women, and the associated intensified labor of women left behind, produce a direct subsidy at low cost to the social reproduction of households in higher-income countries. A recent debate has emphasized the conceptual distinctions between care work and social reproductive work, and
underscored reasons for privileging the latter (Raghuram 2012).

Domestic workers who leave children in their home countries tend to practice transnational mothering while overseas, but their long absences from home are often traumatic for family relationships over the life course (Pratt 2012). Moreover, the experience of returning “home” tends to be fraught, in practical and emotional terms, for both migrant domestics and their families (Yeoh and Huang 2000). Research has only begun to examine the ways that overseas domestic workers’ experiences play out over the long term, and attention is beginning to address the experiences and needs of aging and elderly current and former migrant workers, many of whom work in home care for the elderly (Raghuram 2012).

The political horizons of the future of global domestic work look promising from some angles. In 2011 the United Nations International Labour Organization (ILO) passed the Domestic Workers Convention (C189), which covers a range of basic human and labor rights specifically for domestic workers, and, as of early 2016, 22 countries had ratified the convention. This success was the result of decades of organizing on the part of domestic workers worldwide, and alongside its passage several countries and states have passed their own new laws creating new rights for migrants (e.g., a minimum wage for overseas domestics from the Philippines; a requisite day off for domestics working in Singapore; and a Domestic Workers Bill of Rights in four US states covering overtime pay and a weekly day of rest, among other protections). Domestic workers’ rights advocates have taken courage from these legal changes, fueling the proliferation of organizations in support of domestics (including, for example, national alliances in many countries, regional centers, and the International Federation of Domestic Workers).

In addition to these political gains, research has argued that, while domestic work is work and while domestic workers deserve rights, recognition, and respect for their work, domestic workers are more than workers. They are also family members, artists, and lovers, and often in addition to their work as domestics many have also had careers as nurses, entertainers, office professionals, and teachers. They and their allies have created artistic, poetic, and theatrical performances that enrich and deepen the complexity of their experiences in a way that traditional social scientific methodologies have not been able to capture. As research continues to deepen its appreciation for the wide range of domestic workers’ experiences, geographers can continue to contribute to the exciting theoretical and empirical work tying together the geographies of their lives. Studies of domestic workers have been at the forefront of collaborative methodological innovation with activists and artists, and such work is vital for continuing to understand the relational production of not just public and private spaces, and productive and reproductive labor spheres, but also the dynamic interlinkages between the intimate and the global.
