Droughts or water shortages are repetitive natural hazards created by lower than expected moisture levels at a given location. Drought and water shortages occur across the globe but can only be clearly identified and addressed within a regional and impact specific context. The core concept of a drought or water shortage definition is the physical condition of below “normal” moisture levels. Such moisture levels may be, but are not limited to, average monthly precipitation, average annual stream flow, or mean seasonal soil moisture. The moisture levels represent the amount of water available at a given time in the hydrologic cycle which includes all states of water (liquid, vapor, ice) at a given time and place. The hydrologic cycle includes evaporation and transpiration from the Earth’s surface, condensation to form clouds, precipitation followed by runoff, and movement or storage of water underneath the Earth’s surface. Water shortages associated with drought are identified by tracing the paths that water takes through the hydrologic cycle, what the water is doing at various stages along each path, and how the quantity and characteristics of water are altered as they pass through the cycle.

Critical to the analysis which leads to the identification of a water shortage (or a surplus of water) is the concept of a water budget. In this approach, the net available water at any given location is represented as a function of gain from precipitation, loss by evapotranspiration, loss to or gain from soil moisture, and addition or subtraction by other physical (such as groundwater flow, stream flow) or human (such as irrigation, drinking water withdrawal) processes. Commonly, a water budget is expressed by the equation.

\[ W = P - E_v T \pm S_m \pm P_{misc} \pm H_{misc} \]  

Each variable in the equation offers an account or “budget” of water as it travels through the hydrologic cycle within a local landscape. A surplus occurs when the input of water from precipitation, soil moisture, or other processes is greater than any withdrawal of water from the system. A shortage is when all withdrawals are greater than the inputs. It should be noted that a shortage or surplus is rarely created by a single human process or a single physical process. Rather, most problems are created by a combination of physical and human processes. For instance, an agricultural water shortage may be created by both low precipitation and inefficient water delivery systems. The key in identifying a drought or water shortage is to complete a water budget analysis.
DROUGHTS AND WATER SHORTAGES

that incorporates all processes which account for
the storage and movement of water at a given
location.

In combination with the core concept of low
moisture conditions, the definition of a drought
also includes a link to the supply and demand
of an economic good, service, or other human
activity. Such goods, services, or activities are
dependent on water in one of its three states for
production, delivery, or completion. Some of the
more direct examples of these goods, services,
and activities include agricultural crops that
require water for growth or river water used for
municipal water supply. Examples of less direct or
less obvious goods, services, or activities depen-
dent on water are when livestock in one area
are impacted by drought in another area because
not enough feed can be grown due to dry
conditions and decreased supply of goods due to
the inability of barges to navigate rivers because
of low water levels in the navigation channel.

As one attempts to identify a drought or water
shortage, it is very important not to confuse a
drought or water shortage with arid conditions.
Arid conditions exist at a location or area that
consistently has very low rain fall totals and high
evaporation rates. The two most common forms
of arid conditions on the Earth’s surface are the
steppe and desert. Such an arid location is Alice
Springs in central Australia which only receives
on average 252 mm (about 10 in.) of rain a year.
Accordingly, a water shortage in Alice Springs
represents a deviation from an expected rainfall
or moisture level pattern or, in the case of Alice
Springs, when a year’s rainfall is lower than
252 mm.

General types of drought

Once a drought has been identified it can be
classified as one of four types: meteorological
drought, agricultural drought, hydrologic
drought, or socioeconomic drought (Wilhite
2000). Meteorological drought refers to precipi-
tation deficiencies alone and does not include a
link to a good, service, or activity. An example
of a meteorological drought is below aver-
age precipitation for the summer at a specific
location in a given year. Typically meteorolog-
ical drought serves as the physical framework
within which impacts upon human activities are
identified. Agricultural drought refers to preci-
pitation and/or soil moisture deficiencies that
impact agricultural production. Such impacts
are not limited to crop production alone, such
as drought in the midwestern United States
that reduces soybean production, but can also
include drought impact on livestock through
less drinking water available and less water for
production of feed crops. A classic example of
agricultural drought was the Dust Bowl which
was an extreme drought that impacted the Great
Plains region of the United States for consecutive
years in the 1930s. During this event, wheat
and corn yields plunged by 50% to as much as
75%, and millions of tons of topsoil were lost as
desiccated soils were eroded by wind (Schneider
and Londer 1984). It should be noted that
tilling, cropping, and other agricultural practices
contributed significantly to this drought event
and associated soil erosion, highlighting the need
to combine both physical or social conditions
and processes to understand the true nature of a
drought event.

Hydrologic drought represents a shortage in
surface or subsurface water supply that impacts
a good, service, or other human activity. A
common form of hydrologic drought is the dry
conditions which lead to reduced urban water
supply from rivers or reservoirs. For example,
beginning in the winter of 2005–2006 through
summer 2008, much of the southeastern United
States experienced a significant rainfall deficit
DROUGHTS AND WATER SHORTAGES

which led to an extreme drought event (Manuel 2008). Due to this drought event, the region experienced widespread restrictions on water use, dangerous drops in reservoir levels, damages to crops, and conflicts within and between states on access and use of scarce water resources. Low reservoir and lake levels forced power companies such as the Tennessee Valley Authority and Duke Power to reduce hydroelectric generation and temporarily replace it with more expensive fossil fuel generation. Water levels of Lake Lanier, GA, source of drinking water for 3 million people in Atlanta, were reported to be as low as 5 m below normal.

Socioeconomic drought represents all other forms of drought in which a water or moisture shortage impacts supply, demand, production, or occurrence of some good, service, or other human activity. Given the broad definition, this type of drought includes the widest variety of events. Examples of this drought type are poor fish catch due to high salinity from low freshwater stream flow into an estuary or reluctance of tourists to visit a resort community due to an unpleasant odor produced by dead fish as a lake lowers due to drought. Socioeconomic droughts usually have the widest impact in terms of the sectors of society involved and geographic area impacted. It has been suggested that this type of drought is linked to the collapse of civilizations, such as the Classic Maya collapse in 800–1000 CE (Gill 2000). This megadrought event contributed to the death of millions of Mayans and played a role, along with internal strife, in the collapse of the empire (Dunning, Beach, and Luzzadder-Beach 2012).

It should be noted that these four drought types are not mutually exclusive and frequently overlap, which limits their use beyond organizational or conceptual guides. For instance, it is possible to identify a drought which represents both a meteorological drought and an agricultural drought; lower than normal rainfall at a specific location that impacts maize production. It is also possible to have an event which represents a combination of more than two of the definitions. A combination of meteorological, hydrologic, and socioeconomic droughts can exist when low rainfall causes low stream flow that reduces rafting trips down a river, and the inability of barges to use the river due to too shallow a navigation channel. Such overlap between the four types underscores the complexity of drought as a natural hazard.

The study of drought

The importance and relevance of drought to society is drawn from its ubiquitous and insidious nature (Tannehill 1947). Drought is ubiquitous in that it occurs across the globe, in water “rich” and water “poor” areas. Deserts or arid areas can experience droughts as well as rainforests, as illustrated with the example of Alice Springs. The insidious nature of drought is evident in that it is a slowly developing phenomenon that does not have a discrete beginning or ending point and most people do not notice or react to drought conditions until they are in the middle of a water shortage and faced with its greatest impact. Given such characteristics, drought is considered the most complex and most difficult natural hazard to effectively address. Further, drought can impact a very wide geographic area in contrast to other natural hazards which typically have a relatively small area of impact (i.e., tornados or landslides). The Dust Bowl, referred to in terms of agricultural drought, impacted an area greater than 900,000 km² from Nebraska to Texas. Given the existence of drought over a wide variety of landscapes, the difficulty in identifying drought event onset, repeating occurrence, and the potential to impact a wide area, drought has received much attention from
DROUGHTS AND WATER SHORTAGES

academic, governmental, and nongovernmental entities. As a result, a wide variety of literature exists in the fields of meteorology, climate science, agronomy, geography, and natural hazards that pertain to drought as well as volumes of government documents concerning drought policy which attempts to plan for, respond to, and mitigate drought. Within this large body of drought research and literature four main themes or approaches can be found: (i) physical science approach to drought; (ii) social science approach to drought; (iii) holistic human–environment approach to drought; and (iv) drought policy.

The physical science approach to the study of drought focuses on the specific environmental components and mechanisms through which drought develops, unfolds, and recedes. Examples of these components and physical mechanisms include, but are not limited to, precipitation, soil moisture, stream and groundwater hydrology, plant physiology, cropping techniques, and irrigation systems. Common themes in the physical approach to the study of drought include identification of the environmental components and processes which allow for prediction and identification of the onset of drought, monitoring drought conditions, engineering and management techniques for drought prevention, and engineering and management techniques to mitigate the impacts of drought.

The social approach to understanding droughts focuses on how humans contribute to the existence of drought and the impacts of drought upon society. Some common social science topics in the research of droughts include community drought preparedness and mitigation, social adaptation to drought, economic dimensions of drought, prediction and management of societal water demand, community and individual vulnerability to drought, drought risk management, and transboundary watershed management.

The holistic human–environment approach to drought emphasizes analysis of how physical and social processes, entities, and agencies interact and combine to produce drought. In this approach to the study of drought, researchers do not follow an atomistic approach in that physical and environmental aspects of drought are studied separately from the social aspects of drought. Rather, an attempt is made to combine the two components (physical and social) together to understand drought. Examples of such analyses include the study of desertification, drought within the context of global change, and drought as a natural hazard.

The final approach to the study of drought is drought policy which focuses on how government agencies contribute to drought management, response, adaptation, and mitigation. Drought response represents action taken to diminish negative impacts once a drought has started. Drought adaptation refers to the development of a course of action through which society or individuals adapt to the occurrence of drought before, after, and during a drought event. Drought mitigation refers to government action to stop or hinder the occurrence of drought. Given this wide array of approaches to studying drought, it is obvious that the study of drought is multidisciplinary. However, the study of drought’s physical science aspects has a tendency to fall within the disciplines of meteorology, climate science, geology, geography, ecology, hydrology, plant science, agronomy, and engineering. The social, human–environment, and policy approaches to the study of drought typically fall within the disciplines of geography, economics, sociology, political science, planning, public administration, and environmental studies.

Geography offers a unique perspective to the study of drought, a perspective that focuses on the spatial components and scale of drought.
Such a perspective is needed because supply and demand of water are not in equilibrium with geographic space and time (Dzurik 2003). Within the context of drought, this equates to the demand for water being greater than what is available at a specific place and/or time. Geographic analysis of drought is a problem-solving approach that explicitly recognizes the role of spatial characteristics and interactions of entities across the Earth’s surface. Hydrologic features (watersheds and aquifers) and social structures (water management districts and varied stakeholders such as landowners, environmental activists, and so on) manifest themselves differently in different geographic locations.

In order to conceptualize the differences of drought across geographic space, geographers find it useful to employ the concept of scale. Scale is a concept that allows geographers to think of water moving across local, regional, national, and international levels through physical and human systems which operate in a variety of interrelated geographical scales from the individual to international and global politics (Swyngedouw 2004). Such a characterization illustrates the importance of scale to water resources and drought. Scale can refer to the areal extent of an entity (e.g., a county within a state) or to the entity’s area of influence (e.g., a company that operates at local, regional, national, or international scales). Droughts unfold within and across these scales with each of the component environmental systems and social entities existing at one of these scales or across multiple scales. For instance, the watershed of the Jordan River is shared by Jordan, Israel, Palestine, Syria, and Lebanon. Consequently, drought management in this region unfolds across all geographic scales: local towns, state or department administrative units, and across international boundaries. Such a situation creates a very complex geography of water resources. Analyzing the political and environmental relationships across the scales is essential to understanding and reconciling competing perspectives in drought management.

The existence of multiple-scale components in a drought issue means that water resource managers inevitably are dealing with interrelated geographic scales. Typically, interrelated geographic scales create poorly defined boundaries of stakeholder influence, which can in part lead to conflict between stakeholders, such as local versus international or regional versus national interests. In the case of the Jordan River system, a local versus international mismatch may represent stakeholders in the city of Jerusalem versus stakeholders in Syria; or stakeholders in the West Bank versus the stakeholders of Israel. Without the identification and understanding of interrelated geographic scales, managers will experience little success in addressing drought management issues.

Current and future study of drought

A review of the history of the research on drought indicates that it has consistently evolved over time through advances in associated disciplines and adaptation of new technology by stakeholders. Despite such advancements, one of the most consistent themes in the study of drought has been the struggle to craft a universal definition of drought (as evident in the overlap of the four general drought types). For years, scholars, government officials, and stakeholders have attempted but still have to develop an accepted universal definition for drought (Wilhite 2000). Such debate has led many drought experts to conclude that a universal, precise definition of drought is unattainable and only a vague, generic conceptual definition can be provided that applies to all drought occurrences. Consequently, experts indicate the only appropriate approach
DROUGHTS AND WATER SHORTAGES

to defining drought is from an operational standpoint within a regional and use-specific context. Such a regional, use-specific operational definition allows for the identification of precise drought characteristics and specific threshold values that define the onset, continuation, and termination of drought episodes, as well as their severity. Such an approach takes into account the climatology and typical hydrologic conditions at a local or regional scale (e.g., county, state) and examines how this local or regional setting impacts a specific good, service, or activity (e.g., maize production or tourism). The characteristics used to identify a drought event can be a meteorological value such as soil moisture and an agricultural variable such as the amount of crop lost to drought. The thresholds are specific values for each of these two variables which indicate onset, continuation, termination, and severity of a drought. For instance, onset of a drought event may be identified as when soil moisture falls below 20% water content and at least 30% of crop planted are lost due to a lack of soil moisture. A severe drought is then defined as soil moisture below 15% water content and loss of crop to dry conditions greater than 50%.

Outside of the fundamental question of defining drought, several other themes have recently received focused attention in the current study of drought. With the development of modern ecology and environmental sciences in the 1970s, a greater emphasis has been placed on the human–environment approach to drought analysis, stressing the recognition that neither a physical nor a social component alone can be used to fully understand drought. In this approach to studying drought, researchers attempt to combine physical and social aspects/components of drought from the beginning of analysis and then determine how they interact or coevolve to produce a drought event. A current example of a holistic human–environment approach to drought is the concept of double exposure and vulnerability to drought. Double exposure refers to community or individual exposure to both economic change and environmental change which combines to create increased vulnerability or the susceptibility to experience a negative impact due to drought (Leichenko and O’Brien 2008). For instance, a farmer may receive a low price for tomatoes harvested due to a more competitive global food market. As a result, the farmer is unable to afford installation or repair of an irrigation system on their farm. This loss of financial capital for irrigation due to a change in the global food market combines with drier conditions created by global climate change, resulting in greater farmer vulnerability to drought. Thus, double exposure to both economic and climate change creates vulnerability to drought, a vulnerability that cannot be completely understood without investigating the combination of both the physical and social aspects of economic and climate change over time.

Another current focus in drought studies is the application of new satellite data and numeric modeling technology to improve the forecast and identification of drought and drought monitoring methodologies (Hayes et al. 2005). Meteorologists have continued to develop and improve operational monthly and seasonal predictions of drought based upon empirically derived statistical relationships from satellite data and numerical ocean atmosphere coupled computer models that identify teleconnections between moisture conditions in one location and global scale atmospheric dynamics and processes such as variability in sea surface temperatures, ENSO events, jet stream variability, and development and absence of long-term wind and storm systems (Ropelewski and Folland 2000). These techniques have led to recognition that the absence of moisture advection, increased
DROUGHTS AND WATER SHORTAGES

Evapotranspiration, and increased regional atmospheric subsidence are the major physical contributors to the occurrence of drought.

A major component of the recent efforts to improve forecasting and monitoring of droughts is directed toward the development of effective drought indices (Keyantash and Dracup 2002). A drought index is a numeric or alphanumeric expression that clearly and efficiently communicates drought conditions at a given location based upon an aggregation of in situ observations, statistical comparisons, model assessment, and expert analysis. A successful drought index is useful (robust), data compatible (tractable), clear (transparent), applicable across time (extendible), and uses fundamental units or a ratio (dimensions) (Keyantash and Dracup 2002). Some of the most common drought indices used by drought experts are rainfall decile, standardized precipitation index (SPI), total water deficit (TWD), Palmer hydrologic drought index (PHDI), and the crop moisture index (CMI). The US Drought Monitor, the official monitoring product of the US National Drought Mitigation Center, displays drought conditions across the United States in the form of a drought index ranging from D0 (abnormally dry) to D5 (exceptional drought) as well as the designation of S for short-term water shortage (less than 6 months) and L for long-term water shortage (greater than 6 months) (Svoboda et al. 2002). The D0–D5 alphanumerical value is derived from six key physical indicators and expert evaluation and was designed to be easily recognized by the public as inspired by Fujita tornado scale and the Saffir-Simpson hurricane scale.

Linked to this current theme of use of new technologies and data to predict and monitor drought is the application of such techniques to determine the potential for increased drought and water shortage in a future anthropogenically warmed climate. The Intergovernmental Panel on Climate Change (IPCC 2013) states that the warming of the global climate system is unequivocal with a linear trend of 0.85°C (0.65 to 1.06°C) in combined land and ocean surface temperature for the period 1880 to 2012. Corresponding to this warming trend is an analysis of drought (using the PDSI drought index) that indicates very dry areas have more than doubled since the 1970s, particularly in the tropics and subtropics, due to surface warming (Dai, Trenberth, and Qian 2004). In the future, predictions indicate this drying trend is likely to continue in mid-latitude and subtropical dry regions while high latitudes, the equatorial Pacific Ocean, and mid-latitude wet regions will likely become wetter. The result is a future climate in which contrasts in amounts of precipitation in wet and dry regions will increase causing greater potential for drought in already dry areas alongside less probability for drought in wet areas. Further the changes in precipitation and melting of snow will alter regional hydrologic systems which in turn may cause regional water shortages or drought. Some of the key risks associated with the increase of water shortage and drought and changes in regional hydrologic systems are the breakdown of infrastructure networks and critical services associated with water supplies, food insecurity caused by the breakdown of food systems, and loss of rural livelihoods due to insufficient access to drinking and irrigation water and reduced agricultural productivity (IPCC 2014).

Conclusion

In conclusion, drought is a ubiquitous and insidious natural hazard that can potentially impact any location worldwide. Given the unique nature of drought at any given location, it is very
DROUGHTS AND WATER SHORTAGES

difficult to develop a universal definition and prescription for drought. Each drought event must be evaluated within its regional geographic and human activity context. Drought events can be classified as one of four types: meteorological drought, agricultural drought, hydrologic drought, or socioeconomic drought. Over the years the study of drought has followed four main themes or approaches: (i) physical science approach to drought; (ii) social science approach to drought; (iii) holistic human–environment approach to drought; and (iv) drought policy. Currently, drought experts are utilizing new technology to monitor and to improve forecasts and predictions of drought. These improvements will be vital to address the greater potential for drought in mid-latitude and tropical dry regions due to anthropogenic climate change. Geographers are poised to contribute to these efforts by using a unique perspective that stresses the spatial components and scale of drought.

Daily mobility

Sandrine Wenglenski
Université Paris-Est, France

A matter in progress

Mobility is not a straightforward concept. In its common usage, it simultaneously describes a potential for action (the capacity to move) and a real action (the actual movement). In its academic usage, it covers several dimensions (social, spatial, symbolic, etc.) and does not only refer to physical movement: its early use applied to social mobility, which relates to a change in position at a social level. Even when mobility specifically addresses geographical concerns, it considers various entities (individuals, goods, data, ideas, etc.) and fields (international, residential, daily, virtual movements, etc.). Gradually, the concept has been adopted in many studies, expressing the perception of an increasingly changing world, sometimes referred to as a “mobility turn.”

At first sight, daily mobility is more straightforward. It is commonly agreed that it relates to the day-to-day physical movements of people. However, this simple statement leaves areas of uncertainty: what are day-to-day actions? Who are the people involved? Should not virtual movements (distance communication) be taken into account in view of their possible interactions with physical movements? What about the links with social or other types of mobility? How research answers these questions depends on the environment and concerns of the day. The initial study of daily travels was prompted by the need to solve practical and technical problems related to increasing urban traffic and congestion, in which recurrent trips such as commuting to work played a key role. Accordingly, the travel survey protocols that were developed considered mobility as the outdoor physical movements of local residents pursuing their everyday life agenda, in the sense of activities carried out fairly close to individuals’ homes as opposed to long-distance journeys. These surveys still provide the basis for the statistical knowledge of daily mobility. Although the mobility of tourists, freight, and information, as well as long-distance travel, is acknowledged to be partly linked to that of residents, currently no common framework binds them all.

Yet, from the time it was first studied on a regular basis, daily mobility – as well as the physical and social environments within which we live – has changed substantially. The trends and changes involved have been a key field of observation and a means of gaining a better understanding of mobility, thanks to input from a variety of disciplines and methods. Such input has participated in the continuous questioning of the scope, implications, and meanings of daily mobility. Daily mobility appears to be linked to many dimensions of social life and social issues. Depending on the social, economic, and technological context, it both derives from ways of life and spatial forms and also influences them.

Mobility as a by-product

With the exception of travel for the sake of pleasure, traveling arises from a forthcoming
DAILY MOBILITY

activity that cannot be performed on the spot. We need to travel in order to buy food we do not have at home, even though our primary desire is not to travel but to feed ourselves. This is why daily mobility is considered to be a by-product; it is a “demand” which is derived from purposes other than itself. The study of travel was initiated by engineers responsible for forecasting transport demand so as to adjust infrastructures to growing travel needs. Consequently, thinking about mobility was largely inspired by the figure of homo economicus. Analysis focused on single trips, perceived as the derived demand of the need to achieve one primary activity – for example, working, consuming, entertaining – regardless of the number of an individual’s trips during a period of time or of the interplay of several purposes. One action has one reason. In addition, travel was regarded as a pure cost: a loss of money and time. As a result, all things being equal, it was assumed that people will attempt to minimize their travel costs and distances: the lower the cost the better.

This view was supported by the orders of magnitude observed in trip structures. It grounded the gravity model which expresses the amount and direction of flows between origins and destinations within (and between) cities as a function of the economic importance of areas (generally the number of job opportunities as a proxy for the potential of a location to provide destinations of activities) and the distance between them. The denser and nearer a zone, the greater the flows it attracts. Yet, it has hardly helped us to understand the variety of behaviors and the spectacular increase in distances traveled daily observed from the 1970s to the end of the 1990s in Western countries, and also apparent today in emerging countries. Unpredicted flows and increasing distances ran counter to the pervading theoretical conception of travel being strictly dependent on economic urban hierarchies and a willingness to minimize distance.

The fact is that all things never are equal. People are subject to various constraints and have many goals, not all of which can be achieved under the same conditions, and daily mobility is rarely the automatic consequence of the desire to perform either a single or a primary activity which would be the trip’s obvious purpose, and the nearer the better. For example, the mode of transport people use to travel to the location of their first activity of the day generally impacts how they travel to the second, and vice versa. Similarly, the characteristics of a person’s journey to work depend on the location not only of their job but also of their home. The home location choice may be one of their primary purposes in travel decision-making. Mobility encompasses many dimensions and factors and, depending on them, individuals may place uneven importance on close distance and minimizing travel costs.

Mobility as a tradeoff

Two major perspectives contributed to the development of a view that humanized and contextualized the protagonists of mobility: one analyzes the constraints that weigh on people; the other emphasizes their degree of choice.

Torsten Hägerstrand (1970) highlighted that people are limited by a wide range of circumstances. Because there are only 24 hours in each person's day, the number of distant activities (number of trips), the size of the area within which a person can carry out these activities in a day (length of trips), and the choice of their location (destination of trips) are determined by his/her characteristics and spatial and social environment. An individual’s daily mobility depends on his/her possible travel speed (relying
on his/her physical capacities, the economic budget he/she can afford to spend on a nonmuscular means of transport, the local transportation supply, and existing technologies); the spatial distribution of activities; the working or opening hours of companies, retail outlets, and public services; and the social conventions that allocate different roles and activity programs to members of the household and the community (by race, gender, or age). Hägerstrand’s work provided a more realistic picture of the physical and social experience of traveling, revealing factors and constraints that restrict mobility potentials and behaviors.

In contrast, Yacov Zahavi (Zahavi and Talvitie 1980) drew attention to the dimension of choice that lies behind mobility behaviors. Zahavi noticed that, across Northern and Southern countries of the world and at different periods, people appeared to spend the same average amount of time a day traveling. What distinguished travelers living in different geographical and technological contexts was not how much time they could spare but rather how far they could go. Counterintuitively, people who are able to use faster modes of transport do not seem to take advantage of them to spend less time traveling, but instead travel greater distances. This phenomenon challenged the traditional assumption that trip production is fundamentally determined by the minimization of travel costs. Within undoubtedly limited time and money budgets (on average one hour a day and 10% to 15% of the household income per month), people may extend their range of travel rather than reduce their budgets whenever this increases the choice of possible destinations and the chance of one of these better meeting their aspiration. All things not being equal, all individuals have a specific set of options within which they make tradeoffs and act, depending on what they value – for example, living in a larger house or a wealthier neighborhood, getting a higher-paying job, attending a better school – all of which affect their travel. This means that daily mobility is not just a pure cost derived from a single and immediate need. It can be seen as a means, the result of tradeoffs that are made in order to achieve personal goals in a constrained world.

The spatial footprint of social phenomena

This research paved the way for a great deal of work on the part of geographers, socioeconomists, sociologists, and planners that explored and deepened our understanding of the many determinants of daily mobility (Hanson and Giuliano 2004). Travel abilities and behaviors vary (Orfeuil 2004). Sociodemographic characteristics (age, gender, household composition, etc.) determine the physical autonomy of individuals and the social obligations weighing on their personal schedules. Social and economic positions (cultural and social patterns of exposure to others, monetary capacities) determine the freedom to break free of (or afford) proximity and to access diverse destinations. Spatial locations (with respect to the location of urban resources and transport provision) determine accessibility to opportunities and resources. These factors affect individuals’ potential mobility, which shapes mobility practices. Through these factors, the values and trends that pervade society at large affect the characteristics and changes of daily mobility. They influence the two-way relationship that links mobility to both lifestyles and places of living.

The sociologists of the Chicago School were among the first to analyze the changes in urban life in expanding cities, and to demonstrate how spatial mobility was involved in it. First, cultural and economic clusters in city districts
created the need to travel every day from one specialized place to another. Second, the progressive social and economic integration of new residents allowed them to move from the centers to distant, pleasant, neighborhoods from where they had to travel long distances. This meant that social reality is translated into spatial terms: social organization has effects on spatial interactions and organization. For example, upward social mobility often created spatial mobility. The increase in distances traveled daily, coupled with the constancy of travel budgets, proved to be a means of accessing ownership of single-family houses in low-density environments for car-owning households. Extensive daily mobility was the price for the achievement of residential aspirations in a wealthy economic period when car use and out-of-town housing were highly valued. In most cities worldwide, depending on the population’s level of wealth and the extent to which individuals have adopted the values of the consumer society, daily mobility sustained a way of life based on car and home ownership, and a new pattern of urban expansion leading to edgeless cities, where mass transit was nonexistent or worthless. The potential for daily mobility provided by the automobile opened up residential choice and released spatial configurations from the “tyranny of distance.”

The relationship between space and mobility patterns has stimulated an important line of research which investigates how urban form and daily travel influence each other – and whether and how to plan cities so as to reduce car use and traveled distances (Newman and Kenworthy 1989; Cervero and Ewing 2010). Not only have people who located far from city centers because of the ease of travel contributed to urban sprawl and are nowadays held responsible for growing congestion and pollution problems, but, since the beginning of what has been called the “white flight” in the United States, this move has raised concerns about segregation and access to jobs. The massive departure of the middle classes from inner areas to the outer suburbs (sometimes avoiding proximity to ethnic minorities) has had impacts on both residential specialization and the location of jobs. The inner-city neighborhoods vacated by the middle classes became impoverished and dominated by disadvantaged groups. Meanwhile, following the residents, and in view of their ability to commute by car, a great number of jobs relocated to outlying suburbs, where rents were lower. This geographic context created a “spatial mismatch” (Kain 1968), with the poorest residents from the dense neighborhoods being unable either to move closer to jobs or to travel the considerable distances needed to reach them. According to John Kain, this spatial mismatch was a cause of the higher unemployment rate experienced by the lower classes living in inner cities. Ultimately, one group’s ability to travel created a spatial context that worsened the consequences of the other group’s lower travel ability.

The evidence of social change – and permanence

Because it allows people to free themselves from the constraint of geographic closeness and affects spatial locations, social interactions, and the organization of everyday life, daily mobility has come to be blamed for weakening social ties. Easy travel is sometimes said to increase distances between people by fostering dispersed urbanization and the conversion of social distances into geographic distances, led by those being able to afford great travel distances. However, it is noticeable that one of the major spatial trends that dominated the second part of the twentieth century (urban sprawl) had moderated by the end of it. Living in core cities and being
able to benefit from urban amenities and to socialize locally came to be more and more highly valued. In many urban areas, the upper classes reconquered the central places, which became synonymous with quality of life and sustainable mobility. In city centers, mean daily traveling distances have recently decreased. This trend does not contradict Zahavi’s conjecture, since he stated that people prioritize their goals, of which minimizing travel costs may not be the most important, since shorter travel distances do not necessarily equal shorter travel times. Cycling from home to work is nowadays the prerogative of the happy few who live and work in town and are able to choose slow, environmentally friendly modes of transport. This has not curtailed the tendency for urban segregation: it occurs via other means. This suggests that daily mobility can serve various purposes and that its significant characteristics and relationships with space reflect deep social values and changes. On this ground, it has been said to be a “total social fact” (Bassand and Brulhardt 1980).

The social trends and ways of life that are embedded in daily mobility are obviously interconnected with the state of technology. In large cities, the spread of personal motorized vehicles and the development of efficient mass transit has combined with social and economic pressures to go faster and further. These changes have affected various segments of the population. Emerging countries are currently experiencing huge, albeit uneven, traffic growth. In Western countries women’s travel behaviors are in the process of catching up with men’s. Clerical staff and blue-collar workers are no longer distinguished by short home-to-work trips. As transport technologies have improved, extensive mobility has become an increasingly important feature of everyday life. According to some researchers (Bacqué and Fol 2007), not only has daily mobility increasingly become the rule, but it has also become more and more unavoidable, as it is required both by social norms and by the nature of modern life. The highly efficient transport that is accessible to part of the population has raised the norm of mobility expected of all. Nowadays, being mobile is a minimum requirement. In addition, urban sprawl, the instability of employment, and the growing pace of urban life require mobility and reactivity. One has to be mobile, and to be able to reform one’s practices in order to be able to keep up with change. Thus, daily mobility is actually less and less a choice for those who perform it, while those who have difficulties doing so are excluded from social integration – as mobility, although widespread, is still not equally accessible to all. Local travel and simultaneously benefiting from a high degree of individual accessibility is a rare privilege. In a number of cities, low-income households have now little option but to select less expensive and less accessible outlying locations from where they spend a lot of money on commuting.

It is as if social status matched travel practices, the hierarchy of which had shifted according to changing norms.

In contrast, two overall observations show constancies in mobility behaviors. First, it is not really contested that, over time, the average daily travel-time budget has remained basically unchanged: despite growing distances, there was no significant increase in the amount of time spent traveling in a day. Second, the same applies to the mean number of trips per day per person (between three and four). While long-distance communication has greatly increased, daily out-of-home occupations have neither decreased nor increased (there are still only 24 hours in everyone’s day). The good news is that the importance of face-to-face contact remains undiminished. The bad news is that it
DAILY MOBILITY

DAILY MOBILITY does away with the initial hypothesis (and hope) that virtual mobility (through information and communication technology) could provide a way of reducing physical mobility and its ecological impacts.

The future of mobility

Today, one of the significant issues that arises from daily mobility is its environmental impact. The need for mobility and the main means by which these needs are fulfilled are acknowledged to be considerably harmful in terms of the energy consumed and the pollutants emitted. In the near future, rising mobility is set to be more of an issue in developing countries. In Western countries, car ownership is already at a high level and car use has even fallen in some regions. Overall daily distances should not increase to any marked degree as the population is aging and not due to grow much. Yet, private modes of transport accounted for 9 out of 10km daily traveled in the United States in 2009 and 8 out of 10km in the United Kingdom in 2012. In France, the transport sector generates one-third of carbon dioxide emissions, and car use is responsible for half of this. But the most worrying issue is caused by the rising standards of living in large countries where car ownership used to be low. In recent years, car ownership has dramatically increased in China and India. This state of affairs is leading academics, planners, and politicians to look for ways of reducing car use or travel distances. This requires public policies that act together on the transport system, land use, and real estate markets – because where people are able to live defines how they are able to travel. The issue is challenging. Just-in-time and ultra-competitive economic models that require fast interaction, the decline in the resources available for improving public transport, and the laissez-faire attitude toward urban sprawl which leads to car dependency all stand in the way of virtuous behaviors. However, norms and attitudes are changing. Laws are gradually implementing environmental obligations, and environmentally friendly travel solutions are being developed (e.g., car sharing, electric cars, bike-share services).

Finally, daily mobility ties in with many other types of mobility (social, residential, and virtual) and aspects of social life (social norms, economic models, technological change) that affect how and where people live. This pivotal position, together with the growth of all other types of physical mobility (professional long-distance journeys, freight, tourism), and the dramatic state of flux that characterizes contemporary social organizations in an increasingly connected world, has led researchers to think of mobility as a broad concept referring to today’s changing world. The “mobility turn” scientific community does not advocate a specific vision of mobility itself or a specific way of grasping it. It is much more concerned with an overall vision of the contemporary world where actual spatial movements, the opportunity to move, and the pace of lifestyle changes increased significantly throughout the twentieth century and dramatically since the start of the twenty-first. It encourages experts and stakeholders to include this phenomenon in their analysis and policies. John Urry (2000) goes even further, taking the view that sociology should no longer be the study of structures (of societies) but of the movement (of individuals, goods, ideas, information, images, money, and so on). Although debatable, this proposal has the merit of inviting us to open up the conceptual boundaries of scientific approaches and to initiate new questions and methodologies in the area of mobility. Over time, quantitative approaches have improved. More recently, qualitative tools
have been developed in order to grasp less visible and less measurable aspects of travel behaviors such as experiences, representations, and perceptions. Thus the overall societal context and academic endeavor continue to pose questions about the definition and nature of daily mobility. The future of debate on mobility is assured.

Dams

William H. Renwick

Miami University, USA

Definition of dams

Dams are barriers constructed with the purpose of restricting water flow. Most dams are constructed across streams, but some are built at upland sites that did not previously have flowing water, but which can impound water that falls as precipitation or that is otherwise delivered to these sites.

Summary statement of extent, purposes, and consequences

Today millions of dams exist around the world. Their impacts on human societies and on natural processes cannot be understated. They provide reliable supplies of drinking water to billions of people and irrigation water that has dramatically increased the extent and quantity of agricultural production and renewably generate 17% of the world’s electricity. These benefits come with significant costs, however. Construction of new dams displaces thousands and sometimes millions of people. Worldwide, dams impound over 6000 km$^3$ of water, or about 16% of total annual stream flow, significantly altering downstream aquatic and riparian environments. In addition to storage, an unquantified but certainly substantial portion of the world’s river flow passes through reservoirs that trap sediment, carbon, nitrogen, phosphorus, and other key components of global ecosystems. Dams have altered the distribution of plants and animals, both creating new fisheries and causing extinctions of riverine species.

Dams vary tremendously in size, with respect to the height and length of the dams themselves and also the reservoirs that they create. The highest dams in the world are hundreds of meters high, and the longest ones are tens of kilometers long. These very large structures typically impound the largest amounts of water, but are relatively few in number. Large dams – those that impound at least 0.1 km$^3$ of water – number in the thousands. Smaller dams, down to those that create small ponds of 1 ha or less, number in the tens of millions. These smaller dams account for more than 99% of all dams, but probably only about 20% of total reservoir surface area. The number of dams in the world continues to grow, especially small dams.

Because of their imposing size, importance to society, and environmental significance, dams are controversial. When they are built they displace natural ecosystems and human populations as well as inundate valuable land. Dam failures, while relatively few, are among the great disasters in history. Dams become semipermanent features of the landscape with lasting and profound impacts on water resources, infrastructure, economic activities, and the distribution of population. Opposition to construction of large dams has grown in recent decades and this, along with the existence of alternative sources of electricity and approaches to water-resource needs, has contributed to a decline in the rate of large dam construction, particularly in industrialized countries. However, we continue to build new small dams.
DAMS

by many thousands each year. In some areas older
dams – both large and small – are being removed
as sedimentation or changing needs have reduced
their value to society, and removal can reverse
some of their negative environmental impacts.

History of dam-building

Ancient dams

The earliest known dams are located in the
Middle East, associated with irrigation-based
civilizations that developed in present-day Jor-
dan, Syria, Iraq, and Egypt, and date from
the fifth–third millennia BCE (Fahlbusch 2009).
Ancient dams also survive in South Asia, China,
Japan, and Central America. Dams were an
integral part of the co-development of irri-
gated agriculture and hydraulic engineering that
supported early civilizations. While irrigation
remained the dominant function of most early
dams, they also supplied water for other pur-
poses such as domestic use, often carried in
via complex systems of canals and aqueducts.
The Roman Empire made many contributions
to hydraulic engineering technology, including
dams. Several Roman dams survive and are in use
today, including Cornalvo Dam in Spain, Subi-
aco Dam in Italy, and Lake Homs and Harbaqa
Dams in Syria.

Ancient dams were mainly earthen and/or
masonry dams that relied on their weight and
gravity to remain in place and resist the pressure
of water on the upstream side. The Romans built
such gravity dams but also were among the first to
use masonry buttresses and arches to strengthen
dams. Concrete was also used extensively in
Roman dams, as it is today.

Dams are intimately connected with civi-
lization. Dam construction inevitably requires
high levels of social organization to mobilize
labor and capital resources to build dams and
distribute the water that is made available by
them. Nearly all large dams in the world have
thus been built by governments, or at the
very least with government authorization and
coordination.

Dams and hydropower

In addition to providing water for irrigation
and human uses, dams have also been used for
millennia for generating mechanical power – for
grain milling, sawing lumber, and more recently
powering industrial facilities and generating
electricity. Mill dams were common in the
middle ages in Europe as well as in colonial
times in North America, but the industrial
revolution of the eighteenth and nineteenth
centuries as well as accompanying urbanization
spurred a dramatic increase in the number of
dams. These new dams were built for industrial
purposes (especially sawmills in North America),
as feeders for canal systems, and for urban water
supply. Examples include Bosley Reservoir and
Anglezarke Reservoirs in the United Kingdom,
built circa 1830 and circa 1850 for canal water
and drinking water supplies, respectively, and
Telos Dam in Maine, built in 1841 to support
timber harvesting.

With the nineteenth century development
of efficient water turbines as opposed to water
wheels, the use of dams for hydroelectric power
became much more feasible. The first hydro-
electric power station opened in Appleton,
Wisconsin, in 1882. Use of dams for hydropower
grew rapidly thereafter in the industrialized
world, with many dams of varying sizes con-
structed in the early twentieth century. Today
hydroelectricity is a dominant use especially
in very large reservoirs: more than half of the
world’s reservoir storage capacity is used primar-
ily for generating electricity.
Modern multiple-use dams

Because reservoirs offer diverse benefits to society, most reservoirs today are used for multiple purposes although one or two purposes are typically foremost. The most important uses for dams today are irrigation, hydroelectricity, water supply, flood control, waste containment or processing, navigation, and recreation. The opportunity for multiple uses increases the political attractiveness of undertaking construction of dams.

The middle to late twentieth century was the period of greatest dam-building around the world, as measured by volume of water storage capacity (Figure 1). Ninety percent of world capacity was built between 1940 and 1995; 50% was built between 1960 and 1980. The era of big dam-building was slightly earlier in the United States: 90% of capacity was built between 1915 and 1980; 50% was built between 1950 and 1968. Since about 1980 the pace of dam construction in the world has dropped dramatically, particularly in industrialized nations.

Large dams today

Dams are among the largest human-built structures in the world, and if one includes the reservoirs they impound they are probably the largest. For example, the Three Gorges Dam in China incorporates more than 27 million m$^3$ of concrete, and the impounded reservoir is 1045 km$^2$ in area with a volume of 39.3 km$^3$. Hoover Dam in the United States was the world’s largest concrete structure when it was built in 1935 (2.4 million m$^3$). It is 223 m high and impounds a reservoir 640 km$^2$ in area and 37.3 km$^3$ volume. The Rogun Dam in Tajikistan, at 335 m high, is among the world’s highest. The Grande Dixense in Switzerland is 285 m high. These very high dams tend to be in narrow valleys. The longest dams in the world are tens of kilometers in length. The Yacreta Dam in Paraguay is composed of an 800 m long concrete structure and a 65 km earth dike. The Martin Power Plant just east of Lake Okeechobee in Florida is supplied by cooling water from a reservoir that is contained within a 27 km-long dike, 10 m high.

Figure 1  Historic capacity growth of large reservoirs in the United States and the world (in km$^3$). Data sources: US Army Corps of Engineers (2013) and Lehner et al. (2011).

World

Dams are found throughout the world (Figure 2). Reservoirs cover >500 000 km$^2$ of Earth’s surface – an extent comparable to the total area of the world’s cities. They are also extremely common: in the conterminous United States there is an average of about one dam for every 2 km$^2$ land area. The greatest concentrations of large dams are in relatively industrialized
countries, but some of the largest dams are in less-industrialized countries. As of 2011 there were nearly 6900 large reservoirs in the world with a storage capacity of >0.1 km³ each (Lehner et al. 2011). The total storage capacity of these reservoirs is about 6200 km³, or about 16% of annual runoff from land areas of the world to the oceans. Among the largest dams in the world, by impounded water volume, are Kariba (Zambia, built 1959), Bratsk (Russia, 1964), Aswan (Egypt, 1970), Akosombo (Ghana, 1965), and Daniel Johnson (Canada, 1968). The five countries with the greatest impounded water volume in large dams are Canada (14% of world total), Russia (13%), United States (12%), Brazil (8%), and China (7%). These five countries account for more than 50% of total world reservoir capacity. In addition to these very large artificial reservoirs, many large lakes have dams at their outlets that allow water level regulation. These dams are typically of only modest height and may only regulate lake levels by a few meters, but because the lakes are very large the total storage is also large. Dams at the outlets of Lake Victoria (Uganda, 1954) and Lake Superior (Canada/USA, 1921) account for the largest storage volumes in the world and the United States, respectively.

The principal uses of the world’s large dams are irrigation (34% of dams) and hydropower (29% of dams) (Lehner et al. 2011; Table 1). About 67% of storage capacity is in hydropower reservoirs and 19% in irrigation reservoirs. Hydropower represents more capacity because more humid and often remote regions are often favorable sites for large dams. Areas that need irrigation water are dry and so less water to fill a large reservoir is available, and also land that would be lost to inundation may be more valuable. Water supply is the third most common primary use of large reservoirs, followed by flood control and recreation. Today, navigation is a relatively minor purpose of dam construction, although in the nineteenth century when canals were more central to the transport systems of industrialized countries they were proportionately more significant.

DAMS

United States

In the United States, most large dams are found in the northern plains (Upper Missouri River), west and southwest (Pacific Coast and Colorado River drainages), south-central (Texas and Oklahoma), and southeastern (Tennessee Valley, southern Piedmont) regions. These regions, though varying widely in climate and land use, were all foci of government dam-building activities in the twentieth century. In the west, need for irrigation water stimulated the 1902 Reclamation Act, which ultimately led to the construction of many dams including Hoover and Glen Canyon Dams (Arizona, 1935 and 1963, respectively) on the Colorado River, Garrison and Oahe Dams (North and South Dakota, 1963 and 1953 respectively) on the Missouri River, and Grand Coulee Dam (Washington, 1941) on the Columbia. The Tennessee Valley Authority, created in 1933 to address a variety of economic and environmental problems that plagued the region, built many large dams including Kentucky and Wolf Creek Dams (Kentucky, 1944 and 1951, respectively), and Norris Dam (Tennessee, 1936). The Army Corps of Engineers, through its authority to improve navigation and conduct flood control activities, has built many dams including Sam Rayburn Dam (Texas, 1965), Bull Shoals (Arkansas, 1951), and J. Strom Thurmond Dam (Georgia, 1954).

The Corps of Engineers maintains a National Inventory of Dams (NID; US Army Corps of Engineers 2013), which includes dams that are more than 7.6 m (25 ft) high, hold more than 800 000 m³ (650 acre-feet) of water, or are considered a significant hazard if they were to fail. In 2013 the database contained 86 461 impoundments; some of these are contained by multiple dams. The total storage capacity of these dams is 1689 km³, or about 58% of total annual runoff from the United States. Ninety-two percent of this capacity is in 1205 large dams with capacity >0.1 km³. Considering just the 99.7% of NID dams that are within the conterminous 48 states, storage is 103% of total annual runoff.

The primary uses of large dams (capacity >0.1 km³) in the United States differ from those in the rest of the world: flood control is the most common primary use, followed by hydroelectricity, water supply, and irrigation (Table 1). The emphasis on flood control probably results from the United States’ longer history of dam construction combined with a level of economic development and urbanization that places populations and valuable facilities at risk. When the uses of the 1205 large dams in the NID are compared with the relatively smaller 85 256 remaining dams, the differing uses of large and smaller dams are evident. Among the smaller dams in the United States recreation is the most common primary use, followed by “other,” flood control, and irrigation. The “other” category includes fire protection (which accounts for 13% of dams but only 1.6% of capacity), wastewater treatment, power plant cooling water, mine tailings storage, and erosion control. These are uses that tend to be widely dispersed and typically do not require large volumes of impounded water. Finally, about 3% of the dams in the NID are “off-stream,” which means that the dam is built on a level or upland area rather than across a stream. Many of these off-stream dams are for water treatment (including tailings storage), fisheries, power plant cooling, and pumped-storage hydroelectricity.

While the NID is a very comprehensive database, it includes only a fraction of the dams in the United States. We have a relatively accurate inventory of all the lakes and reservoirs in the United States in the National Hydrography Dataset (NHD) – a digital version of the detailed topographic maps produced by the US Geological Survey (n.d.). The NHD includes about 6.57 million lakes, ponds, and reservoirs, but does not
distinguish between those of natural origin and those created by dams. In the aggregate we can estimate how many of these features are likely to be of natural or human origin based on known lake-forming conditions. For example, natural lakes are common in glaciated areas, while unglaciated areas with rolling or steep topography rarely contain natural lakes. Using this knowledge we can infer that about two-thirds of the lakes/ponds/reservoirs in the United States are of human origin. In other words, there are perhaps 4 million to 4.5 million dams, most of them too small to be included in the NID. Roughly half of the ponds created by these dams are less than 0.1 ha in size (about a quarter of a football field). So while very small reservoirs less than 0.1 ha in area are extremely numerous, they do not account for a very large portion of total water surface area – only about 1%.

Environmental consequences

Flow and flow regime

Dams are designed to store water and thus alter stream flow: to prevent floods, augment low flows, or indirectly modify flow by releasing water in relation to electricity demand, irrigation needs, or other purposes. Dams also divert water from streams to off-stream uses such as irrigation that increase evapotranspiration and thus decrease total stream flow. Although each individual dam will vary in its hydrologic effects, in general the hydrologic effect of dams is to reduce the magnitude or frequency of flooding, reduce total flows, and sometimes increase low flows.

The effects of dams on flow regime are determined by the design of the dam and its reservoir and, for dams that have outlets that can be manipulated, the operation of those outlets. Most large dams have outlets that are controlled by gates or valves, and so the amount of stored water (also known as pondage) can be deliberately varied. For hydroelectric power dams, the rate outflow is usually governed by demand for electricity, and the outflow from such dams may vary accordingly by time of day as well as by season. Dams with the principal function of flood control are usually operated so as to have relatively little water stored at the beginning of the high-flow season, to make room to store runoff. Dams primarily intended for irrigation typically retain water during times when irrigation demands are lower, and release it when those demands are higher, with corresponding impacts on downstream stream flow.

In contrast, most small- and many medium-sized dams have little or no pondage, and so the amount of water that spills over the dam is mainly a function of inflows. Such dams are sometimes referred to as run-of-the-river dams. But even these store a small amount of water during times of rising inflow and release it when inflows are lower, and so exert some moderating influence on downstream flows, reducing peak discharges.

In addition to their direct impacts on flows, dams are key components of water withdrawal and consumption systems that have resulted in reduced total flow in many areas. Such effects are most dramatic in arid and semiarid regions with large irrigation water use, such as the southwestern United States, China, and central Asia. Well-known examples of such impacts include the catastrophic reduction in the size of the Aral Sea in Kazakhstan and Uzbekistan, and the elimination of perennial flows in the lower Colorado River (US and Mexico) and the Huang He (China).

Sedimentation and sediment transport

Sedimentation is probably the most significant water quality effect of dams and their reservoirs. Sediment transported by streams that flow into reservoirs is trapped in the reservoir and thus not carried on downstream. All dams trap some
sediment and large reservoirs often retain nearly all the sediment they receive. Because of this sedimentation, reservoirs eventually can fill with sediment if loads in inflowing streams are high enough. Most dams are built with anticipated reservoir life spans of at least several decades, although some are built specifically for the purpose of removing sediment from the water. In the conterminous United States today, total reservoir sedimentation is estimated at 2–3 km$^3$ per year, or about 0.1 to 0.2% of total reservoir capacity (Renwick et al. 2005). This estimate masks great local variability, however: in areas of substantial stream sediment loads it is common for reservoirs to lose a substantial portion of their total capacity in as little as a few decades. Sometimes reservoirs are dredged in order to remove accumulated sediment.

Because dams are so ubiquitous, the total amount of sediment that is removed from the world’s river systems is very large. Perhaps 50% of all sediment transported by rivers is trapped in reservoirs (Vorosmarty et al. 2003). In addition to reducing the storage capacity and usable lives of reservoirs, this sedimentation has downstream effects. Sediment loads are reduced below reservoirs causing some streams to erode their beds and banks, particularly in the area immediately downstream from the dam. The loss of sediment from streams can also have ecological consequences to downstream environments, particularly in very dynamic streams where sediment deposition and erosion are important parts of riparian ecosystems. Such problems have been a major concern in the Grand Canyon below Glen Canyon Dam, for example.

**Aquatic communities**

Dams and their reservoirs transform riparian environments by breaking relatively continuous free-flowing streams into a series of stream segments separated by deep, low-velocity impoundments and the physical barriers created by the dams themselves. Whereas a river is relatively shallow, with frequent variations in depth and width associated with stream flow variations, reservoirs may have large surface areas and large volumes of water that has only limited interaction with adjacent shallow-water and terrestrial habitats. Deep water may become depleted in oxygen, especially in eutrophic reservoirs common in populated regions where inputs of nutrients are high. Aquatic communities are thus transformed from those that require higher velocity flowing water and high oxygen content to those that are more typical of lakes (Nilsson and Berggren 2000). Because they typically have higher inflow rates in relation to water storage than in natural lakes, reservoirs are more likely to suffer from water quality problems associated with high nutrient and sediment levels.

Impoundment of flowing water in reservoirs has water quality consequences, some of which are positive. Sedimentation removes mineral and organic matter from the water, and along with it excessive nutrients may also be removed. If water is released from deeper portions of a reservoir, river reaches immediately downstream from dams may have low temperatures and/or low oxygen content.

Dams also form formidable barriers to upstream–downstream migration of fish and other aquatic organisms. Perhaps most important among these are anadromous fish such as salmon that are economically important as food sources as well as key components of some ecosystems. Salmon have been virtually eliminated from portions of the Columbia River system upstream from dams on several major Columbia River tributaries. Today salmon stocks on the Columbia are at less than 2% of their levels prior to the era of big dams and several populations are considered endangered.
The possibility that snail darters, an endangered species of fish that lives in Tennessee, would become extinct as a consequence of completing a major dam was the focus of a major controversy involving endangered species protection. The controversy, which ultimately did not prevent the dam in question from being constructed, increased public awareness of the environmental effects of dams.

**Dam failures**

Dam failures are relatively rare, but when they occur they are major disasters. Dam failures can cause great loss of life when populated areas lie downstream, which is often the case given the importance of dams in meeting human water needs. The floods that result from dam failures are large and often unpredicted, and the water rises very quickly, making it difficult for those in the path of the flood to escape. Dam failures have occurred throughout the history of dam engineering, and still occur despite the increasing sophistication of dam engineering. A review of some recent dam-related catastrophes provides some insight as to the range of causes and impacts.

- The Machhu failure in Gujarat, India, 1979, occurred when heavy rains caused flooding that exceeded the capacity of the emergency spillway (a channel intended to carry water when normal water-release structures are insufficient). The resulting flood inundated the town of Morvi downstream, killing thousands. The design criteria in use at the time the dam was built were found to have been inadequate, and the dam has since been rebuilt with a larger spillway.
- The Teton Dam, an earth-fill dam in Idaho, collapsed in 1975 as the reservoir was being filled, killing 14 people. The rock adjacent to the dam was highly permeable, and although during dam construction efforts were made to seal the rock this work was inadequate. Water seeped through the rock and undermined the dam, which then collapsed.
- A coal slurry impoundment dam failed during heavy rains in West Virginia in 1972, causing a flood on Buffalo Creek that killed 125 people. The dam had been built on unconsolidated mine waste and was not constructed to prevailing engineering standards.

These examples, among many others, show that dam failures are nearly always attributable to lack of adherence to standard engineering practices. In general, the existing knowledge base is sufficient to support dam construction and management practices that will prevent dam failures.

**Future of dam-building**

**Potential for new large dams**

The greatest potential for construction of new large dams is in less-densely populated regions where displacement of communities is less controversial. Worldwide, the greatest potential for hydropower production is in China, Russia, Brazil, and Canada. The US Energy Information Administration (2013) projects an increase in total world hydroelectric production of over 75% between 2015 and 2040; presumably most of that increase would be accomplished by building new dams although some could come from adding hydroelectric capacity to existing dams. There will also be increased demand for irrigation water as well as public water supply, and this will certainly mean construction of additional new dams.
DAMS

Where population growth has slowed, growth in water demand is also slower, and the shift from industrial to service economies has also reduced growth in water demand. Resistance to dam construction has also increased, driven by interest in conserving natural environments and concerns about displacement of populations in areas that would be inundated. Given the combination of decreasing availability of dam sites and major untapped water resources, as well as increasing public opposition to dam construction in at least some areas, it is unlikely that we will see a return to the fast pace of dam construction that was witnessed in the mid- to late twentieth century.

Dam removal

In some areas, notably the United States, there has been a significant increase in dam removal. Among the millions of dams that exist in the United States are many that have outlived their former utility and are no longer serving important purposes. Some of these have lost value because of sedimentation, while others have become unsafe as a result of structural deterioration. Removal of these dams is motivated by a desire to restore the ecological health of the rivers that they impound. While some dams in the United States were removed in the early twentieth century, the pace of dam removal has increased rapidly since the 1980s, and in recent years typically 50–70 dams have been removed each year. Over 1000 have been removed as of 2014. Most of the dams removed have been relatively small dams (2–5 m tall), but some larger dams have been removed. Among the more prominent dam removal projects is that on the Elwha River, Washington, in which two major dams have been largely removed allowing five species of Pacific salmon to return to the upper Elwha River.

Dasymetric mapping

Jeremy Mennis
Temple University, USA

Definition

A dasymetric map is a type of thematic map intended to represent a statistical surface of density, that is, a measurement that varies continuously over space and which captures the rate of occurrence of some phenomenon over space. In a dasymetric map, the statistical surface is represented by partitioning the space into a set of spatial units where the unit boundaries occur at the steepest escarpments of the surface, that is, where the density transitions most abruptly from one location to the next. Thus, a dasymetric map has spatial units that maximize within-unit homogeneity while minimizing between-unit homogeneity. Ideally, the density within any given spatial unit of a dasymetric map should be approximately equal. A dasymetric map is often contrasted with a choropleth map, which is also a thematic mapping technique used to represent the spatial distribution of a quantitative variable, density or otherwise. Unlike a choropleth map, however, where the spatial unit boundaries are typically derived from some convenience of enumeration or data collection that has little or nothing to do with the actual spatial variation in the data, a dasymetric map’s spatial units are derived from, and are intended to depict, the nature of the spatial variation in the mapped variable.

Consider, for example, the map of a set of points shown in Figure 1(a). A dasymetric map of this point distribution would depict the point density as a set of spatial units. Figure 1(b) shows such a dasymetric map, where the colors of the units correspond to densities ranging from relatively sparse (blue) to highly concentrated (red).

The depiction of a statistical surface using a dasymetric map demands that the true point distribution, or at least its representation in a statistical surface, is known. Most research in dasymetric mapping, however, is actually geared towards situations in which the true point distribution or underlying statistical surface is unknown, and the objective is to develop a strategy to infer and represent such a surface given the limitations of the available data. The process of dasymetric mapping, also called dasymetric modeling, typically refers to a set of techniques used to transform data encoded in a choropleth map representation into a dasymetric map, or at least a representation that better approaches a dasymetric map as compared to the original choropleth map encoding.

For this purpose, dasymetric mapping utilizes ancillary data, a spatial dataset separate from the original variable being mapped, but related to it. By defining a functional relationship between the ancillary data and the original mapped variable, data in the original choropleth map may be redistributed within a new set of spatial units that more accurately and precisely depict the true spatial distribution of the variable. Dasymetric mapping thus spatially disaggregates data encoded in a choropleth map to produce a more precise representation of the distribution of a density variable.
Figure 1  A dasymetric map representation of point density. (a) Distribution of points. (b) Corresponding dasymetric map representing the point density using a red to blue color gradient, where red indicates higher density and blue indicates lower density.

Origins and development

The idea of dasymetric mapping can be traced back to early modern maps of population distribution such as George Julius Poulett Scrope’s 1833 world map of population density. Petrov (2012) established that the term “dasymetric” (roughly fusing the Greek words for “density” and “measure”) was coined by the Russian cartographer Benjamin Semenov-Tian-Shansky in 1911 and implemented for an ambitious project to map the population of Eastern Russia. The technique was introduced to American cartographers in a handful of articles appearing in the journal *The Geographical Review* in the first half of the twentieth century, perhaps the most notable being J.K. Wright’s (1936) article, which described the basic form of the dasymetric mapping approach in detail. With a few exceptions, dasymetric mapping remained a somewhat obscure cartographic corollary to the more established choropleth mapping approach until the early 2000s, when geospatial technologies such as geographic information systems (GIS) and environmental remote sensing provided the data and computational processing to facilitate dasymetric mapping, resulting in a rapid rise of research articles advancing dasymetric mapping techniques.

The development of these geospatial technologies, and their application to mapping, has facilitated the convergence of cartographic dasymetric mapping research with related research in spatial statistics and environmental remote sensing. In statistics, the topic of areal interpolation addresses the issue of incompatible spatial
units, that is, where one has two spatial datasets to be analyzed but they are encoded in different tessellations of spatial units. Areal interpolation refers to the transformation of data from one set of spatial units to another, typically to facilitate data integration for analysis. Dasymetric mapping can be considered a specific type of areal interpolation, where an ancillary dataset is used to facilitate the transformation of data from one set of spatial units to another, finer set of spatial units. Such an approach using an ancillary dataset is also referred to as intelligent areal interpolation (Goodchild, Anselin, and Deichmann 1993).

Researchers in environmental remote sensing have also focused on modeling population distribution using remotely sensed imagery. This requires the development of a functional model between remotely sensed pixel values and population, which is typically derived using pre-existing population data encoded in a choropleth map. Thus, the use of remotely sensed imagery to derive population estimates is inherently dasymetric in its approach.

Applications

Dasymetric mapping can be applied to any spatially distributed variable that is conceptualized as a statistical surface representing density. However, it was developed specifically for population mapping, and in practice the vast majority of dasymetric mapping applications remain population mapping. Thus, the emphasis here is on population mapping, although the principles of dasymetric mapping may theoretically be applied to mapping the density over space of any punctiform variable. Dasymetric mapping has been applied to a wide variety of areas where more spatially precise population information is required compared to what may be available through surveys. In less developed countries, where census surveys may produce rather coarse spatial estimates of population, dasymetric mapping may be used to develop higher spatial resolution population estimates. Thus, dasymetric mapping has been used to develop high-resolution population datasets at national, continental, and global scales (Bhaduri et al. 2007).

One of the most prominent applications of dasymetric mapping has been for emergency disaster planning, where precise information on population distribution is required for identifying populations at risk due to floods, earthquakes, and industrial accidents, as well as to other hazards such as pollution. Here, dasymetric mapping is used to match incompatible spatial units containing population data and data describing degree of hazard or vulnerability. Relatedly, social services provision analysis, such as for health care, has utilized dasymetric mapping to develop more precise measures of population relating to accessibility to services. Dasymetric mapping has also been used extensively to develop historical series of population data, first, in cases where historical population data are encoded at a very coarse resolution and more spatially precise population estimates are desired, and, second, in cases where census enumeration units have changed over time (Gregory and Ell 2005). Dasymetric mapping has been used to develop a time series dataset of population change encoded using a single spatial tessellation and, thus, to facilitate the analysis of population change.

Ancillary data

Dasymetric mapping employs an ancillary spatial dataset to transform data from a set of choropleth map spatial units to a map that more precisely depicts the underlying statistical surface. The ancillary data layer is often an area-class map,
where the region of interest is exhaustively tesselated into a set of spatial units taking on nominal values, as with, for example, land cover classified into residential, industrial, agricultural, and vegetated categories. Typically, the result of dasymetric mapping is not necessarily an idealized dasymetric map, where the spatial units perfectly partition the surface into maximally homogeneous regions, but rather a map partitioning the original choropleth map units into a finer tessellation of spatial units using the ancillary data. This is typically performed by overlaying the original choropleth map with the ancillary data layer to produce a dasymetric map, where the dasymetric map units are perfectly spatially nested within the original choropleth map units.

The most common ancillary dataset for use in dasymetric mapping is land cover, often derived from classified remotely sensed imagery. In its most basic form, for instance, inhabited and uninhabited land may be distinguished between, and the dasymetric mapping procedure would then apportion the population within each spatial unit of the original choropleth map only to those portions of the dasymetric map with a land cover classified as inhabited. Thus, the population density of the inhabited portions of the map would increase compared to their original encoding in the choropleth map, and the population density of those uninhabited regions would be reduced to zero.

This basic formulation can be extended depending on the attribute precision and classification scheme of the ancillary data. For example, a land cover dataset that classifies inhabited land as either high-density residential, medium-density residential, or low-density residential, may be used to apportion a greater population density to high-density residential areas compared to the other land covers. Other useful land cover classifications include distinctions between various types of forest cover, agricultural land, impervious surface cover, and distinctions between developed and undeveloped land. While such land cover classes may not directly indicate habitation, they may be used as rough proxies for population density. For example, it might be expected that agricultural regions have a lower population density than urban regions, or that higher percentages of impervious surfaces indicate developed land with relatively higher population density compared to areas with a lower percentage of impervious surface. It is precisely these differences in the relationship of population density with different types of land cover that dasymetric mapping techniques seek to identify and exploit to transform population density data from a choropleth map representation to a dasymetric map representation.

While land cover is the most prominent ancillary dataset used in dasymetric mapping, many other types of datasets have been employed. Remotely sensed data from satellite and airborne platforms have been used extensively, including the use of raw spectral reflectance values, aerial photographs or panchromatic imagery for the manual and automatic detection of residential structures, and light detection and ranging (LIDAR) for estimating building volumes. Remotely sensed data indicating nighttime lights, vegetation indices, and digital elevation models (DEMs) have also been used. Road network data have been used effectively in dasymetric mapping (Reibel and Bufalino 2005), where higher road density is associated with higher population density, and may be used to distinguish developed areas from more rural areas. Parcel-level data, including zoning and building attributes, have also been used (Maantay Maroko, and Herrmann 2007), as has address-point data which encode the locations of addressable units. Publicly available spatial data
such as bus stops, schools, and raster pixel maps have also been used effectively (Langford 2013).

Techniques

Dasymetric mapping seeks to transform population data encoded in a choropleth map, or what can be termed a set of “source zones,” into a finer resolution dasymetric map composed of a set of “target zones.” Generally, this is done by overlaying the sources zones with an ancillary spatial data layer within a GIS software package, where the target zones are composed of the resulting polygons that spatially nest within the original source zones. This might be considered a process of dis-aggregation of the original source zones into a greater number of smaller target zones. Allocation of population to the target zones is dependent on defining the functional relationship between the underlying surface of population density, which is unknown, and the ancillary data layer.

Techniques for defining the ancillary data–statistical surface relationship for dasymetric mapping can be divided into those techniques that stem from the original cartographic basis of dasymetric mapping and those, generally more recent, methods that take a more statistically oriented approach. The most basic formulation, sometimes called the “binary” method, is simply to use an area-class map with only two categories of inhabited and uninhabited land. The entire population of each original choropleth source zone is then allocated wholly to the portion of the source zone that is occupied by inhabited land.

As an illustration of ‘binary’ dasymetric mapping, consider, for example, Figure 2. The map on the left of Figure 2 shows a set of source zones with the population density values for each spatial unit annotated. The map in the middle of Figure 2 shows the ancillary data layer with inhabited and uninhabited regions annotated. The map on the right of Figure 2 shows the resulting dasymetric map, created by overlaying the source zones and ancillary zones to create a set of target zones. Note that the target zones perfectly nest within the source zones. Here, the target zone component of each source zone that is spatially coincident with the uninhabited region specified in the ancillary layer is assigned a population of zero. The target zone that occupies the remaining inhabited portion of the source zone thus has a higher population density as compared to its original host source zone, as the

![Figure 2](image)

**Figure 2** Illustration of the “binary” method of dasymetric mapping: source zones (left), ancillary layer (middle), and target zones (right).
entire portion of that source zone’s population is assigned to the inhabited target zone that lies within it. For example, consider the source zone in the northeast corner, which has a population density of 10 people/km². This source zone lies half within an inhabited region and half within an uninhabited region, resulting in the original source zone being split into two target zones in the dasymetric map. Thus, the target zone in the uninhabited region has a population density 0 people/km² whereas the target zone in the inhabited region has a population density 20 people/km² – double that of the original host source zone – because the inhabited target zone accounts for the entire population of the host source zone in only half the area.

An extension of the binary method is the multiclass method, where, as the name implies, more than two categories of an area-class map are used. Here, however, the functional relationship of population density and the area-class map categories is not restricted to simply inhabited versus uninhabited areas, but rather indicates magnitudes of expected population density for each area-class map category. For instance, we might distinguish between agricultural, suburban, and urban land cover, where population density is assumed to increase in magnitude from the former to the latter land cover category. Thus, the population of a source zone composed equally of each of those three land cover categories would ascribe the most people to the urban land cover target zone, less to the suburban zone, and even less to the agricultural zone. The allocation of population to each ancillary class can be imposed a priori by the analyst, or may be derived empirically from the data.

A central principle for both the binary and multiclass dasymetric techniques is that of the limiting variable. That is, a nominal value in an area-class map serving as ancillary data limits the population density ascribed to areas with that nominal value. Once that population density threshold is reached, population is distributed to other dasymetric zones of other area-class map values. The binary method is the simplest implementation of the limiting variable approach, as the technique limits uninhabited land to a population density of zero, and then distributes that population within any given source zone to the other, inhabited, target zones within the original host source zone.

Another important principle of dasymetric mapping is the pycnophylactic property – the idea that the dasymetric map represents the same total population for the region as the original choropleth map. More specifically, the sum of the population for all the dasymetric target zones that fall within a given source zone (recall that the target zones spatially nest perfectly within the source zones) will be equal to the total population of the source zone in the original choropleth map. In dasymetric techniques that produce population estimates outside the bounds of the original choropleth map, the pycnophylactic property can be enforced by simply scaling the estimated population density for each ancillary class, such that the dasymetric technique distributes the population of the source zone to its constituent dasymetric zones based on a proportion of its population density estimates.

A key parameterization of dasymetric mapping is the functional relationship between the nominal ancillary data map categories and population density. This may be done through the expert knowledge of the analyst (Eicher and Brewer 2001), for instance an analyst may enforce a population density limit of zero for areas covered by water. More typically, however, the functional relationship between ancillary data and population density is derived through some sort of sampling (Mennis 2003). If it is possible to identify a source zone in the original choropleth map that lies entirely within a single type of land cover,
Figure 3  (Continued overleaf)
the population density of the source zone can be used to indicate the population density of that land cover class. Alternatively, if ancillary data polygons occur wholly within a choropleth map polygon, the population density for that ancillary data class can be observed. Various types of sampling techniques have been proposed to identify candidate sets of observations to estimate population density values for different ancillary classes. Various statistical approaches have been developed to define the functional relationship between the ancillary data and population density. A simple approach, given a sample of observations associating the ancillary data classes with population density values, is to simply calculate the mean population density for each ancillary data class and scale the figures to preserve the pycnophylactic property.

Figure 3 (from Mennis 2009) shows an example of this approach developing a dasymetric map of population for Delaware County, PA, where population data from the US Bureau of the Census at the tract level (Figure 3(a)) have been disaggregated using classified remotely sensed land cover data (Figure 3(b)) to produce a dasymetric map of population density (Figure 3(c)). Figure 4 shows a close-up view of the red boxed area in Figure 3(c). It can clearly be seen that the spatial precision of the population distribution has been substantially increased, with many
portions of the original tracts being assigned zero population while other tract components have increased in population density.

Regression has also been widely used for dasymetric mapping, where, say, the percentage that a particular ancillary class occupies within a target zone serves as the explanatory variable to estimate the total population. Other approaches include the use of the expectation maximization (EM) algorithm and maximum entropy (ME) modeling to iteratively refine the estimated population density for different ancillary data classes, as well as the use of kriging to improve the estimates derived from regression.

Considerations and future research

One of the major challenges of dasymetric mapping is in assessing the accuracy of its results, which is typically measured using root mean square error (RMSE) or similar metrics. Research has demonstrated that dasymetric mapping clearly offers a more accurate representation of population density than areal weighting, which does not employ an ancillary dataset and simply allocates population from source zones to target zones assuming a homogeneous distribution of the population. However, no single statistical methodology has been shown to be consistently better than the others. And while certain types of high-resolution ancillary data, such as parcels (Maantay, Maroko, and Herrmann 2007) and address points, have been shown to produce better results than coarser-resolution ancillary data, such datasets are not nearly as accessible or widely available as remotely sensed imagery indicating land cover, for which global datasets are publicly available. This issue is particularly germane in the case of less developed parts of the world where population data are

Figure 4  A close-up view of the red boxed area in Figure 3, comparing the dasymetric map (left) with the original choropleth map (right).
DASYMETRIC MAPPING

particularly coarse or unreliable and dasymetric mapping may be most useful.

The performance of dasymetric mapping is also highly dependent on the characteristics of not only the statistical technique and the ancillary data employed, but also the character of the region to which dasymetric mapping is applied, that is, whether it is urban versus rural, the types of settlement patterns, and so on. Comparisons of different dasymetric methods have shown that the most accurate method and most useful ancillary dataset can differ from region to region, even in a single country. So, while the use of ancillary data and dasymetric mapping clearly produces more accurate population maps, there is no single approach or dataset that is considered best for all situations.

Data model, event-oriented

Kathleen Stewart
University of Maryland, USA

In recent years, the development of theories that address spatiotemporal aspects of data modeling has attracted an increasing number of researchers from different disciplines. One aspect that has gained traction with researchers in the field of geographic information science is the development of theories and data models for events, that is, distinct happenings or dynamics, that involve change and are distinguished with both beginnings and endings (Galton 2006). Events have been identified as a core concept for using spatial information. This view holds that a spatiotemporal perspective is key for bridging different disciplines, and is necessary for addressing many contemporary grand challenges involving, for example, sustainability, biodiversity, climate, energy, and health (Kuhn 2012). Many of the dynamics that users are interested in representing in geographic information systems (GIS) can be understood as events – for example, the different interactions by individuals or vehicles as they move through a city (e.g., traffic jams, or stopping for traffic lights), and the kinds of dynamics that are experienced when a natural hazard such as flooding or wildfires strikes (e.g., setting up flood or fire barriers, or evacuating individuals). The interest in developing data models for events stems from the need for one or more of the following: to understand the range of events for a particular domain, that is, distinguish and classify different kinds of events that hold for a domain; to track the sequence of events over space and time; and to represent patterns and trends involving events, and predict where and when future events will occur.

In an event-oriented data model, events are given first-class status and treated explicitly in the data model. Events are spatiotemporal by their very nature (Grenon and Smith 2004; Worboys and Hornsby 2004). Events are associated with settings defined as spatiotemporal regions where events occur. This gives rise to representations of events that include space–time points, trajectories (space–time paths), and space–time narratives, or histories. Time is an integral part of events, and they may be formalized as being durative or punctual (Galton 2006). When event durations are modeled, this opens up possibilities for describing relations between events, for example, events that are spatially disjoint, overlapping, or simultaneous. Modeling events from the perspective of being durative (i.e., intervals) or punctual (i.e., instants) also invokes discussions of granularity, which is another core topic for geographic information science.

Events may be classified in a subsumption hierarchy or ontology. In this way, higher-level events (e.g., hazard events) as well as more specialized domain events (road closure events) may be classified and formalized. Methods for extending ontologies such that they capture dynamics as well as more commonplace static features are being discussed among researchers (http://vocamp.org/wiki/GeoVoCampSB2014).

Understanding the evolution of events over space–time or describing a sequence of events can be key for comprehending change in a domain; for example, for vegetation monitoring it may be useful to distinguish periods of abrupt versus gradual vegetation changes and the
events that may be driving these variations in vegetation (Kulik, Stewart Hornsby, and Bishop 2011). New details about the evolution of storm events at sea are revealed through the use of geosensor networks such as ocean observing buoys that measure barometric pressure over space–time in the ocean (Rude and Beard 2012). Different kinds of changes in pressure signal the onset or presence of storms and can be tracked as a series of events. In another study, changes experienced by different environmental regions, such as oil spills, may be similarly tracked, in this case as a series of topological events (e.g., appearance and disappearance, splitting, and merging events), and monitored by sensor networks (Sadeq, Duckham, and Worboys 2012). The evolution of such topological events gives insight into behaviors in the domain, offering opportunities for evaluation and management.

The patterns of different kinds of events can reveal important information about the dynamics experienced by a domain. Recently, researchers have applied geographic information retrieval techniques to automatically extract spatiotemporal information from a set of documents. Such extraction can result in a rich representation of spatiotemporal knowledge that is described in text, capturing what events have been reported in the documents and where and when they were reported. In this case, the motivation may be to understand the different kinds of events that occur. These events can be extracted and used in combination with associated spatial and temporal information that is also extracted from the documents to reveal more about the dynamics described within the documents. For example, spatiotemporal information from online news reports about severe storms impacting an area includes domain-related events associated with hazards (e.g., power outage or evacuation events), as well as higher-level events (e.g., more general hazard response or hazard recovery events) (Wang and Stewart 2014). Automated extraction of events from documents followed by geolocating the extracted events makes it possible to produce geographic visualizations of the extracted dynamics, highlighting the spatiotemporal progression of different kinds of events. In other research, an integrated software system called STempo offers users a set of exploratory and interactive tools for tagging or labeling events, analyzing sequences of extracted events, and interacting with visual representations of events detected by the analysis of text or media content (Hardisty et al. 2011; Stehle and Peuquet 2014). Used to extract and analyze, for example, political events from RSS (rich site summary) news feeds, this system offers capabilities to discover sequences of events that may contribute insights into political processes in a big data setting and contribute new methods that impact spatiotemporal knowledge discovery and analysis.

Data model, F-objects and O-fields

Thomas J. Cova
University of Utah, USA

A data model describes how reality is to be represented in a database. More specifically, it defines the logical entities, attributes, and relationships that comprise the structure of a database. An important step in data modeling is selecting the real-world phenomena to represent. A second step is deciding how to represent these phenomena in a simplified manner to yield a database schema. This process is defined in three steps: conceptual data model design, logical data model design, and physical data model design. The most challenging decisions lie at the conceptual level because this is where the domain semantics are defined. In contemporary database design, the focus at the logical level is on representing the conceptual model as a set of related tables, and the physical level, which addresses storing and retrieving information from a digital medium, is managed by a database management system (DBMS). As data modeling is the means by which the real world is represented digitally, it lies at the heart of database theory and practice.

In a geographic data model (GDM), some of the logical entities in the conceptual model will have a spatial expression. Furthermore, entity pairs will have well-defined qualitative and quantitative spatial relationships. A common entity type in transportation applications is a road, and an example relationship between two roads might be crosses if one road intersects another. In this case crosses is a relationship class, given the many ways in which two or more roads can cross. Geographic data modeling is described using the same three steps as data modeling, but additional design decisions must be made regarding which entity types require spatial representation, as well as how each one will be represented. Raster and vector are the two primary GDM approaches, with the former relying on subdividing geographic phenomenon into nonoverlapping spatial units of equal size and shape (e.g., square, triangle, hexagon) and the latter relying on representing geographic phenomena using points, lines, and polygons.

As noted, a significant step in geographic data modeling is deciding whether geographic reality comprises discrete geographic objects or continuous fields (Couclelis 1992). In the former view, space is viewed as a container populated with geographic objects, each with identity, extent, attributes, relationships, and behavior. This view is very compatible with natural language, as geographic reality is generally described using objects. From physiographic features such as mountains, rivers, and lakes, to cultural ones such as roads, buildings, and cities, people have an inherent tendency to ascribe identity and extent to geographic features. A good example is weather phenomena, as in, “A cold front (object) is crossing the desert (object) and heading towards the mountains (object).” The alternative to an object view is a continuous, field-based view where geographic reality comprises surfaces. In this view, every location is assigned a value drawn from an attribute domain. Temperature, elevation, and land cover are three themes that are commonly viewed as fields, and it is common to view every location on the landscape as having a scalar value for each of these.
attributes. Using weather phenomena again as an example, “The temperature at every location (field) on the earth’s surface is influenced by its elevation (field) and land-cover type (field).”

It is important to recognize that the field and object views are not inherent properties of geographic phenomena. Rather, they are conceptual perspectives that can be adopted based on the application needs of the user or decision-maker. Thus, any geographic theme can be perceived through the lens of either view. For example, an object view of terrain might treat landform features as entities with identity, attributes, and spatial relationships with other features (e.g., an alluvial fan that abuts a mountain or a meandering river that bisects a valley). In contrast to a landscape populated with objects, adopting a field view of terrain involves viewing every location as having a value for each landscape attribute, as in elevation, slope, and aspect. In many cases, the view that a decision-maker adopts is revealed in casual conversation. For example, reference to a region’s highpoint or “the location of greatest annual rainfall” reveals a field view, but reference to a count of geographic features such as peaks, lakes, and canyons reveals an object-based view.

In the case of the field view, geographic phenomena are conceptualized as surfaces where every location in an infinitely dense space (in theory) is mapped to a value drawn from an attribute domain. In most cases, the attribute domain consists of a single value drawn from a nominal, ordinal, interval, ratio, or cyclic scale. A land-cover map is a common example of assigning every location a designated land-cover type (e.g., forest, grassland, impervious), and a temperature map is an example of mapping every location to a value selected from an interval scale (e.g., Fahrenheit or Celsius). In addition to nominal and scalar fields, vector fields refer to the case where every location is mapped to a vector with direction and magnitude. Vector fields are often used in modeling physical processes such as the flow of wind, water, or fire across a landscape, but they are also applied in human geographic settings including modeling migration, economic, and transportation flows. Tensor fields are a unique case where every location is mapped to a matrix that represents strain at that location, and this class of field is widely used in geologic applications such as seismology.

In an object view, geographic space is conceptualized as an infinitely dense set of locations populated by discrete objects that represent geographic features. Objects can be point, linear, or areal in nature and may be contiguous or not. Example features routinely viewed as objects include buildings, roads, rivers, subdivisions, and airports. However, real-world features are not limited to being viewed as one object type. For example, a city may be viewed as a point at one map scale but a polygon at another. Objects can also be combined to create composites, as in the case of a subdivision object that comprises a set of constituent parcel, building, and road objects, each represented differently using points, lines, and polygons. In theory, each finite geographic object still occupies an infinite number of locations because there is no limit on locational precision within its boundary. However, precision limits are introduced in representing objects and fields using raster and vector geographic data models in the context of a finite digital store.

Although the field/object dichotomy is well articulated and widely accepted, there are interesting examples that blur the line between the two views. One example is a density surface where a filter (or kernel) of a fixed size and shape is used to define a count at each location of a particular object type contained within the filter. The term “density” implies an object view, as something is being tallied per areal unit, yet the term “surface” implies a field view. Population
density surfaces are a common example where the underlying object of interest is an individual, but a filter is used to assigns a value to each location in a field based on an estimate of the number of people within the filter (e.g., circular buffer of 1 mile). Thus, a peak in this surface would be the location with the highest population density using this size and shape of filter, and a valley would be a lower-density area. A second case that blurs the field-object line is a fuzzy spatial model of a geographic feature. In a fuzzy spatial model, each location is defined by a function ranging from 0 (not in the object) to 1 (completely in the object) that defines the degree of membership of that location in the object. While the underlying feature of interest is an object (e.g., lake, mountain, valley), the result is a field view of the locations that comprise the object to varying degrees.

Although fields and objects address a key means by which geographic phenomena are conceptualized, representing them in a computer requires a finite data spatial model. While it is common to map a field view to a raster data model and an object view to a vector data model, fields are also represented using a vector data model and objects are represented using a raster data model. There are many examples of representing a field using vector data, as in a soil class map where every location has a soil class defined using polygons. Contours are another example where every location has an elevation (albeit with some interpolation) but the representation relies on the vector model. An example of using a raster to represent objects is using the fuzzy membership example above where every cell in the raster represents the degree of membership of that cell in a larger object using a 0–1 scale.

While the field/object dichotomy is widely accepted, researchers have explored hybrid views for decades. An obvious line of inquiry is to combine or link these two views. One example is objects that possess internal field-like qualities where every location within the object’s boundary is assigned a scalar value (Yuan 2001). A good example of this form of representation arises in the context of Doppler radar data for a moving thunderstorm. In this case, a storm is considered a moving object with identity, extent, and relationships with other objects (e.g., the storm is over the city). Yet pulse-Doppler radar data routinely reveal significant variation within a storm cell regarding spatial attributes such as precipitation type and rate (e.g., intense rain). This representational approach has also been applied to wildfires which are viewed as objects within identity and extent. While object-based statistics are commonly used to describe wildfires, such as percent contained, which requires a well-defined boundary, they also have important internal field-based variation in spatial attributes such as burn intensity and severity. This hybrid view has been dubbed a field-object or F-object.

Another approach to combining the field and object views is to define a field of spatial objects (Cova and Goodchild 2002). Similar to scalar, vector, and tensor fields, an object-field (or O-field) assigns to every location one or more objects, which may or may not include this location in its footprint. One example that arises in hydrologic theory is the case where every location on the landscape has a watershed defined by an uphill catchment or basin. In this case, a field of watershed objects can be defined where every location is mapped to its watershed (object). In moving to a more practical finite context, each location’s watershed can be represented as a set of contiguous raster cells or a polygon. Another interesting example is a viewshed, or the set of locations that can be seen from a given location. If every location is mapped to its viewshed, which may or may not be a contiguous region, this defines a field of viewsheds. To generalize O-fields, every location is mapped to one or
more objects that can be point, linear, or areal in nature (or a combination), and these objects may or may not contain the original field location in their extent. These mappings can be viewed as a spatial hyperlink that explicitly links a location to an object or set of objects. For example, the location of a residence could be linked to each family member’s work, school, or current location, which might be useful in designing household dispersion metrics.

One application area where O-fields are useful is in interactively exploring a large set of spatial alternatives that are too difficult to view in a single static map. This problem can arise in using spatial decision support systems (SDSS) to generate candidate solutions derived from an optimization model. Examples of spatial optimization model classes include location-allocation, corridor, and land-allocation models. The focus in an SDSS context is often identifying a single best solution, or a small set of nondominated solutions if the problem is multi-objective, to present to a decision-maker. This can place too much value on a single best solution, which may include a significant amount of model and data uncertainty. This uncertainty arises from the quality of the input data, the sensitivity of the model to changes in its parameters, or the very definition of “optimal.” For most spatial optimization models, a facility or location can be constrained to being in the solution, which can then be used to generate a field of solutions (point, line, or area), where every location has an optimal solution that includes that location (Cova and Goodchild 2002). This field can then be provided to a decision-maker for interactive exploration to view a larger number of possible solutions to a spatial planning problem. While many of these solutions may not be nondominated in the globally optimal sense, the resulting O-field allows a decision-maker to ask the question, “What is the best solution if we put the facility here?” where the definition of “here” can be controlled by the decision-maker.

A second area where O-fields and F-objects may have application is in representing new types of geographic variation. While scalar, vector, and tensor fields cover much of what we perceive in geographic reality, there are many types of variation that remain unexplored and unrepresented. Examples of this often arise in considering the universe of possible geographic features that might exist in any context. For example, consider the geographic variation that arises from visualizing all possible biological reserves, facility location patterns, watersheds, urban futures, fire-spread scenarios, or spatial interaction flows in a given study area. The results of this thought experiment yield very different types of geographic variation than typically handled by traditional fields, which excels at representing variation such as temperature and elevation. Similarly, the internal variation within geographic objects that is not often represented, such as the temperature variation across a residential rooftop throughout the diurnal cycle, or the variation in albedo across an aircraft’s fuselage, is also an example of where an F-object may have value.

Geographic dynamics also raise very interesting cases where F-objects and O-fields may have application. Consider the case where F-objects and O-fields are allowed to vary over time in location, shape, or internal variation (Goodchild, Yuan, and Cova 2007). For example, a field of biological reserves, where every location has an associated optimal reserve that includes that location, may be allowed to change in shape so as to incorporate the impact of climate change predictions on the elements used to define habitat suitability over time. This would allow a decision-maker to ask questions as to how resilient a given biological reserve might be under climate change. Resilient reserves in this
DATA MODEL, F-OBJECTS AND O-FIELDS

In summary, while fields, objects, and current hybrids are established concepts in geographic information science, there are numerous areas for further research. One example is exploring the deeper structure of fields and objects, particularly as it relates to theories that might unify the two perspectives (Goodchild, Yuan, and Cova 2007). Another example is dynamic geographic modeling, as much of the phenomena in the geographic world of interest are in motion (Galton 2004; Pultar et al. 2010). Spatial uncertainty is another area that holds opportunity for advancing our understanding of F-objects and O-fields, as models of uncertainty in this context would be hybrids of existing uncertainty models. Designing geocollaborative spatial decision support systems is another area where hybrid models may show promise in helping decision-makers visualize and compare a larger number of spatial alternatives. Multiscale geographic objects is another area that may have potential to advance theory and practice, as in the case where geographic features are viewed as different object types at different scales (e.g., a crowd of people as an object at one scale but a set of individuals at another). Finally, the intersection of each of these areas is also a potentially rich area for exploration as in uncertainty in dynamic geographic domains, or scale in spatial decision support systems.

Data model, moving objects

Atsushi Nara
San Diego State University, USA

A data model for moving objects is a blueprint that describes data of interest related to movements of objects and a set of operations represented in an information or database management system. Designing an appropriate data model fosters conceptual understanding of the dynamic phenomena of moving objects, yields efficient data storage and retrieval, and further facilitates spatiotemporal analytical processes.

Various data models have been proposed to efficiently and effectively store, manage, query, and analyze moving objects data. This entry starts with the description of fundamental elements of moving objects and their abstract data types. Then it reviews data modeling approaches for representing moving objects including conventional spatiotemporal data model, constraint model, moving object data model, semantic trajectory data model, event-based data model, and models for handling big moving object data.

Fundamental elements and abstract data types

Fundamental elements of moving objects can be defined by space, time, and objects, where each element has its own properties represented by values of attributes. Space consists of locations or places, where a reference system is necessary to distinguish positions in space, such as coordinate-based referencing, division-based referencing, and linear referencing (Andrienko et al. 2013). Using a coordinate reference system, positions can be defined by a pair of coordinates (2-D) or a trio of coordinates (3-D), such as global positioning systems (GPS) points. Division-based referencing defines positions based on compartments of a geometric or semantic-based division of the space, which can describe movements based on visited places (e.g., city and state). Linear referencing refers to relative positions of a moving object along linear objects such as streets. For instance, movements can be described by a sequence of street addresses.

The time element in moving objects refers to a moment, or position in time. The Gregorian calendar and standard units of time (i.e., seconds, minutes, and hours) are used as a typical temporal referencing. Natural and human cycles are also common temporal referencing, such as the weekly/monthly/seasonal cycle and the cycles of working hours/days. In addition, a set of two successive time elements can represent the interval or period of moving objects.

Moving objects are entities that change their position over time. In the physical world, an act of moving objects or movement is a continuous phenomenon in space and time, where the spatial continuity is a 2-D or 3-D process and the temporal continuity is a 1-D and unidirectional process. Due to technical and technological limitations, moving object data can only be collected in the form of spatially and temporally discrete objects. Such moving object data may be modeled by treating movements as discrete entities in space and time. On the other hand, a continuous data model, which employs a function to represent movements in order to retrieve any
temporal snapshot location of a moving entity, may be used.

Common abstract data types for moving objects are moving points, moving lines, and moving regions, which are extended from basic vector-based spatial data types: points, lines, and polygons, respectively. The moving point abstraction describes an entity moving around in a 2-D plane or higher dimensional space, for which only the time-dependent location is of interest; examples of moving point entities are pedestrians, cars, animals or packets represented as points. The moving line abstraction is defined as an entity moving around in the plane or higher dimensional space, for which the time-dependent shape and/or the 1-D extent are of interest; examples include traffic congestions on a road network, a shoreline, or a fire front of a wildfire event represented as polylines. The moving region abstraction represents an entity moving around in the plane or higher dimensional space, for which the time-dependent shape and/or 2-D extent are relevant; examples are hurricanes, city/urban expansions, and flocks of migrating birds represented as polygons. Each abstract data type can be represented discretely or continuously (Figure 1).

Spatiotemporal data model

Moving object data consist of three fundamental elements, space, time, and object, which are generally classified as spatiotemporal data; therefore, any existing spatiotemporal data model can represent some aspects of moving objects. The historic development of spatiotemporal models, including snapshot model, space–time composite (STC) data model, simple time-stamping model, event-oriented model, three-domain model, history graph model, spatiotemporal entity-relationship (STER) model, object–relationship model, spatiotemporal object-oriented data model, spatiotemporal unified modeling language (STUML), and moving object data model, has been reviewed by Pelekis et al. (2004). Their review describes the taxonomy in detail in terms of temporal semantics, spatial semantics, spatiotemporal semantics, and query capabilities.

Almost all models can handle discrete changes, while movement and continuous change was not in the priorities in earlier approaches such as snapshot, STC, and simple time-stamping models (Pelekis et al. 2004). In addition, most of the models can capture some aspects of

Figure 1  (a) Discretely changing point, line, and region; (b) continuously changing point, line, and region. Source: Güting and Schneider 2005. Adapted with permission of Elsevier.
the notion of change, including changes in geometry, topology, and/or attribute; however, the earlier models mentioned previously do not support all types of change. More recent approaches support these two concepts (movement and continuous change) and provide functionality that is related to the evolution of spatiotemporal objects; for example, recent data models based on object-oriented and moving object approaches maintain methods and functions for defining the topological relationship and measuring the evolution of spatiotemporal objects in space and time (Pelekis et al. 2004). These two approaches permit the database representation of the complex structure of moving objects, which arise from continuous motion modeling, multiple time line representation, complex behavioral and semantic spatiotemporal queries, and big data management (Pelekis et al. 2004).

Constraint model

The basic idea of the constraint approach for modeling a continuous movement is to finitely represent the movement by means of a Boolean combination of polynomial equalities and inequalities (Macedo et al. 2008). Generally, a constraint model is defined as:

\[ \{ (x_1, \ldots, x_k) \in \mathbb{R}^k | \Phi(x_1, \ldots, x_k) \} \]

where \( k \) is the number of variables, and \( \Phi(x_1, \ldots, x_k) \) is a formula over variables \( x_1, \ldots, x_k \). A constraint model can represent trajectories by considering them as a collection of infinite points connecting a finite number of sample points. For example, with observed moving points, \( P_{(t,x,y)} = \{ (0, 2, 1), (3, 1, 2), (5, 1, 4) \} \), the 2-D movement can be described by the following linear constraint model.

A moving object data model considers time as an integral part of the spatial entities and captures both change and movement of entities represented by abstract data types: moving points, moving lines, or moving regions. A trajectory-based approach is a specific moving object data model that focuses on moving points. A trajectory is defined as the expected route of a moving object from one location to the next. As a simple abstraction, a trajectory \( (T) \) can be a model for a motion path of a moving object consisting of a sequence of sampled time-stamped locations \( (p_i, t_i) \) where \( p_i \) is a 2-D point \( (x_i, y_i) \) and \( t_i \) is the recording timestamp of \( p_i \) defined as (Pelekis and Theodoridis 2014):

\[ T = \{ < p_1, t_1 >, < p_2, t_2 >, \ldots, < p_n, t_n > \} \]

By assuming that the moving object moves with constant speed along a straight line connecting two succeeding observed points in the unconstrained Euclidean space, a simple liner

\[ \{(t, x, y) \in \mathbb{R}^{14^2} | t \geq 0 \land t \leq 3 \land x + y = 3 \land x \geq 1 \land x \leq 2 \lor t \geq 3 \land t \leq 5 \land x = 1 \land y \geq 2 \land y \leq 4 \} \]
interpolation function can find a location \( (p_t) \) at a nonrecorded timestamp \( t \) as follows:

\[
p_t = \left( x_i + \frac{t - t_i}{t_{i+1} - t_i} (x_{i+1} - x_i), \right.
\]

\[
y_i + \frac{t - t_i}{t_{i+1} - t_i} (y_{i+1} - y_i) \right)
\]

where \( x \) and \( y \) represent a coordinate of a 2-D space, and \( t_i \) and \( t_{i+1} \) are two consecutive recorded timestamps. For modeling network-constrained movements (e.g., a moving vehicle on a transportation network), segment-oriented model, edge-oriented model, or route-oriented model can represent the location of an object by segment, edge, or route respectively.

Trajectory-oriented queries are expected to be of great interest in a database that supports trajectory data models. Figure 2 shows examples of trajectory-oriented queries: (i) a timeslice query to find the locations of trajectories at a given timestamp \( (Q1) \); (ii) a spatiotemporal range query to find the portions of trajectories inside a given spatial region during a given time interval \( (Q2) \); (iii) nearest-neighbor queries to find the trajectories that lie nearest to a given point during a given time interval \( (Q3) \), nearest to a given trajectory during a given time interval, and nearest to a given point in every time instance of a given time interval \( (Q5) \); and (iv) a trajectory similarity query to find the trajectories that are the most similar to a given trajectory \( (Q6) \) (Pelekis and Theodoridis 2014).

To efficiently perform queries on moving object data, the design and construction of index structures play a significant role in a database. The main task of an index structure is to ensure fast access to target records in a database on the basis of a search key (Güting and Schneider 2005). One of the earliest techniques for indexing trajectories of moving objects is the 3-D R-tree, which is an extension of R-tree in a 3-D space (Pelekis and Theodoridis 2014). 3-D R-tree for trajectory data treats time as an extra

DATA MODEL, MOVING OBJECTS

Spatial dimension and it decomposes trajectories in 3-D segments storing segments’ minimum bounding box (MBB) in its nodes (Peleakis and Theodoridis 2014). One challenging issue with 3-D R-tree is to find the optimal number of MBBs per trajectory. Other proposed indexing techniques for moving object data include, for example, TB-tree for free space movement, and FNR-tree and MON-tree for network constrained movement.

To facilitate effective representation and data management of moving objects in a database, several spatiotemporal database management system (DBMS) prototypes have been developed. SECONDO, one of the first database system prototypes that can handle moving objects, is an extensible DBMS and provides a native implementation of the moving object model (De Almeida, Güting, and Behr 2006). HERMES is another database engine that can process, manage, and analyze moving object data (Peleakis et al. 2008).

Semantic trajectory data model

Semantically enriched trajectories can support a meaningful interpretation of the behavior of moving objects. The process of semantic enrichment involves the annotation of a whole trajectory or parts of a trajectory with behavioral characteristics. For example, trajectory segments of an individual can be contextualized with transportation modes. Similarly, a trajectory from raw GPS data can be converted to a sequence of visited places and then labeled with activities performed. Spaccapietra et al. (2008) introduced a semantic trajectory data model based on the concept of stops and moves. A stop is defined as a part of a trajectory where a moving object stays for a minimal amount of time, while a move is the movement of the moving object between stops. Figure 3 represents a trajectory design pattern, which holds object types for representing trajectories and their “begins,” “ends,” “stops,” and “moves” (Spaccapietra et al. 2008). In the model, stops are described by a group object type B.E.S. consisting of begin, end, and stop objects, while moves are described by an object type Move. Both B.E.S. and Move objects have a life cycle and a geometry. Moreover, a life cycle corresponds to a time interval and a geometry is shown as a point for B.E.S. or as a time-varying point for Move. Two relationship types From and To bearing both a topological constraint and a synchronization constraint enforce the connection between a B.E.S. and a Move in space and time. A B.E.S. and a Move can be linked to a hook spatial object type SpatialOT that represents the corresponding location, such as city, lake, road, and store.

Event-based data model

Instead of focusing on the location-based aspect of movement or quantitative descriptions of motion, an event-based model of moving objects employs the perspective of events associated with movement. Hornsby and Cole (2007) introduced an event-based approach and reveal notable patterns of events. In the model, an event sequence, $E$, is represented as a set of events:

$$E = \{ e_{i,z,v,t(1)}, e_{i,z,v,t(2)}, \ldots, e_{i,z,v,t(n)} \}$$

where $e$ is an event (e.g., departure, arrival), $i$ is the identifier of the object for which the event is associated, $z$ refers to a spatial region or zone where the event happens, $v$ is an event attribute, and $t$ is a timestamp reflecting when the event happened. Events are modeled as being instantaneous (i.e., no duration and mark a change in state of an object). To reveal distinguishing patterns from event sequences, the model uses
pairwise groupings of events or event combinations based on three key attributes: object id, event description, and location. The event combinations identify eight possible patterns of events in transits (Table 1). While P1–P4 are patterns of events arising from multiple sequences that correspond to the movements of single objects, P5–P8 represent patterns of events involving multiple objects. The combination of key attributes of events can identify three notable patterns of events such as repeating (P1), collocating (P2), and reiterating (P5), whereas P1, P3, P4, P6, and P7 can be classified as common patterns in routine transits unless further information is available. P8 is a nonrelated pattern where different objects experience different events in different zones. A repeating event pattern (P1) describes that a transit occurs when a moving object is associated with two events having the same description and occurring in the same spatial region. A collocating event pattern (P3) explains that different event combinations of the same object take place in the same spatial region.
A reiterating event pattern (P5) represents occasions where the same event combinations occur to multiple objects in the same zone within a constraining time window. This pattern captures the convergence of objects into an area or the exodus of objects out of an area such as traffic congestion and evacuation respectively.

Handling big moving object data

Wearable devices equipped with location-aware technologies are rapidly becoming a part of everyday life. These devices enable us to collect data about moving objects in large volume, high frequency, and high variety. A massive amount of data, a very fast update cycle, and a heterogeneous data structure pose new challenges of how to efficiently and effectively store and manage such big moving object data in database systems.

One solution is to utilize the high performance computing (HPC) in the form of parallel and/or distributed databases, such that data processing and computation can operate simultaneously on multiple moving objects, for example. A parallel database system is implemented on a tightly coupled multiprocessor and increases performance through parallelization of various database tasks, such as loading data, building indexes, and evaluating and executing queries. There are three architectures for passing information in parallel database systems: (i) shared memory: any processor has access to any memory module or disk unit; (ii) shared disk: any processor has access to any disk unit; and (iii) shared nothing: each processor has exclusive access to its main memory and disk units. A distributed database system is a collection of logically interrelated databases distributed over a computer network usually in a shared-nothing architecture.

An alternative approach to handle big data is to utilize MapReduce, a simplified programming framework with an associated implementation for processing and generating large datasets using a scalable distributed file system. MapReduce consists of two processes: mapping and reducing. Mapping is a process that restructures an input dataset of key-value pairs into groups of intermediate key-value pairs. Reducing is a process that takes an intermediate key and a collection of values to generate a smaller set of tuples. Tan,
Luo, and Ni (2012) developed a scalable big spatiotemporal data storage system, CloST, to support data analytics using Hadoop, which is an open source implementation of MapReduce along with the Hadoop distributed file system (HDFS). A data model used in CloST consists of three core attributes: object id, location, and time along with other attributes (Oid, Loc, Time, A₁, ..., Aₙ). CloST introduces a three-level hierarchical partitioning approach based on the core attributes to enable efficient parallel processing of all object queries with any possible spatiotemporal ranges (Figure 4).

Parallel SECONDO is another data model that combines Hadoop with a set of SECONDO databases to perform queries and analyses on massive sets of trajectory data in the cloud (Lu and Güting 2014).

Data models for moving objects are, by definition, spatiotemporal and multidimensional. Hence, the data object representation involves semantic, spatial, and temporal components. Various data models have been developed to support management, query, and analysis of moving objects. Now, ubiquitous location-aware mobile devices have been generating a deluge of
moving data that can be benefitted greatly with HPC and MapReduce to meet data processing, management, and computational challenges.

Levels of representation

The representation of space involves three levels of abstraction, including conceptual models, spatial data models, and spatial data structures. Conceptual models describe the conceptualized space, that is, the essential spatial components and the relationships between them. For example, a population can be conceptualized as individuals at various locations, subpopulations within administrative regions, or population density varying continuously in space. The relationships between them refer to those between locations, between regions, and within a continuous space. At the second level, the spatial data model formalizes the spatial components and their relationships in terms of basic geometry (e.g., points, lines, polygons, and grids) and topology. The spatial data structures at the third level implement these components and relationships in a computing environment.

There are various nomenclatures used to refer to the three levels, but it is widely accepted that the spatial cognition process of humans is at multiple levels and the number of levels is often three, as discussed in the literature. The conceptual models, spatial data models, and spatial data structures represent three distinct yet sequential perspectives. That is, a naive observation, a formalization of the observation, and an implementation of the formalization.

Spatial sciences are interested in the spatial distribution and temporal dynamics of phenomena, be it environmental or human behavioral. Unlike those models that directly describe environmental and behavioral processes, spatial data models are models of data. They focus on the representation of spatial forms of phenomena, such as geometry and topology.

One limitation is essential to the formulation of these data models. The computing environment is finite and discrete; a geographic space must be divided into a finite number of discrete pieces to allow for the implementation of a data model. Because of this limitation, spatial data models focus on the design of the discretization and the relationships between the discretized pieces.

Three types of information are associated with a spatial data model: location, attributes, and topology. A location is represented by a pair of coordinates. Attributes describe properties of partitioned pieces. Topology, on the other hand, represents the spatial relationships between these pieces. There are two classic data models: vector and raster. These are two fundamentally different types of data model, representing two different ways of dividing space according to the two commonly recognized dichromic views of space: object and field views.

Object and field views

Field is a fundamental concept in science, especially in mathematics, physics, and other science disciplines that are built on mathematical and physical principles. The concept of object came
DATA MODEL, OBJECT-ORIENTED

with the rise of object orientation, the current computing paradigm since its introduction in the late 1980s. When the two concepts were extended to the spatial sciences and paired together, the object-field view offered a profound framework for conceptual models of spatial phenomena. With the object view, reality is conceptualized as discrete objects littered in space (hereafter referred to as “spatial objects”). In contrast, the field view conceptualizes the reality as a continuous plane with variations at an infinite number of locations. The object versus the field view has been used to guide the conceptualization of spatial phenomena.

It is easy to conceptualize certain phenomena as discrete spatial objects and other phenomena as continuous fields. A continuous phenomenon can be divided indefinitely without changing its essential nature, while a discrete phenomenon most likely cannot be divided without altering its identity. For example, the water in a bucket may be continually divided into halves and yet remain water, but once a bucket is divided into two halves, neither half is a bucket any more. The object and field views are inclusive. A phenomenon can be represented as either a spatial object or a field depending on the spatial scale of the observation, the purpose of a study, and convention. The two conceptualizations can coexist as well.

In addition to easily recognizable spatial objects and fields, spatial regions are a third phenomenon that has been discussed in the literature. Spatial regions have dual qualities. They appear to be discrete as spatial objects, but are not quite as independent because they are always parts of a continuous field. The spatial objects, spatial regions, and fields are considered conceptual models of spatial phenomena. They are not directly tied to either of the two spatial data models, vector or raster. It is first necessary to understand the characteristics of spatial objects, spatial regions, and fields before selecting the ideal data model to formalize them.

Characteristics of spatial objects, regions, and fields

The characteristics of spatial objects, spatial regions, and fields have been actively discussed in the geographic information science literature. Spatial scale, boundary, attributes, process, and mobility have been used to characterize the three types of conceptual models as well as to distinguish between them.

Spatial scale is an essential characteristic of all spatial phenomena. From an ontological perspective, this characteristic uses the human body as the reference scale to categorize spatial phenomena into small and large objects, as well as small and large fields. The small objects include everyday tabletop objects that are smaller than the human body and can be manipulated. The large objects are larger than the human body, but can be easily conceptualized as objects, such as buildings. Spatial scale is applicable to spatial regions when they are equated with spatial objects. Fields can be small or large although they are continuous. The small fields are those that can be experienced by humans, although not completely all at once, such as a landscape. Large fields are an extension of small fields beyond the range of direct human experience, such as space beyond the Earth. These categories of objects and fields have important implications in identifying appropriate conceptual models for spatial phenomena.

Boundary is also a common characteristic of spatial phenomena, especially for those that are conceptualized as spatial objects and regions. Boundaries are as essential as the internal content to the ontological makeup of spatial objects and spatial regions. The aforementioned small and
large objects, along with spatial regions, are commonly considered as well bounded. There are three types of boundaries for spatial objects and regions: bona fide boundaries, fiat boundaries, and indeterminate boundaries. The bona fide boundaries include those that exist physically and can be precisely located in space, such as the boundary between a lake and land. The fiat boundaries include those that do not exist physically but can be precisely placed in space, such as administrative boundaries. The third type refers to indeterminate boundaries that physically exist but cannot be located precisely, for example, the boundary between “tall grass prairie” and “short grass prairie” or between “Midwest” and “Northeast.” With boundaries, spatial objects and spatial regions can be readily identified. Fields are spatially extended without a boundary or the boundary is not a concern.

Attributes are a third characteristic. From the ontological viewpoint, things are distinguished from one another by their unique attributes. These attributes can be spatial (e.g., area, adjacency) or nonspatial (e.g., magnitude, type). The distinction between spatial objects or between spatial regions is assessed by the attribute values. These include, for example, the magnitude or threshold of attribute values (e.g., climate zones), the homogeneity or dominance of attribute values (e.g., land-use and land-cover zones), or the spatial association of attribute prototypes (e.g., soil associations). Fields, on the other hand, are viewed as a mapping between attributes and an indefinite number of spatial locations. Each location is associated with attributes, and these attributes vary continuously across the space.

Process is another essential characteristic of spatial phenomena. According to ontological principles, all things change. Process represents changes to the state of spatial objects, spatial regions, and fields. Similar to attributes, processes can be spatially oriented (e.g., direction, speed) or nonspatial (e.g., magnitude, type). There are numerous examples of identifying spatial objects and spatial regions by environmental and socio-behavioral processes, such as the delineation of watershed and traffic generation zones. Similar to attributes, each location of field is associated with processes, and these processes vary continuously across the space. Because process can be represented as an attribute change, the attribute and process characteristics are often paired together in the identification of spatial objects, spatial regions, and fields.

Mobility can be considered as a special case of the process characteristic, but because mobility implies the independence of objects from locations, this characteristic stands in its own right. While moving, objects maintain their identity, properties, and behavior. Many spatial objects can be mobile or moved, such as an animal or a vehicle. When an object moves, all parts of the object move together. Spatial regions can also be mobile, but it is their attributes and processes that are passed to the adjacent regions, not their own parts. The same “pseudo” mobility applies to fields. A field does not move, nor does its parts. It is its attributes and process that move across space. A close analogy is the movement of an ocean wave. When the water molecules make a vertical motion, but have zero horizontal displacement, the attributes (the wave crest) and process (force on the shore) of a wave move forward. Another example is the movement of a “wave” in a sports stadium. By a sequence of vertical motions of the members of an audience (standing up and sitting down), a wave moves around the stadium, while its parts (the audience members) do not change their locations. The style of mobility helps distinguish between spatial objects, spatial regions, and fields.
In summary, spatial objects, spatial regions, and fields possess any number or combination of the aforementioned characteristics. The spatial objects exist in both small space and large space, have discrete boundaries, properties, and processes, and are mobile (or movable). Spatial regions have definable boundaries, attributes, processes, and can be mobile. They are extracted out of a continuous field and yet they are often conceptualized as objects. They carry dual qualifications but do not comply fully with the discrete definition of objects or the continuous definition of fields. The dual qualification of spatial regions presents challenges as well as flexibilities in their representation. Fields have large scales, no boundaries, continuous change of the attributes and processes, and pseudo-mobility.

Spatial networks are a unique form of spatial phenomenon (e.g., stream and transportation systems). A network consists of nodes and links. Unlike single-formed spatial phenomena, such as polygon-formed phenomena or line-formed phenomena, the geometric makeup of networks requires two forms, points and lines. The dual formed nature of networks adds unique complexity to its conceptualization. Of spatial object, spatial region, and field models, spatial networks most closely resemble fields. They are 1-D fields embedded in a 2-D space. Networks can be fields because they exist in small and large space; they are continuous although in a linear form, carry attributes and processes, but occur only in the network and not in the intervening spaces, and move following the pseudo-mobility principle. The formal model of fields is applicable to networks, where there is an infinite number of locations constrained to this linear field. The attributes can be any of the types defined for 2-D fields. Linear segments extracted from a network are equivalent to those spatial regions in a 2-D field.

Due to their dual form, it is easier to extract spatial regions out of networks than from their 2-D counterpart. The spatial regions in networks can be well bounded because nodes and links bound each other. Both nodes and links have their own attributes and processes. The attributes associated with links are consistent with those of 2-D fields, while the direction attribute of networks is more prominent. The attributes and processes of networks can vary on a continuous basis along a link, but it is more often the case that the attributes and processes associated with a node and a link are considered homogeneous. Given these traits, it is conceptually easier to conceptualize individual nodes or links as objects than spatial regions in 2-D fields.

Spatial objects, spatial regions, and fields in geography

Geography deals with a variety of spatial phenomena. Some of these can be easily thought of as spatial objects, some as fields, and others as spatial regions. The five characteristics discussed already, namely scale, boundary, attributes, process, and mobility, help further categorize these spatial phenomena into different types of spatial objects, spatial regions, and fields. This typology helps the selection of appropriate spatial data models for the intended geographic study. Five typical categories of spatial objects, spatial regions, and fields are identified and discussed here.

1 Individuals. Individuals exist in both small- and large-scale space, and have clear boundaries, attributes, and processes. They can be mobile or sedentary. Mobile individuals are independent of spatial locations, while the sedentary individuals are bound to their locations. The most typical examples of mobile individuals are individual animals.
or vehicles, while the typical examples of sedentary individuals include individual plants and buildings. These individuals are characterized by their unique identity, attributes, and behavior (including the mobility). Individuals, both mobile and sedentary, are normally conceptualized as objects. Both types are fundamental subjects of many geography studies.

2 Masses of individuals. This category is an extension of the category of individuals. As the constituents of the mass, the individuals are identifiable but are small in size or large in quantity, or both. These constituents can be mobile or sedentary, relative to the temporal scale of a study. The most common examples of the masses of mobile individuals include an animal population composed of mobile individual animals or a traffic flow composed of individual vehicles. Examples for the masses of sedentary individuals include vegetation composed of individual plants or an urban landscape composed of individual buildings. The collective attributes and processes across space, and the mobile or sedentary nature of the masses, mean they are conceptualized as fields. Their field-like traits are attractive for the environmental and sociobehavioral subdisciplines in geography.

3 Regions of individuals. This category is an extension of the masses of individuals or, alternatively, an extension of the individuals. These are spatial regions extracted from the continua of the masses of individuals or an aggregation of the individuals. A region can be mobile or sedentary, depending on whether the location of the region as a whole is mobile or not. A school of fish and traffic flows are examples of mobile regions of individuals. Plant biomes carved out of continuous vegetation and electoral districts extracted from the spatial distribution of a population are examples of sedentary regions. The unique identities, attributes, and processes associated with the regions, either mobile or sedentary, often mean they are conceptualized as objects and are of great importance to geographers.

4 Continuous masses. Phenomena of this type are spatially extended, continuous, and spatially varying. The attributes and processes of this type vary across space, and the mass may be dynamic or static. Temperature and population density can be examples of dynamic masses (note that population density refers to a continuous surface expressed as a rate, while the population example used in the masses of individuals refers to a collection of discrete individuals). Land and roads are examples of sedentary masses in 2-D and 1-D spaces, respectively. The continuous form and the dynamic or static nature of the attributes and processes of this type are of great interest to geographers. Both continuous sedentary mass and continuous dynamic mass are typically conceptualized as fields.

5 Regions in mass. This category is an extension of the continuous masses because the regions are extracted out of the continua. Similar to regions of individuals, the constituents of the regions in mass can be mobile or sedentary. Hurricanes and pollution plumes are examples of mobile regions. Land-use and land-cover areas extracted from the continuous land and high-accident sections of a road are examples of sedentary regions in a mass. Both mobile and sedentary regions are often conceptualized as objects. The unique attributes and processes of these regions are important for research in geography.
DATA MODEL, OBJECT-ORIENTED

The five categories discussed above represent a spectrum of spatial continuity with the most discrete type, objects, on one end and the most continuous type, fields, on the other, with both gradually transforming to spatial regions in the middle of the spectrum. The first three types begin with phenomena that are conceptualized as spatial objects and then aggregated into spatial regions and fields. The other two types begin with continuous fields and are then discretized into spatial regions. The mass of individuals as a field can always be decomposed into individuals.

Spatial phenomena in geography can be placed anywhere along this spectrum of spatial continuity, but not necessarily in distinct categories. The same phenomenon may qualify in a number of categories depending on the objective, scale, and conventional treatment of a study. For example, a population can be conceptualized as either mobile or sedentary individuals, a mass of mobile or sedentary individuals, regions of individuals, a continuous mass if presented as population density, either dynamic or sedentary, or regions in the mass of population density.

The characteristics of these spatial objects, spatial regions, and fields help select the appropriate spatial data model for the intended study. The next section describes the design principles of the two classic data models, the vector data model and the raster data model, to help assess the compatibility between conceptual models and data models.

Spatial data models

Both vector and rater data models formalize the conceptual models of spatial phenomena. They both divide the space into a finite number of discrete pieces, but by fundamentally different principles.

Vector models divide the space into spatial “features,” which are implemented in the geometric forms of points, lines, and polygons. Each feature is associated with the three types of information – location, attributes, and topology – as previously discussed. The location is recorded as the coordinates of points, turning points of lines, and outlines of polygons. Each feature has multiple attributes. The vector data model can explicitly represent topology between the features, such as which polygonal features are on either side of a line feature or which point features are at either end of a line.

Semantically, the geometric features correspond well to spatial phenomena, whether they are conceptualized or physically present. This allows the vector data models to represent these phenomena in a meaningful way, in terms of their geometric form, attributes, and topology. Vector data models are mostly advantageous for spatial phenomena that have a clear identity, are discrete, internally homogeneous, and static.

Raster models divide the space into a matrix of regular cells (or points). These cells have a predetermined and identical geometry in terms of their shape and size. The coordinates of a cell are implicitly referenced by its row and column positions. A single attribute value is associated with a cell. The adjacency between cells in the four cardinal and the four diagonal directions is explicit.

In contrast to the vector data model, the regularly shaped cells do not correspond directly to any spatial phenomena. Usually an assemblage of a number of cells does. This assemblage is not recorded in the raster data models. Consequently, the attributes of the spatial phenomenon and the topology between phenomena are not recorded either. Because the cells, not the phenomena, are the basic spatial unit in the raster data model, raster models are advantageous for phenomena that are continuous, heterogeneous, and dynamic. The explicit adjacency between cells...
DATA MODEL, OBJECT-ORIENTED

is particularly effective for supporting localized simulations that often query information about areas adjacent to a local cell.

Spatial data models are often implemented in spatial databases. The databases are developed as generic tools to manage the data and to support their usage. These tools are mostly for basic spatial operations, not for the modeling and analysis of specific environmental and behavioral processes.

There is no information in the database about what phenomena these data models should represent. The separation of the spatial data models from the phenomena that they represent allows the spatial databases to be flexible, a necessary quality to support a wide range of applications. This separation, however, makes it critical for users to choose data models appropriate for the intended study. There are almost always multiple spatial data models that can be used to represent the same phenomenon. The choice of the data model can have significant impact on the outcome of a study. An appropriate choice depends on many factors, but the first and foremost is how a phenomenon is conceptualized and how it subsequently is represented.

Object-oriented implementation of data models

Today’s geographic information system (GIS) data models are implemented in an object-orientation environment. As the current computing paradigm, object orientation is based on several basic principles that closely resemble the human cognition process. The most important are the encapsulation and composition principles. With encapsulation, an object has a unique identity, attributes, and behavior. Attribute values describe the state of the object, whereas behavior can change the state. These identities, attributes, and behavior are encapsulated within the object. Here the behavior can be equated to the processes discussed earlier. With the composition principle, objects can play different roles when organized in several different ways: as a subclass in a class hierarchy, an integral part of an aggregated entity, or a member of an association set.

Because these principles are intended to resemble the general human cognition processes, they are independent of specific domain applications. There are several hidden assumptions behind the application of object orientation. For example, it is the responsibility of the domain users of object orientation to identify their objects and that the objects should be identifiable. Further, because field-like phenomena are not explicitly considered in the object orientation, it is the responsibility of the domain users to conceptualize fields into some types of objects. These assumptions brought both conceptual advantages as well as difficulties in the design of object-oriented GIS databases.

The spatial data models implemented in the object-orientation environment bear the same geometric form as that in the pre-object-orientation era. Geometric primitives, such as points, lines, polygons, their derivatives in the vector data models, and grids of cells in the raster data models are implemented as software objects. Attributes and functions (equivalent to process) are encapsulated within the software objects and are organized into various hierarchies, aggregates, and associations. Note that these software objects should be distinguished from the spatial objects discussed earlier. The spatial objects in the earlier sections are discussed in the context of conceptual models to represent how spatial phenomena are conceptualized by humans. The software objects in this section are discussed in the context of the technical implementation of the spatial data models.
In the vector data models during the pre-object-orientation era, locations were the base of the data model. Attributes and topology were attached to the location. In a current object-orientation environment, the software objects are built on their identifiers. Location is treated as an attribute, such as the “shape” attribute in ArcGIS™. With this approach, changes in location can be easily implemented by updating the location attribute, while the identity, other spatial and nonspatial attributes, and functions of the software object remain intact. This change is one of the major improvements of object-oriented vector models over traditional ones and the change has significantly increased the utility of GIS in many applications.

The object-oriented raster data model keeps the same geometric form of cell arrays as that in the pre-object-orientation era. In the object-orientation environment, the cells may be aggregated into different levels of blocks according to the needed granularity. Each block can be treated as a software object. While technically feasible, the conceptual advantage of this implementation is inconclusive. Because object orientation has become the software industry standard since the early 1990s, the pressure to comply with the standard might have compromised the conceptual considerations in the implementation of object-oriented raster data models.

The five types of conceptual models of spatial objects, spatial regions, and fields discussed earlier can be formalized by various vector and raster data models, although to various degrees. The appropriate selection of spatial data models for the representation of spatial phenomena in a study depends on the compatibility between the characteristics of conceptual models and the design principles of data models along with their object-oriented implementations.

GIS data models for spatial objects, regions, and fields

Spatial data models for spatial objects

Spatial objects include the category of individuals discussed earlier. The vector formalization of spatial objects is rather straightforward, as these data models are designed to focus on the unique identity, discrete forms, and the encapsulated attributes and functions. These principles readily support the representation of scale, boundary, attributes, processes, and mobility of spatial objects.

The attributes of the vector data model can support many characteristics of spatial objects. These characteristics can be represented as their internal (geometric, biophysical, socioeconomic, etc.), background environment, and spatiotemporal attributes, for example. The representation of the scale and boundary can be accommodated by internal attributes, such as geometry. The representation of other attributes is straightforward. The processes of spatial objects may include the actions of individuals, the interactions between them, and their interactions with the background environment. These processes can be represented as an attribute change. Similarly, the mobility of an object can be represented by updating the spatial and temporal attributes.

For raster data models, a single cell or an assemblage of connected cells may be used to approximate the shape of a spatial object, but the representation of boundary is implicit. All cells have an attribute value and can support processes. However, the attributes and processes are associated with a cell, which normally does not correspond to a meaningful spatial object. Additional programming tools are normally needed to identify the spatial objects and support their related functions. The mobility of spatial objects can be represented by the pseudo-mobility...
approach. This is done by a sequential change of an attribute for a cell or an assemblage of cells along the path of movement.

Raster data models are not readily compatible with the spatial object conceptual model. A square cell does not resemble most spatial phenomena and the lack of identity for meaningful spatial phenomena prevents the raster models from being a good choice for formalizing spatial objects.

Spatial data models for spatial regions
Spatial regions include two categories, the regions of individuals and regions in mass. A spatial region is more likely to be conceptualized as a spatial object rather than a field. The design principles of vector data models, for the most part, are conceptually compatible with these regions, especially those taking polygonal and linear forms. The vector representation can support the scale, boundary, attributes, and processes associated with spatial regions as they would for spatial objects. However, the representation of mobility is an exception. Unlike spatial objects that are independent of their background environment, spatial regions are bound to the field. The representation of their mobility needs to follow the pseudo-mobility approach typically used for representing the mobility of fields.

Raster formalization of spatial regions faces similar challenges to that for spatial objects. This is primarily due to the inability of the raster data model to identify a meaningful spatial region. On the other hand, the raster data model has an advantage when representing the mobility of spatial regions due to its ability to represent continuous, heterogeneous, and dynamic phenomena.

The dual quality of spatial regions, that is, they are discrete spatial objects but are always parts of a continuous field, makes them partially compatible with vector and raster data models.

Spatial data models for fields
Fields include the categories of masses of individuals and continuous masses. Both vector and raster data models can be conceptually compatible with a field. The design principles of both data models can support the characteristics of a field, that is, the spatial continuity, the spatial variation of attributes and processes, and the dynamics of these attributes and processes. Six data models have been discussed specifically for the representation of fields. These are polygons, triangulated irregular networks (TINs), contours, cell grids, point grids, and irregular points. Of these, polygons, TINs, contours, and irregular points are vector data models, while cell grids and point grids are raster models.

Of the four vector models, the polygon and TIN models formalize a field as contiguous regions across a planar space. Although each polygon has explicit boundaries, there is no overlap and no holes between polygons in the space. The spatial continuity of a field can be appropriately represented. Other characteristics of a field, such as the spatial variation of attributes, processes, and their dynamics can also be supported. The TIN model is considered a special kind of polygon model.

Contours and irregular points, although in a vector form, are intended to formalize a continuously varying field. The contour lines and irregular points represent attribute values of a field at sampled locations, either along the contour lines or at certain point locations. Attribute values for the rest of the field can be estimated based on those values observed at the sampled locations. In addition to spatial continuity, these two models
DATA MODEL, OBJECT-ORIENTED

can support the representation of spatially varying attributes and processes, and their dynamics through a sampled form.

The two raster data models, cell grids and point grids, bring their advantages into full play when used to formalize fields. Their simple form, the explicit representation of attributes and their spatial variation, and the support for spatial functions allow the grid models to effectively represent the spatial continuity, spatial variation of attributes and processes, and their dynamics of fields. This is especially so for those continuous fields without explicit regions, where each cell is a part of a continuous field and not part of any spatial object or region.

Composite structures

Both raster and vector data models have been implemented in a layered structure. Raster data models are inherently limited to a single type of data (scalar, vector, or tensor) in the layer. While vector data models are confined within a planar space and limited to a single theme and geometry. For example, a school bus routing project may involve the student population in census block groups (polygons), the bus route (lines), and bus stops (points). In many GIS software packages, this project must be prepared with a minimum of three layers, a polygon, a line, and a point layer, respectively, although all belong to a single theme. Today, it is both theoretically and technically feasible to develop a “composite” structure to support the assemblage of different geometries or themes in a single layer. For the example above, all three types of geometric features can interact in a single layer for the intended study.

A multigeometry and multitheme “object field” has been proposed. Vector data of various geometries and themes are integrated with a continuous raster field with a different theme. Moreover, spatial objects, regions, and fields can be organized into hierarchies, aggregates, or associations according to the needs of the study. A composite structure requires a more sophisticated topology between different types of geometries. The nine-intersection system has provided a notable theoretical framework to support the complex topology between points, lines, and polygons. Spatial data models are a classic topic in geographic information science. Since the 1980s, the research in data models has experienced enormous advancement. When both this research and the GIS industry matured, the spatial data models implemented in proprietary software packages stabilized. Continued theoretical development in the research community and the technical development from the GIS software industry are critical for advancing this composite structure or for the development of other advanced spatial data models.

Couclelis, H. 1992. “People Manipulate Objects (but Cultivate Fields): Beyond the Raster-Vector Debate in GIS.” In Theories and Methods of Spatio-temporal Reasoning in Geographic Space, edited...
“Practically overnight, access to terabytes of geographical information, much of it in three dimensions, has changed the way people work, live and play” (NGAC 2009). As geographic data have become ubiquitous and widely used, more and more people are relying heavily on spatial information to support a wide range of applications. Geographic information has evolved from being shared exclusively via paper maps to data shared on networks, first exclusively within the domain of geographic information systems professionals, and, only recently, beyond the realm of professionals to anyone with a web browser or a smartphone. This invaluable ecosystem of digital maps, spatial data, and location-aware applications and devices is made possible through the leveraging of many different standards. Standards-setting bodies like the Open Geospatial Consortium (OGC), the World Wide Web Consortium (W3C), and the International Standards Organization (ISO) have enabled the seamless and efficient discovery, exchange, and exploitation of geographic information through the development and advancement of numerous internationally recognized geospatial technology standards.

Data quality standards enable data producers to provide quantitative and qualitative information regarding the accuracy and validity of the data they make available to potential consumers. In turn, data consumers can use this information to determine the data’s “fitness for use.” The concept of fitness for use highlights the importance of the consumer’s perspective of data quality, as it is ultimately the consumer who must determine whether any given dataset can or should be used for a specific purpose. When using any source of data that originates from other individuals or organizations, data consumers should review a standardized description of the quality of that data in order to best support defensible and sound decision-making. Data quality standards have evolved over time to help ensure that producers are able to sufficiently describe their data so that others can understand any dataset’s strengths, weaknesses, and limitations, as well as how to access and process the data.

In the field of geography, and specifically with regards to the use of geographic information, the challenges associated with documentation and appropriate interpretation and use of information on data quality have increased over time as geospatial information has become widely available and more heavily used. In the past, the primary consumers of spatial data were geospatial science and technology experts and geographic information systems (GIS) practitioners. Techniques and practices for measuring and documenting data quality evolved primarily in support of the technical requirements of geographic data producers and a relatively specialized audience of data consumers.

Specific measures of spatial data quality typically vary, based on the type of spatial information being described. There are specific parameters often used to report the accuracy of computer-classified satellite imagery, for example, which differ from those tailored particularly to enable producers to measure and
document the quality of vector-based geographic features such as roads. Sensors that produce and collect observational data with geographic parameters sometimes have their own specific measures of data quality that are useful to data consumers. A number of standards initiatives have been advanced to help document data quality in ways that are consistent and repeatable across data sources and providers.

Standards bodies including the US Federal Geographic Data Committee (FGDC), the French Institut Géographique National (IGN), Open Geospatial Consortium (OGC), the International Standards Organization (ISO), and others have developed data quality standards that enable data producers to describe geographic data quality using relatively similar constructs. The ISO standard ISO 19157:2013, “Geographic Information–Data Quality,” builds on these efforts and standardizes the components and structures of spatial data quality measures while enabling the documentation of data quality to be captured from the perspectives of both data producers and data consumers.

Information on data quality can be documented in metadata records associated with the data themselves. In the United States, the Federal Geographic Data Committee released the Content Standard for Digital Geospatial Metadata (CSDGM) in 1998, with data quality attributes based on the 1992 Department of Commerce Spatial Data Transfer Standard (SDTS). Today, many organizations across the United States and throughout North America utilize the CSDGM standard when publishing geospatial metadata and documenting quality. Many of these concepts have contributed to the development of an international metadata standard developed through the collaboration of many nations under the umbrella of the International Standards Organization (ISO). ISO 19115:2003, “Geographic Information–Metadata,” defines a standard schema that allows data producers to consistently describe data quality using a set of structured fields. ISO 19115 and other commonly used metadata schema typically include a structured methodology for documenting spatial data quality in a number of general categories including the following.

- **Lineage/source/processing steps:** describes the origin and provenance of the data, including a description of how the data were transformed or otherwise processed to produce the final product.
- **Spatial/positional accuracy:** measures how close (in three-dimensional space) locations in the dataset are to their actual locations.
- **Attribute accuracy:** an assessment of the accuracy of the identification of entities and assignment of attribute values in the dataset.
- **Semantic accuracy:** the quality with which features are described in accordance with the selected data model. Semantic accuracy is often used to characterize geospatial datasets generated from aerial photographs or satellite imagery as a way to depict the relative certainty that spatial features captured from the imagery (e.g., roads and wetlands) are categorized correctly.
- **Temporal accuracy:** measures of the accuracy of time measurements present in the dataset.
- **Completeness:** the relative degree of presence or absence of geographic features and their attributes.
- **Logical consistency:** degree of adherence to logical rules of data structure, attribution, and relationships between data elements.

The practice of using formal metadata records to document data quality has been a long-standing requirement within many government organizations that produce and manage important geospatial data assets. In the United
DATA QUALITY STANDARDS

States, Executive Order 12906 (1994) directs all federal organizations to develop metadata records for the geospatial data they collect or produce, either directly or through indirect mechanisms, including the issuance of grants to other organizations. Under Regulation 1205 (2008) of the Infrastructure for Spatial Information in the European Community (INSPIRE) Directive, metadata requirements and policies are clearly defined for government organizations in the European Union. Other nations and units of government have similar policies and requirements in place, and, as a result, metadata that adequately and accurately documents the quality of spatial data is available from many governmental organizations. Additionally, many governments have policies and laws in place that require government data producers to adhere to a set of standard practices and procedures to maximize data quality and report on certain metrics. In the United States, the Information Quality Act was passed into law in 2001, and requires the Office of Management and Budget to issue government-wide guidelines that “provide policy and procedural guidance to Federal agencies for ensuring and maximizing the quality, objectivity, utility, and integrity of information (including statistical information) disseminated by Federal agencies” (Office of Management and Budget 2002).

These types of policy directives have ensured that, for many spatial datasets produced and maintained by governmental organizations around the world, metadata records have been made available to help users understand the relative quality of data from these providers so they can make an appropriate determination as to the fitness of the data for their specific purposes. However, it is increasingly important to be mindful of the fact that private companies are generally not required to comply with well-known data quality standards or to publish formal metadata with their data offerings. The geospatial community has grown and changed rapidly, and the private sector has taken on a primary role in the production and dissemination of spatial data. At the same time, the use of GIS to support decision-making has grown across all sectors of the economy, as has the relative degree of reliance on data from external providers in these efforts. This situation is perhaps summarized best by Goodchild (1995, 424): “GIS is its own worst enemy: by inviting people to find new uses for data, it also invites them to be irresponsible in their use.”

The long history of publishing spatial data for open access, combined with the relative ease with which tremendous volumes of geographic information can be quickly and easily assembled and analyzed using geospatial technology, brings particular challenges with regards to the appropriate use of data. To make matters more complicated, new types and sources of geographic information are becoming available at an accelerating rate, and the tools to exploit that data quickly and easily via the construction of web “mashups” and other methods are widely available and heavily used. With the rapid advancement of the “Internet of Things” and sensors of all types and sizes producing and sharing data in volumes that were, only recently, unimaginable, the reality is that much of this data will not be sufficiently characterized with respect to quality. This presents challenges for users who are faced with trying to utilize this data for decision-making without fully understanding the consequences of using data of initially unknown quality.

As the Internet has evolved beyond a one-way communication medium toward an infrastructure that is participatory and collaborative via Web 2.0 concepts and technologies, opportunities now exist for data consumers to publish and share information on the quality of data they utilize. While outside the scope of evaluating data
quality per se, perhaps the best-known example of this type of consumer-based evaluation of quality is the use of star rankings for products made available through Amazon.com and other online commerce sites. These rankings and the comments that users provide build a valuable information resource that helps subsequent consumers determine whether the product will suit their needs or interests. Examples of this type of consumer-based feedback with regards to data quality and utility are becoming more commonly incorporated into open data catalogs. The City of Asheville, NC, for example, allows users to rate and comment on datasets accessed in its open data catalog. One of the largest commercial sharing environments for geospatial information, Esri’s ArcGIS Online, also incorporates capabilities to facilitate user feedback and rankings on many of the datasets that are available through this catalog.

This feedback can be of substantial benefit to a data consumer who is evaluating the fitness of use of a given dataset for their purposes. Moreover, even when structured, quantitative data quality metrics may be available from a data producer, and this type of user feedback can be beneficial to data consumers. Research has shown that, in some instances, data producers may believe that their data has “perfect” data quality in terms of assessed accuracy, yet end-user perceptions of the data quality can vary substantially (Wang, Strong, and Guarascio 1994). Wang, Strong, and Guarascio (1994) suggest that the parameters of data quality that are important to data consumers are substantially different from the largely accuracy-based measures that data producers often report on, and include, the following.

- **Intrinsic data quality:** consists of believability, accuracy, objectivity, and reputation.
- **Contextual data quality:** consists of relevancy, timeliness, completeness, and appropriate amount of data.

- **Representation data quality:** consists of interpretability, ease of understanding, representational consistency, and concise representation.
- **Accessibility data quality:** consists of accessibility and access security.

More and more geospatial data discovery and distribution systems are incorporating increasingly sophisticated capabilities for data consumers to document and share their perceptions and measures of data quality. These community-generated measures and assessments of data quality will continue to play an important role in helping end users determine whether data are appropriate for their intended use. As technology advances, and open data initiatives expand and gain momentum around the world, the audience for geospatial data will continue to grow and consumer-developed measures and indicators of data quality will play an increasingly important role. When these are combined with measures of data quality developed by data producers and distributed via formal metadata records, end users have a full spectrum of information available to them to help inform and support decision-making using data from the widest possible variety of sources.

Data structure: spatial data on the web

Stefan Steiniger  
Pontificia Universidad Católica de Chile

Andrew J.S. Hunter  
University of Calgary, Canada

Spatial data on the web and in our daily life: Where do we need spatial data and what are spatial data?

Everyone who has a computer or television at home looks at or uses spatial data that have been transferred over the Internet. Weather forecasts on TV or weather maps on the Internet are based on spatial data: temperature, humidity, precipitation, and so on that are gathered and sent mostly automatically from weather observation networks. These data may arrive every 10 minutes or so at a weather office; then derived maps, forecasts, and other information are generated or updated. Similarly, spatial data are analyzed and transferred over the web when one searches for the shortest or fastest route to a vacation destination, when one gathers statistics on one’s weekly biking or running activities, or when consulting traffic and location services using Google Maps, for example. Sensing services used to monitor and analyze earthquakes or to forecast flood risk need to transfer spatial data over the web. Similarly, many public sector activities including transportation, planning, and development require large volumes of spatial data. Authorities that collect spatial data, for example, a forestry service, land registries, or a transportation agency, often send data to other agencies to plan and undertake day-to-day activities. Some uses are tolerant of long (slow) data responses, but other applications are time critical.

“Data structures for spatial data on the web” denotes specialized data formats that are used to transfer spatial data from one place to another place via communication networks and allow (almost) immediate display, manipulation, and, perhaps, further processing of the data. Note that either a person or a computer can be at the receiving end of the data transfer. In the case of a computer, data are transferred between two web servers. Here one web server “serves” data to another server, which is also known as the “processing web server”, which may generate maps, statistics, and so on. In the case of a person requesting such maps and statistics, by using their home PC, mobile phone, or a tablet, data are transferred between a server and a client. A client displays the data and may even improve data presentation. But the client does not serve the (processed) data to someone else.

The types of geographic data that are transferred over the web are similar to information that we see on daily news sites, nytimes.com, for example, or social networks such as facebook.com. that is, images and text. What makes the data “spatial data,” however, is the fact that the data contain additional information, called “geographic coordinates,” that allows us to relate the information to a place.

Spatial data are stored and transferred in two very distinct data formats: as vector and raster
data. Both of these formats are described in detail below. However, to summarize: if we transfer raster data over the web, then we transfer some type of image format (e.g. a *.jpg or a *.png file), which stores “continuous” information in a grid structure – raster data examples include satellite images, terrain elevations, or temperature surfaces for a region. One or more discrete real-world objects, such as a bridge, a building or a forest, are transferred as vector data. When using vector data, each object is described by a geometry, a set of attributes that characterizes the real-world object (see the example given later in Figure 2), and often styling information for presentation of the information.

Discussed here are important considerations when sending spatial data over the web, how data can be transferred from one location to another, and what data formats and standards exist for storing and transferring spatial data.

Important technical considerations for sending spatial data on the web

Previously, spatial data formats have often been developed for use with desktop geographic information system (GIS) software to store data in some practical and convenient way on hard disks. File format development has focused on re-use of data with desktop GIS programs. That is, developers have been concerned about the speed of data read and write operations to disk, accessibility of file content, file size, and so on. However, many initial formats were not developed to support the interoperability that is necessary when data need to be transferred from one computer to another. Hence, the requirements and constraints that are important when transferring spatial data via the Internet are examined.

(i) Probably the most important thing for the average Internet map user is that they can see the map or map data as soon as possible after sending their request to a web server. Rapid display and update of online maps depend, among other minor factors, on available network bandwidth and the amount of map data to be transferred. Reducing data size is possible by restructuring the data, by generalizing the data (see Map generalization), by using compression methods, or by sending only the data that the user really needs or wants at that very moment.

However, there are also other requirements. (ii) The format of the data should not be prone to transmission failure due to network interruptions; that is, if there is a network interruption, then the data do not need to be resent from the beginning, but can be restarted from where the interruption occurred. (iii) Data formats need to be independent of the computer platform, that is, a format can be read regardless of the operating system that the sending or receiving computer uses. This independence is also termed interoperability; it is discussed further in later sections.

Depending on the particular use of the data, it may be useful for the user to preview the data, choose the level of detail needed (which is similar to viewing maps at different cartographic scales), and select the themes and geographical areas that they are interested in – before sending a data request. This means that, on the one hand, (iv) the spatial data format should contain or link to metadata that describe the datasets spatial extent, the phenomena included in the dataset (e.g., roads or forests), the purpose of its generation, the year of creation, and so on – so that the user can decide if a dataset is of interest. On the other hand, (v) a data transfer service, which answers a user’s request for data, should allow data browsing, as well as content and spatial filtering of the data, to avoid sending out data that is irrelevant.
(vi) Data formats should ensure data consistency. This means that when compression methods are used to reduce the size of the data, then the compression method should not change the data in any way. If we look at the geometry of two geographic objects, such as a field and a forest that are adjacent to each other, then the relationship between their borders and their topology should be the same before compression and after de-compression. (vii) The final important criterion for spatial data web formats and services is the separation of content and styling. That is, a user may be interested in knowing about all the forests near a certain city for an environmental assessment; but the user may not be interested how the forest should be portrayed on a map, that is, its fill color and pattern, line style, and so on. In this case, sending map styling information is not important.

The importance of standards for sending spatial data over the Internet

When data are transferred between two computers the data server needs to understand what data are requested, and the client needs to understand the format used to send the spatial data so that the data can be stored, processed, and displayed. Syntactical interoperability deals with information exchange between systems through the use of common data formats. Several organizations, such as the World Wide Web Consortium (W3C), the International Organization for Standardization (ISO), and the Open Geospatial Consortium (OGC), have developed and published many XML-based formats, along with their data schemas, as well as standardized image formats, such as JPEG, TIFF and PNG, to support interoperability. W3C is mainly concerned with general Internet standards, whereas the OGC has a particular focus on standards for web mapping applications and spatial data exchange. In particular, the OGC has released standards to describe spatial data and data format encodings (examined later). OGC has produced numerous XML schemas for web applications and services, for instance the web feature service (WFS), data encoding languages such as the geography markup language (GML), style languages such as the styled layer descriptor (SLD) for visualization, and filter encoding (FE) specifications. However, several de facto spatial data formats are also frequently used that have not been standardized by ISO, OGC or W3C. Examples include ArcGIS's Rest API, the GeoJSON format (examined later), and the GPX format.

How to send spatial data over the Internet

Solutions for sending data: files versus services

To send spatial data over the web, one can distinguish between two options: sending files and sending data via a data service (Figure 1). Sending files is convenient if the dataset is small or the user understands the data structure. Using a data web service makes sense when the content of the data is unknown, when data sets are large and only a subset is needed, and when data should be updated. It is important to note that sending data via a service is very often a file-based process, with the files being created ad hoc for transfer.

Sending files. If data are sent by file, then they are often compressed first to reduce file size, for instance using GZIP compression. Transferring data by (compressed) file, however, does not allow the user to see and browse the data before they receive them completely. Furthermore, the send process is not responsive in that it may
Figure 1  Two general approaches to sending spatial data via the Internet.
fail during network interruptions, and users are not able to select a subset of the data. Probably even more importantly, the user needs to be sure that their software can read the data format. For instance, the user may download geometry data in Autocad’s DWG format, but few GIS are able to read this format. Here, syntactic interoperability is not ensured. Converting the data into a standardized geospatial file format, such as GML or KML, before making them available to others can resolve this interoperability problem. In comparison with the DWG format, OGC’s GML and KML format specifications are open to the public, and hence can be implemented freely by software developers. However, in practice only a few (desktop) GIS support the GML standard fully.

Using data web services. If a data web service, such as OGC’s WFS and Web Coverage Service (WCS), is used, then several of the problems previously outlined can be avoided. For instance a data service, such as a Spatial Data Infrastructure (SDI), enables browsing of the data, selection of subsets, can cope with network interruptions, and ensures interoperability. HTTP GET and DESCRIBE communication commands, such as GetCapabilities, GetMap, GetFeature, DescribeFeatureType, and so on, are used to inform the client about the offerings from the data services and to select data subsets. The use of standardized methods and data descriptions enables the client application to identify in which data format the requested data can be sent so that the client can read the data correctly. Spatial data are mostly transferred using one of four data serialization standards: URLs that contain key-value pairs, eXtensible Markup Language (XML), JavaScript Object Notation (JSON), and protocol buffers (Table 1). Some data serialization formats, such as XML and protocol buffers, provide a schema in addition to the data. The schema contains a description of the data structure and data types for the data during data transfer. This allows easier parsing and validation of the data received.

While we will discuss particular spatial data formats in more detail below, note that XML and JSON-based data formats are not designed to minimize the amount of information to be sent. Hence, standard HTTP compression capabilities are often employed (e.g., gzip) to reduce the transmission time. Furthermore, choosing a subset of the data can significantly reduce the size of the dataset that needs to be transferred. Several of the OGC’s spatial data service standards allow the selection of subsets using filter encoding standards. One can select data within a particular geographic area of interest, by geographic theme, image band of interest, and by level of detail (similar to map scale), and one can select certain geographic objects or raster images based on client-specified criteria. Standards that allow subset selection include OGC’s WFS, WCS and the web map tiling standard (WMTS).

2-D – Vector data formats and services

As outlined, vector data can be transferred as files or via a data web service. Common vector data formats include ESRI’s Shapefile format and AutoCAD’s DXF format. Both data formats are proprietary and pre-date the geospatial web. Hence, data transfer via the Internet was not likely a design objective for Shapefile and DXF formats. The Shapefile format, although fairly small in size because of its binary form, allows only one geometry type (i.e., polygons or lines or points) per file, and all features must have the same attribute set within a file – so trees cannot be mixed with buildings in the same dataset. Furthermore, one Shapefile consists of at least four files that need to be packaged together. Similar
## Table 1  
Internet encoding/serialization standards used for transferring spatial data.

<table>
<thead>
<tr>
<th>Name (specification)</th>
<th>Purpose</th>
<th>Elements and example</th>
<th>Characteristics</th>
</tr>
</thead>
</table>
| Key-value pair (IETF RFC 2616) | For data requests and data submission, i.e., HTTP GET, HTTP POST | - Form: “keyword = value”, separated by ampersands (&) appended to an URL  
- Example: http://example.com?name=Smith&initial=JS | Human readable, keyword-value pairs |
| XML (IETF RFC 3023) | For description of data, including documents, to request and send data | - Version and character encoding declaration  
- Elements declared by a start tag and end tag, e.g., `<step>` and `</step>`  
- Element attributes, e.g., `<step number = "3">`  
- Example: `<person> <name>Smith</name> <initial>J S</initial> </person>` | Human readable; can be used for hierarchical structured data; self-describing, extensible |
| JSON (IETF RFC 4627) | For sending data objects (not for documents) | - Array and record based  
- Curly brackets to indicate object start and end  
- Attribute-value pairs  
- Example: `{"name":"Smith","initial":"JS"}` | Human readable, attribute-value pairs. Simpler than XML (smaller grammar); can be used for hierarchical structured data; self-describing |
| Protocol buffers (Google) | For sending and storing structured data objects | - Using a proto schema file to describe data first, followed by serialization of one or many data objects  
- Proto schema example: `message Person { required int32 id = 1; required string name = 2; optional string initial = 3; }` | Binary: i.e., small size but not human readable; name-value pairs, can be used for hierarchically structured data; not self-describing – requires .proto files, extensible, forward and backward compatible |
problems exist for the popular DXF format. DXF does not allow user-defined attributes. This means that DXF files cannot carry information to characterize a tree as an oak tree with a height of 10.5 m and a stem diameter of 80 cm. Hence, new web-specific spatial data formats were developed to address such requirements.

Based on XML serialization, the OGC developed and standardized two spatial data formats: the geography markup language (GML) and the keyhole markup language (KML). Another existing XML-based format not adopted as a standard by OGC is OpenStreetMap XML (OSM). GeoJSON, derived from JSON, has not been formally recognized as a standard yet (in 2016), but GeoJSON is widely supported by browser-based mapping applications (e.g., Leaflet and OpenLayers). Finally, spatial data formats based on the protocol buffer file (PBF) standard are the OpenStreetMap PBF format and MapBox’s vector tile format. Table 2 presents the characteristics of several vector data formats.

GML, KML, and GeoJSON formats have adopted the OGC simple feature specification (OGC SFS) to describe the geometry of geographic objects. This specification, among other things, defines the basic geometry elements: Point, LineString, and Polygon, as well as GeometryCollections of those (see Data structure, vector). GeoJSON files and protocol buffers are compact formats in comparison with XML-based data formats. However, GeoJSON and XML formats (i.e., GML, KML or OSM) can be compressed. Some of the vector formats, in particular KML and GML, can include styling information for point symbols, labeling, line width, color, and so on, for display. Each of the formats has its advantages and disadvantages with respect to size, extensibility and flexibility. Hence, choosing a transfer format should be based on the characteristics of the particular use case. Since formats for 2-D vector data only are being discussed, readers with an interest in 3-D vector data are referred to OGCs CityGML standard and the American Society for Photogrammetry and Remote Sensing (ASPRS) organization’s LAS format.

There are two web service standards for transferring vector data: the OGC web feature service (WFS) and ISO 19142: 2010 Geographic Information – Web Feature Service. The OGC standard forms the basis of the ISO WFS standard. The standards utilize the GML standard to send vector data. Operations described by the WFS standards, such as DescribeFeatureType and GetFeature, allow a client to browse, retrieve (get) a subset of a dataset, or even a single geographic object only using their respective filter encoding specifications, and also create, delete, and update features in a dataset using a transaction service.

Figure 2 presents a vector data example (see image on the bottom left) showing how different geographic objects can be described in GeoJSON and KML formats. The dataset contains: a building with the attributes “name” and “address;” a road with the attributes “name” and “road type;” and two trees, with the attributes “tree type” and “height.” As can be seen, the geometry type of the building is Polygon, the road geometry is of type LineString and the trees are described as Points. In both formats the locations, that is, coordinates, are geographic coordinates, latitude and longitude. GeoJSON coordinates are assumed to be in the coordinate reference system CRS84, (urn:ogc:def:crs:OGC:1.3:CRS84) unless specified otherwise, whereas KML is WGS84 (EPSG:4326). GML, not shown here, expects that the coordinate reference system (CRS) will be defined explicitly as an attribute of the feature, and requires a schema (.xsd) describing the feature types included in the GML document. In the given example, no styling information

(KML) is included for the display of the objects. When compared, the GeoJSON format is more compact (1788 Bytes) than KML (4343 Bytes). GML is generally more verbose (3358 Bytes plus a 2408 Byte schema).

2-D – Raster data formats and services

Examples of spatial raster data include satellite images, gridded elevation models, and temperature or wind speed snapshots of a region. Spatial raster data also include image tiles used by web mapping services to render a base map, such as Google Maps or Here.com.

Raster data and raster maps are usually transferred in an image format, such as JPG, TIFF or PNG. Supplemental information is added to each raster image indicating the real-world coordinates of the image corners, the map projection used, and perhaps information describing any image transformations applied (e.g., stretching and rotation). Spatial data web services offer the same image formats. Since JPG, TIFF and PNG have built-in data compression methods, HTTP compression is usually not applied when transferring image formats. Which type of image format is best to use depends on whether the user is looking for a ready-made map (with styling), or the actual raster dataset. In the case of a map, it makes sense to use JPG or PNG formats. JPG employs lossy data compression, whereas with raster data the TIFF format is recommended as it offers lossless LZW compression. The image formats, JPG, TIFF and PNG, do not allow separation of data and styling information. However, newer formats may support this (see for instance the OGC symbology encoding specification).

There are at least three Open Geospatial Consortium (OGC) standards for distribution of raster data using a data web service: the OGC web mapping service (see also ISO 19128), the OGC web coverage service (WCS), and the web map tiling service (WMTS). However, there are other standards that address distribution of raster data as well, such as OGC GML in JPEG 2000, OGC GML version 3, OGC NetCDF, and ISO 19123.

An OGC WMS returns complete maps of (dynamic) spatially referenced data in an image format. The WMS service may offer its own styling, or an OGC styled layer description (SLD) file can be sent with the map request. A fully conforming OGC WMS service returns PNG, GIF, JPEG, and TIFF formatted images. The bounding box of the area of interest, image dimensions, themes of interest, and the map projection can be specified in the WMS request. The service does not allow updates, so-called transactions, to the data on the server.

An OGC WCS service is not used for retrieving completely styled maps but allows detailed access to raster data of space/time-varying phenomena. Supported output formats may include GeoTIFF, GRD, NetCDF, and JP2000. However, metadata about the raster data are sent using OGC GML. The user request to the service can specify parameters such as the bounding box for the area of interest and the time – to select data for a particular date and a particular image band (e.g., near infrared) to ensure that only data of interest are received. The map projection, image dimensions, image resolutions, and interpolation methods for the rescaling of an image can be specified as well. Version 2 of the standard extends capabilities to work with multidimensional and time series raster data as commonly encountered in meteorology and climatology. Extensions that allow a WCS to be transactional, that is, to update datasets (WCS-T) and to process and filter data (WCPS), exist as well.

The introduction of a web map tiling service (WMTS) resulted from deficiencies (response time) encountered when working with a WMS
service. Often WMS services require a few seconds to respond to an image request, because the map image is generated on the fly. When there is a large number of concurrent users, for example, serving many users at the same time, these CPU-intensive services become impractical. Google Maps and later OpenStreetMap were the first to use the so-called “slippy map” approach to address this processing problem. Here, one may imagine that a big map image is rendered first and then cut into many small images that are called “tiles.” Only a few of those tiles are of interest to the user and need to be sent to the client. Individual tiles for a complete map can be precomputed over a range of map scales (different levels of detail) so that when a user zooms in and out tiles can be retrieved more rapidly. This technique was formalized in the OSGeo TMS standard and later in the OGC WMTS standard. A restriction of this service is that each tile map can have only one map projection and so-called “faces” are needed to cover the Earth’s polar regions. It is recommended that tiles be sent in JPG or PNG formats and tile sizes are 256×256 or 512×512 pixel large. The number of zoom levels (scales) available usually depends on the map projection used and the WMTS data provider. The storage structure generally takes the following form: “www.domainname.com/mapfolder/z-zoom level/tile-column/tile-row.”

Sending event data: web updates and sensors

So far, we have discussed formats best suited for data requests for a particular geographical object or an entire regional dataset. However, many real-time applications require event data with constant updates of spatial information. For example, when traveling by car the car navigation system may send information about the vehicles current position every three seconds. Another example of event data is seismometer data collected to record earthquakes. To map and analyze earthquake events over time the information from the seismometer should include the strength of the earthquake, the time stamp for the earthquake event, the geographic location of the seismometer, and perhaps a reference to calibration metrics for the instrument.

Formats that are commonly used to send event data include two XML-based formats: rich site summary (RSS) and Atom, and JSON. Similar to GeoJSON the RSS format has a spatial equivalent called GeoRSS (described in Table 2), which is also used for Atom-formatted data. Use of the GeoRSS or Atom format makes sense for updates on world news webpages. Since 2013, GeoJSON seems to have established itself as the de facto standard for transmitting location events. For instance, the US Geological Survey’s Earthquake Hazard Program makes real-time earthquake information available in GeoJSON and Atom formats. However, some webpages offer location event data in KML format.

The Open Geospatial Consortium has also defined a set of “sensor web enablement” standards for description, communication and data exchange with (environmental) sensors. One particular standard of this sensor web enablement set is the OGC Sensor Observation Service – OGC SOS. This service standard defines a GetObservationService request that returns sensor measurement data. Other, optional, commands allow the retrieval of information about the sensor itself (e.g., its location) and information about the object that is monitored. (More information on this topic is to be found in Sensor networks, wireless.)

Current developments

As with most technical fields there are many development activities in the area of spatial data
transfer techniques and standards. In particular, we see work focusing on the delivery of background maps as vector tiles instead of raster tiles. In this context, new vector data encodings are being introduced. Among those is the Topo-JSON format by M. Bostock (Table 2). This format was developed to reduce the size of the datasets that are to be transmitted by exploiting their topological relationships. For instance, a common border of two touching polygons is stored only once, rather than twice, as in a purely object-based geometric model.

A second format that may find wider application is MapBox’s VectorTile format, which is based on the protocol buffer serialization (Tables 1 and 2). Several objectives have led to the development of the format. Two of them are that vector-based tiles can be much smaller than image-based tiles for geographic regions with few map objects, such as a desert, a forest, or water environments, and that using the vector format allows the immediate application of custom map rendering styles (e.g., chosen by the user) as opposed to pre-rendered image tiles. The development and testing of vector map tiling were and are performed not only at MapBox but also by others; for instance, Apple and Google Maps use vector tiling for map display on mobile devices now (in 2016) as well.

Finally, it should also be mentioned that substantial ongoing research investigates efficient data transmission of spatial data for use in multiplayer online games. If one thinks of online games as places where people explore cities and landscapes (such as in first-person shooter games), then large volumes of terrain data need to be transferred and rendered by the game engine. Developments in this area are of importance to GIS developers because the gaming engines are used for online games but also play an increasing role in pilot and driver trainings, as well as in military and medical simulations.

**Further reading**

The raster data structure is an approach for encoding spatial data computationally for use within a geographic information system (GIS) or remotely sensed image processing software package. Its general organizational approach is the exhaustive tessellation of space into a set of nonoverlapping spatial units, typically square grid cells. Each individual grid cell contains a value that represents a property of that grid cell location, whether it is the presence of a geographic feature or measurement of some kind. The raster data structure, along with the vector data structure, composes the primary geometric approach for representing spatial data computationally.

Raster-based GIS has its roots in the late 1960s and 1970s. Its development was driven in part by advances in computer graphics data handling and the limitations of line printers for cartographic output at the time, which operated by overplotting characters in individual cells of a rectangular grid to create shaded regions. The raster structure is also closely related to the products of digital scanners and environmental remote sensors affixed to airborne and satellite platforms. Notable early academic research included the raster data handling software packages IMGRID and MAP (Tomlin 1990) and the development of standards for raster data structures and processing (Peuquet 1979; Samet 1984). Many of these early contributions are now embedded, and have been substantially advanced, within academic, open source, and commercial GIS and remotely sensed image processing software packages, such as GRASS GIS, ERDAS IMAGINE, IDRISI, and ArcGIS, among others.

Raster data can be used to represent nearly any type of geographic phenomenon but certain types of raster data are particularly prominent. Remotely sensed digital imagery gathered from ground, ship, and satellite platforms are encoded in raster format, and these data form a large portion of GIS data generally, particularly for their use as base, or framework, data on which other datasets may be registered. Other important raster data sources are digital raster graphics (DRGs), scanned maps of US Geological Survey topographic quadrangle maps, and digital elevation models (DEMs). DEMs encode elevation data in grid form and, though they were initially created by interpolation from contour line data, most current wide-extent DEM datasets, such as the shuttle radar topography mission (SRTM) data with coverage over nearly the entire Earth, are derived from remote sensing. In addition to elevation data, many other environmentally oriented datasets, such as those related to hydrological and meteorological modeling, are in raster format, due to the spatially continuous nature of these types of environmental variables as well as the affinity of many computational simulations of environmental processes with raster data organization.

**Raster data modeling**

Data structures, including the raster data structure, are a component of spatial data modeling, which details how a geographic phenomenon in the real world is conceptualized and ultimately
represented and encoded in a computer. Data modeling proceeds through a series of stages, where each stage represents a greater degree of abstraction in the representation of a real world phenomenon (Peuquet 1984). The stages include the conceptual model, data model, data structure, and file structure (Figure 1). The file structure concerns the actual physical encoding of data on a storage medium, and is not relevant to the discussion here. The present chapter thus focuses on the conceptual model, data model, and data structure as they relate to raster modeling.

### Conceptual model

The conceptual model concerns how a geographic phenomenon is conceived of in the mind of the analyst who is creating the computational representation. Generally, two high-level conceptual models are recognized – object based and field based. An object-based conceptual model of the world is one in which the world is viewed as an empty space occupied by individual objects whose boundaries are discrete and definable. The field-based conceptual model of the world is often used for phenomena that are not thought of as discrete entities but rather which are considered to vary continuously through space. Often, such phenomena are considered qualities that vary from location to location, and thus while they have no discrete boundaries they can be measured or observed at any given location. Many environmental phenomena fit this description, such as temperature, relative humidity, and soil salinity, things which are qualities that can be measured but are not distinct entities or features in and of themselves. Such conceptual models are often materialized in language, such that while it makes perfect sense to say “Look at that building over there,” it does not make sense to say “Look at that temperature over there,” simply because temperature is conceptualized not as a discrete object but rather as a quality that exists as a continuum throughout space.

### Data model

A spatial data model is an approach to using a certain type of geometry to represent geographic phenomena computationally, where the geometric configuration extends from the conceptual model. There are two primary spatial data models – vector and raster. The vector data model uses point, line, and polygon geometric primitives to represent the spatial expression of a geographic phenomenon. The raster data model utilizes an exhaustive tessellation of space into a set of spatial units as a representational device. Each spatial unit encodes a value that represents some property or measurement at that location. Though irregular tessellations can be used, regular tessellations are the norm. Several different types of regular tessellations have been used, including tessellations of triangles, hexagons, and squares (Figure 2). Hexagons,
unlike triangles and squares, have the advantage of having their centroids equidistant to all adjacent hexagons, which is a substantial advantage when performing operations related to the measurement of distance from one spatial unit to another. Note that for a tessellation of squares, the distance from the centroid of one square to the centroid of an adjacent diagonal square (i.e., two squares that share a point) is 1.4 times the distance between the centroids of two adjacent squares that share an edge.

The tessellation of space into squares has, however, several advantages that tessellations of hexagons and triangles do not share. Tessellations of squares are similar in structure to remotely sensed imagery derived from aerial and satellite platforms, which serves as a major source of data for GIS. Square-based tessellations also have an affinity with conventional computer graphics data structures, which supports the adaptation of computer graphics processing and manipulation to the GIS environment. Such a structure is also directly compatible with the Cartesian space of planar coordinate systems used to georeference data within GIS. Squares can be recursively subdivided into smaller spatial units of the same shape and orientation, too. In other words, a square can be subdivided into a set of smaller squares. This provides substantial efficiencies in data encoding, retrieval, and analysis.

For these reasons, by far the most common approach in raster data models is to employ a tessellation of squares in a matrix, also commonly called a grid, or sometimes, a raster. Each individual square in the grid is called a pixel, formed from an amalgamation of the words “picture element,” a term commonly used in computer graphics and image processing. Pixels are also referred to as grid cells, which is the term that will be used here. Each grid cell encodes a value that captures some observation or measurement at that grid cell location. For example, a standard raster data model representation of Earth surface elevation would be a grid, where each square grid cell contains the elevation at that grid cell location. Because, unlike with vector, the property of a phenomenon is attached to a location, rather than some geometric representation of an object, the raster data model is often said to be “location based.”

The reader may notice a logical extension of the raster data model from the field-based conceptual model and the vector data model from the object-based conceptual model. Certainly, the raster data model, with its location-based orientation, has a natural affinity for the representation of phenomena that are conceptualized as varying continuously over space, as such continuous variation can be represented by the set of values encoded in the raster’s grid.
cells which are distributed regularly throughout space. And vector is a logical choice for phenomena that are conceptualized as objects, where points, lines, and polygons are used to capture the location and spatial extent of features. However, it should be emphasized that any geographic phenomenon can be represented using either the raster or vector data models.

**Data structure**

A data structure is the encoding strategy for the spatial data model, a specific design of how to store the geometry expressed in the data model within a computer. It is typically expressed as a set of diagrams and tables that illustrate the computational storage of spatial data in a database or set of files. The data structure is implemented within a programming language. Thus, while the raster data model encompasses the idea that spatial information can be stored using a tessellation of space into regularly spaced spatial units, with each unit encoding an observed value, there are many different raster data structures that specify how to actually computationally encode such a geometric configuration. The raster data model may be thought of as composing a family of specific raster data structures. The algorithms that form the analytical raster component of a GIS package are developed for the specific raster data structure implementation employed by that GIS package.

Perhaps confusingly, the terms “raster data model” and “raster data structure” are often used interchangeably. There is an ambiguous semantic boundary between a data model and a data structure, as the former implies the concept of data organization while the latter implies a more specific encoding strategy. However, even the same general encoding strategy can be implemented somewhat differently in different programming language for different data formats. Many GIS software vendors have developed their own proprietary raster data formats, all of which are based on the same idea of tessellating space into a regular grid, but which differ in their implementation details.

**Fundamental principles of raster**

Considered here is by far the most common type of raster data model, the raster grid, where the space is tessellated exhaustively into a matrix of square grid cells. The grid is oriented so that the rows express the coordinate position along the north–south axis and the columns express the coordinate position along the east–west axis. Encoding a value for each grid cell is thus based on recording a value for each row and column position. GIS packages handling raster data typically represent geographic features using a set of grids in which each grid can be considered an individual spatial data layer. Each layer represents one theme – that is, the spatial distribution of one specific type of geographic object, spatial property, observation, measurement, or characteristic. Some basic layers, for example, would be elevation (above sea level), the locations of rivers, and the locations of cities. There are many possible themes, and the specific themes involved are determined by the database creator. These multiple layers are stored in a GIS database to depict the salient features of a region.

**Resolution**

A key property of any raster is the resolution, which refers to the size of the grid cell. The resolution is given as the length that one edge of a single grid cell measures on the Earth surface. For example, a 12 km resolution grid consists of a matrix of grid cells, each of which measures 12 km along its side. Thus, the area of each grid cell in such a grid is $144\text{km}^2$ ($12 \times 12$...
The resolution of a grid is a measure of its spatial precision—the finer the resolution, the greater the precision. Given a raster of a particular extent, as the size of the grid cells gets smaller the degree of precision increases, but the number of grid cells necessary to cover the extent also increases. Every time the resolution is cut in half, the number of grid cells necessary quadruples. Consider the example shown in Figure 3 for an analog map of two polygons, labeled “1” and “2,” with an extent of 12 km. At a resolution of 2 km, 16 total grid cells are required to cover the entire area. If the resolution is doubled (made coarser) to 4 km, the number of grid cells drops to nine, and at a resolution of 6 km, only four grid cells are required. Note also how the precision, that is, the level of detail at which the raster captures the spatial variation of the boundary between the two polygons, is reduced as the resolution is made coarser.

The decision of what resolution to use resides with the analyst, if it is not predetermined by the technology used to generate the data (e.g., as with an image derived from remote sensing technology). While, ideally, it is preferable to have the finest resolution possible, there is a tradeoff in the granularity of the representation and the storage volume necessary to hold an increasing number of grid cell values. A raster with a very fine resolution over a large extent can be cumbersome in terms of the memory required for storage and also for processing. Thus, the analyst should consider the precision required for the application of the data when deciding on a resolution.

### Encoding

The most basic raster encoding scheme uses only values of one (“1”) and zero (“0”) to encode the presence and absence, respectively, of some geographic feature. Consider, for example, an analog map of a landscape presented on the left hand side of Figure 4, which shows two lakes bisected by roads, along which are located three houses. In the analog map representation, the lakes are represented as areas, the roads as lines, and the houses as points. In a raster representation, each type of feature is encoded as a separate layer—thus there is a houses grid, a roads grid, and a lakes grid. Every grid cell that contains that feature is given a value of “1,” otherwise the grid cell is given the value of “0.” Figure 4 shows grids of houses, roads, and lakes for the analog map.

A pertinent question relates to how a grid cell is assigned a “1” or a “0.” For point features, the assignment is relatively simple. If a grid cell contains a point, it is given a value of “1”; if

---

Figure 3  Impact of changing the resolution for a raster representation of a mapped area with an extent of 12 km: 2 km resolution grid, 4 km resolution grid, and 6 km resolution grid.
not, it is given a value of “0.” For line features, if a line crosses or touches a grid cell, that grid cell is given a value of “1”; if not, the cell is given a value of “0.” For polygon features, the issue of assignment may be more complex, as a polygon may only partially overlap a grid cell, or multiple polygons may overlap a single grid cell. Two conventional approaches are used for polygon assignment. The first approach is the “centroid rule,” where a grid cell may be assigned the value of the polygon that contains the grid cell centroid. The second approach is “winner-take-all,” where the polygon that occupies the greatest area within a grid cell is used for assignment. Occasionally, other criteria may be used to prioritize assignment for certain themes. For example, if a raster is being created that describes the presence of certain animal species with the aim of habitat preservation, one may want to code any grid cell that overlaps with that species distribution as containing that species, even if the species range did not occupy a majority of the grid cell area.

There is also the question of whether the value of each grid cell is assigned to the entire area of the grid cell or only to its centroid. Theoretically, if one conceptualizes the geographic phenomenon being represented by the raster as a homogeneous entity, it makes sense to consider the entire cell as occupied by that entity. For example, a raster representation of city neighborhoods indicates that each entire cell belongs to a neighborhood. If, however, the phenomenon is conceptualized as a continuously varying statistical surface, as with an elevation surface, then it makes sense that the raster is a set of samples of that surface occurring at the centroids of the grids cells. Notably, this distinction occurs only conceptually – there is no difference in the nature of computational encoding whether one considers the value occurring over the entire grid cell or only at its centroid. However, certain raster functions operate on the centroid of a grid cell, often when measuring, say, the distance between grid cells, while other functions treat the area of the grid cell.

Grids can take on a variety of values beyond simply zero and one, and can contain nominal (categorical), ordinal (ranked), and interval/ratio (continuous) data types. Most GIS packages that handle raster data, however, encode only numeric, not text, values. Thus, in the case of nominal data, numeric values are used to stand for nominal categories. For example, Figure 5 shows an analog map of four nominal category land covers and its representation in raster form.

**Figure 4** Raster representations of an analog map with point (houses), line (roads), and area (lakes) types of features.
Ordinal data and interval/ratio data can be encoded directly as numeric values in the grid.

**Data types**

Early raster GIS packages were mainly limited to integer values due to the storage and processing demands of encoding and handling rational numbers, which demand a greater amount of memory devoted to storing the value of each grid cell. While today’s computers have greater storage and processing capabilities, many GIS packages continue to distinguish between grids that are intended to hold integer values from those that are intended to hold rational values. While not enforced as a rule, integer values are often used to encode nominal and ordinal data, whereas rational values are used to hold interval/ratio data. Nominal values in raster are often used to depict features, such as roads and buildings, as well as partitions of an area such as neighborhoods, political districts, and census boundaries. Here, each grid cell holds a nominal value that stands for the identity of the feature; for example, a neighborhood can be represented by a group of adjacent grid cells that hold the same nominal value.

Phenomena that are continuous in nature, such as elevation or temperature, likely have grid cells values that do not repeat but change in a continuous manner throughout space. Thus, rational values stored as a floating point data type are used to depict this continuous variation. The choice of integer versus rational values has implications for volume of storage, as the assignment of a short integer data type (with values ranging between 0 and 255) to store the value of each grid cell is less demanding in terms of memory than the assignment of multiple bytes of storage for each grid cell, as required by rational numbers. Additionally, redundancy in the values of integer type grids can be exploited to reduce the memory required to encode the raster, as explained below.

The grid data type also has implications for the storage of attribute data. Traditional raster data structures did not include attribute data in separate tables, as is the norm with vector data, but were limited to a set of grids, each representing a single theme. Some GIS packages have linked the raster data structure to the relational data model to handle attribute data, as with the vector data model. The standard approach is for an individual grid to be associated with a table, where each row in the table represents one unique value that occurs in the grid. It is NOT the case that each grid cell is represented by a row in the attribute table. Consider, for example, the grid of land cover presented in Figure 5. There are four unique values that occur in the grid: 1, 2, 3, and 4, each representing a particular land cover. Each unique value is

**Figure 5** Raster representation of nominal data: a land cover map with residential (1), commercial (2), industrial (3), and agricultural (4) land covers. The table (right) shows an attribute table attached to the grid.
represented as a single row in the associated attribute table; thus, there are four rows in the attribute table. The table contains a field that encodes that grid value (the “value” field, which can serve as the primary key in the table) and a field that encodes the count of the number of grid cells that contain that value (the “count” field). As with any table in the relational data model, other fields may be added to include additional properties, such as the name of the land cover and the area of the land cover.

This approach for linking the raster data model to tabular data is generally limited to integer grids intended to represent nominal or ordinal data types. In a grid holding rational number data, each grid cell may have a unique value, as the grid is typically used to represent a continuously varying surface. In such a case, the attribute table would have a number of rows equal to the number of grid cells. In even a medium-size grid this results in a number of rows that would be cumbersome to manipulate in most desktop-based GIS packages – a grid with just 1000 rows and 1000 columns would have an attribute table with 1,000,000 rows.

### Raster encoding and compression

#### Full raster encoding

The most basic raster encoding is simply a matrix or 2-D array of values, where the row and column position of the value in the array indicates its position in geographic space. This is termed “full raster encoding” or “cell-by-cell encoding.” Notably, it is unnecessary to explicitly store a coordinate position, or row and column position, for a grid cell value. A header file typically accompanies the data file, and contains information on the total number of rows and columns in the grid, the grid resolution, the memory allocated to each grid cell value, and information regarding the coordinate system. The coordinate system information often also includes the extent of the grid as captured in the minimum and maximum x and y coordinates of the area covered by the grid. Also of note is that because the data are often stored in an array, the row and column positions of a grid often begin at the upper left (northwest) corner of the grid, where for instance the top (northern) row is numbered row zero and rows below (to the south) are numbered sequentially. Likewise the column to the left (west) is numbered column zero and the columns to the right (east) are numbered sequentially. This is in contrast to most planar coordinate systems which typically have an origin to the southwest of the area being mapped.

Because a value is encoded for each grid cell position, the volume of raster datasets can grow to be very large and unmanageable. Thus, there are compression algorithms that allow for the storage of raster data with reduced memory requirements. All compression algorithms seek to exploit the principle of spatial autocorrelation – for raster, the idea that grid cells nearby or adjacent to one another are more likely to have identical, or at least similar, values. Such a spatial pattern allows for encoding schemes that may be more efficient than storing the value of each individual grid cell. Compression algorithms can be divided into “lossless” and “lossy” approaches. As the name implies, lossless compression allows for the recovery of the full raster encoding without any loss of data, whereas lossy compression results in some loss of data – the original full raster encoding cannot be completely recovered from the compressed file.

#### Lossless compression

A prominently used lossless compression for encoding raster is called “run length encoding.” Run length encoding stores runs of the same value, that is, sets of adjacent grid cells that share
the same value. For example, consider the analog map of three areas, labeled areas “1,” “2,” and “3,” shown on the left of Figure 6. To the right of the map is the full raster encoding in a $6 \times 6$ cell matrix, where 36 values are required. The run length encoding file shown to the right of the full raster encoding contains three columns: val (the value in the grid cell), run (the number of adjacent grid cells that hold this value), and row (the row number for that run of values). The encoding proceeds from the top left grid cell and reads left to right, top to bottom. The file reads that the value “1” occurs in the first row six times, the value “1” occurs in the second row six times, the value “1” occurs in the third row two times, the value “2” occurs in the third row four times, and so on through the entire grid. Note that this run length encoding approach requires only 24 values to encode the entire grid, and that the original full raster encoding can be easily reconstructed from the run length encoding table.

An even greater degree of compression can be had by eliminating the need to store the row number, and storing runs of adjacent cells that extend from one row to the next, again starting at the top row of the grid and reading each row from left to right. Here, only the value and the number of adjacent grid cells need to be encoded. Such an approach is illustrated in Figure 6 on the far right, where it is recorded that the value “1” occurs in a run of 14 cells (stretching from the first row to partially through the third row), the value “2” occurs in a run of four cells, and so on. Obviously, the reconstruction of the full raster encoding using this approach requires the GIS software to know how many rows and columns are in the grid, information that is contained in the header file.

Another well-known compression strategy for raster data is the region quadtree data structure, a recursive tessellation that utilizes a variable resolution (Samet 1990). It is similar in concept to run length encoding but is extended to two dimensions. The quadtree structure recursively partitions an area into quadrants, labeled “0,” “1,” “2,” and “3.” Any quadrant that is not homogeneous, that is, not all grid cells within the quadrant share the same value, is further partitioned into quadrants recursively until the resolution of the raster is reached. Only values of homogeneous quadrants are stored, which

Figure 6  Run length encoding (RLE). The analog map on the left is encoded using full raster encoding (middle left), run length encoding by row (middle right), and run length encoding by value (far right).
Figure 7  Quadtree raster data structure. Representation of the analog map (far left) using a recursive partitioning into quadrants to three levels. The gray square grid cells represent the gray polygon shown in the map.

reduces the redundancy of data storage for areas of the raster with repeating values.

Figure 7 shows an example of a quadtree. On the far left is an analog map with one polygon shown in gray. The first partition into quadrants is shown to the right, where each quadrant is labeled. Note that quadrants “2” and “3” are homogeneous, that is, there is not variation within the quadrant, but quadrants “0” and “1” are not, that is, the polygon occupies only a portion of the quadrant. Therefore, quadrants “0” and “1” are further divided into subquadrants and labeled accordingly, where, for example, quadrant “0” is subdivided into quadrants “00,” “01,” “02,” and “03.” Each of these quadrants is subdivided again, if not homogeneous. The final quadtree structure is represented on the far right, where grid cells – of various resolutions – are colored gray if they represent the gray polygon in the map.

Figure 8 shows a diagrammatic representation of the same quadtree shown in Figure 7. Here, one can clearly see the tree structure composed of nodes in the tree, where a node occurs at the beginning and end of each line, or edge, in the tree. The node at the very top of the diagram is called the root, and every other node, each of which represents a quadrant, has the potential to be subdivided into four other nodes, called children, that is, four subquadrants. When a node is homogeneous, and thus is not split into subquadrants (does not have any children), it is referred to as a leaf node. Other nodes which have children are referred to as branching nodes. In Figure 8, the leaf nodes that represent the gray polygon shown in the map in Figure 7 are colored gray.

Ordering strategies

A variety of different ordering strategies for storing series of grid cells can be employed. These strategies are called “space-filling curves” as their purpose is to transform data in two dimensions (i.e., the rows and columns of a raster) into one dimension for storage on a disk (van Oosteroom 1999). For example, the run length encoding example shown in Figure 6 employs a row ordering strategy – first the grid cells in row 0 are encoded, then the grid cells in row 1, and so on. There are variations of this strategy whereby the rows may be read from right to left, or alternate from left-to-right and then to right-to-left as one traverses from the top of the grid to the bottom (called row-prime ordering), or proceed from column to column rather than row to row. The row ordering strategy (and its variants), however, gives preference to row adjacency, and thus has the disadvantage of having two adjacent cells that share the same column position but are in different rows separated in the 1-D storage.
To address this, certain space-filling curves have been proposed to maximize the degree to which grid cells near one another in 2-D space will also be located nearby one another in the 1-D ordering. The space filling curve depicted by the ordered labels in the quadtree data structure in Figure 8 is one such strategy and is called a Morton curve (also called a Peano curve, an N-curve, or a Z-curve). The Hilbert curve is another commonly used space filling curve. Figure 9 illustrates each of four commonly used space filling curves.

Run length encoding and quadtree data structures are appropriate for raster data with large numbers of grid cells with redundant data values, typically raster representations of nominal or ordinal data. For continuous raster data, such approaches are inefficient, and may even increase the data storage requirements. For compression of continuous raster data, lossy approaches adapted from computer graphics have been used. These approaches typically capture the spatial patterns expressed in a raster through mathematical functions that approximate the continuous variation in grid cell values over space. They often allow the analyst to choose the degree of compression (and, consequently, loss of information) employed.
Lossy compression

An approach to compression of continuous raster data gaining in prominence is the wavelet transform. Here, a mathematical function expressing a regular wave, or oscillation, is used to model the continuous variation embedded in the raster. The deviations of each pixel from the wave are recorded as a set of coefficients. These coefficients can be used to reconstruct the original raster, in which case the compression is lossless. The coefficients can also be summarized statistically by taking averages of adjacent grid cells, thus decomposing the original wave into smaller wavelets. This process may be used recursively, such that two adjacent grid cells may be averaged, and then those averages may be averaged again to attain a greater degree of decomposition of the wave. This latter approach of statistically summarizing the grid cell values allows for substantial compression of the original raster, but is lossy, if only the summarized data and not the original coefficients are retained. One primary advantage of wavelet compression is that it supports storage and retrieval of the raster data at variable resolutions, as the raster can be retrieved using different levels of decomposition of the original wave.

Raster formats

Band sequential, or “BSQ” for short, is a way of organizing multiband imagery – that is, raster data in which there are multiple values per grid cell. Such data may be thought of as multiple individual raster layers in GIS, where each raster layer is a separate “band,” but within computer graphics and image processing it is common to store multiple values at single location, for instance, in order to store the magnitudes of red, green, and blue colors at each grid cell location in a graphic image. Or, in remotely sensed image data, each grid cell may have several values collected by different sensors. Band sequential encodes all the data for the first raster band, or layer, encoded in the file first, followed by all the data for the second band, and so on. Band interleaved by line, or “BIL,” implies the file is organized line by line, such that the first row of grid cell values is encoded for the first band, then the first row of grid cell values is encoded for the second band, and so on. A third organizational approach is band interleave by pixel, or “BIP,” where the values of the first grid cell are written for all bands, then the values of the second grid cell are written for all bands, and so on.

There are numerous raster file formats available, many of which are used in, or descend from, compression formats used in computer graphics. Many of these are open (i.e., their specifications are made public), patent free, or intended for cross-platform use. The JPEG (Joint Photographic Experts Group) format, with files having a “.jpg” filename extension, is a lossy compression algorithm that employs a discrete cosine transform (DCT) to model the variation in an image as a series of mathematical functions. This format was originally developed for sharing photographs and other images on the World Wide Web and continues to be widely used for that purpose. JPEG images with high compression ratios often have a blocky appearance, due to the nature of the compression, which operates over discrete square portions of the raster. JPEG2000, with the filename extension “.jp2,” is an updated approach that uses the wavelet transform. A metadata standard for georeferencing has been defined for JPEG2000 by the Open Geospatial Consortium (OGC) such that JPEG2000 images can be registered with other raster data in a GIS package.
The TIFF (tagged image file format) format, with filenames having the “.tif” extension, is now controlled by Adobe, Inc. It is a compression format that employs a form of run length encoding and has been widely used by digital graphics professionals because it is lossless and thus preserves the original full raster encoding. It has been extended to GeoTIFF, which includes a metadata standard for georeferencing information to support the seamless integration of TIFF files into GIS packages. The GIF (graphics interchange file) format has the “.gif” extension and also is widely used for graphics on the World Wide Web. It utilizes a lossless compression but is limited in the range of values that can be stored in each grid cell as compared to some other raster formats. The PNG (portable network graphics) format, using the file extension “.png,” was developed as a replacement for GIF. It is also lossless and offers a greater range of values as compared to GIF. MrSID (multiresolution seamless image database) is another raster format developed at Los Alamos National Laboratory and owned by LizardTech, Inc. It employs the wavelet transform and offers both lossy and lossless compression options.

There are also many proprietary formats developed for specific GIS and remotely sensed image processing software packages. GRID is the native raster format for the ArcGIS GIS package developed by Environmental Systems Research Institute, Inc. (ESRI). It is a lossless compression format using run length encoding. Another run length encoding-based lossless compression format is the “.img” format used by the remotely sensed image processing package ERDAS IMAGINE. The file format used by the remote sensing/GIS package IDRISI, with the extension “.rst,” is a full raster encoding.

Outlook

The raster data structure has distinct advantages and disadvantages. Advantages include its simplicity both in encoding and in the application of analytical algorithms. Basic encoding of raster data as a 2-D array is straightforward in nearly all programming languages, and raster algorithms can be built on well-defined array operations for the development of more sophisticated modeling and analysis functions. And because raster is the native format for much remotely sensed imagery and computer graphics, there has been a natural cross-pollination of raster data handling in GIS with these closely related fields. A disadvantage of raster is its blocky appearance for cartographic products, though this depends on the raster resolution. The main challenge with raster, however, has always been the large data volumes required, which can make storing and analyzing raster data problematic. Even given the rapid advances in computer storage capacity and processing speeds, this issue continues to be a prominent one, due to the ever-increasing volume of spatial data generated from the advances in, and increasing ubiquity of, geospatial technologies.

Future research in raster data structures should address the issue of efficient data encoding, and the relationship of such encoding to support raster analysis. Such research is particularly important for extending raster data structures and analysis from two dimensions to three dimensions in space, and four dimensions when time is also included (Mennis 2013). Other research frontiers include the development of data structures for more sophisticated semantic representation, which often integrate raster, vector, and object-oriented modeling principles (Goodchild, Yuan, and Cova 2007), as well as tighter integration of raster GIS with research in
DATA STRUCTURE, RASTER

computational simulation of environmental and socioeconomic processes.

Data structures are ways in which data are organized in a computer. This entry focuses on the topic of vector data structure for organizing geographic objects in a geographic information system (GIS). A GIS based on a vector data structure has been customarily called vector GIS. Another common way of organizing data is the raster data structure, which is the topic of another entry in this encyclopedia. On a paper map, geographic features are typically represented as points, lines, and polygons. In the vector data structure, the location of a point is represented by a pair of coordinates, a line is represented by an ordered sequence of shape points connected by line segments, and a polygon is represented as a set of lines in a given sequence forming the boundary of the polygon. Network data structure for supporting network analysis is also a form of vector data structure; it is covered in a different entry.

To understand the historic evolution in the development of vector data structure, it is necessary to have some background information about the traditional manual map production process before computers were used for mapping. In that process, the coordinates of a geographic feature to be mapped were first obtained through field surveying and/or photogrammetry. The feature was then drawn on a piece of paper either manually or by a mapping instrument based on the coordinates and a predefined symbol representing the geographic feature. This was a very labor-intensive process involving not only the initial mapping of any area but also the subsequent process of keeping the map current when any changes on the ground had to be reflected on the paper map.

Many paper maps were accumulated over the years since maps were invented for communication and archiving. In the 1950s and early 1960s when people began to realize the potential of using computers to support mapping, the immediate challenge was to transfer the paper maps into the computer. To store large volumes of maps in a computer requires a “good and efficient way” to organize map data. Therefore, the search for a data structure to organize maps in a computer based on coordinates was one of the most significant research challenges in automated mapping.

Figure 1 is a map generated from modern GIS showing some basic geographic features in San Marcos in Texas, the home city of Texas State University. This is a typical reference map that shows some basic geographic features in an urban area. Although it is a computer-generated map, it still serves the purpose of illustrating what a paper map usually looks like. If you are new to the fields of GIS and mapping, and are asked to find a way to organize the geographic features shown on the map in a computer, how would you get started and conceptualize it? Moreover, what data structures would have the power and versatility to support sophisticated analysis of geographically referenced data to solve complex problems beyond mapping?
Figure 1  A typical reference map of San Marcos, Texas.
In the rest of this entry, we will first walk through some of the key developments in the evolution of vector data structures in GIS together. These developments led to the topological vector GIS data structure that is widely used in different parts of the world today. Then, we will manually construct a vector data structure using an example to understand how it actually works. Furthermore, we will illustrate the power of topological vector data structure in supporting computations in GIS and discuss some of the constraints of the existing data structures as well as the challenges related to the development of vector data structures.

Evolution: contributions from the US Census Bureau

The simplest and earliest vector data structure is the so-called “spaghetti model” – a direct line-for-line translation of the paper map using simple points, lines, and polygons. Among other problems, the spaghetti model does not represent the inherent nature of topology between features on a map. Topology refers to the relationships between geographic features represented on a map that do not change after geometric transformations such as translation, scaling, and rotation. Examples of these relationships include connectivity and adjacency. Since the beginning of the development of computer mapping and GIS technologies in the late 1950s and early 1960s, many researchers naturally began to search for a vector data structure that could adequately represent both geometry and topology.

Although Robert Dial developed a data structure related to mapping in his master’s thesis in the early 1960s (Dial 1964), and Tomlinson stated in his 1984 paper in the Operational Geographer that the Canadian GIS developed in the 1960s had functions to correct topology in the data (Tomlinson 1984), it is now widely recognized that the most influential innovations in the development of topological data structure have been through the contributions from the US Census Bureau, beginning in 1967 in New Haven, Connecticut, in the United States. Milestones in the developments at the Census Bureau include: (i) the development of the DIME (dual independent map encoding) in 1967 (Cooke and Maxfield 1967; Cooke 1998); (ii) the development of a 2-D version of DIME in the 1970s and early 1980s that helped the US Census Bureau complete its digitizing project in time to support operations related to the 1980 decennial census (White et al. 1981; Lockfeld and Smartt 1984; Cooke 1998); and (iii) the development of the nationwide TIGER (topologically integrated geographic encoding and referencing) database from 1982 to 1990 to support the 1990 decennial census (Marx 1986; Cooke 1998). Table 1 is a summary of the data structures and key individuals involved in these developments.

The US Census Bureau made a decision in the mid-1960s to use a mail-out/mail-back approach in its 1970 decennial census instead of employing enumerators to deliver questionnaires to households and collect the completed questionnaires in the field. To prepare for the mail-out/mail-back operation, the Census Bureau established a research unit called Census Use Study in New Haven. Among other responsibilities, researchers of the New Haven Census Use Study team were charged to automate the processes of geocoding each address to a census block and evaluate methods of mapping that could be used to support operations of the Census Bureau.

Donald F. Cooke and William H. Maxfield were hired by the New Haven Census Use Study
team in early 1967 while finishing their studies at Yale. One of their tasks was to conduct the mapping experiments. Naturally they started with information from the New Haven Address Coding Guide (ACG) provided by the Census Geography Division in their mapping experiments as early as February 1967. The ACG used block side (one side of a city block) as the geographic entity to record address information for census enumeration. Basic information in each record of the ACG included: street name, state code, county code, place code, ZIP code, census tract number, block number, and address range.

In their initial experiments, Cooke and Maxfield used coordinates of the two ends of each block side and the line between the two ends to map a block side, amended the coordinates to the ACG records, and generated maps using the amended ACG data. They quickly realized that the ACG was not a good geographic base file for mapping. Among other problems (Cooke and Maxfield 1967), each cross-street intersection had to be read as many as eight times. In addition, the “true” shape of a block side of a curvilinear street was lost when only the two ends of a block side were recorded.

Because of the limitations of the ACG as a geographic base file for supporting mapping, James Corbett of the Bureau’s Statistical Research Division and George Farnsworth, then working as a statistical intern at the Bureau, proposed an alternative mapping database structure (Cooke and Maxfield 1967). This data structure was initially called dual incidence matrix encoding (DIME) and renamed to dual independent mapping encoding later. DIME is theoretically grounded in graph theory. More details about the topological principles of maps can be found in a technical paper of the Census Bureau (Corbett 1979).

Technical innovations in the development of DIME, as we see it today, include: (i) the introduction of topological principles from graph theory in applied mathematics to mapping; (ii) the use of the line (street) segment as the most fundamental unit of the data structure in mapping; (iii) the first use of “node” in a (cartographic) data structure, the beginning of “assigning numbers (identifiers) to nodes,” as well as organizing the numbered nodes in DIME; and (iv) the design and implementation of the “topological editing” procedures for quality control. Cooke implemented the procedures for topological editing without directly using the concepts of incidence matrices introduced by Corbett (Cooke 1998). This innovation is also the beginning of the algorithms for “topology building” of vector data in subsequent generations of GIS in the decades following the invention of DIME. More details about “topological

Despite the innovative features in DIME, it suffers several limitations. Among the limitations, it is very inefficient to retrieve and update the records because the line segments are stored in the system without any particular order. This means that all records in an entire file had to be scanned to search for a particular line segment. This is a very time-consuming and inefficient process from a database management perspective.

Because of the limitations of computing technologies at that time, the DIME system developed by the New Haven Census Use Study team was an offline and batch processing system that did not provide graphic feedbacks to operators who performed digitizing and editing activities. A transition to an online interactive environment with 2-D graphic display had to be made to overcome the limitations of the original DIME system. This transition was achieved about a decade later, in the late 1970s, by Marvin S. White, who was a researcher at the Statistical Research Division of the Census Bureau from the 1970s to the early 1980s.

Starting with the online DIME editor called ARITHMICON left by Corbett at the Census Bureau after Corbett’s retirement, White designed a 2-D version of DIME and implemented it in a microcomputer environment using Pascal (White et al. 1981; Lockfeld and Smartt 1984). The system was based on the topological principles of 2-D maps described by Corbett (1979). It used 0-cells, 1-cells, and 2-cells to organize nodes, lines, and blocks. The system employed the B-tree data structure to index the data for faster data retrieval and manipulation. It provided an interactive environment for 2-D graphic display that facilitated a much more efficient process of creating and updating DIME files (Lockfeld and Smartt 1984). Under the pressure of meeting deadlines of the digitizing project to support census operations related to the 1980 census, the Geography Division of the Census Bureau implemented the system based on White’s design. This newly implemented system helped the Geography Division complete the digitizing project on time (Cooke 1998).

The usefulness and potential of the 2-D system apparently played a significant role in convincing managers at the Census Bureau to make the decision in 1982 to develop a nationwide TIGER database to support the 1990 decennial census (Cooke 1998). In the 1980s, Robert Marx, then serving as the Chief of the Geography Division at the Census Bureau, spearheaded the development of the first nationwide TIGER database through collaborations with the US Geological Survey (USGS) (Marx 1986).

The overall architecture of TIGER is well documented (Marx 1986; US Census Bureau 2006). Theoretically, it is based on the topological principles of 2-D maps described by Corbett (1979). Although the basic units (nodes, lines, and polygons) of TIGER are still the same as the ones used in DIME, the data structure of TIGER is more sophisticated. TIGER uses lists to store the topological relationships among 0-, 1-, and 2-cells. The 0-cell and 2-cell lists can be accessed through directory files that are the entry into the TIGER database (Marx 1986). Directory files are stored in a B-tree structure to enable efficient access, fast manipulation of data, and optimal computer storage. Directory files contain one record per cell and a pointer to the corresponding record in the cell list. The list files contain more fields than directory records. For example, the 0-cell list contains the coordinates for each record, selected attributes, as well as a pointer to the first record in the 1-cell list that has this 0-cell as one of its end points. The 1-cell
lists hold feature attributes and several pointers (e.g., a pointer to the start and end 0-cells and a pointer to the left and right 2-cells). The 2-cell lists include several feature attribute fields and pointers such as pointers to 1-cells (Marx 1986).

The TIGER database and the products from the Geography Division of the Census Bureau have evolved over the years. The Census Bureau adopted the terminology used in the spatial data transfer standard (SDTS) (USGS 1992). In the 2006 edition of the TIGER database, the concepts of complete chain and GT (geometry and topology)-Polygon replaced those of line and polygon mentioned earlier in this chapter. In addition, the concepts of spatial objects, features, left- and right-side data fields, and single-layer topology are used (US Census Bureau 2006).

Spatial objects are the digital representation of real-world spatial phenomena (e.g., Texas State University and Spring Lake). Spatial objects defined in the TIGER database support geometric drawing and topological operations, which have coordinate locations, shapes, as well as topological relationships. There are three types of spatial objects in the TIGER database: zero-dimensional (e.g., node, entity point, and shape point), one-dimensional (e.g., complete chain or network chain), and two-dimensional (e.g., GT-Polygon) spatial objects. The term feature defined in the TIGER database is used to describe spatial objects that are more complex than node, complete chain, or GT-polygon. For example, a street that consists of a set of complete chains is defined as a feature in the TIGER database. The left- and right-side data fields list information about the left and right spatial objects or features of a complete chain based on the start node and end node of that chain. Therefore, the fields provide necessary information about complete chains for users to construct polygons or features.

**Evolution: development of vector data structures at other institutions**

The evolution of vector data structures extended far beyond the efforts at the US Census Bureau. Reports about research activities of the development of vector data structures by other institutions in the United States and different institutions in the rest of the world are scattered in the literature. It is beyond the scope of this entry to provide a comprehensive review. Other institutions in the United States that made significant contributions include the University of Washington, Harvard Laboratory for Computer Graphics and Spatial Analysis, USGS, Environmental Systems Research Institute (ESRI), and Intergraph Corporation.

As mentioned earlier, one of the earliest documented innovative research activities in the United States was Robert Dial’s master’s thesis research completed in 1964 at the University of Washington under the supervision of Professor Edgar M. Horwood (Dial 1964; Mark et al. 1997). The title of the thesis is “Street Address Conversion System” (SACS). SACS was developed to meet the need for geocoding street addresses in a large database. It translates street addresses to point coordinates using an efficient segment file structure. Although similar to DIME, the system developed by Dial had an important innovation which was not available in the initial implementation of DIME — the use of a grid for indexing nodes (Mark et al. 1997).

In the 1970s, the Harvard Laboratory for Computer Graphics and Spatial Analysis implemented the concept of POLYVRT (POLYgon conVeRT) (Peucker and Chrisman 1975). POLYVRT is a hierarchical vector data structure. One important contribution of POLYVRT is the introduction of the concept of “chain” that is widely used today. In addition, POLYVRT explicitly defines neighborhood relationships...
DATA STRUCTURE, VECTOR

that are important in certain applications of spatial analysis.

The digital line graph (DLG) developed by the USGS is another vector data structure. It was converted from hardcopy maps and stored in ASCII format. DLG files are available at 1:2 000 000, 1:100 000, and 1:24 000 scales. After several revisions, the DLG–3 data structure in the mid-1980s consisted of three basic elements: nodes, lines, and areas. Line is the basic element and users must start by processing line records. DLG contains one-way pointers to nodes at each end of a line and to areas on each side of a line. Unlike some other vector data structures, DLG does not explicitly store attribute information but stores unique feature codes to represent the attribute features.

In 1992, the USGS released the spatial data transfer standard (SDTS) to meet the need of supporting data transfer and exchange (USGS 1992). The SDTS facilitates Earth-referenced spatial data transfers between different computer systems, while minimizing the potential information loss. It includes standards for meeting a wide range of transfer needs such as spatial data concepts, attributes, data structures, and logical and physical file structures. Although SDTS cannot be categorized as any data structure type, it is mentioned in this entry because of its importance in facilitating transfer of vector data.

Among other data structures, ESRI introduced the arc–node data structure (coverage) and shapefiles to organize vector data in GIS. In the arc–node data structure, “arcs” are the same as “lines” and “chains” mentioned earlier in this entry. Topology is represented in the arc–node model in a way similar to those of DIME and TIGER. Like most of other vector data structures, shapefile represents spatial objects using points, lines, and polygons. However, shapefiles use a nontopological vector data structure that does not have built-in topology in the data.

A shapefile consists of three separate and distinct types of files: main files, index files, and database tables. The main file is a direct-access file that contains the shape as a list of vertices. The index file contains character length and offset information for locating an element. The database table contains attributes of the shapes. A main advantage of shapefiles is that it allows rapid cartographic representation of large geographic datasets.

Autodesk developed the design exchange format (drawing exchange format now) (DXF) in 1982. DXF is used for communicating design information between computer-aided design (CAD) and other programs. The DXF data structure is a tagged data representation that uses an integer number (called “group code”) to define each data element. Unlike some vector data structures that use features to define spatial objects, DXF format uses listing elements consisting of strings of vertices. A DXF file consists of several sections: header, classes, tables, blocks, entities, objects, thumbnailimage, and end of file. The DXF format has data redundancy because it is a nontopological data structure.

Two other vector data structures, GeoMedia and imagestation feature collection (ISFC), were introduced by Intergraph Corporation. GeoMedia has no proprietary data format. It accesses data in a variety of formats (e.g., ESRI shapefile and CAD data) using technologies such as geographic data object and data server without translation. ISFC is a MicroStation-based format that can be used to facilitate digital photogrammetry workflows.

GeoJSON is an open standard format used by many open source GIS packages. Like other vector data structures, GeoJSON uses points, lines, and polygons to represent spatial objects. Additionally, it uses multipart collections of these three types of data, including multipoint, multilinestring, and multipolygon. However,
compared with the data structures described above, GeoJSON was developed and maintained by a group of volunteers. It also differs from some other vector data formats in that it uses objects consisting of members. Each member in GeoJSON has a name represented by a string as well as a value represented by a number, string, object, or array.

A vector data structure can be implemented using the keyhole markup language (KML). KML was initially developed by Keyhole Incorporation (now part of Google). In 2008, KML became an international standard of the Open Geospatial Consortium (OGC). As of 2014, KML is one of the most widely used ways to support operations related to vector data. For example, it can be used to describe geographic annotation and visualization (e.g., polygons, place marks, and 3-D models) involving internet-based 2-D or 3-D maps.

State of the art of vector data structure by example

It helps to understand the concepts related to vector data structure if a topological data structure is manually constructed for the features shown in Figure 2 using a five-step procedure. Recall that a node is used to represent either an intersection of two or more linear features or the end of a linear feature. The direction of a chain starts at a “from node” and ends at a “to node” (Figure 3). Based on the direction of a chain, its left-side and right-side polygons can be determined. In the five-step procedure, we first define the nodes and assign an identifier (ID) to each node. Second, we give an ID to each chain connecting a pair of nodes. Third, we construct a “Node” table. Each record in the “Node” table contains all attributes associated with a node, including the coordinates representing the location of the node. Fourth, we build a “Chain” table. The essential attributes of a record in the “Chain” table include an ID, the “from node,” “to node,” left-side polygon, right-side polygon, and any other attributes associated with a chain. Fifth, we construct the “Polygon” table. The contents of the tables are shown in Figure 3.

In practice, most of the work in the five-step procedure mentioned above can be done automatically using topology-building functions available in a GIS. After digitizing the coordinates characterizing the shape of a chain into GIS from a paper map, a commercial GIS at present has the capabilities to build the three tables mentioned above and the topological information in the tables automatically. When building topology, planer enforcement requires that all features (node, chains, and polygons) are on a 2-D surface. No overlaps among chains or polygons are allowed on the same layer. Additionally, there must be an intersection at each chain crossing.
Figure 3  Basic components of a topological vector data structure for the nodes, chains, and polygons shown in Figure 2.
Power of vector data structure to support database management and analysis

The vector data structure plays a vital role of supporting database management. It lays the foundation to facilitate computational procedures that are necessary to solve complex problems involving processing geographic data in a vector form. The topic of spatial database management is covered in a different chapter. As for the computational aspect of vector GIS, it is not the intention of this entry to provide a comprehensive coverage. Instead, we only illustrate the usefulness and power of vector data structure in supporting computational procedures using some simple examples.

These computational procedures in vector GIS may be used to support spatial search, spatial analysis, and other sophisticated analysis and computational tasks. Spatial search is used to provide an answer to a query about geographic data based on spatial relations between geographic objects. These relations may include distance relations, directional relations, and topological relations. Because coordinates of features are explicitly stored in a vector data structure, the search of the locations of features can be easily accomplished. Distance calculation is a simple procedure based on the coordinates representing locations of the features in question. Additionally, a spatial search involving topology is more efficiently supported in a topological data structure than that in a nontopological data structure because the relationships among points, lines, and polygons are well defined. For example, the task of searching for countries sharing a border can be efficiently solved by searching the left and right polygons representing the countries sharing a border from the chain topology table illustrated in Figure 3.

Spatial analysis refers to the analysis of geographically referenced data using statistical and/or other quantitative methods to reveal patterns hidden in the data and gain insights about the phenomena observed. Vector data structure facilitates spatial analysis in performing analytical and computational procedures involving topological relations such as adjacency, connectivity, and containment. For example, it is often necessary to determine adjacent polygons in some tasks of spatial analysis. These tasks can be easily accomplished by “walking” along the boundaries of a polygon in question when the polygon is represented in a topologically structured vector format.

As a simple example, imagine that you have a map showing several layers of geographic features covering the United States. These layers include cities, counties, major roads, water bodies, and parks. A simple spatial search that one may perform is to “find all counties with a passing-through river whose county seats are within 200 km of a straight distance from the City of San Marcos in Texas.” This is a simple spatial search that involves a topological relation and a distance relation. In vector GIS, this search can be easily accomplished using a few steps. First, calculate the distance between the location of each county seat in Texas and the city of San Marcos, and select the counties whose county seats are within 200 km from San Marcos to form the first set of counties. Let us assume that the data are in the Cartesian coordinate system and the effect of the curvature of the Earth can be ignored for the sake of simplicity. The distance is a simple Euclidean distance. Second, determine if a county in the first set of counties has a passing-through river. In computational terms, this means that we will check if any chain forming the boundary of a county in the first set of counties intersects with a chain representing a river. Any county with its boundary intersects with a river is kept in the set of counties. Otherwise, a county is deleted from the set of
counties. The counties left in the set are the counties satisfying the search criteria.

Topological overlay is one of the most widely used operations in GIS. It is a computationally intensive operation when the overlay involves two map layers each consisting of many polygons. The overlay operation first determines the boundaries of new polygons in the output map layer from the two input map layers, and then updates the attributes of the new polygons based on the rules dictating the overlay. For example, Figure 4a is a map layer showing polygons of four different soil categories (I, II, III, and IV) in an area of interest, Figure 4b is a map layer of polygons covering the same area, and the type of planned development in each area covered by a polygon is marked as residential (R), industrial (I), commercial (C), and agricultural (A). The city wants to obtain a map showing areas that are planned for residential development and have either soil category I or III.

The topological data structure in vector GIS can be used to support this type of overlay analysis. In addition to support operations involving other spatial relations, topological data structures facilitate analyses concerning adjacency, coincidence, and connectivity. Coincident topology allows one boundary from a layer to lie on top of another boundary from another layer. In the example presented in Figure 4, because layers 1 and 2 share some common edges along boundaries (coincident geometry), coincident topology in vector data structure can facilitate the overlay analysis between these two layers. Figure 4c is the output map layer showing the resulting polygons marked in different colors. Polygons in light blue are the areas that are planned for residential development with either soil category I or III. Polygons that are not colored are areas that do not meet the conditions.

There are several computational procedures involved in this overlay. First, for each chain forming the boundary of each polygon in the first input map layer, the GIS checks the chain against every chain forming the boundaries of polygons in the second input map layer and determines if the two chains intersect with each other. If the two chains intersect with each other, then the GIS computes the intersection of two chains, and records that intersection as a node of a new chain in the topological data structure of the output map layer. This process is repeated for all possible pairs of chains of the two input map layers that intersect. Second, the GIS builds the topological data structure of the output map layers and generates new polygons in the output layers and generates new polygons in the output

![Figure 4](image)

**Figure 4** An overlay example: (a) input map layer 1: polygons showing areas with different soil categories; (b) input map layer 2: polygons illustrating areas planned for different land uses; and (c) output map layer: initial resulting polygons after the overlay showing residential areas with either soil category I or III (in light blue) and other areas.
map layer. Third, the GIS assigns an attribute to each polygon in the output map layer based on the rules dictating the overlay operation.

In actual implementations, the efficiency of the computational procedure and exact algorithm can be improved by limiting the search space of the pairs of the intersecting chains in the two input map layers to reduce the search space. These topics are beyond the scope of this entry. From a computational perspective, the “line intersection” procedure and the “topology construction” procedure are two critically important computational procedures for supporting the overlay operations in GIS. Indeed, they are two of the most fundamental and widely used computational procedures in vector GIS and play important roles in a variety of applications.

The computational power of vector GIS can also be observed in its functions to support spatial analysis. For example, spatial autocorrelation is a fundamental concept in spatial analysis. It means that the observed value of a variable at one location is correlated with the values of the same variable in nearby locations. When areas are used as the geographic units for observation, almost all existing methods for determining whether or not spatial autocorrelation exists in a given dataset use a contiguity matrix to measure the nearness of area units represented by polygons. The contiguity matrix then is used to calculate a statistic to evaluate the existence of spatial autocorrelation. The contiguity may simply be the number of boundaries shared by two adjacent polygons. When the number of polygons is large, it is a time-consuming process to search for all adjacent polygons of each polygon in the study area. Fortunately, the topological data structure in vector GIS provides a convenient and efficient way to facilitate this type of search, and supports the computational tasks related to spatial autocorrelation analysis.

For organizing, processing, and visualizing objects in 2-D space, vector data structures described in this entry serve their purposes well for most applications. It is almost a necessity to use a vector data structure in applications where the demand on positional accuracy is high. For data involving more than two dimensions, 3-D vector data structures and other data structures are needed to adequately represent and process 2-D data. The development of vector data structures to support the management and handling of higher dimensional data is a challenging task and it is discussed elsewhere.

Decision analysis

Yupo Chan
University of Arkansas at Little Rock, USA

Decision analysis is a key methodology in the field of “methods, models, and geographic information sciences,” or “GIScience and technology” for short. The term decision analysis in the context of GIScience usually refers to the siting or locating of an object, facility, or land use on the landscape. For example, locating an airport is a complex decision that is the result of a consensus between the public and the authorities, if not beyond, who must account for a variety of considerations. Central to classic decision analysis is the concept of utility, which serves to quantify the value of a decision; in this case, the value added to the community by the new airport. The public, the authorities, and other stakeholders need to agree on the fact there is value in constructing a new airport and ideally account for costs and benefits. To quantify value, a utility function is employed to convert different attributes to a single measure called “utile;” these attributes may include accessibility to the airport and environmental concerns among others. Following classic multi-attribute utility theory (MAUT), these attributes need to be collapsed into a single measure, or a “common currency of exchange,” through a utility function. The process by which this utility is established is the heart of decision analysis.

Basics

The last 50 years have witnessed significant advances in the field of MAUT, in which meticulous methodologies have been crafted to overcome many challenges, and the field is still evolving. A central challenge is the fact that attributes can be incommensurate. Combining them may very well require comparing “apples” to “oranges;” for example, how does the decision analysis process reconcile the cost of noise pollution with the benefits of economic activity that come with an airport? More than that, there are many other intangibles, such as the attitudes of the public or the attitude of the authorities, both of which are difficult to quantify.

The simplest case of decision-making is termed dominance, which allows straightforward ordering among alternatives. An example is a “less expensive and better quality” shirt in a department store, which is preferred by all shoppers, all other factors being equal. The shirt that is both less expensive and better quality simply dominates other shirts because they are more expensive and of poorer quality. Note that a nondominated alternative is not necessarily a singleton, meaning that there are usually several shirts (if not more) in a department store that are equally attractive to shoppers. In fact, there are typically a huge number of nondominated solutions (many different shirts in this example) and the challenge is to focus on the ones that are most appealing.
More complicated than dominance is a situation where tradeoffs are involved, or Pareto preference. Continuing the example of shirts, the nondominated shirts may include those that are superior in quality yet more expensive, and others that are the less expensive ones but may not last as long. Here the tradeoff is between cost and longevity as a proxy of quality. The field of multicriteria decision-making (MCDM) addresses these tradeoffs, where the two criteria under discussion are price and quality. Multicriteria optimization (MCO) is a key component of MCDM besides MAUT. Central to MCO is the concept of Pareto optimality, defined as the choice in which one or more criteria achieve a higher utility without compromising any other criteria. This precisely describes the diversity of shoppers’ decisions with different pocket books while the department stores seek to stock items that will please a cross-spectrum of shoppers.

Of particular interest in MCO is interactive multicriteria optimization (IMCO). In considering shirts, buyers do not negotiate with the shirt manufactures, but in many real-world applications of decision analysis, the process of assessing options is interactive. With the airport example, the stakeholders’ perception of value will change as they negotiate and interact with one another. There is no rigid utility function that remains unchanging in many real-world problems, especially those that are controversial. By interacting with one another, the stakeholders’ preferences change, and through negotiation these evolving preferences are often revealed. Due to its applicability to a range of problems, IMCO is an exciting body of knowledge that has drawn a lot of attention in recent years, and new concepts are still emerging.

This entry uses a case study of choosing an airport location to illustrate the IMCO process, in order to examine how decision analysis works. First, the context of the airport-location case study is introduced to illustrate generic features of decision analysis, starting with basic facility-location concepts. (See elsewhere in this encyclopedia for details on facility location.) Such concepts include medians and centers, where a median is an airport location that is closest to all the travelers on the average, and a center is one that is closest to the furthest traveler. This is followed by defining a multi-attribute utility function that captures the incommensurate attributes of accessibility to the airport and environmental concerns in a single measure. This is accomplished by an interactive process rather than by a static function because the attitudes of the stakeholders, including the public and the authorities, emerge as they work together. More formally, an IMCO procedure is carried out as it is emerging, which means that it does not depend on an explicit definition of the utility function. This implicit quantification process shows the potency of MCDM in addressing intangible values and representing the intent of this chosen case study. Decision analysis is then further shown to shed new light on some of the classic problems of facility location in GIScience and technology. This entry ends with a projection of how the field of decision analysis will evolve to serve the GIScience and technology community.

Interactive location decisions: an airport example

Two central concepts in facility location are median and center. Some facilities, such as a distribution center for goods or services, are best located at the median, so that the retailer can best serve its clientele in aggregate. In contrast, a fire station may be located at a center, so that the furthest citizens are as likely to receive a fast response. Elsewhere in this encyclopedia, the reader can find procedures to locate medians and
centers in networks and planes (in the sense of a surface). Let us define a network as a representation of a geographic area in terms of nodes (such as street intersections) and arcs (such as the streets themselves). A plane is simply a blank map on which there are no streets or intersections. For a linear-cost function of accessibility, Hakami’s extremal condition (Hakami 1964) suggests facilities tend to locate at extreme points, or at a node of a transportation network rather than a “central” location on an arc. This is sometimes referred to as the nodal-optimality property. For a simple two-node network linked by an arc, a facility will be placed at either end of the single arc. Likewise, a facility will be located at the three nodes that make up the three corners of a triangular network connected by three arcs. Locating a center will be different, with the airport placed in between the two ends (on the arc) even for a linear cost function (when \( \beta = 1 \)). In other words, the optimal airport location is invariably at either end of the arc connecting the two nodes should travel cost assume a linear function of distance, such as \( c_{ij} = d_{ij} \). It can be shown that the airport will be located somewhere other than at the end points on the arc should noise pollution be the only concern. In this case, the cost function is increasing return to scale, or more precisely with \( \beta < 1 \). An example noise cost function is \( c_{ij} = d_{ij}^{-2} \). As plotted in Figure 1, one can see the progression of \( \beta \) as it keeps decreasing from \( 1/2 \) to 0, and onto \(-2\). It suggests that noise can be mitigated at a farther distance.

The case study and solution algorithm

Consider the example of selecting a site between Cincinnati (C) and Dayton (D), Ohio, for a regional airport so that both travel cost and noise impacts are minimized. The Cincinnati and Dayton metropolitan regions have populations of approximately two million and one million, respectively. Consider the simple linear network shown in Figure 2, where \( x_1 \) is the distance from Cincinnati and \( x_2 \) is the distance from Dayton. In
this referencing scheme, an airport located at the mid-point on the arc will carry the coordinate \((x_1, x_2) = (30, 30)\), or thirty minutes from either Cincinnati or Dayton. Travel cost is simply \(2x_1 + x_2\) passenger-minutes-of-travel, and noise impact is simply \(2x_1^2 + x_2^{-2}\) passenger-decibels.

The locational decision can now be modeled by the following MCO mathematical program:

\[
\begin{align*}
\min \ & \nu(f_1(x), f_2(x)) = \nu(2x_1 + x_2, 2x_1^2 + x_2^{-2}) \\
\text{s.t.} \ & x_1 + x_2 \geq 60 \\
& x_i \geq 0 \quad (i = 1, 2)
\end{align*}
\]

While travel cost \(f_1(x)\) and noise impact \(f_2(x)\) are quantified, notice the model is set up without specifying the precise form of the utility/value function. It is simply expressed as an open function of the two attributes \(f_1(x)\) and \(f_2(x)\), \(\nu(f_1, f_2)\). In this model, the criterion functions \(f_1\) (for accessibility) and \(f_2\) (for noise impact) are not necessarily all linear. In particular, the noise function, with a \(\beta\) value of \(-2\), certainly has \(\beta << 1/2\), suggesting a strongly increasing return to spatial scale, as shown in Figure 1.

The undefined value function and the nonlinearity of noise impacts complicate the solution of this MCO problem. Let us propose a simple solution by a gradient search procedure based on a linearized value/utility function, and an interactive marginal-substitution procedure. The former will approximate a nonlinear, yet to be determined, value function by its local tangent. The latter will take care of the two criteria by evaluating \(\lambda_1\) versus \(\lambda_2\), defined as the weight placed on travel cost and noise impact respectively. As will be shown, the Frank–Wolfe (F–W) gradient search procedure may be employed for the former. To apply the F–W solution method, the following condition must exist: all \(f_i(x), i = 1, 2,\) are convex and continuously differentiable in their respective domain and the constraints form a convex and compact set (a set that is closed and bounded).

Suppose the feasible region for the mathematical program shown in equation 1 is defined as \(\kappa\) in Figure 3. This 2-D figure illustrates the computational procedure of the F–W algorithm, should it start at a chosen initial feasible solution \(x^0\). First, the tangent at this point is constructed and taken as an objective function. Together with the feasible region \(\kappa\), the solution to this linear program (LP) is obtained, yielding the interim optimum at location \(x^1\). Another tangent is now constructed at \(x^1\). Together with the first linear objective-function and the feasible region \(\kappa\), it forms another LP. For the current LP, the optimal

![Figure 3](Frank–Wolfe algorithm.)
solution is again obtained at \( x^2 \). This procedure is repeated as many times as required. It can be seen that after \( k \) iterations an optimal solution \( x^k \) to the original nonlinear mathematical program, consisting of the bimodal objective function and the linear feasible region \( \kappa \), is obtained. Notice step size determination is part of the F–W procedure, as shown by the step size \( \alpha d^0 \) in this figure for the initial step. Here \( d^0 \) is the initial gradient of the climb, and \( \alpha \) is the step size, with \( \alpha \) ranging between 0 and 1. The F–W procedure, while being a robust algorithm, can only find local optima, rather than global optimum. (There is no guarantee of a single, best solution.) Whether a local or global optimum is obtained will be determined by the choice of the initial feasible solution or the starting point, in this case \( x^0 \). It can be shown that should one start at an alternate location, \( x^{0'} \), at the other end of the feasible region \( \kappa \), a global optimum will be obtained.

Importantly, the F–W procedure can be used in an interactive manner by stakeholders to overcome a “hidden” value function form, where the explicit form of \( v() \) is unknown. Taking the gradient of the value function yields:

\[
\nabla_x v(f) = \frac{\partial v}{\partial f_1} \begin{bmatrix} \frac{\partial f_1}{\partial x_1} \\ \frac{\partial f_1}{\partial x_2} \end{bmatrix} + \frac{\partial v}{\partial f_2} \begin{bmatrix} \frac{\partial f_2}{\partial x_1} \\ \frac{\partial f_2}{\partial x_2} \end{bmatrix} \tag{2}
\]

Let us approximate the nonlinear value function by its tangent at the location \( x \) where the gradient is evaluated by equation 2. Setting \( \partial v/\partial f_1 = \lambda_1 \) and \( \partial v/\partial f_2 = \lambda_2 \), with both evaluated at alternate airport locations \( x^0, x^1, x^2, \ldots x^k \), and so on yields a tangential linear function for each alternate location \( x^k \) (shown in Figure 4):

\[
\lambda_1 f_1 \big|_{x^k} + \lambda_2 f_2 \big|_{x^k}
\]

The relevant decision-makers decide interactively on the marginal rate of substitution \( \lambda_1/\lambda_2 \) to trade between accessibility and noise impacts. At the initial location \( x^0 \), halfway between Cincinnati and Dayton, for example, the decision-maker is asked about the increment of travel cost) \( f_1 \) for which s/he is willing to trade against a decrement of aircraft noise) \( f_2 \). The slope of this indifference curve is precisely \( -\lambda_1/\lambda_2 \), which is perpendicular to the gradient \( \nabla v(f_1, f_2) \). Suppose the decision-makers decide that the marginal rate of substitution is “fifty-fifty,” or \( -\lambda_1/\lambda_2 = 1 \). Without loss of generality, let us set \( \lambda_1 = 1 \), which means \( \lambda_2 = 1 \) in this example. The initial gradient at the half-way point between Cincinnati and Dayton \( x^0 = (30, 30) \) is now obtained as follows:

\[
\nabla_x v(f(x^0)) = \lambda_1 \begin{bmatrix} 2 \\ 1 \end{bmatrix} + \lambda_2 \begin{bmatrix} -4x_1^{-3} \\ -2x_2^{-3} \end{bmatrix} \big|_{x^0 = (30, 30)} = \begin{bmatrix} 2\lambda_1 -0.00015\lambda_2 \\ 1\lambda_1-0.00007\lambda_2 \end{bmatrix}
\]

This gradient leads toward an equivalent LP:

\[
\min_{x \in \chi} \nabla_x v^T(f(x^0)) x = \min_{x \in \chi} (2\lambda_1 - 0.00015\lambda_2, \lambda_1 - 0.00007\lambda_2) \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}
\]
Now substitute $\lambda_1 = \lambda_2 = 1$ into the above. By solving the following LP, the optimal solution $x^* = (0, 60)$ is determined:

$$\min \{2x_1 + x_2 | x_1 + x_2 \geq 60; x_i \geq 0 \} \quad (i = 1, 2)$$

Thus at this iteration, we are moving the airport toward Cincinnati from the halfway point between the two cities according to the steepest “ascent” direction $d^0 = x^* - x^0$, where $x^0 = (30, 30)$ and $x^* = (0, 60)$ or $d^0 = (-30, 30)$. In the space of the LP, this is illustrated in Figure 5.

**Algorithmic iterations**

The decision-makers (DMs), consisting of the authorities and the public, now determine the step size $\alpha$ to move along the direction $x^0 + \alpha d^0$. The DMs, assisted by tabular or graphic displays of the function $f(x^0 + \alpha d^0) = [f_1(x^0 + \alpha d^0), f_2(x^0 + \alpha d^0)]$ determine the step size $\alpha^0$ between the values of 0 and 1. One possible way to obtain the best step size $\alpha$ is to display the values for the two criterion functions $f_i(x^0 + \alpha d^0)$ for $i = 1$ and 2 as a function of $\alpha$ over the selected values of $0 \leq \alpha \leq 1$ in a tabular or graphic way. The DMs then determine a value of $\forall$ for the most preferred values of the corresponding criterion functions. In short, the following optimization problem is solved: $\min_{0 \leq \alpha \leq \nu} (f(x^0 + \alpha d^0))$. Suppose $\alpha^0 = 0.5$.

We are now at $x^1 = x^0 + \alpha^0 d^0 = (30,30) + 0.5(-30,30) = (15,45)$, and the iterations continue until the incremental “ascent” of the preference function $\nu$ is minuscule, as with most “hill-climbing” algorithms.

To fill in the details, let us now derive the example travel function for starting point $(30, 30)$, which results in $d^0 = (-30, 30)$ for the first step of the F–W procedure, moving toward Dayton with a step size $\alpha$ yet to be determined. This is shown in Figure 5, with $\lambda_1$ and $\lambda_2$ already determined to be equal to 1 each. The linear travel-cost function is now a function of the step size $\alpha$, as shown in Figure 6: $f_1(x^0 + \alpha d^0) = 2(30 + \alpha [-30]) + (30 + \alpha [30]) = 90 - 30 \alpha$. Notice the function is decreasing with step size, suggesting the closer we move the airport toward Cincinnati, the less passenger-minutes-of-travel becomes. Similarly, the nonlinear noise function is now a function of the step size $\alpha$. The parametric noise function used for determining the step size $\alpha$ is the following for the initial $(30,30)$ location: $f_2(x^0 + \alpha d^0) = 2(30 + \alpha [-30])^{-2} + (30 + \alpha [30])^{-2} = 3(30 + \alpha [-30])^{-2}$, and the function can be plotted as Figure 7. Notice the noise function is increasing with step size, in contrast to the
travel cost function, which is decreasing. Notice also that the travel-time and noise functions will change as the potential airport location changes.

Both the travel and noise functions are displayed side-by-side in Figure 8. With such a graphic display, the travelers and environmentalists are invited to reach a consensus on a common step size $\alpha$, where they are comfortable with both the travel cost versus noise levels. It can be shown that for equal weights upon the two criteria, that is, the decision-maker is indifferent between noise and travel and a fixed step size of $\alpha = 0.5$, an airport location converges. From Table 1, it can be seen that while the airport steadily moves toward Cincinnati in the first five iterations, starting at iteration 6, there is a directional reversal toward Dayton. If we make subsequent iterations, it will begin moving toward Cincinnati again (Figure 2). However, there is a limit to this westward movement — namely at a point east of the previous reversal point $(0.9375, 59.0625)^T$. This point is further from Cincinnati and closer to Dayton, or $x_1 > 0.9375$ and $x_2 < 59.0625$. As this point subsequently moves east toward Dayton again, there is once again a limit to its movement. In this case, it falls short of $(30.46875, 29.53125)$ — the previous “point of reversal.” Thus, the airport location bounces back-and-forth within a shrinking interval, eventually converging toward a final equilibrium point at $(1.587, 58.413)$, or about 1.6 minutes (or 2.6 km) outside Cincinnati.

As shown in Table 1, each computational step simply recommends another potential location for the airport, starting with the midpoint $(30, 30)$. In terms of the real-world context, this decision analysis framework can be placed in a public participation context. For example, public hearing could be held at each location and corresponding charts for travel cost and noise similar to Figure 8 be displayed in order to determine step size. Decision analysis provides the tools for determining the location of the airport as a function of noise vis-à-vis

Extending the basic model to two dimensions

Beyond network-center location problems like that examined above, decision-analytic techniques are equally applicable to median and center location on a plane. As above, the locational decision involves spatial organization articulated through the cost functions as shown in Figure 1. In the following planar example, we identify the cases in which $\beta = 1$, $> 1$, and $< 1$. Through the lens of decision analysis, one can view median locational decision as a system optimization model, whereby the “common good” is being upheld. Let us build upon the above airport case study by considering a regional airport for three cities (instead of two): Cincinnati, Columbus, and Dayton, Ohio. Suppose the population in Cincinnati is two million, the population in Columbus is three million, and the population in Dayton is one million. Note that the population in Columbus is the same as the population of Cincinnati and Dayton combined. This is done on purpose to show an ambiguous case for the Hakami extremal condition—a planar median-location decision based on system optimization. It is challenging because the solution is sensitive to model formulation and computational procedures.

Now, refer to Figure 9, which illustrates various locational solutions. For a linear-cost accessibility criterion, the airport will be located at the largest city—Columbus in this case—as shown by the label LB, with LD serving as the alternate solution. Here, the notation L stands for an LP solution, B stands for base solution, and D stands for alternate solution. Please note that numerical approximation may result in imprecise locations, shown here as “wedges.” Using planar gradient search, HB denotes the base solution, and HD is the alternate solution, where H stands for employing a planar gradient search procedure. Notice that both LP and gradient search yield the same base solution at Columbus. However, the alternate solutions LD and HD are in the middle of the triangle (instead of at a corner) and the two locations—LD and HD—are disparate. When noise concerns are the focus, spatial cost becomes nonlinear with $\beta < 1/2$, and the airport is now located at HB_n, where B_n stands for the base solution for noise abatement. Obtained by gradient search, the noise-abatement HB_n solution is somewhere between the accessibility-based LD/HD solutions and the LB/HB locations (at Columbus).

Viewed in decision-analytic terms, the center location problem is a user optimization problem, where the most-distant user is being taken care of. It can be shown that the airport will be located among the three corners of the triangle representing the three cities, even for a linear cost function. Of particular interest is that an MCO airport-location solution will juxtapose the single-criterion results shown above, essentially being sited by an interpolation of the locations shown in Figure 9. This result is similar to the two-city case study. It suggests that real-world
decisions, which invariably include multiple considerations, tax classic facility-location approaches.

Returning to the two-city study, it can be seen that an effective way of performing multicriteria nonlinear programming is the interactive Frank–Wolfe approach. A key feature of the F–W algorithm is to convert a nonlinear program into a set of LPs. We extended this concept by assuming the existence of an underlying preference function, as illustrated in Figure 4, but never actually requiring this preference function to be identified explicitly. All that is necessary to do so is to construct a tangent approximation of the value function at each candidate airport location. The tangent approximation helps to weigh accessibility against noise through the tangent slope $-\lambda_1/\lambda_2$. Meanwhile, the simultaneous graphic display of the travel and noise functions in Figure 8 helps to determine the next potential site for the airport through the step size $\alpha$. The basic idea is that even if the DMs cannot specify an overall preference function, they can provide local information regarding a preference at a particular situation. In so doing, we narrow the number of nondominated solutions to one at each iteration. The iterative approach moves from an initial feasible solution toward the optimal solution by finding the direction of steepest “ascent” and the optimal step size toward that direction. Again, explicit knowledge of the overall preference function is not essential. Only local information concerning the revealed preference of the decision-makers is required and this, in turn, is sufficient to determine the relocation direction and step size.

It is apparent from the above case study that interactive programming of this sort is highly numerical in nature and there are issues not addressed in this entry. Aside from convergence issues, for example, different attribute functional forms may give rise to drastically different solutions for a preset set of weights and step size. An example is to re-write the value function in terms of $v(f_1(\mathbf{x}), f_2(\mathbf{x})) = v(-2x_1-x_2, 2x_1^2+x_2^2)$, with the criterion functions to be maximized (instead of minimized). In practice, however, such an extreme result is unlikely to occur, since the weights and step size is anything but constant. The above cited computational results are built upon the assumption of $\alpha = 0.5$ and $\lambda_1 = \lambda_2 = 1$ throughout the iterations. This simplifying assumption is made mainly for our computational convenience. In fact, the entire foundation of interactive procedures of this sort is to explore the DMs’ revealed preferences, guided by charts and tables, in various situations. Correspondingly, their reactions, as reflected by values of $\alpha$ and $\lambda$s, are expected to be different at each iteration. Convergence in this case is obtained not so much from numerical properties as it is from the decision-maker’s behavioral changes through the process of negotiation and deliberation. These shifts from one iteration to another can compensate for the effects of different numerical procedures, leading toward consistent location decisions (Chan 2011). More detailed discussions of interactive multi-objective programming are found in Seo and Sakawa (1988) and Haimes and Steuer (2002).

**Future research directions**

What are the challenges of multicriteria decision analysis in the foreseeable future? One answer lies in the view that MCDM can be seen as comprising four different subareas. First, multicriteria mathematical programming will continue to focus on advancing our ability to formulate and solve decision problems mathematically. Second, research on multicriteria discrete alternatives (including integer MCO) will focus on problems where tradeoffs do not
DECISION ANALYSIS

vary smoothly, but instead have set, discrete values. Third, multi-attribute utility theory will examine the larger issues of how decisions are made. Finally, negotiation theory deals with how individuals can or should work in concert to come to decisions. In all four areas, extending the state-of-the-art lies not only in advancing a particular set of issues, but also addressing larger questions. For example, do stakeholders have multiple, conflicting objectives that must be reconciled? Is there significant uncertainty in the decision outcomes? Is one making a single, one-time decision or a sequence of decisions over time? Answering these questions will involve working across research areas.

If the problem calls for involving multiple stakeholders and multiple competing attributes, for example, then tools that emphasize group support and value elicitation are worth exploring. Group decision-making remains an interesting problem that should be further investigated, and has traditionally been addressed using incentives, game theory, facilitation, and other methods (Abbas 2012).

Fortunately for researchers and policymakers, there are decision analysis and multicriteria decision-making software packages available. Most of the examples given below cover multi-objective decision analysis and MAUT. Ideal software should be intuitive to the user, explainable to a variety of stakeholders, and readily support iterations among the various stages of the decision analytic process.

- 1000Minds – 1000Minds Ltd.
- Crystal Ball standard, professional & premium editions – Oracle.
- DPL – Syncopation Software.
- ForeTell /Æ – DecisionPath, Inc.
- Hiview3 – Catalyze Ltd.
- RPM-Decisions – Systems Analysis Laboratory, Helsinki University of Technology.
- SMILE (structural modeling, inference, and learning engine) – University of Pittsburgh.

Recent decision-analysis techniques tend to have a number of features in common and future research will very likely continue to enhance and expand on these features. First, they should not cramp the style and involvement of decision-makers. Second, they have interactive feedback mechanisms including graphics. A visual display, possibly through the use of computer graphics, can greatly assist the decision-makers in performing MCDM analysis. (We have seen such an example in Figure 8.) Third, they have a built-in evolutionary process, allowing modification of the model as the analysis progresses; improvements should include problem structuring and elicitation features. Finally, these software packages can provide decision-makers with fast-turnaround analysis techniques.

In some cases the analytic team will have large quantities of data that can be used to formulate and support the decision-making process (Chan 2011). Some of these decision-making software packages (as well as some statistical packages) have learning algorithms that will build the joint probability distribution from the available data. If this option is available, the analysis team can supplement automated efforts by involving subject matter experts in the review of the resulting model. These experts can help find errors in the data and, just as importantly, they can supplement the model with their knowledge. Combining what is learned from data and what is learned from experts usually yields a better model and results in a higher likelihood that the effort devoted to decision analysis will be successful. The primary advantage of involving experts is to increase the information learned as a result of asking preference questions of decision-makers.
Finally, there are broader issues of power and knowledge at play. In a competitive environment, such as the relationship between the airport authorities and the public in the above example, recent research suggests that those with better knowledge about other stakeholders tend to do better than those who do not. Under this situation, it is important to assess the role of epistemic knowledge, which is defined as knowledge supporting a belief, truth or hypothesis. Epistemic utility is a measure of the value of this knowledge in supporting a hypothesis, that is, a measure of the importance of the information about the other stakeholders relative to the belief that the other stakeholders are going to adopt a certain strategy. Epistemic utility theory has so far furnished us with a number of arguments for some of the central norms governing partial beliefs (Pettigrew 2010). For example, is it legitimate to employ the notion of expected utility when the belief function with which the expected utility is calculated is not a probability function? Stirling (2002) proposed a theory of multi-agent coordinated decision-making using epistemic utility, which represents an alternate theory of multi-agent decision-making, termed satisficing games, which is designed to address the limitations that are imposed by the assumption that players are motivated exclusively by self-interest. However, it does not abandon the principles of value and performance that are vital to rational behavior, which includes both common good and self-interest. Aside from our observations reported here, there will no doubt be other evolving schools of thought that differ from both the classic-utility- and epistemic-utility-theoretic schools.

Deep mapping and sensual immersive geographies

Trevor M. Harris
West Virginia University, USA

It is apposite that the term “geographic information system” (GIS) was coined at an early stage in the development of geographic information science (GIScience) not least because of the fundamental spatial concepts and spatial reasoning that underpin the technology. But while GIS and other labels such as spatial information system are often viewed as synonymous terms, in reality an important distinction might be drawn between them. Both represent digital spatial information systems, but the leading adjective represents an important nuanced differentiation in that the geographic serves a broader audience within the field of geography whereas emphasizing the spatial alludes to a more specific focus on spatial objects, spatial metrics, and spatial analysis. Within the field of geography this is an important distinction, and while GIS has seen dramatic diffusion and uptake within academia and almost every sector of the economy, it has nonetheless experienced resistance within parts of the discipline of geography. This is less a reluctance to embrace the technology but more a resistance to the way in which GIS represents nature and society, which appears at odds with many conceptual and theoretical advances made in human geography since the quantitative turn.

Many have questioned the epistemological and ontological construction of GIS and the perceived inability of a positivist GIS to address the needs of humanists and human geography. The important broadening of GIS from a focus on system toward one on science has not diminished concerns about the positivist and reductionist tendencies of GIS, embedded as it is within the scientific method. Critical GIS, critical cartography, and the GIS and society debates of the 1990s captured the early social theoretic critique of GIS and the concerns of human geography in particular, which saw GIS as a return to the positivist traditions of the quantitative revolution and which questioned the ways in which GIS represented nature and society. GIScience is clearly not a panacea for geography, but the primary focus of GIS on the spatial has contributed to a lack of engagement with other important aspects of geography such as place. While it is quite appropriate to contend that certain aspects of geography lie outside the bailiwick of GIScience, it is argued here that this space–place divide prematurely concedes considerable ground. Recent advances in both the technology and innovative approaches indicate that GIScience has a role to play in addressing aspects of geography previously considered beyond the purview of a spatially focused technology.

It is in the engagement of GIScience and the humanities that many of these issues have come to the forefront and also where possible advances have been made toward bridging this divide. There are good reasons why the sciences and social sciences were early adopters of GIS and have seen demonstrable success, yet the humanities have lagged these early adopters except where GIS lends itself to the mapping project or the analysis of spatially structured data such as within historical GIS. It is in the conceptual and methodological engagements between GIScience and the humanities, and in what
has been termed “the spatial humanities,” that scholars have sought to bend GIScience to the needs of humanists. In so doing, advances in the conceptualization and application of geospatial and geovisualization technologies indicate ways in which GIS might escape its reductionist spatial corset and embrace representations of human behavior, events, and place that enable GIS to contribute to a more human-centered geography. This entry examines ways in which deep mapping and immersive geographies point to alternative GIS representations of space and place.

Spatial representations – placial representations

GIS provides a powerful digital technology with sophisticated spatial data handling, spatial analysis, and mapping capabilities that brings with it a particular representation of the world. GIS necessarily represents an abstraction of the real world, for capturing reality in its entirety would involve an improbable 1:1 relationship. GIS captures, stores, and represents the world as spatial primitives, objects and fields, with the topological connectivity that relates them. Objects must have a geographical location invariably recorded according to some measured Euclidian coordinate geometry. GIS is driven by concerns to be error free and to achieve high accuracy and precision in the location and attribution of objects. Considerable effort is thus expended on issues concerning spatial data acquisition, data categorization, scale, distance and direction, datum and projections, and geometric topology. GIS seeks to be reproducible and verifiable, hallmarks of the scientific method. Sophisticated GIS mapping capabilities draw upon long-established cartographic traditions to effectively map spatial data that are difficult to describe through narrative, which is ill suited to represent the higher-order dimensionality of complex spatial data. System functionality enables sophisticated spatial analysis and spatial statistics to be performed on the data. Space thus provides a powerful integrating theme in GIS that enables multiple scaled explorations of spatial relationships by virtue of their common location and in ways that many alternative approaches cannot. Yet, despite the digital construction of an “authentic” representation of reality, GIS and maps possess an objective, authoritative, and reductionist allure and there is a tendency to separate and disembodied spatial analytical geographies from the mixed methods approaches of social, cultural, and political geographies (Sui and DeLyser 2011).

The social-theoretic critique of GIS through the GIS and society debates of the 1990s, critical GIS, and critical cartography, provides a valuable context for exploring many of the issues associated with the epistemology, ontology, assumptions, and biases of GIS in representing nature and society (Pickles 1995). As a result of these largely academic endeavors, particular types of data, representation, logic systems, and ways of knowing the world were seen to be privileged over others. There can be no question that the ability to deconstruct and reconstruct spatial entities and regions within GIS has brought about a profound technological transformation. However, the heavy reliance on available spatial data at an appropriate spatial and temporal scale and attribution, the commodification of data, the Boolean logic system of GIS, spatial determinism and the silences in the data, structural knowledge distortion, and the emphasis on mapping have all contributed to a particular representation and way of knowing the world.

Ultimately, GIS privileges reductionism and disambiguation in its organization and analysis of knowledge, and the map has assumed a seemingly unassailable sense of spatiality, surety, and finality. In many respects this disambiguation may have
contributed to the marked success of GIS as a critical decision-making support tool in many areas of society. Critics contend, however, that GIS privileges master narratives and categorical causation at the cost of contingent causation and alternative interpretations and renderings of space and particularly place. This reductionist metanarrative stands in contrast to many parts of human geography and the humanities that are heavily versed in multivocality, intertextuality, and contingency, and where place is equally important as space in the construction of human geographies. In this regard GIS is considerably less empathetic to scholarly work where knowledge is nuanced, individualized, spatially imprecise, uncertain, ambiguous, and part of a world of multiple realities. Handling ambiguity in GIS represents a challenge, though, this entry contends, not to a GIScience engaged in a meaningful reciprocity between geospatial technologies and humanist traditions.

But this raises the question about the role of place as inhabited space. Space and place, as intertwined phenomena, are central to the works of geographers (Cresswell 2004) and historians (Ethington 2007). For Tuan (1974) the individual’s relationship with the livable world, their being-in-the-world, and the connectedness between the physical fabric of landscape and human emotion lies at the heart of understanding place and the larger networks of places that is space. Tuan argues that human experience, while highly individualistic, is based on biological and cognitive traits that are common to everyone and that these innate traits allow our experiences of space and place to be shared. However, any experience of place carries with it the observer’s own reflexivity and worldview, encapsulated within social and cultural meanings that have been layered onto the landscape. While the work of Tuan, Tilley (1994), and others is compelling in its focus on the lived experience of space, place, and landscape, these ideas are difficult at best to translate into the medium of GIS and geospatial technologies (Goodchild 2011). The success of GIS as a tool for synthesizing, displaying, and analyzing geographic information is clear, but the limitations imposed by current data models and modes of representation make it difficult to develop a digital framework for humanistic and experiential aspects of place. Blending a phenomenological and experiential approach to interpreting places that are relative, mediated, and socially produced represents a real challenge to GIScience because place encompasses not only the physical but also the symbolic, the emotional, and the many meanings associated with place. As Entrikin (1991, 10) points out, “To understand place in a manner that captures its sense of totality and contextuality is to occupy a position that is between the objective role of scientific theorizing and the subjective role of empathetic understanding.” The quantitative nature of GIS favors representations of space that are absolute, whereas addressing issues of place requires a sensuous and reflexive GIS that is nuanced and sensitive to the traditions and epistemology of humanists.

Humanists place considerably greater emphasis on place than on space. The question then arises as to how it might be possible to link and explore the processes that make up place and place-making, such as locale, memory, experience, myth, ideology, symbology, and events, the grain and patina of place, to GIS. The spatial turn in the humanities confronted the perceived undue emphasis on historicism and reinserted space as an active participant in human events and behavior (Soja 1989). Ironically, the reinsertion of space in the humanities has been the result not only of the spatial turn but also of the (re)discovery of the power of the map through the application of GIS and historical GIS: social theory and positivist science together. However, the spatial analytical power of GIS does not
easily accommodate the ways in which humanists explore or interpret phenomena and place. Humanists struggle to fit their questions, data, and methods, the emphasis on narrative and storytelling, and a resistance to pre-emptive resolution, into the rigid parameters of the technology. In these instances, where knowledge is multi-valent, equivocal, contradictory, and conflictual, and where social life is contingent, implicated, or unpredictable, interfacing with the spatial precision and reductionism of GIS is problematic.

Deep mapping

Deep mapping arose out of the imaginary of the spatial humanities and represents a critical engagement between geography, GIScience, and humanist traditions (Bodenhamer, Corrigan, and Harris 2010). Deep mapping is aspirational and methodologically largely untried, but the concept pursues a GIS-humanist theme and engages a GIScience-enabled representation of place. It is too simplistic to speak in terms of a qualitative-oriented humanismandaquantitative GIS, yet the contrasting emphases on conceptual mapping rather than cartographic mapping do represent a significant methodological divergence. The intellectual origin of deep maps lies in a combination of eighteenth-century antiquarian approaches to geography, history, people, culture, and place; in the detailed local histories of historical geographers such as Hoskins (1955); in the insightful observations into deep mapping and performance drama of Pearson and Shanks (2001); in de Certeau’s (1984) spatial stories and practices of everyday life; in the early work of the Situationist International (DeBord 1955); in psychogeography (Stedman 2002); in Tuan’s Topophilia (1974); and in the thick description of William Least Heat-Moon’s PrairieErth (1999). Deep mapping challenges GIS to move beyond a view of humans as entities and data points and to include not only the material but the imaginary embodied world, together with the behavior and relationships that make up a nuanced, nonreductionist, and scaled conception of place and a habituated world. Deep mapping engages the material and the contingent world and interrelates theories of practice and agency and how people both create their material world and, in turn, are created by it. This linking of critical geographies, postmodernism, and GIScience provides a conceptualization of a recursive humanist GIS that is negotiated, nonauthoritative, and nonobjective, and which is framed not as a statement but as a conversation. Deep mapping is thus inherently unstable and continually changing in response to new data, new perspectives, and new insights (Bodenhamer, Corrigan, and Harris 2015).

Maps remain a crucial instrument in deep mapping because space contextualizes place. Traditional GIS maps, however, emphasize precision and accuracy and the mapping of material physical features, infrastructure, population, and other features traditionally found on topographic maps. The term “thin” map, rather than “shallow” map, the antonym to deep map, is used to describe these map products to avoid implications of shallowness, superficiality, or inconsequentiality for which there is abundant evidence to suggest otherwise (Harris 2015). These “thin” maps have formed the backbone of GIS and myriad applications.

Deep maps, in contrast, interlace autobiographical, art, narrative, folklore, stories, and memory with the physical form of a place. As Pearson and Shanks (2001, 64–65) suggest, deep maps “record and represent the grain and patina of a location … [through the] juxtapositions and interpenetrations of the historical and the contemporary, the political and the poetic, the factual and the fictional, the discursive and the sensual; the conflation of oral testimony,
DEEP MAPPING AND SENSUAL IMMERSIVE GEOGRAPHIES

anthology, memoir, biography, natural history and everything you might ever want to say about a place.” Deep maps speak to the contingent nature of cultural processes and the agents of change and transformation and for dismembering generalizations through rethinking and recombining (Bodenhamer, Corrigan, and Harris 2015). Deep maps are the stories, conversations, and lives lived out in a place, which are inseparable from the cultural context in which they exist. Deep maps are place-based and capable of integrating multiple voices and views based on a GIScience that is sensitive to the needs of humanist scholars. Deep maps resist reductionism and universal truths and grand narratives in favor of discursive collaboratories abounding with multiple voices, contingency, and contested meanings.

Moving from deep map concept to method is not without its challenges. There have been several attempts in GIS to explore place and latent place-rich geographies through GIS (Cooper and Gregory 2011). Perhaps the early focus on GIS has diverted attention away from other promising approaches under the GIScience umbrella even though GIS would appear to be an obvious analog for deep mapping through its layering and emphasis on space as a bounding framework. Under the umbrella of GIScience, a cornucopia of tools, techniques, and methods are now available, including geovisualization (Dykes, MacEachren, and Kraak 2005), geotagged social media and technologies, crowdsourced volunteered geographic information (Sui, Elwood, and Goodchild 2012), and Web 2.0 geospatial web mapping, mashups, and tools including neogeography (Turner 2006), capable of generating, storing, accessing, and mapping spatial data in multiple ways. Deep maps represent hybrid methodologies that fuse positivist and quantified geospatial technologies with qualitative data and nuanced analysis: a distinct move toward qualitative GIS (Cope and Elwood 2010). Deep maps thus draw heavily on space and place as an organizing framework to understand the world and yet challenges GIS as to how this might be achieved. A number of approaches have been proposed to achieve deep maps, including neogeography (Warf 2015); ghost maps of highly detailed and layered text, photographs, and maps (Ethington and Toyosawa 2015); geographical text analysis combining GIS with corpus linguistics (Gregory et al. 2015); ethnographic biographical storytelling, ethnopoetry, and tender mappings that weave the personal, memory, emotions, behaviors, and attachment to place into everyday geographies (Aitken 2015); infinite depth systems for storyboarding (Corrigan 2015); narrative generation platforms (Yuan, McIntosh, and DeLozier 2015); and coordinate frameworks for narrative recording (Martin 2015), each of which have sought to identify potential avenues for deep map development.

Embodied sensual GIS and immersive geographies

To illustrate one possible approach to deep mapping and deepening GIS into the experiential, emotional, and local associations that constitute place, an example exploring the literary work of a nineteenth-century writer, Rebecca Harding Davis, is used. Text analysis represents a continuing issue for GIS and yet it is the mainstay of the humanist tradition. In examining the writings of Davis (1861) the GIS back end is augmented by drawing on a fusion of three-dimensional (3-D) modeling and serious game engines displayed within the immersive virtual environment of a cave automatic virtual environment (CAVE). The intent here is to move beyond the reductionist two-dimensional map of the material fabric of a landscape toward an
Deep mapping and sensual immersive geographies

Experiential immersive environment that enables the emotional, the sensual, and the immaterial to be included to create a nuanced dimensional richness of place. Linking phenomenology and the experiential in such a manner in GIS is problematic for reasons detailed above, yet this study suggests ways in which it is possible to drill deeper into the geography of space and place.

Rebecca Harding (née Davis) (hereafter Davis) (1831–1910) was a leading American literary figure of the nineteenth century who lived in Wheeling, then Virginia and now West Virginia, and who wrote evocatively about the industrializing nature of the antebellum town. Davis witnessed dramatic changes in Wheeling as the town became an industrial center. While the distinction between factual and fictional sources, and between realism and the imaginary, is often blurred, Davis’s writings for the local newspaper and for fiction paint a fascinating picture of Wheeling as a place that augments the massive data repositories of newspapers, travelogs, and other archival papers available for Wheeling. The degree of fidelity to geographical reality in Davis’s writings is difficult to assess, though there is good reason to pay heed to her insights as one of the nation’s first realist writers and because of her personal knowledge and experience of Wheeling. Brosseau suggests that readers often assign the subjective element within fiction to the physical elements of a place while assuming that the interpretation of the relationships between places and people is reliable as novelists are seen as “some kind of spokesperson … They immerse us in the various attitudes, values and conflicts shared by the people of a particular region in relation to their environment” (1994, 336). Darby (1948), for example, suggests that Thomas Hardy manipulated some topographical details in his novels to facilitate his storyline and yet remained true to the underlying social relations. This is an important point that seeking insight into the human–environment relations rather than spatial description is perhaps most revealing and rewarding, and especially so in historical contexts where corroboration of these social–cultural–economic–environment relationships is so difficult to establish.

Davis’s seminal work, Life in the Iron Mills (1861), is recognized as among the most important works in nineteenth-century American Literature (Baym 2011). Davis writes in powerful evocative prose of mid-nineteenth-century Wheeling: “A cloudy day: do you know what that is in a town of iron works? … The air is thick, clammy with the breath of crowded human beings. It stifles me. I open the window and looking out, can scarcely see through the rain the grocer’s shop opposite … I can detect … the foul smells ranging loose in the air . . . . I want you to hide your disgust, take no heed to your clean clothes, and come right down with me, here, into the thickest of the fog and mud and foul effluvia. I want you to hear this story . . . . I want to make it a real thing for you” (Davis 1861, 1–2).

Yet, while her writings identify township locations, the world of emotions and place-based qualities evoked and experienced by Davis exceeds the representational dimensionality of a two-dimensional map. Davis’s world is multidimensional and sensual for her writings are awash with references to smell, texture, light, touch, and sound—all elements of a sense of place. Capturing the textual, experiential, and nuanced world of Davis’s Wheeling, to make it a “real thing” for the reader, requires moving beyond the strict spatial framework of GIS and its focus on the material townscape.

Within the past few years, a number of advances in computer science, computer hardware and software, computer graphics, virtual reality, 3-D GIS modeling, serious gaming engines, and geovisualization have made possible impressive rendered immersive representations.
that more closely emulate the world around us (Fisher and Unwin 2003). Immersion, augmented by geosensory inputs, more closely creates a sense of place and of “being there” (Harris and Baker 2006/2007). Immersion is a powerful psychophysical experience that draws a user into a seemingly real but virtually rendered environment and transforms the user from passive observer to active participant (Harris and Hodza 2011). The visual-cognitive model draws on the creative power of the mind to move seamlessly between the physical, virtual, and imaginary world and to be disengaged from the physical reality of the projection space. The effect is a powerful one in transporting users into a multidimensional and multisensory environment embedded within GIS in which users interact with the displayed scene in a highly dynamic way through multiple viewpoints.

The CAVE used in this study is a specially designed structure comprising three walls and a floor made up of 10-foot screens (Figure 1). Stereo images are rear projected and bounced via a mirror from above onto the floor display. The projected images are computationally made into one seamless image projected across the CAVE walls (Cruz-Neira et al. 1992). Users standing in the CAVE wearing 3-D glasses experience a feeling of immersion within a lifelike sensory environment. The sense of immersion is attained through a combination of stereo depth perception, peripheral vision capture, head tracking devices, and interactive handheld controllers. The effect is to make images appear holographic.

DEEP MAPPING AND SENSUAL IMMERSIVE GEOGRAPHIES

and for the user to maneuver through and around the imagery as if it were a real environment. Such an experience is difficult to describe, but the user has a profound sense of being in and experiencing the virtual world.

To situate Davis’s neighborhood, the urban fabric of Wheeling was reconstructed and rendered using 3-D modeling software such as Trimble SketchUp (www.sketchup.com) and ESRI’s rule-based City Engine (http://www.esri.com/software/cityengine). The 1884 Sanborn fire insurance maps detailed building footprints and dimensions, and the material from which buildings were constructed, as well as the number of floors and their height. Historical photographs and extant buildings were used to generate architectural styles and building appearance typical of the era. The intent here is not to be photorealistic but to capture a scene representative of the geography of Davis’s neighborhood at that time. Terrain and surface imagery was ingested and the entire scene displayed through ArcScene and a game development platform, Unity3D (www.Unity3d.com), which provides a visually stunning 3-D graphical rendering. Unity has superior graphics, interaction and navigation capabilities, animation, particle physics to emulate flowing water and smoke, and the capacity to trigger sound events.

Not only does the virtual environment provide a visually stunning immersive insight into the Wheeling described by Davis, but additional senses are also engaged to reinforce the sense of place (Figures 2 and 3). Davis describes streets adjacent to her neighborhood where she felt concern for her personal safety. A GIS map of her geography of fear was created and the 7.1 sound system of the CAVE was used to capture her emotional response to these contested places. As a user navigates through the virtual Wheeling scene the sound of a steady beating heart is heard until the GIS detects intrusion into the areas of

Figure 2  The Wheeling skyline with the persistent smog and smoke. Attribution: Christabel Devadoss, Fang Fang, Aaron Ferrari, Trevor Harris, Deborah Kirk.
concern identified by Davis’s map of fear. The sound of the beating heart increases in pace as the user moves deeper into these spaces and diminishes as the user recedes to the margins. In this way an atavistic sound is used to emulate Davis’s fight or flight reality and to replicate her innate emotional response to place. Additional soundscapes are triggered as a user navigates the scene, with a mix of ethnic voices in conversation, everyday sounds of street life, commercial activity, animals, and machinery. Even the presence of drunken groups as described by Davis can be captured with off-scene catcalls and ribald comments.

Additional geosensory inputs augment the visual and soundscape. The smells of Wheeling permeate Davis’s writings. In one instance she describes the everyday street smell of rotting detritus and of a street where a tannery and a brewery were in close proximity and comments on the resulting mix of smells that pervaded the area. Smell has a powerful effect in triggering and evoking memory and place, and smell was added to the CAVE scene to reinforce the virtual scene and soundscapes. A ScentAir (www.ScentAir.com) smell diffuser was used to create smellscapes throughout the virtual city whereby street garbage, livestock, food, cut grass, and burning wood were variously inserted into the virtual scene at appropriate locations. Tactile senses were not enabled in this particular scene, but in another study re-creating the virtual Cherokee Trail of Tears, a walking device used in the gaming industry enables users in the immersive scene to walk the scene, which, while not coming close to the experience of the Cherokee, does at least extend the experience beyond interacting from a standing or sitting stance. The addition of geosensory inputs adds to the sense of place as identified.
by Davis and moves beyond an otherwise rather sterile map. The effect of these sensory inputs is pronounced when compared with just the visual immersive experience. The graphics of Pudding Lane (Dempsey et al. 2014), a re-creation of seventeenth-century London using the Crytek serious game engine, is visually dramatic but is accompanied by incidental music which detracts markedly from experiencing the place that is graphically depicted so incredibly well. The soundscapes and smellscapes of Davis’s virtual Wheeling create additional dimensions of depth to the experience of place.

The immersive, sensual, and emotional geographies drawn from Davis’s writings articulate lifeworlds and places and an evocative image of life in an industrializing town. It is suggested here that such a phenomenological and experiential framework and representation of place, combined with the spatial analytical power of GIS, will resonate with readers as a means to investigate notions of place not previously possible through a conventional mapping of space. In the absence of other narrative writings, Davis’s work and its immersive representations become a primary source and medium for exploring and understanding mid-nineteenth-century Wheeling as place. Immersive geographies reside in the classic “uncanny valley” where the perceived distinction between reality and representation becomes more noticeable the closer one gets to representing reality (Mori, MacDorman, and Kageki 2012). There is rightful concern about striving for hyperrealism and verisimilitude in virtual modeling where the reconstructions are seen to stand in an inferior position to the original referent (Gillings 2002). At some level the human mind fills in the spaces of an obviously nonreal representation and yet becomes uncomfortable and hypercritical the closer a building depiction or human portrayal emulates the real. It is for this reason that human avatars were used with caution in this study. Although the virtual scenes stand as a subjective rendering of a bygone place, this should not detract from their value in augmenting traditional cartographic products which are arguably equally subjective constructions (Crampton 2001).

Drawing upon soundscapes and smellscapes in an immersive representation of a place opens up additional opportunities to pursue a sensual and experiential GIS for exploring place and geography. The approaches outlined here enable the representations of place embodied in text to extend beyond the physical and locational referents of space and allow us to peer into the symbolic, the emotional, and the sensuous aspects of, in this case, literary places.

**Conclusion**

Tuan (1974, 3) suggests that “Space and place are basic components of the lived world,” yet any digital representation of space and place is mediated in its creation and interpretation by our own experiences and worldviews. Capturing the vividness and complexity of place within the vector and raster representations of GIS is challenging, not least because a defining characteristic of place is the meaning gained through experience and abstract qualitative elements. The early focus on GIS as a system may have diminished the potential impact of GIScience on humanist research, though an ever-growing range of advanced geospatial technologies and approaches that augment the power of GIS to handle, manage, and analyze spatial and placial representations are increasingly available and add considerable sophistication to the armory of GIS tools and techniques available. Deep maps provide a conceptual goal for broadening the nature of the mapping process and examining the nuanced and qualitative aspects of place as
well as space, and in the process raise unexpected meanings and questions not previously pursued.

Immersive geographies move beyond the two-dimensional plane to provide an experiential and shared representation of geography. The representation is more intuitive because it replicates the three-dimensionality of our own lived world. In his argument for nonrepresentational theory, Thrift seeks to counter what he sees as an undue emphasis on mapping in human geography and emphasizes the need to move beyond representation and the practices of “witnessing” that produce “knowledge without contemplation” (Thrift 2008). Nonrepresentational theory focuses upon practices and how human actions are enacted, rather than on representing social relationships and what is produced. In the process, phenomenology, poststructuralist theory, and hybrid geographies come together (Whatmore 2002). In this regard, a fusion of hybrid geographies forces us to explore the familiar with unfamiliar technologies and to extract more from the geography than spatial associations. A nuanced, reflexive, sensual GIS, with geosensory inputs such as smellscapes and soundscapes, moves GIS beyond the visible fabric of society and reinforces the sensual nature of place and the role of emotion in understanding the cultural, social, and behavioral sensations, ideas, and feelings related to place. A critical, self-aware approach to these technologies is important to separate the layers of meaning embedded in place, and to recombine them in meaningful ways. Such nuanced representations provide open-ended experiential frameworks which, in combination with the spatial analytical approach of GIScience, enable the deep mapping of humanized space and a thick weave of multiple voices and viewpoints to destabilize our understanding of both space and place.

Deindustrialization

Peter W. Daniels
University of Birmingham, UK

Deindustrialization represents a reversal of an earlier period of structural change in societies and economies that involved a shift from agrarian pursuits to industrial activities. In this sense it is the opposite of industrialization. It has been shown that all economies experience a structural shift that involves moving from a reliance on primary sector activities, to manufacturing sector activities and finally to tertiary (or service) sector activities (Gershuny and Miles 1983).

A key characteristic of structural change is that it is persistent and long-term, and results in changes in the relative importance of the different sectors that make up an economy. This is usually measured, for example, by examining changes in the sectoral share of employment, output, or exports. This process of structural change is a phenomenon that has received much attention in economic theory. It is commonly understood as “the different arrangements of productive activity in the economy and different distributions of productive factors among various sectors of the economy, various occupations, geographic regions, types of product, etc.” (Machlup 1991, 76). Such shifts in the structure of economies may be related to the level of economic development or to changes in the composition of a production system that are necessary to sustain economic growth.

In line with the principles of structural change, after a phase of industrialization economies undergo changes caused by a contraction of their industrial capacity, notably in labor-intensive traditional manufacturing industries such as textiles, shipbuilding, or iron and steel. The process has been widely observed in the advanced economies since the 1970s and is now widely referred to as deindustrialization (Blackaby 1979). Although it was primarily a twentieth-century phenomenon, a degree of deindustrialization occurred during the eighteenth and nineteenth centuries in countries like China and India where manufacturing declined following colonization by the British or the French. The shift from hand to machine production methods was at the heart of the Industrial Revolution that took place in Great Britain between 1780 and 1840. Major advances in technology, such as the development of the steam engine, combined with the rapid exploration of new scientific ideas that led to innovations in machines, products, and modes of transport, enabled the construction of canals, railways, roads, mills, and factories. The period also witnessed the transformation of life and work accompanied by the emergence of large towns and cities. This model of industrialization was adopted later in Western Europe and North America and, depending on levels of development, by the rest of the world throughout the nineteenth and twentieth centuries. It is continuing into the twenty-first century, with industrialization continuing apace in East Asia and Latin America. Since it was the first to
DEINDUSTRIALIZATION

industrialize, Great Britain was also, arguably, the first to experience deindustrialization, followed later by the economies of Germany, France, the United States, and others.

The causes of deindustrialization are numerous but there are a number of key determinants. Some of them are internal to each of the advanced (and more recently the emerging) economies, while others, such as trade flows, are external. One of the most important determinants is the way in which improvements in the productivity of manufacturing, compared to services, has reduced the demand for workers while the converse is true in service industries. At the same time, the process of industrialization has caused household incomes to rise and the resulting increases in disposable incomes (after things like housing, food, and energy have been paid for) has fueled a propensity to increase the demand for services more than for manufactured goods. The expansion of global trade linkages between the advanced and the emerging economies is another important influence on deindustrialization; it has both direct and indirect effects on employment patterns in economically advanced countries.

The widespread occurrence of deindustrialization across the advanced economies over the last 40 years, which are themselves different with respect to the structure of economic activities, means that there are also variations in interpretations of the phenomenon. One of the most widely utilized interpretations is that deindustrialization occurred when the share of total employment or output in manufacturing is lower than the equivalent values for services. Another interpretation is that deindustrialization is evident when there is a decline in employment or output of manufacturing industries. Some care is needed when evaluating both interpretations since short-term trends may reflect short-term cyclical economic effects that do not ultimately show up as long-term trends. A third interpretation of deindustrialization arises from the importance to national economies of external trade in manufactured goods; where such exports constitute a declining share of total exports, it becomes more difficult to achieve a positive trade balance (a surplus of exports over imports) because it becomes more difficult to generate sufficient revenues to pay for the imports required for the further production of goods. This does rely on the assumption that revenues from service exports cannot make up for the loss of revenue from goods exports; in the case of the United States, the United Kingdom, Hong Kong, and Singapore, for example, this is certainly no longer the case. Finally, deindustrialization is seen as arising from the new international division of labor whereby the competitiveness of goods exports from countries like China has encouraged manufacturing to shift away from the advanced economies, leaving service industries to fill the gap.

At the start of the twenty-first century the emerging economies are undergoing deindustrialization, with a structural shift toward tertiary industries. However, there is a difference in that advances in communications and in information technology have enabled developments in the structure and organization of production activities that have blurred the previously clear distinction between manufactured goods and services. Many service activities support manufacturing or are based on material inputs and technology-intensive goods produced by the manufacturing sector. Therefore the links between manufacturing and services have become stronger and more complex, epitomized by the rise and role of producer services. In this way deindustrialization of the emerging economies will not necessarily be measured with respect to reductions in the share of employment in manufacturing or in the share
of goods exported. It may be more useful to analyze contemporary structural changes in the emerging economies as a process of quaternarization, whereby the rise of sophisticated producer services are used as inputs both before and after the production of goods (Peneder, Kaniovski, and Dachs 2003). Deindustrialization is now a less clear-cut process than it was in the advanced economies during the second half of the twentieth century.

Deindustrialization is not confined to the national scale; it has a geographical imprint that varies across time and space in regions, cities, and at the local scale (Martin and Rowthorn 1986). At a country level, an example is the United Kingdom, where by 1979 employment in agriculture and in manufacturing accounted for fewer jobs than in 1964. This trend continued through to the present. By 2010 manufacturing employed only one-quarter of the number for 1964 even though total national employment had grown from some 22.5 million to more than 30 million. In the case of agriculture the change was even more dramatic; employment in 2010 was less than 15% of the level in 1964. The losses of manufacturing and agricultural jobs were balanced by increases in services, especially financial, professional, and scientific services, as advances in technology improved employee productivity and rising average incomes increased the demand for consumer services such as tourism or retailing. Thus, service sector employment expanded by 11.9 million as manufacturing employment contracted by some 4 million, leaving a net increase of some 7 million in total employment. Deindustrialization along these lines, even if the precise details vary from one country to another, has taken place in most of the advanced market economies as well as in many emerging economies. Service industries now account for both the largest share of employment and gross domestic product (the total value of economic output) in many countries.

Whether deindustrialization is seen as a positive or as a negative consequence of structural economic change will depend on the scale of analysis. For some UK regions such as the northeast and Wales, as well as cities such as Manchester and Newcastle, deindustrialization has not involved the full replacement of shrinking manufacturing and primary industries with service employment. Many of the services are in the public sector and are not wealth-creating, market services in the way that is typical of the southeast region, particularly London. Here, deindustrialization is visible at every turn, with services providing more than 80% of employment, the lion’s share of total economic output, and has a physical impact in terms of numerous existing and new office complexes that eclipse equivalent developments in all the other cities and regions of the United Kingdom put together. This, in turn, means that the southeast region and London continue to attract a disproportionate share of new national, and particularly international, investment in services and related activities at the expense of other places. This reinforces the view that deindustrialization may not be avoidable but it occurs at the expense of increasing economic and social disparities between regions and cities within a country.

DEINDUSTRIALIZATION

Demand and supply for producer services

William B. Beyers
University of Washington, USA

Markets are at the heart of systems of demand and supply in capitalist economies. Demand comes from household consumers, governments, investors, and on “intermediate” account – as an input into the production and consumption of goods and services. The supply of goods and services is offered by producers across all categories of economic activity in markets. This entry first describes the general principles of supply and demand before turning to issues of supply and demand for producer services.

The neoclassical approach to supply and demand is conceptualized as a market environment in which buyers and sellers are presumed to have perfect knowledge. The quantity demand for a particular good or service is generally assumed to be an inverse function of the price offered, as depicted in Figure 1; a high price is related to relatively small quantity demand, while a low price is related to relatively large quantity demand. From the supplier’s perspective, the quantity offered in the market is presumed to be proportional to the price offered. The intersection of the demand and supply functions \(D_1\) and \(S_1\) in Figure 1 describes the equilibrium situation, in which market price and quantity supplied are defined as \(P_1\) and \(Q_1\).

Changes in demand and supply functions can alter the equilibrium market price as well as the quantity demanded. In Figure 1 a contraction in the level of demand, from \(D_1\) to \(D_2\), and a simultaneous increase in supply from \(S_1\) to \(S_2\) would result in a lower equilibrium price \((P_2)\) and also a lower level of quantity demand \((Q_2)\). The reduction in the demand function could occur due to changes in the tastes and preferences of consumers, or if the market involved is one related to production of a good or service it could be the result of technological change in the way that a particular input is utilized. Similarly, the change in supply functions could be related to market adjustments of various types, including expansion or contraction of the number of suppliers in a particular market, or changes in cost functions for particular goods or services that alter the willingness of suppliers to offer goods in particular markets.

The simple model depicted in Figure 1 is the basis for many variants. The slope of the demand and supply functions can vary, leading to situations of varying “elasticity.” If quantity demand is totally insensitive to price, then the demand function in Figure 1 is a vertical line, referred to as perfectly inelastic demand. However, if quantity demand is highly sensitive to price differences, then demand functions are considered to be highly elastic. If demands by an individual consumer are aggregated with other consumers, demand functions become more elastic. Similarly, if supply functions of individual suppliers are aggregated to total supply in a given market, supply functions become more elastic.

In the capitalist economy markets can be viewed as a system (Figure 2). Final demand is divided into consumption by households and demand for government goods and services. It also includes a link to the investment process, which is required by all productive components as well as by households (for purchases such as...
housing stock) and governments (for purchases such as infrastructure). Savings from households become a part of the source of funds for investment. Households sell their labor and receive income from work (loop 1). Factor markets exist for labor, also for resources and goods and services, as well as for capital. Inputs from factor markets power industrial production in all categories of economic activity, described in greater detail in the entry on Input–output analysis (loop 2). The output of the industrial system involves vertical linkages, defined by the technology of production in each industry. Goods and services from the system of industrial production are destined for product markets (loop 3), or become embodied as new investment. Product markets (for goods and services) deliver output to households (and government) for consumption, with payments for these goods and services flowing into product markets (loop 4). This circular system should be viewed as dynamic, with a changing mix of output over time due to changes in the tastes and preferences of consumers (and governments), technological change, and processes of innovation and invention that continually amend the spectrum of goods and services produced in economies. From the perspective of a region or a city, this system should be viewed as open, with imports and exports associated with all of the system components defined in Figure 2.

The structure of markets is also variable, as measured by the number of buyers and sellers. A schematic diagram (Figure 3) arrays these numbers from a single seller or buyer to markets with many buyers and sellers. In some cases, these markets could be highly competitive (as in a situation where there are many buyers and sellers); in other cases there could be essentially no competition, such as in a market with only one buyer and one seller. Figure 3 could also be conceptualized within a particular geographic context – ranging from a national or global market system – to a localized market environment. The explicit introduction of space into models of markets is at the heart of location theory.

Markets in capitalist economies may also fail to provide a sufficient supply of particular goods or services, as judged from a public policy perspective. This leads to government intervention to supply levels of these goods and services through taxation; examples include public education and national defense. There are significant variations among countries in the degree to which governments intervene in the supply of goods and services. For example, in the United States most health care is provided by the private sector, while in Canada most health care is provided by the public sector.

**Producer services**

The general discussion of demand and supply was based on the common neoclassical economic approach to markets, a framework that makes strong assumptions about the knowledge that producers and consumers have about elements of
the market environment. One broad component of modern economies for which the basic tenets of demand and supply differ from the neoclassical framework is producer services. These activities have expanded relatively rapidly in advanced and developing economies, as measured by employment, suggesting growing markets for the services that they provide.

Businesses may choose to produce the inputs that they require in-house or they may turn to the marketplace and buy these services from freestanding suppliers. The literature suggests different tendencies in this regard among countries. A tendency for German firms to produce more services in-house when compared with those in the United Kingdom and the United States was documented. Analyses of structural change in the United States through the lens of input–output models have found rising levels of purchase of producer services, suggesting that, over time, firms may be making more decisions to buy rather than make producer services. However, there is also evidence that the overall utilization of producer services has expanded for a variety of reasons, implying that there could be growth simultaneously in the
DEMAND AND SUPPLY FOR PRODUCER SERVICES

Figure 3 Alternative market structures.

internal production of producer services, as well as their external acquisition. Analyses of the occupational structure of nonproducer service firms find this growth takes the form of internalized work of a producer services nature. The neoclassical model described earlier implied that these decisions would be made purely on a cost basis. However, the literature on the demand for producer services finds strong noncost bases for expanding the acquisition of these services in the marketplace.

Scholars have distinguished between cost-based, quasi-cost-based, and noncost-based reasons for producer services acquisition. The transactions cost approach focuses on elements of internal costs (such as wages, administration, or overhead) versus the costs of external acquisition (including transactions costs related to external acquisition). It has been argued that external acquisition has led to supplier firms being able to take advantage of scale economies, and thereby offer their services at a lower cost than the cost of internal provision. Another thread in the literature argues that firms want to be “lean and mean,” to externalize functions not core to their markets, leading them to increase external purchases to lower internal production costs.

Quasi-cost considerations have also been argued to be a basis for the growth of the supply of producer services. Flexible specialization arguments revolve around the way in which demand for many types of producer services is unpredictable, making it necessary for firms to make choices as to whether or not to retain internal staff to provide these services. Strategies used by Danish firms were documented and shown to increase flexibility, allowing risk reduction while dealing with infrequent demand, and a desire to concentrate on core skills.

Noncost considerations have been shown to influence decisions on the external acquisition of producer services. These include the fact that some producer services are specialized and require very advanced levels of expertise for them to be supplied, and it has been argued that the development of in-house capabilities is simply not possible in these cases (Goe 1991). In addition to cost barriers to developing this type of expertise, the length of time that it would take to develop this expertise could also be a major barrier to internal provision of a producer service. Buyer/supplier dynamics have also been argued to be a major noncost consideration, such that rapid changes in the market and technological environments of clients of producer service firms lead to fluid relationships with suppliers of these services. Other factors seen as important are third-party information needs, such as independent audits, expert testimony, and government requirements for analysis, or the growing complexity of the management environment that encourages firms to seek outside experts to assist with their management needs.

Survey research has documented the relative importance of cost, quasi-cost, and noncost factors related to the demand and supply of producer services. A large-scale survey of producer service suppliers found that noncost factors dominated the reasons why their clients sought their services (Beyers and Lindahl 1996). Using a sample of 403 establishments in 11 producer
service industries, this survey used a Likert-scale to determine the importance of 16 different dimensions explaining why their clients sought their service. The importance of particular factors varied by industry but cost factors were not found to be an important determinant of producer service demand; quasi-cost factors were found to be moderately important. These findings suggest that the neoclassical framework does not offer a robust explanation for the growth in the demand for producer services.

Paralleling Beyers and Lindahl’s analysis of the perception of reasons why the clients of producer services sought their services were analyses of actions taken on the supply side by these establishments to position themselves in their marketplace. It was found that most producer service firms tried to position themselves in a “niche” market – to differentiate themselves in the eyes of the buyer from their competitors (Beyers and Lindahl 1996). This analysis was extended to incorporate aspects of Porter’s approach to the construction of a position of competitive advantage by firms (Porter 1990). His framework builds on two paradigms – market position defined through cost leadership strategies versus market position defined through differentiation from competitors. Lindahl and Beyers (1999) found clear evidence that producer service firms embraced differentiation strategies consistent with efforts to identify niche market positions. In addition, sales per employee and sales growth in the previous five-year period before the firms were surveyed were significantly higher for businesses pursuing differentiation or focused differentiation strategies than for businesses pursuing a cost or cost focus strategy. These results are consistent with work undertaken in the United Kingdom by O’Farrell, Hitchens, and Moffat (1992).

The issue of externalization was also explored by Beyers and Lindahl, building on work by Coffey and Drolet (1996). This research explored whether growth in demand for producer service firms came about because of externalization of producer service functions by their clients. About 41% of clients did not have in-house departments providing services similar to the producer service firms being interviewed, while about 36% had noncompeting in-house departments. In the remaining firms (23%) there were competing in-house departments. Regarding the tendencies for externalization by those establishments that did not have in-house departments, the majority had never produced the service provided by the producer service establishment. This result is consistent with the strong tendency, already noted, towards niching and differentiation. For the noncompeting in-house departments, the results were mixed, with some tendency for externalization, suggesting an expansion of the procurement of a producer service simultaneous with the internal production of that service. In contrast, firms with competing in-house departments were split between externalizing and not externalizing (Beyers and Lindahl 1996).

It is also useful to look at the supply side with respect to changes in services offered, changes in industries to which services are sold, and changes in the geographic locations in which services are sold (Beyers and Lindahl 1997). This analysis was framed within the notion of adaptive behavior and business success developed by Ansoff (1965). Firms that were the most adaptive in changing these supply dimensions showed higher growth rates in sales and employment than those that did not adapt.

The modes used to supply producer services have also been examined (Beyers 2000). The strong evidence for differentiation processes on the supply side, and the lack of externalization tendencies on the demand side, are related to ways that the outputs of producer
service businesses find their way to clients. The unstandardized nature of much of this work means that clients and suppliers must get together on a personal face-to-face basis to conceptualize exactly what the producer service firm will deliver. These face-to-face meetings were overwhelmingly important, either with or without written documents, in the production and delivery of producer services. Supplementing these face-to-face meetings were contacts using the telephone and electronic media such as fax and e-mail. Contrary to some expectations, face-to-face meetings had not diminished in importance, even following the inexorable rise of digital technologies.

The survey research of Beyers and Lindahl was conducted in the 1990s. It clearly supports Porter’s differentiation strategy as a foundation for the growth in supply of producer services, and it leads to the conclusion that on the demand side growth has not been the result of externalization but rather has been driven by noncost and quasi-cost considerations. Survey research was primarily conducted in the United States, the United Kingdom, and in Canada on these demand and supply issues. Survey research on this theme does not seem to have been conducted recently; current research could lead to different conclusions.

There has been much speculation about how the rise of new information technologies could revolutionize the supply and demand of producer services as a consequence of the “the death of distance” and arguments that “the earth is flat,” implying fundamental restructuring in the organization of economies. Thus far, there is no evidence to suggest that, even in the face of Internet commerce, smartphones, and other forms of digital communication, the fundamental foundations for the demand and supply of producer services have been altered. The continuing, relatively rapid growth of this segment of contemporary economies is related to the underlying forces of demand and supply, including innovations in the lines of service offerings that find a marketplace. Forecasting industrial structural change is risky, and it is certain that new innovations in producer services will emerge as people develop ideas that find their legs in the marketplace.

Murray Low
London School of Economics and Political Science, UK

Democracy has a straightforward meaning: “rule by the people”; however, the meaning of “the people” and of “rule” is far from straightforward. The historical geography of democracy is a story of various attempts to find answers to practical problems such as: Who belongs to the demos? How should rule be organized? What is the scope of the activities over which democratic rule should be extended? Disagreement over basic definitions, practices, and institutions is constitutive of the dynamism of actually existing democratic politics.

Questions of the scope of rule and the delimitation of the people include important geographical questions. For example, the problem of rule raises issues of the spatial reach and territorial organization of the mechanisms of popular rule. Is democratic rule synonymous with electoral practices and representative mechanisms? At what geographical scales are such activities best organized? And does democracy also extend to more participatory practices such as citizens’ juries or local participatory budgeting? Likewise, the problem of defining “the people” raises questions about how to determine membership of a polity. Should cultural criteria of shared belonging to a community prevail? Should criteria of place of residence be used? Or should a spatially expansive principle of affected interests be used to define the identity of those who should have a say in shaping decisions?

Despite the centrality of geographical questions to the practical politics of democracy, democracy has not been an explicit object of analysis in geography until very recently. Heightened interest in this topic is in part a reflection of real-world processes of democratization, and an awareness of the significance of electoral processes to the exercise of power in the real world. It is also, however, a reflection of shifts in the normative paradigms which underwrite critical human geography in particular. Until recently, there has been little explicit focus in human geography on the normative issues that are at the core of debates about the relationship between democracy and spatiality. Geographers have often avoided issues raised in fields of political philosophy on the grounds that they seem to be too “liberal.” Since the 1990s, however, there has been a shift in various subdisciplines toward investigating the ways in which normative problems central to democratic theory play out in practice. These issues are reflected, for example, in discussions of citizenship, deliberation, and participation in areas such as development geography, urban studies, planning studies, and environmental studies. The absence of democratic institutions is now recognized as a key factor in the reproduction of social injustice and inequality, and the exposure of vulnerable or marginalized groups to serious harm. At the same time, geographers have begun to investigate innovative mobilizations by social movements that reconfigure the meanings and practices of democracy. At a more abstract level, the theories of spatial ontology

DEMOCRACY

developed by geographers have opened up new understandings of “the political,” and have drawn the discipline into debates informed by a distinctive strand of contemporary political theory that focuses on the agonistic, dissensual aspects of democracy. This strand of theory supports critical evaluations of the contemporary world as increasingly “postdemocratic” and/or “postpolitical” (see Swyngedouw 2011).

In short, issues of democratic practice and problems of democratic theory are now much more evident in human geography than they once were. Broadly speaking, this increased concern with democracy is divided across two areas of inquiry: research on geographies of liberal democracy and explorations of a variety of alternative forms of democracy.

Geographies of liberal democracy

Liberal democracy is usually taken to refer to forms of institutionalized popular representation, involving periodic mass election of representatives to authoritative legislatures (and, in many cases, of executive heads of state), under conditions of freedom of speech and of association. This is a model unevenly developed in the Global North, and widely emulated and/or imposed in other parts of the world. Liberal-representative democracy is usually legitimated by appealing to the basis of politics in the preferences and liberties of private individuals recognized as equal citizens under the rule of law. There is an enormous field of literature, largely in political science, devoted to examining the conditions under which such liberal democratic institutions develop, as well as to particular aspects of these systems, including political parties, elections, voting behavior, citizenship, and the media. There is also a substantial body of liberal political theory associated with the justification of institutions of liberal democracy, a body of work that often provides critical insights into the operations of actually existing liberal democracies. Both political science and political theory assume a given spatial formation of democracy as the norm: territorialized national states, internally divided in some way or another.

Modern democratic theory has therefore developed around a particular geographical imagination. It assumes that democracy is framed around bounded national territories which are internally organized through a nested hierarchy of scales. In geography, research on liberal-representative democracy has focused on two areas: electoral geographies and geographies of democratization.

The subfield of electoral geography focuses on explaining and mapping the spatial distribution of votes. Geographical processes can make a significant difference to the outcomes of elections in terms of who wins and who loses. Geographers have demonstrated how the spatial organization of electoral systems affects how votes are translated into representative majorities in liberal democracies. Recent attention has focused on developing more sophisticated and contextually sensitive explanations for voting behavior. Research on electoral processes has broadened out to include the geographies of campaigning, party formation, and political communication. Work in electoral geography has shown, then, that the spatial organization of formal democracy has consequences for outcomes in terms of criteria of equality, fairness, and representativeness. Accordingly, recent research in electoral geography has more explicitly addressed the normative issues raised by practices of gerrymandering, political redis-
Geographers have also explored the process of democratization as part of a broader examination of the conditions for the formation and maintenance of liberal democratic polities around the world. The diffusion of liberal democracy as a global norm of governance since the 1980s has followed in the wake of the collapse of communism in Eastern Europe; political transitions away from authoritarianism in Latin America, Africa, and Asia; and the application of norms of democratic governance in the geopolitics of Western international financial policy, trade negotiations, and military engagements. Geographers have investigated the degree to which the adoption of democratic forms of governance can be accounted for by specifically geographical factors. This research contributes to debates over whether democracy can be established and sustained only after various socioeconomic and cultural prerequisites have been met, or whether it is itself the prerequisite of economic development or peace-building.

Geographers have also critically assessed the theoretical assumptions through which liberal forms of electoral democracy have been circulated as the global norm. Debates about democratization raise questions regarding the degree to which the norms of Western liberal-representative democracy can and should be practically applied in non-Western contexts and deployed as normative benchmarks of critical analysis. Rather than democracy having a single form that is traceable to a unique origin point, the mobility of democratic practices suggests that the devices through which different imperatives of democratic rule are enacted can be combined and adapted in different ways. As a consequence, the values enacted through these devices — for example, the ways in which interests are represented, conflicts resolved, participation practiced, accountability enforced — may be highly variable in different geographical contexts (Bell and Staeheli 1998).

Alternative democratic spaces

Criticisms of theories of liberal-representative democracy that assume the nation-state as the natural container of democratic politics have encouraged geographers to give increasing attention to various alternative models of democratic politics. There are two aspects to this focus: a concern with scales of democratic politics above and below that of the nation-state; and a concern with the potential for radicalizing democratic politics in established and new arenas.

The first aspect of the attention to alternative models of democratic politics is the focus on the spaces of democratic politics that exist above and below the level of the nation-state. While electoral geography tends to focus on the translation of subnational electoral outcomes into aggregate national election results, a burgeoning literature focuses on the city or the region as a privileged scene of democratic politics in its own right. The focus on these subnational scales is related to the argument that place is the key spatial modality in which identities and interests are experienced and negotiated. At the same time, in political science and political theory, the territorial framing of democracy is increasingly subjected to critical investigation by confronting democratic theory with the facts of contemporary transnationalism and globalization. Increasingly, settled assumptions about inclusion and participation in democratic politics at national scales are thrown into question by transnational social mobilizations and identifications, which point up the limitations of territorialized models of representation. Settled assumptions about the objects of democratic decision-making are, likewise, increasingly under strain with the
proliferation of nonterritorial concerns, such as global climate change, pandemic disease, and integrated transnational financial markets.

The shift of attention to the complexity of spaces and scales through which democratic politics operates is related to a second aspect of research on alternative democratic spaces in geography. It is concerned with searching out and affirming various fractures in liberal representative regimes. These explorations are committed to thinking of democracy as more than simply a procedure for legitimizing the decisions of centralized bureaucracies and holding elected representatives accountable. Critical human geographers tend to think of democracy first and foremost in terms of contestation and dissent. It is assumed that “the political” is a realm in which new identities are formed and new agendas generated, and through which the stabilized procedures, institutions, and identifications of official politics are contested and potentially transformed. Such an assumption is related to an alternative sense of “democratization,” understood not so much as the geographical diffusion of established norms of democracy but as the deepening of democratic impulses and their extension of new arenas of everyday life. In contrast to the focus of electoral geography and mainstream political science on the formal democratic procedures of elections, voting, and parties, attention is paid to the diverse practices and sites where questions of accountability, citizenship, justice, and participation are contested.

Different schools of democratic thought which inform geographers’ focus on alternative democratic spaces tend to share an emphasis on “participation” as the central normative value of democratic politics. Geographers have drawn on a broad family of egalitarian thought about the relationships between democracy, rights, and social justice, including post-Rawlsian political philosophy; post-Habermasian theories of democracy, including feminist critical elaborations of this tradition; various postcolonial liberalisms; agonistic liberalisms and poststructuralist theories of “radical democracy”; the revival of republican theories of democracy, freedom, and justice; and anarchist and “autonomist” traditions of political activism. All of these traditions share a conviction that democratic politics is about more than formal procedures for the aggregation of individualized voter preferences. Taken together, they amount to a tradition of thinking about “radical democracy.” In geography, radical democracy has most often been conceptualized with reference to a post-Marxist approach developed by the political theorists Ernesto Laclau and Chantal Mouffe (see Massey 1995). Their work emphasizes the idea of democracy as a diverse set of practices of challenging the boundaries of “the political” in two senses: by establishing new issues as counting as political, and by focusing on the active formation of subjectivities and identifications in and through political practices of agonistic contestation and collective mobilization. Another feature of this style of radical democracy is the considerable emphasis it puts on issues of space, understood as a scene of multiplicity and encounter with difference, and therefore as the very site of democratic culture. It is an understanding which emphasizes the idea that democracy is an inherently contested, evaluative, incomplete formation that is always open to further perfection, without hope of its finally culminating in a pure form.

Rather than being restricted to this tradition of post-Marxist theory, heavily inflected by poststructuralist ideas, the notion of radical democracy might actually be better thought of as referring to a variety of approaches that emphasize the inclusive, participatory, and contestatory qualities of democratic politics.
The most influential of these approaches is the family of theories of so-called “deliberative democracy,” often shaped by a critical interest in the ideas of Jürgen Habermas. Approaches that develop strategies for informed, structured participatory discussion and decision-making are now central to debates on democratic theory. These approaches propose a much more active role for citizens in all facets of decision-making, as well as, in many cases, the extension of democratic norms to a far wider array of activities. They also involve thinking about a range of activities that are not directly political, in the sense of being tied directly to decision-making processes, as nonetheless important facets of a broader democratic culture by virtue of their contribution to the quality of the public sphere.

Theories of radical democracy, whether of a Habermasian or poststructuralist inflection, often focus on forms of noninstrumental cultural practice and performance. These are understood as key mediums of democratic opinion formation or democratic subject formation. In turn, both traditions share the problem of whether the forms of influence that can be generated in the public sphere or in cultivating an agonistic democratic ethos can or should be articulated with the institutionalized exercise of power. Post-Habermasian approaches finesse this issue through concepts of weak and strong public spheres. Poststructuralist theorists who address the communicative conditions of pluralistic democracy through figures of democratic ethos are even more wary of drawing too close to sites of decision-making and rule. For them, the force of democratic politics is reserved for the disruptive energies of contestatory practices that reconstitute the dimensions of the political arena.

In practical terms, theories of radical democracy are often associated with calls for the decentralization of decision-making and political participation to subnational scales of regions and cities. This localizing impulse easily falls into the trap of assuming that subnational scales of governance are somehow more democratic by virtue of being closer to people’s everyday concerns. In contrast, the rescaling of political authority away from the nation-state is sometimes presented as being a means of depoliticizing issues. At the same time, increasing attention is given to emergent forms of transnational democracy, focusing on whether systems of globalized economic and political governance can be subordinated to democratic oversight. In work on issues of global justice and transnational democracy, one finds sustained attention to the diverse agents of justice through which democratic justice can be pursued and secured, moving beyond an exclusive focus on states as the privileged containers of democratic politics. Again, sometimes this process of rescaling is seen to exemplify the development of “postpolitical” or “postdemocratic” forms of rule. It may be more productive to think of emergent transnational aspects of democratic politics as raising two important challenges to how the geography of democratic ideals and practice are conceptualized. First, this process challenges any simple contrast between representative and participatory forms of democracy (Low 1997). Any viable form of democratic polity is likely to combine aspects of these practices in different ways. For both practical and normative reasons, representation seems an irreducible aspect of any viable, pluralistic model of democracy. Not only do representative procedures enable the “time–space distanciation” of democratic politics, but they also embody important principles of difference and nonidentity within the “demos.” Representation is also an unavoidable mechanism for the integration of so-called mute interests, such as future generations or nonhuman actors. Second,
DEMOCRACY

Transnational political processes are suggestive of a move beyond the predominant territorial framing of the spatiality of democracy. Rather than thinking simply in terms of the need to articulate subnational and national scales with global scales, discussions of these topics increasingly focus on the diverse spatialities of democracy, ones that articulate territorial and nonterritorial practices, and on scalar and nonscalar conceptualizations of space.

Conclusion

Geographers’ contributions to spatializing the analysis of democratic practices such as elections, and to imagining alternative democratic geographies, overlap with emerging concerns about how democracy can be understood in a world where the sites of politics are multiplying and crucial decisions are made in ways that cut across territorially organized political regimes. In political science and political theory, contemporary debates about democracy often hinge on geographical themes and geographical problems. In short, geography is at stake in a new way across the social sciences: understanding contemporary democracy requires geographical contributions by everyone, and democracy as an object of analysis offers considerable potential for new forms of cross-disciplinary engagement. Further engagement with these debates by geographers, however, presents a challenge for prevalent understandings of critical vocation in the discipline. The predominant understanding of critical analysis in human geography has always distanced itself from what are presented as “liberal” approaches, where liberalism is usually understood by reference to economics. It is difficult to appreciate the concerns of contemporary theories of radical democracy without acknowledging the degree to which such theories draw on key themes from traditions of political liberalism, such as pluralism, citizenship, rights, or the separation of powers. Radical democracy in this expansive sense is not best thought of as a rejection of liberalism tout court.

One of the lessons learned by diverse strands of radical political theory from the experience of twentieth-century history is that struggles for social justice can create new forms of domination and inequality. Liberalism can be thought of as a potential source of insight into the politics of pluralistic associational life. The problems of coordination, institutional design, and justification, on which liberal political theory dwells at length, are unavoidable in any normatively persuasive and empirically grounded critical theory of democracy. It is tempting to see in the energy of theories of radical democracy a promise that everything can, and should be, democratized, and that all interests can, and should be, included in democratic practices; however, an abiding aspect of liberal theories of democratic politics is a concern with the justifiable limits of collective decision-making, a concern informed by an acknowledgment of the potential harms, injustice, and violence that can be generated by the putatively democratic exercise of coercive power. Democracy, it should be remembered, is a way of doing politics, and not a substitute for politics. Thinking about the ways in which commitments such as those based on faith, or practices mediated through bureaucratic institutions, or relationships underwritten by the force of violence, can and should be democratized remains a pressing problem of empirical, normative, and theoretical analysis.

Further reading

The term *demographic transition* refers to the shift in vital rates within population groups (local, regional, and national) from a pattern of high birth (fertility) and death (mortality) rates to one of low rates. The *epidemiologic(al) transition* is part of the mortality decline side of this transition, referring to the change from an infectious disease-dominated cause of death regime (e.g., diarrhea, pneumonia, and tuberculosis) to one in which chronic, degenerative ailments/"noncommunicable diseases" (e.g., cancers, cardiovascular diseases, mental disorders, and dementias) predominate. An important consequence of demographic and epidemiological transition is changing population age structure, from “youthful” to “aged” numerical dominance, that is, an *aging transition*. Various other transitions are, in turn, associated with these changes, in both cause and effect interactions, for example, nutrition, mobility, urbanization, technology, and social and economic development (Figure 1).

**Demographic transition**

In pretransition populations, high birth and death rates virtually cancel each other out and population growth is, therefore, slow. Typically, the first stage of demographic transition is a fall in death rates, while fertility remains high. As a result, population growth begins to accelerate. Later, birth rates also begin to fall. Ultimately, fertility and mortality reach relatively similar low levels, producing a new slow population growth equilibrium. Post-transition societies also have slow (or even negative) growth as the new lower birth and death rates similarly virtually balance each other.

This broad three-stage typology of population change – pretransition, transition, post-transition – is one of demography’s longest established models. The label “demographic transition” was first used in 1945 by American demographer, Frank Notestein, but the idea of transition and similar terminology can be traced back to earlier writings. Notestein is also generally credited with providing the first definitive statement of demographic transition theory, explaining the observed different patterns and levels of fertility and mortality around the world in the context of social, economic, and political modernization. His and other modernization-centered work of the time is now referred to as classic demographic transition theory.

Decades of subsequent research have, not unexpectedly, produced a more complex and nuanced understanding of fertility and mortality decline. The emphasis on modernization has been long dismissed, with detailed research at various scales showing that while modernization can stimulate birth and death rates to drop, it is not essential. Numerous examples of improving mortality and falling fertility in the absence of any significant social and economic development can be cited (e.g., Bangladesh and Sri Lanka).
**Figure 1** Demographic, epidemiological, aging, and nutrition transitions. Source: McCracken and Phillips (2009). Reproduced by permission of Elsevier.
The world of gradual birth and death rate change that Notestein and other early transition theorists wrote about has in the decades since changed to one of accelerated change, of national government involvement in population health and reproductive matters, of formal family planning programs, international assistance agencies, cheap and effective reproductive control technologies, and enormously increased life-saving public health capabilities. Explanations of the fertility decline side of demographic transition are now couched in a variety of perspectives – social, economic, cultural, ideational, and institutional (Kirk 1996).

Demographic transition first occurred in Western Europe, with death rates in various countries showing signs of decline from around the mid-eighteenth century. The exact reasons for the early improvement in health conditions have been and still are a matter of debate, though better nutrition is generally accepted as having been one key factor. Fertility subsequently started to drop, at first gradually, but then rapidly over the latter nineteenth and early twentieth centuries. A similar fertility transition occurred at much the same time in overseas European populations (e.g., North America, Australia, and New Zealand), and by the late 1920s the transition to low birth and death rates was essentially “completed.”

During the 1930s and 1940s, falling death rates and incipient fertility decline were apparent in Japan, some Latin American countries (e.g., Cuba and Argentina), and a small number of other developing nations; however, for most parts of the “developing” world the transition did not discernibly begin until after the World War II. In the immediate postwar years, public health campaigns achieved rapid life expectancy gains in many such countries, and rates of population growth accordingly accelerated. Widespread fertility transition across the developing world started in the 1960s and has continued in the decades since. Progress through the transition has varied (Table 1). Some erstwhile developing nations (e.g., China and South Korea) now have well below replacement level fertility comparable to or even lower than many developed nations. Other nations are at a more intermediate stage in the transition, with birth rates still well above replacement level. Meanwhile in a few cases (mainly in sub-Saharan Africa) fertility transition has essentially still to begin, with current total fertility rates above six births per woman.

In developing nations, the fall in death rates has generally been faster than historically occurred in Europe and other more developed regions. This difference, with the normal lag in fertility decline, has resulted in considerably more rapid mid-transition population growth than experienced in developed countries. Also, over time birth and death rate transition has started at progressively lower levels of development. Within contemporary developing countries fertility decline is usually substantially more advanced in urban than in rural areas. Similarly, fertility transition has generally progressed further in the more developed provinces/regions of countries.

Today, over one-third of the World Health Organization’s member states have below replacement level fertility (usually assumed as a total fertility rate (TFR) of 2.1 children per woman). In around 40 of these, the TFR has fallen to 1.6 or lower, this move to extremely low fertility being termed a second demographic transition by some population analysts (Lesthaeghe 2010). This new stage in demographic development is seen as reflecting the virtually full control now enjoyed over fertility and a shift in norms toward materialism and individualism leading to a move away from formal marriage and parenthood.

In a number of European countries and Japan, the crude birth rate is now lower than the death rate, and natural population decrease is occurring. United Nations’ projections see this phenomenon becoming more widespread in coming decades. Whether long-term population decline becomes the norm in many countries, however, obviously cannot be foretold.

Epidemiological transition

The term epidemiologic(al) transition describes the change in patterns of health and disease as populations undergo demographic transition and was introduced by Abdel Omran in 1971 in what is now considered one of the classic papers of epidemiology and public health. The notion of such change, though, can be found in earlier demographic and international health writings.

1. That mortality is a fundamental factor in population dynamics.
2. That during the transition, pandemics of infection are gradually displaced by degenerative and “man-made” (human induced) diseases as the chief form of morbidity and primary cause of death.
DEMOGRAPHIC AND EPIDEMIOLOGICAL TRANSITION

3 That the most profound changes in health and disease patterns during the transition occur among children and young women.

4 That the shifts in health and disease patterns that characterize the transition are closely associated with the demographic and socioeconomic transitions that are part and parcel of modernization.

5 That variations in the pattern, pace, determinants and consequences of population change differentiate three basic models of epidemiological transition.

From these propositions Omran went on to build his theory around the ideas of “transition stages,” “models of transition,” and “disease determinants.”

The shift in diseases during the course of demographic transition referred to in Proposition 2 was argued to involve three major successive stages (“ages”) (Omran 1971, 737–739), as follows.

1 The age of pestilence and famine: the period before the transition when mortality is high and fluctuating and dominated by epidemics, famine, and wars.

2 The age of receding pandemics: when mortality declines progressively, and epidemic crises become less common.

3 The age of degenerative and man-made diseases: when mortality continues to decline and the shift from an infectious to degenerative disease-dominated health profile is completed.

Three basic models of epidemiological transition were identified (Omran 1971, 739–739).

1 The classical (Western) model, in which the shift in mortality patterns occurred gradually and progressively over a century or more.

Most western countries were seen as fitting this pattern.

2 The accelerated model, in which the mortality change occurred over a far shorter period of time, Japan being cited as typifying this model.

3 The contemporary (or delayed) model, characterizing the “relatively recent and yet-to-be completed transition of most developing countries,” Chile and Sri Lanka (Ceylon) being identified as illustrative examples.

Finally, three major categories of disease determinants were outlined (Omran 1971, 739–741): ecobiologic; socioeconomic, political, and cultural; medical and public health. In the classical (Western) model, primacy was attributed to ecobiologic and socioeconomic factors, with medical factors “largely inadvertent until the twentieth century, by which time pandemics of infection had already receded significantly” (Omran 1971, 741). For Japan and other accelerated model countries, the mortality reduction and disease transition were seen as stemming from “sanitary and medical advances,” along with “general social improvements,” while in the case of the delayed model imported medical technology and public health measures were deemed paramount.

In essence, Omran promulgated a generally uninterrupted progression of countries from the pretransition age of pestilence and famine through to the age of degenerative and human-made diseases. The impression conveyed was of the third stage being the apparent end-point of human epidemiological evolution. Also implicit was the notion of the transition as a universal process, an epidemiological pathway along which all countries would eventually proceed (McCracken and Phillips 2009).

Since Omran’s paper was published, the concept and theory of epidemiological transition
have received wide attention from researchers across an array of disciplines as well as by population health planners and policymakers in both more and less developed nations. As might be expected, there have been numerous critiques and extensions of Omran’s foundational statement. Since his time of writing, the global HIV/AIDS pandemic and health reversals in several of the former Soviet Union republics in the upheaval following the dissolution of the USSR have clearly shown that smooth, uninterrupted passage through the transition is not guaranteed. The third and apparent final stage outlined by Omran has also subsequently been shown not to be the end-point of epidemiological change. Life expectancy in developed (and many less developed) countries has risen to levels well beyond that envisioned by Omran. The degenerative disease domination of late stage transition still applies, but in high income nations there has been a significant delaying of deaths from these conditions to later ages. More attention has also been given to the fact that, during the transition, many countries experience a challenging dualistic phase, when there is simultaneously heavy loss of life and healthy years from both infectious and degenerative diseases – what has come to be variously termed the double burden of disease or epidemiological polarization (WHO 1999). A social pathology type health profile of violence, substance abuse, suicide, accidents, and HIV has also been recognized in seriously disadvantaged groups in some countries – for example, inner city young black males in the United States, some indigenous communities in Australia. As well, greater emphasis has been given to the morbidity side of epidemiological transition and a more complete view of health status and its determinants. This is especially true in the more aged societies, where “epidemics” of dementias have been identified. In this vein, some researchers and policymakers prefer to talk of health transition rather than what they see as the narrower idea of epidemiological transition (Caldwell 1993).

Table 1 shows the current cause of death patterns for the world as a whole and by income groups of countries (as defined by the World Bank). Globally, epidemiological transition has advanced to the stage where noncommunicable diseases account for two out of every three deaths. One-quarter of all deaths, however, are still due to “communicable, maternal, perinatal and nutritional conditions,” despite a large proportion of these being relatively easily and cheaply preventable. In low income countries, over half of all deaths are due to these conditions. The emerging double burden of disease in these countries poses major difficulties in determining respective resource allocation between old pretransition style diseases and new “modern” health problems in pressured health budgets. Lower-middle income countries also face the difficulties of the double burden and many are more advanced in the transition to a degenerative disease-dominated health regime. In upper-middle income and high income countries, “old style” (infectious disease) mortality has largely been displaced by “new style” (degenerative) causes of death. Infections, however, remain a major (and often underestimated) health problem in terms of morbidity and healthy wellbeing in many countries and it is feared that potentially uncontrollable infections may again come to the fore, as antibiotic resistance grows and many new or resurgent viral conditions emerge for which there is currently little effective remedy.

Therefore, comments on future epidemiological transition developments can, by definition, only be speculative. The past half-century has seen both the emergence of numerous serious new infectious diseases (e.g., HIV/AIDS, SARS, hepatitis C, and Middle East respiratory syndrome coronavirus – MERS-CoV) and the resurgence of some that appeared close
DEMOGRAPHIC AND EPIDEMIOLOGICAL TRANSITION

to being beaten (e.g., tuberculosis, especially drug-resistant varieties, and malaria). A global pandemic of virulent influenza is always a threat. Along with the growing problem of antimicrobial resistance amongst pathogens, these examples serve as a reminder that infectious disease is a long way from being vanquished and could produce new and even unexpected epidemiological futures (Fauci and Morens 2012). An obvious major uncertainty regarding infectious disease futures is the impact that global climate change and population concentration into large cities may prove to have.

While infection-based health challenges will almost certainly occur over coming decades, the order of magnitude (i.e., virulence and ease of transmission) required for them to return all humanity to a new infectious disease era is probably unlikely. More likely is a continuing degenerative disease-dominated world, but with evolving patterns. For example, the major decline in cardiovascular disease mortality in developed countries over the past 40 years will probably continue, with cancers coming to be the leading cause of death globally. In turn, the growing importance of dementia morbidity and mortality in developed countries in recent years will almost certainly intensify in coming decades in association with continued population aging. Dementia will also become a major health burden in today's developing countries as they undergo population aging.

Most population health specialists see human life expectancy continuing to improve over the course of the twenty-first century, although there is considerable debate about what ultimate level is biologically achievable or socially likely. A number of subnational population groups around the world have already attained life expectancy at birth levels of 90 years or more and thus give cause for optimism. A few analysts, however, argue that factors such as the growing global obesity epidemic could in fact spur the reverse, that is, average life expectancy falling and/or health status deteriorating. A major issue if longevity does continue to increase will be whether the additional years of life are years of good, bad or indifferent health.

Further reading

Dendroclimatology was the first application of the newly founded science of dendrochronology in the first decade of the twentieth century, based on initial findings and later principles formulated by Andrew Ellicott Douglass of the University of Arizona, United States, when analyzing tree rings from ponderosa pine trees. Douglass noted similarities in the patterns of ring widths over the years from one tree to the next, not just in trees growing next to each other in one forest stand, but also in trees growing at a considerable distance from each other. Recognizing these similar patterns across trees and across a geographic region eventually led Douglass to establish the basic principle and technique in dendrochronology known as “cross-dating” (Douglass 1941). Cross-dating exists because all trees within a region respond to the overarching climatic processes that operate from day to day, month to month, and year to year. This response will impart a common climatic signal in all trees in a pattern of wide and narrow tree rings over the years, despite some influences from other types of environmental process that also affect tree growth, such as insect herbivory, wildfires, and air pollution. The value of cross-dating lies in its ability to provide the dendroclimatologist with a precise chronology back in time with annual resolution by accounting for tree rings that may add inaccuracy, such as locally absent rings (rings that are absent from the trunk of the tree where samples are usually taken) and false rings (rings that display intra-annual density fluctuations that can often mimic a true annual ring). Such problem rings could potentially add “noise” to the climatic “signal” desired in dendroclimatology. By accounting for these problem rings, dendrochronologists minimize the noise and maximize the climatic signal, making it possible to determine which climatic factors are most responsible for that common signal in the tree rings and capitalizing on this to eventually reconstruct climate in the past for the full length of the tree-ring chronology.

Douglass recognized the importance of pushing back the climatic record from tree rings for millennia back in time using the giant sequoia trees of the western slopes of the Sierra Nevada in California, but his efforts soon turned to the dating of prehistoric structures throughout the American Southwest. After founding the first laboratory dedicated to the tree-ring sciences in 1937, the Laboratory of Tree-Ring Research (LTRR) at the University of Arizona, Douglass assisted his colleague and former student Edmund Schulman by initiating an ambitious project that would take Schulman across the Americas and elsewhere in search for old trees to extend the record of Earth’s past climate. Schulman’s expertise lay in climatic applications and he was the first to extrapolate precipitation patterns for the American Southwest back for 800 years. Before his unexpected death in 1958, Schulman had analyzed the climatic potential of many tree species, mainly across North America and South America. Key among his discoveries was the venerable bristlecone pine trees of the
White Mountains in southeastern California and Nevada, which reached unprecedented ages, including many over 4000 years old (Schulman 1958). The current age record for one individual bristlecone pine is 5062 years. This particular bristlecone pine, originally discovered by Schulman in the 1950s, was later analyzed by the eminent dendrochronologist Thomas Harlan of the LTRR, who found several hundred additional tree rings to reveal the first verified 5000-year-old living tree.

Beginning in the 1930s and into the 1940s, dendroclimatology was also taking a foothold in Europe, led by Bruno Huber, then at Tharandt in Saxony, Germany, whom many consider the “father of European dendrochronology” (Liese 1978). By the 1960s, Huber and his colleagues would have laid the groundwork and developed improved quantitative methods for analyzing tree-ring chronologies throughout Europe that would eventually aid in understanding the climate of Europe for the past 10 000 years at annual resolution based on tree rings. Further, techniques developed by European dendrochronologists would eventually aid in the dating of literally thousands of historic structures from the Roman period into the Middle Ages and later all across Europe and beyond. Huber realized early in his career that the ring patterns in Europe were distinctly different in their variability across the years from ring patterns in the western United States, making visual comparisons of tree-ring patterns for cross-dating more challenging. Huber and his colleagues introduced the Gleichläufigkeit (percentage of agreement) statistic, the first of its kind, to help add a degree of statistical rigor in the cross-dating of tree-ring patterns.

More formal quantitative techniques for analyzing the climate signal in tree rings and for reconstructing past climate were later generated by Harold Fritts and his coworkers at the LTRR (Fritts 1976). By then, dendroclimatologists recognized the importance of sound training in botanical and biological principles to better interpret the often confounding signal contained in tree rings. These techniques first focused on generating more accurate bioclimatic models of tree growth that incorporated tree-ring data. In other words, to better understand past climate from tree rings, you must first know how trees grow by embracing a more holistic view of environmental influences on tree growth. By the 1970s, quantitative reconstructions of past climate were becoming commonplace, pushed by an emerging need to also reconstruct hydroclimatic parameters (precipitation, discharge, lake levels) from tree-ring data. By the early 1990s, statistically validated millennium-length reconstructions of regional and hemispheric temperature and precipitation patterns were becoming common, spreading from Europe and the United States to Mexico, Canada, Australia, New Zealand, Chile, Argentina, and the Middle East, later occurring also in Russia, China, Mongolia, and Southeast Asia. Recent efforts in dendroclimatology concentrate on analyzing new tree species for their climatic potential, especially in the tropics; extending our knowledge of climatically sensitive tree species into new geographic regions; evaluating the impact of nonclimatic processes on the climate signal in tree rings; establishing whether the relationship between climate and tree growth has remained stable over recent decades; and incorporating tree-ring data into larger ensembles of proxy data for reconstructing past climate. These tree-ring data and the hundreds of climate reconstructions generated from them in many regions of the world are providing valuable assessments of long-term climate patterns over the past two millennia that play a key role in understanding the probable trajectory of the Earth’s climate in the future, as shown in the 2013 report by the
Techniques

Dendroclimatology assumes that established practices and principles have been followed when identifying and collecting tree-ring samples for understanding past climate. Key among these are the Principles of Site and Tree Selection (Speer 2010; Grissino-Mayer 2014) to ensure that climatically sensitive locations were identified during the project design and field reconnaissance phases, and that trees were carefully chosen and sampled to provide the maximum climatic information while minimizing the adverse effects of noise from confounding ecosystem (both natural and human-caused) processes. Furthermore, tree-ring data analyzed are not limited to total ring widths only. Especially useful climatic information has been obtained using maximum latewood density measurements (particularly for European tree species) and stable carbon isopes ($^{13}$C/$^{12}$C ratios) (especially in Europe and the western United States). Additional physical properties used in dendroclimatology include minimum earlywood density, average ring density, earlywood and latewood widths, latewood percentage, “light” rings (i.e., faint latewood), oxygen isotope values ($^{18}$O/$^{16}$O ratios), and annual basal area increment (BAI).

Two approaches are used in dendroclimatology. The first involves the development of (mechanistic) bioclimatic models of annual tree growth by modeling growth (via annual tree-ring data) as a function of one or multiple climatic variables (usually monthly values). In this strategy, tree growth is a function of one or more climatic parameters. Basically, before tree-ring data are used to reconstruct climate in the past, we must first know to which climate variables the trees are responding, as recorded in the physical or chemical properties of tree rings. Techniques first developed by Fritts (1976) and his colleagues of the LTRR used principal components to first transform monthly climatic data (such as temperature and precipitation) and remove interdependence between the predictor climate variables, then used these transformed data in a multiple regression to determine which monthly data most influenced tree growth on an annual basis. This technique was termed response function analysis (RFA), and the models generated are especially important for (i) isolating the primary climate variable to which the trees are responding (e.g., drought or temperature); (ii) determining which months/seasons are critical for tree growth; and (iii) evaluating potential changes in tree and forest growth responses given a changing climate.

Climate variables analyzed include temperature (mean, minimum, or maximum); precipitation; drought (Palmer drought severity index, or PDSI); snowpack; streamflow; and sea-level pressure. Recent research has focused on large-scale ocean–atmosphere patterns, such as the El Niño–Southern Oscillation, Pacific Decadal Oscillation, North Atlantic Oscillation, and Atlantic Multidecadal Oscillation, among others. The months analyzed and modeled always extend back to the previous growing season because tree growth is strongly influenced by conditions set during the prior year. For example, a year of favorable climate could allow trees to fix abundant carbon in their plant tissues (e.g., tissues in the apical meristems), prior to the dormancy period, that translates to enhanced growth during the following growing season. Although such principal components-based analyses are still common, RFA as practiced today involves more the use of simple correlation functions to determine the primary variables to
DENDROCLIMATOLOGY

which the trees respond during specific months and seasons.

The second technique involves the development of (stochastic) time-series models of past climate as a function of tree growth. In this strategy, historic climate data are modeled as a function of tree-ring data (usually over the twentieth and twenty-first centuries) to develop a calibration model that predicts (or “retrodicts”) climate for the full length of the tree-ring record back in time. The dendroclimatologist must first determine the one primary climate variable to which the trees are responding using RFA before the reconstruction can be accomplished. The climate variable can represent a single monthly value (e.g., July drought as modeled using the PDSI); a range of months over the current growing season and/or months prior to the current growing season (e.g., average summer temperature); or an annualized climate variable (such as water-year precipitation, common in hydrologic studies). Most tree-ring-based reconstructions of climate involve first withholding climate data for a specific period during the twentieth/twenty-first centuries and generating predicted values of climate from tree-ring data for that period. If the predicted values from the calibration model track the actual values for that period (and can be verified statistically), then the climate–tree growth relationship is considered stable enough to use the calibration equation for reconstructing climate back in time. In most cases, however, the calibration model would use the full record of climate and tree-ring data available for the twentieth/twenty-first centuries rather than just a specific calibration period.

Main findings

The response by trees to climate varies greatly across geographic regions. For example, in the American Southwest, precipitation is the primary limiting factor and the primary climate variable to which trees respond in their annual growth. Across mainland Europe and in parts of South America, (summer) temperature is the primary climate variable to which the trees respond. In the southeastern and northwestern regions of the United States, some tree species respond primarily to temperature while other species respond primarily to precipitation. Trees that grow in the tropics and subtropics experience relatively little variation in climate from month to month and season to season, such that trees that grow in lower latitudes have limited potential for climatic analyses, but recent advances demonstrate that tropical trees do harbor climate information that can be extracted. Trees that grow in higher elevations and at higher latitudes display a greater sensitivity to temperature variations, while trees that grow in more arid conditions or at the lower elevation limits for that species display greater sensitivity to variations in precipitation. Even within a specific geographic location, trees can be found that respond to one climate variable while adjacent or nearby trees can be found to respond to a different climate variable because of differences in local topography and microclimate.

Recent research has focused on evaluating whether the relationship between climate and tree growth has remained stable over time during the historic (twentieth/twenty-first centuries) period. A major concern among dendroclimatologists (and scientists in general) centers around the issue of “divergence” (D’Arrigo et al. 2008), which describes the diverging temporal trends between temperature records (increasing in the twentieth/twenty-first centuries) and tree growth (decreasing beginning about 1960), especially for trees in the higher latitudes of the Northern Hemisphere which have been prominently used for reconstructing past temperatures. Prior to this, temperature and
DENDROCLIMATOLOGY

Tree growth showed a strong positive relationship: that is, as temperature changed, so did tree growth. The implications of a temporally unstable relationship between tree growth and climate during the twentieth/twenty-first centuries are substantial because dendroclimatology assumes that environmental processes that operate today also operated in a similar manner in the past—the so-called uniformitarianism principle. If this relationship does not hold (remain temporally stable), then tree-ring data may not be reliable indicators of past climate. Researchers have discovered that some tree-ring chronologies display unstable relationships with climate over time, but most studies have found that the tree growth–climate relationship is indeed stable over the twentieth/twenty-first centuries.

Perhaps the greatest contributions of tree-ring data to society have been the reconstructions of past climate generated for many parts of the world that extend our knowledge on seasonal and annual climate well before historical weather records were kept. Reconstructions have been developed for nearly all the climate variables analyzed, across multiple temporal scales (monthly to multidecadal), for nearly all temperate and high-latitude locations, and now extending into the tropics. For example, water-year precipitation was reconstructed for the American Southwest from 136 BCE–1992 CE and revealed several centuries-long periods of above-average and below-average rainfall, including a “megadrought” in the late sixteenth century that has since been reconstructed for other portions of North America. Reconstructed PDSI for Mesoamerica suggests a strong forcing of drought by the El Niño–Southern Oscillation and a strong influence by the Atlantic Multidecadal Oscillation on summer climate variability over Mexico. Reconstructed streamflow for the Colorado River in the western United States suggests that river discharge during the twentieth century was not representative of discharge in previous centuries, calling into question government policies that allocate water resources to various western states in the United States.

Particularly important for understanding past climate have been the reconstructions of temperature for the Northern Hemisphere generated using primarily maximum latewood density data, although ring-width data also have been used. Temperature reconstructions were first pioneered by Fritts and his colleagues (especially Valmore LaMarche) at the LTRR beginning in the 1970s, before eventually being applied in the 1980s by others in the United States (Gordon Jacoby and Edward Cook of the Tree-Ring Laboratory at Columbia University) and in Europe (specifically Dieter Eckstein, Keith Briffa, Joel Guiot, Tom Wigley, and Malcolm Hughes). These initial reconstructions pushed our knowledge on trends in past temperature back several centuries, covering the important climatic episodes known as the Little Ice Age (ca. 1400 to 1850 CE) and the Medieval Warm Period (also called various other names, including the Medieval Climatic Anomaly), which occurred from about 1000 to 1300 CE. The first well-replicated millennium-length reconstruction was developed for Fennoscandia (Briffa et al. 1990) but showed little evidence for either of these two climate excursions. Evidence from Huon pine trees growing in Tasmania, however, showed enhanced growth during the twentieth century that could be attributed to anomalously warm temperatures, but such enhanced growth was not revealed for long-lived alerce that grow in southern Chile which were used to develop the first multimillennial reconstruction of climate (Lara and Villalba 1993).

Beginning in the late 1990s, dendroclimatologists employed hundreds of temperature-sensitive
DENDROCLIMATOLOGY

tree-ring datasets across large portions of the Northern Hemisphere to reconstruct past temperature, based largely on ensemble methods, a strategy that focuses on the development of several different (though related) reconstructions. The ensemble strategy also occasionally uses different proxy sources of past climate (such as borehole temperatures, ice core data, and speleothem data), and averaging/combining the results of the reconstructed temperature. Such ensemble approaches are desirable because error variance in the final reconstruction can be reduced. Mann, Bradley, and Hughes (1998) focused on reconstructing temperature for the past 600 years and found that annual temperatures during several years in the late 1990s were the warmest since the 1400s, stoking an ensuing controversy surrounding the graphic that would later become known as the “hockey stick” (1998: Fig. 5b and later versions). Later independent analyses, using the original but updated tree-ring data as well as new tree-ring datasets, would later confirm that the latter part of the twentieth century was indeed warmer than at any time during the past 1000 years. Recent tree-ring studies have also confirmed that the rate at which temperatures have increased in the past 100 years has been unprecedented during the past 1000 years. New tree-ring studies, however, point to a general cooling trend over the past 2000 years since the Roman Warm Period, a period claimed to have experienced temperatures warmer than those experienced during the twentieth century.

The significant contribution of tree rings to documenting Earth-surface processes lies in their capacity both to preserve evidence of past geomorphic activity and to provide critical information on their dating with annual or subannual resolution. In many climates, the tree-ring record may represent the most valuable and precise natural archive for the reconstruction and understanding of past and ongoing Earth-surface processes during the last several hundred years. As many geomorphic processes are significant natural hazards, understanding their distribution, timing, and controls provides valuable information that can assist in the development of mitigation of and defense against these hazards and their effects on society.

This entry provides an overview of tree-ring based reconstructions of surficial processes resulting from different geomorphic agents. It outlines the impact of Earth-surface processes on tree morphology and wood anatomy, and clarifies the approaches used for tree-ring reconstruction of past activity of Earth-surface processes. It also illustrates the breadth and diverse applications of contemporary dendrogeomorphology and underlines the growing potential to expand these studies, possibly leading to the establishment of a range of techniques and approaches that may become standard practice in the analysis of specific hazards.

What surficial processes can be analyzed with tree rings?

Dendrogeomorphology has been used in the analysis and reconstruction of a wide range of surficial processes. Some of the earliest applications of dendrochronological research to Earth-surface processes utilized roots rather than stem samples to study erosion processes. In the 1960s exposed tree roots were used as an indicator of ground surface at the time of germination of 5000-year-old *Pinus aristata* Engelm. in California. More recent work focused on areal denudation in badlands in the French Alps and central Spain to illustrate limitations and possible caveats of past approaches using growth rings of roots to reconstruct erosion rates (Stoffel et al. 2013). After a series of pioneering studies conducted on Mount Shasta (California), tree-ring records were used by several European researchers to reconstruct debris-flow activity in the Dolomites, and more recently in the Alps, where the frequency, spatial patterns (i.e., lateral spread and extent of flows), frequency–magnitude relations, and precipitation thresholds of debris flows have been analyzed (Stoffel, Tiranti, and Huggel 2014). Dendrogeomorphic analyses of landslides were realized primarily in Canada and the French Alps (Braam, Weiss, and Burrough 1987) to document spatial patterns of activity,
Dendrogeomorphology

reactivations, and rainfall patterns triggering landslides. In the first study in the subtropics, suppression–release patterns and inception of *Alnus acuminata* Kunth. trees have been used to date landslides in Argentina. The occurrence of snow avalanches has quite frequently been analyzed with tree rings since the mid-1970s. For a long time, tree-ring-based analysis of snow avalanche activity was almost exclusively used in North America (Butler 1979). Work in the European Alps started in the early 2000s, with a focus on runout distances and triggering weather conditions (Schläppy *et al.* 2014). The analysis of growth rings has also been used in paleohydrology. The first studies linking fluvial processes and botanical evidence go back to the 1960s (Sigafoos 1964). Later on, a broad array of flood signatures was defined to date palaeofloods. More recently, scarred trees have been used to estimate flood discharge and to analyze flood frequency distributions (Ballesteros-Cánovas *et al.* 2014). Surprisingly, and despite the potential of dendrogeomorphic methods, rockfall activity has only rarely been studied with tree rings. Studies analyzing the seasonality, frequency, and spatial patterns of rockfalls using tree rings were only very recently conducted, which provided a reliable basis for the analysis of rockfall risks and the accurate assessment of rockfall models (Trappmann, Corona, and Stoffel 2013).

**Tree reactions to Earth-surface processes**

Apart from the site-specific information common to many trees at any site (e.g., genetic information, age, or climatic conditions), individual trees also record the effects of mechanical disturbance caused by external processes. Trees can be injured, can suffer breakage of their crown or branches, and may have their stems tilted or partially buried or their roots exposed. Evidence of these events can be recorded in the tree-ring series of affected trees (Figure 1). The analysis of geomorphic processes through the study of growth anomalies in tree rings is called dendrogeomorphology (Alestalo 1971). Dendrogeomorphic research is normally based on the process–event–response concept where the “process” is represented by any geomorphic agent, for example, debris flows, snow avalanches, or rockfall (Stoffel *et al.* 2010). Individual geomorphic “events” that affect the tree may result in a range of growth “responses.” These events and associated responses are illustrated in the following paragraphs.

Mechanical disturbance and wounding (Figure 2a) are very common in trees affected by geomorphic processes. When impact locally destroys the vascular cambium, increment cell formation is disrupted and new cell formation ceases in the injured segment of the tree. To minimize rot and insect attacks after damage, the injured tree will compartmentalize the wound and start production of chaotic callus tissue (Figure 3a) at the edges of the injury. The extent of wound healing greatly depends on the annual increment rate, the age of the tree, and the size of the scar. After injury, tangential rows of traumatic resin ducts (or TRD; Figure 3a) are produced in the developing secondary xylem of certain conifer species. They extend tangentially and axially from the injury. When wounding occurs during the vegetation period of the tree, resin production will start a few days after the event and ducts emerge within three weeks after the disturbing event. Therefore, in analyzing cross-sections, the intraseasonal position of the first series of TRD can be used to reconstruct previous events with monthly precision. In broadleaved species, cambial damage will initiate various anatomical responses, among those a reduction in vessel sizes (Arbellay, Fonti, and Stoffel 2012).
Inclination of the stem results from the sudden pressure induced by geomorphic processes directly, by the associated deposition of material (e.g., avalanche snow, debris-flow material) or by the slow but ongoing destabilization of a tree through landslide activity or erosion. Tilted trees (Figure 2b) are common in many areas affected by geomorphic processes, and have therefore been used in many dendrogeomorphic studies to date previous events. Subsequent growth in the trunk of a tilted tree will attempt to restore its vertical position, and the reaction will be

Figure 1  Events affecting a tree and its reaction on a cross-section and in ring widths.
Figure 2  Characteristic examples of trees with disturbances visible on the stem surface: (a) open wound induced by rockfall; (b) tilted trees on a landslide surface; (c) buried tree stems standing in a debris-flow levee; (d) multiple decaptitions in a Larix decidua Mill. tree growing on an avalanche slope.

Figure 3  Reactions of trees to mechanical disturbance: (a) callus tissue (right) and tangential row of traumatic resin ducts (left) in Larix decidua Mill. after wounding; (b) severe growth suppression resulting from tree decapitation; (c) reaction wood in Picea abies (L.) Karst. after stem tilting; (d) growth release in a survivor tree following elimination of its neighbors.

most clearly visible in that segment of the tree to which the center of gravity has been moved through the inclination of the stem axis. In the tree-ring record, eccentric growth (and related reaction wood; see Figure 3c for details) will be visible after a tilting event and thus allows accurate dating of the disturbance. In coniferous trees, compression wood will be produced on the underside of the trunk. Individual rings will be considerably larger and slightly darker in appearance compared to the upslope side. The difference in color results from the much thicker and more rounded cell walls of early- and latewood tracheids. Multiple tilting events in the same stem may be recognized by changes in the amount, color, or orientation of reaction wood series in the ring series. In contrast, stem tilting in broadleaved trees leads to the formation of tension wood on the upper side facing the tilting agent. Broadleaved trees also react on
tilting with ultra-structural modifications that are visible only when studied on micro-sections. In addition to the formation of different types of reaction wood, trees may also respond with reduced growth after tilting.

Debris flows, floods, landslides or “dirty” snow avalanches may bury trees (Figure 2c) by depositing material around their stem base. Growth in these trees will normally be reduced (Figure 3b), as the supply of water and nutrients will be temporarily disrupted or at least limited. If stem burial exceeds a certain threshold, trees will die from a shortage of water and nutrient supply. According to case study results from the Italian Dolomites, *Picea abies* may tolerate a maximum burial depth of 1.6 m to 1.9 m in environments dominated by fine-grained debris flows composed of calcareous material. Occasionally, buried trees produce adventitious roots close to the new ground surface. As adventitious roots are typically formed in the first years after burial, the moment of root sprouting can be used to derive an approximate date for the sedimentation processes.

Bouncing rocks and boulders, debris in flowing water, debris flows and lahars, or the windblast of snow avalanches may cause the decapitation of trees (Figure 2d) or the removal of branches. The loss of the crown or branches is more common in bigger trees, when stems have lost their flexibility. Apex (the uppermost part or the growing tip of a plant) loss has also been observed as a result of rockfall impacts close to the ground level. In such cases, the sinusoidal propagation of shock-waves in the stem results in the breakoff of the crown. This phenomenon has been described as whiplash or a hula-hoop effect. Trees react on decapitation or branch loss with distinct radial growth suppression (Figure 3b). One or several lateral branches will form a “leader” that replaces the broken crown, resulting in the tree morphology called “candelabra” growth (see Figure 2d).

Erosional processes and the (partial) denudation of roots may generate different growth reactions, both in the stem and in the exposed roots. The type and intensity of the reaction(s) will depend on the nature of the erosive event, which may be instantaneous or progressive and gradual. If several roots are completely denuded during a sudden erosive event (e.g., debris flow, lahar, flood, or landslide), they are no longer able to fulfill their primary functions and will quickly die. The tree subsequently suffers from a shortage of water and nutrient supply, resulting in suppressed tree growth and the formation of narrow rings in the stem. In cases where only part of a root is exposed and its outer end remains in the ground, the root will continue to grow and fulfill its functions. In the exposed root, however, anatomical changes will occur and individual growth rings similar to those in the stem or branches will be formed. The localization of this change in the tree-ring series may allow determination of the moment of exposure. The continuous slow exposure of roots is usually caused by gradual processes and relatively low denudation rates, for example by overland flow; the slow opening of cracks in soils (e.g., soil creep, landslides) and in disintegrated bedrock, along rivers and streams, and beside lakes and oceans (floods, shore erosion), as well as by faulting activity and displacements in relation to earthquake activity. Provided that the roots are gradually exposed with time, it is also possible to determine the erosion rates in such cases.

Geomorphic processes can eliminate trees along channels or couloirs through uprooting and stem breakage and leave neighboring trees intact. This phenomenon can be observed with, for example, rockfalls, debris flows, lahars, extreme floods, landslides, and snow avalanches. The uninjured survivor trees have
less competition and more light, nutrients, and/or water. As a consequence, they may start to produce larger increment rings (Figure 3d). However, observations indicate that this growth release in survivor trees can be delayed, and therefore this reaction cannot always be used to date past destructive events with yearly precision. Nevertheless, the growth release in survivor trees can corroborate the dating of events that have been identified from evidence in other trees at the same site, for example from scars and tilted stems (Stoffel and Corona 2014).

Many different Earth-surface processes can eliminate surface vegetation including entire forest stands, leaving no direct dendrogeomorphic evidence. In such cases, the germination ages of trees growing on bare surfaces can be used to estimate the time of creation of new landforms and the disturbance event. This approach provides a minimum age for that surface and has frequently been used to date landforms or to assess the minimum time elapsed since the last devastating event in snow avalanche couloirs, debris-flow channels or floodplains. It involves estimating the time between the exposure of the surface and the germination of the first surviving seedling on that surface. This ecesis estimate varies according to the environment, substrate, available seed sources, and several other factors. Problems of ecesis determination have been extensively discussed in studies that attempt to date the formation of glacier moraines (McCarthy and Luckman 1993) where ecesis estimates may vary from a few years to several decades.

Field approach and sampling design

The types of damage to trees described in the preceding section may result from a wide variety of Earth-surface processes. Linkage between the damage and the causative process depends on a critical evaluation of the sampling site. In many cases, investigations are undertaken with a specific context where the process or processes involved are known, and appropriate sampling methods and sampling design may be applied. These vary considerably with the nature of the process or investigation and are best discussed in the specific context of individual processes; for example, the sampling network needed to define past earthquake activity may be very different from that required to reconstruct the history of snow avalanches and debris flows on a large debris cone.

At an individual site the choice of sampling design and selection of the trees to be sampled will depend on the purpose of the investigation and the processes or hazards being sampled. The sampled area and the number of trees sampled may be very small and specific (e.g., on a small landslide) or may involve systematic sampling of a larger area (e.g., within a large runout zone of a snow avalanche) or target individual trees damaged at the margins of an event. As a rule of thumb, processes that tend to spread considerably will likely leave larger spatial footprints and will thus be visible in a larger number of trees. In the case of landslides, a sample size of 50 trees seems sufficient; a slightly larger sample size (100 trees) appears appropriate for snow avalanches, while at least 150 trees are needed to characterize debris flows appropriately. The sample size in rockfall studies will depend on the size of the study site, stand density, and mean rock sizes. The choice of the individual trees sampled is based on an inspection of the stem and on the location of the trees in relation to the processes studied.

The tree-ring record of growth disturbances created by past events is analyzed with cross-sections, wedges, or increment cores. Cross-sections or wedges are normally taken at the
location of the growth disturbance, and provide an excellent and complete insight into the tree’s history. However, in many locations (e.g., protection forests, national parks) felling may be prohibited or is ill-advised for aesthetic or safety reasons. Most tree-ring studies thus use cores extracted with an increment borer. The nature of visible growth defects observed in the tree’s morphology will influence sampling height, sampling directions, and the minimum number of samples to be taken per tree.

In trees with visible scars, previous geomorphic events are most easily dated through the destructive sampling of trees and the preparation of cross-sections taken at the location where the injury is largest. This approach will facilitate an accurate and intraseasonal identification of the onset of callus tissue (and TRD) formation, and therefore allows a reconstruction of the impacting event with very high temporal resolution. Alternatively, wedges can be sawn from the overgrowing callus and an increment core extracted from the side opposite to the wound.

Tilted stems are usually analyzed with at least two increment cores extracted per tree, one in the direction of the tilting and the other on the opposite side of the trunk. The reaction wood will be visible on the tilted side in conifer trees (= compression wood) and on the side opposite to the tilting direction in broadleaved trees (= tension wood). Individual cores are best extracted at the location where tilting is strongest, based on an outer inspection of the tree morphology. However, in situations where multiple tilting events may vary in direction – for example in snow avalanche tracks – additional cores, transverse to the downslope direction, may be needed to develop a more complete record.

In the case of buried stem bases, the sampling of two increment cores in opposite directions (ideally from the upslope and the downslope sides) will normally allow accurate reconstruction of the event that has led to the sedimentation of material around the stem’s base. It is best to sample these trees as close to ground level as possible (ca. 20–40 cm) to extract a maximum number of tree rings and obtain maximum information. However, the influence of roots should be avoided.

The analysis of exposed roots is normally based on cross-sections because they regularly show partially or completely missing rings. The position of samples needs to be carefully noted with respect to the ground surface or the noneroded parts of the root. These samples are essential for the understanding and interpretation of continuous erosion processes and the determination of denudation rates.

The germination of trees on new landforms is best determined by counting the annual growth rings in increment cores taken from the root crown level. However, branches, obstacles, and rot may sometimes require sampling positions higher up on the stem. In these cases, an age correction factor needs to be added to compensate for the time a tree takes to grow to sampling height. A simple height–age correction can be achieved by dividing the tree height by the number of tree rings to get an average rate for the yearly apical increment.

In some cases a reference tree-ring chronology may need to be developed from a nearby forest stand to assist in the cross-dating of trees at the sampled site to verify the age assignment of rings. Adequate sample size varies between species and also depends on the strength of the common signal. In general, 20–30 trees is a useful guide for most species, to minimize the potential influence of geomorphic processes and hidden growth disturbances.
Sample analysis and interpretation

Ring widths of the disturbed samples may also be measured, and the series compared graphically or statistically with the reference chronology. These tools also allow for an assessment of cross-dating accuracy between ring-width series of individual disturbed trees and the reference chronology. Once all tree-ring series are checked, individual growth curves may be analyzed visually to identify the tree’s reactions to geomorphic processes, for example, the initiation of abrupt growth reduction or releases. In addition, the microscopic appearance of the cells may be investigated to yield further evidence of disturbance. Other features, such as callus tissue overgrowing scars or the presence of TRD formed following cambium damage, can only be identified through a visual inspection of the cores and cross-sections. All growth reactions identified in the samples are noted in order to identify disturbance events. Except for processes with limited volumes (e.g., single rocks or boulders involved in rockfalls), one growth disturbance identified in a single tree is not considered sufficient evidence to identify an event, and therefore the identification of events needs to be based on quantitative or semiquantitative thresholds (Stoffel and Corona 2014).

Conclusions

Initially tree rings were employed in geomorphic studies simply as a dating tool and other environmental information and records of damage contained within the tree were rarely exploited. However, these unique, annually resolved, tree-ring records preserve valuable archives of past Earth-surface processes on timescales of decades to centuries. As many of these processes are significant natural hazards, understanding their distribution, timing, and controls provides valuable information that can assist in the prediction and mitigation of, and defense against, these hazards and their effects on society. This entry has provided illustrations of these themes, demonstrating the application of tree rings to studies of snow avalanches, rockfalls, landslides, floods, earthquakes, wildfires, and several other processes. It illustrates the breadth and diverse applications of contemporary dendrogeomorphology and underlines the potential of expanding dendrogeomorphic research, which could lead to the establishment of a range of techniques and approaches that may become standard practice in the analysis and understanding of Earth-surface processes and related natural hazards in the future.

Denmark: Det Kongelige Danske Geografiske Selskab (Royal Danish Geographical Society)

Founded: 1876
Location of headquarters: Copenhagen
Website: www.rdgs.dk
Membership: 350
Secretary General: Henrik Breuning-Madsen
Contact: rdgs@geo.ku.dk

Description and purpose

The society aims to promote knowledge of the Earth and its people and to further interest in geographical science. The society organizes six annual meetings with presentations on geographical topics; publishes a journal, monographs, and atlases; and keeps a library and collection of maps. The society’s activities particularly promote and disseminate Danish geographical research but also form links to other geographical and related societies.

Journals or major publication series

Current activities or projects

The society arranges an annual program of meetings and lectures on geographical themes. It organizes expeditions and research projects and hosted the circumnavigated Galathea 3 expedition in 2006–2007, which visited six of the seven continents. Most recently, the society participated in the interdisciplinary GeoArk initiative in northeast Greenland combining geography, biology, and archaeology.

The society publishes a range of books, an Atlas series, and an international English language journal, Geografisk Tidsskrift–Danish Journal of Geography, which has been the main forum for scholarship on the geography of Denmark and the work of Danish geographers since 1877. The society also maintains a minor museum including books, instruments, and a collection of maps.

Brief history

The Royal Danish Geographical Society was established in 1876 with the dual purpose of disseminating knowledge of the Earth and its inhabitants and promoting interest in geographical sciences.

Up until World War I, the society had an important role in initiating, supporting, and reporting Arctic research, particularly in relation to Greenland. Most of the world’s leading polar researchers were awarded the society’s Gold Medal and gave lectures in Copenhagen.

Exploration remained a leading activity in the time between the two great wars, for example, Knud Rasmussen’s fifth Thule expedition along the entire polar edge of the North American continent to trace Eskimo origins. While Danish expeditions in central Asia (Haslund-Christensen) provided much new information, domestic geomorphology also attracted increasing interest, specifically the dynamics of the Wadden Sea coastal landscape.
DENMARK

After World War II, the society maintained its interest in Arctic research with focus on landscape, soil, and archaeology (Geoark) and it hosted the circumnavigated Galathea 3 expedition in 2006–2007, which visited six of the seven continents.

Since 1876, the society has published Geografisk Tidsskrift–Danish Journal of Geography mainly in Danish until the 1990s when it changed to English. The society publishes atlases and books and arranges at least six public meetings per year.

Denmark: Geoforum
Danmark (The Danish Association for Geographic Information)

Founded: 2001
Location of headquarters: Copenhagen
Website: www.geoforum.dk
Membership: 250 companies and 400 individual members (as of January 1, 2014)
President: Winn Nielsen
Contact: bf04@tmf.kk.dk

Description and purpose

The purpose of the organization is to provide a network for organizations that work with geography on any level in both the public and private sector as well as to promote the use of geography. The organization’s work is heavily based on volunteers and has a variety of groups where members meet to discuss certain themes and aspects of geography. Furthermore, there are five groups that arrange events throughout the year, including the annual three-day conference, Kortdage, where the entire industry meets to catch up with the latest news.

Journals or major publication series

Geoforum (members’ magazine in Danish).
http://geoforum.dk/udgivelser/geoforum/
Geoforum Perspektiv (journal in Danish and English).
http://geoforum.dk/udgivelser/perspektiv/

Current activities or projects

Professional events throughout the year include courses, networks, and the new Geodataprisen (geodata awards) that celebrates new and innovative products created by the industry. Also, the annual Kortdage – a three day conference in the fall – brings the entire industry together.

The board also works on several products to bring attention to the industry, ensure politics in favor of geography and geodata, and improve the subject of geography on all educational levels.

Geoforum provides two Internet portals to share good examples (in Danish): www.brugstedet.dk is the Geoforum collection of examples on the use of geographic information and www.kortfordig.dk is the Geoforum education portal oriented towards high school students aimed at recruiting them for geodata careers.

Density estimation

Fang Ren
University of Redlands, USA

With significant advances in spatial analytical methods and rapid development of geographic information systems (GIS), density estimation techniques have been widely applied in many disciplines that involve spatially referenced data during the past forty years or so. One important use of density estimation is to convert a set of spatially discrete events, including but not limited to disease cases, crime incidents, road accidents, and animals’ locations into a continuous field or density surface to reveal the spatial distribution and spread of the events. In addition to the presentational advantages, the resulting density may be further tested for statistical inference or aggregated to compare to other socioeconomic and environmental variables.

Density estimation, which is rooted in probability and statistics, seeks to construct a probability density function \( f \) from a sample for an unknown population. Converting discrete data values into smooth curves greatly facilitates data distribution analysis (e.g., skewness), confirmatory statistical analysis such as classification, and pattern detection. There are two groups of estimators: parametric and nonparametric. Unlike parametric estimators, nonparametric estimators are not built upon a presumed population distribution. The simplest nonparametric density estimator is the histogram, in which the probability function is calculated as the proportion of observations contained in each bin divided by the width of the bin. Sophisticated estimators include fixed bandwidth kernel estimators, adaptive (or variable) kernel estimators, the nearest neighbor method, orthogonal series estimators, and restricted maximum likelihood estimators, to name a few (Silverman 1986). Because kernel density estimation (KDE) is the most commonly used method, this entry focuses on KDE and its applications in spatial studies.

Kernel density estimation

Given \( n \) observations in a 2-D geographic space, a general formulation of bivariate kernel estimators is expressed as:

\[
\hat{f}(x, y) = \frac{1}{nh^2} \sum_{i=1}^{n} K\left( \frac{d_i}{h} \right)
\]

where \( \hat{f}(x, y) \) is the estimated density at any location \((x, y)\), \( d_i \) is the distance from location \((x, y)\) to the \(i\)-th observation, \( h \) is the bandwidth or smoothing parameter that determines the amount of smoothing, and \( K \) is the weight function that usually is a symmetric probability density function. An illustration is given in Figure 1, where the shape of the “bump” is determined by the choice of the kernel \( K \). The build of the kernel makes itself of particular relevance to the distance decay principle in geography, which implies that spatial interaction declines when distance increases.

The bandwidth of the kernel can be fixed or adaptive. The purpose of using an adaptive kernel is to vary the amount of smoothing based on the local density of data. In a sparse area, a relatively large bandwidth is preferred to include enough observations to avoid under-smoothing (the right kernel in Figure 1), whereas a
DENSITY ESTIMATION

Figure 1 Kernel density estimation with adaptive bandwidth.

A smaller bandwidth is suitable for a dense area to prevent oversmoothing (the left kernel in Figure 1).

There are two ways to implement KDE depending on where the kernel is placed: one is to directly calculate density at each location by putting the kernel on that location (named the site-side estimate), while the other is to center the kernel only at each event and add up the $n$ kernel density functions (called the case-side estimate) (Shi 2010). Although the two methods are mathematically equivalent for fixed bandwidth KDE, the case-side method is more computationally efficient and better suits the scenarios where the distribution of the events varies greatly in space.

It is well known that the bandwidth has a greater effect on KDE results than the choice of the kernel. If the bandwidth is too large, data will be oversmoothed, such that variations in data distribution might be obscured, whereas an incredibly small bandwidth may lead to spurious spikes in the final density surface.

To select an appropriate bandwidth, a variety of selection methods have been proposed, some of which are simple while others are complex. Theoretically, the optimal bandwidth minimizes the discrepancy between the true density distribution and the estimated one, which is commonly measured by mean integrated square error. Unfortunately, both measures depend on the unknown population distribution. To solve this problem, various data-driven strategies have been developed, including least-squares cross-validation, biased cross-validation, “plug-in” methods, smoothed cross-validation, and local polynomial fitting. A comprehensive review of bandwidth selection strategies is available elsewhere (Jones, Morran, and Sheather 1996).

A popular “rule of thumb” of bandwidth selection has been given by Silverman (1986). It assumes the underlying density function is a normal or Gaussian distribution that is the most popular kernel:

$$h_{NR} = 1.06\hat{\sigma}n^{-1/5}$$

where $h_{NR}$ is the normal reference bandwidth, $\hat{\sigma}$ is the estimated population standard deviation, and $n$ is the number of observations. For a set of points, $\hat{\sigma}$ is the standard distance of the point distribution in the horizontal plane.

This computationally simple bandwidth only works well when the population follows a normal distribution. In other cases, however, it is often excessively large and produces over-smoothed densities. To correct for multimodal distributions, Silverman (1986) recommended a slightly different formula:

$$h_{SROT} = 0.9A n^{-1/5}$$

where $h_{SROT}$ is Silverman’s rule of thumb, $A$ is the smaller of the sample standard deviation (or standard distance for a set of points) or sample interquartile range (or interquartile range of distances from each point to the mean center) divided by 1.34, and $n$ is the number of observations. In practice, multiple experiments with different bandwidth values may be useful in determining a reasonable bandwidth for the problem at hand.
Density estimation with spatial data

Due to its strength in data visualization and exploration, density estimation has played an increasingly important role in exploratory spatial data analysis, to reveal spatial patterns of geographic phenomena and their spatial relationships. For example, it is often challenging to identify the location, scale, and orientation of the spatial clusters from a large volume of point data. The overall spatial pattern, however, will become far more noticeable when disconnected points are smoothed into a continuous field. Hence, density estimation has become an effective approach to examining the first-order variation (inconsistent intensity/density) of the underlying spatial processes.

Variants of kernel density estimation

To adapt standard KDE to support the studies that involve spatially referenced data, methodological advances have been made. Brunsdon (1995), for example, developed an adaptive kernel algorithm to determine the probability distribution of a set of point data, which can be applied to points in any dimension in Euclidean space. Diggle (1985) designed the optimal bandwidth that minimizes the mean square error for a set of spatial points, which is widely adopted in epidemiological studies. Edge effects, which often distort point pattern analysis results, have also been corrected in KDE.

It has been found that conventional KDE is not appropriate for mobile objects (e.g., migratory birds) because the points representing a mobile object’s trajectory are not independent. Integrating time geography with traditional KDE, Downs (2010) developed time-geographic density estimation (TGDE) to model the density of moving objects from tracking data. In a typical formulation of TGDE, density is estimated as a function of a geo-ellipse generated for each pair of two consecutive points on the object’s space–time path. Compared to KDE, TGDE excludes the areas that cannot be approached by the animal given its space–time path and the degree of smoothing is determined objectively by the travel velocity of the animal.

For those applications where spatial events only take place over a network (e.g., road accidents or animal roadkill), the planar kernel estimators tend to overestimate the density of the events. To address this issue, Okabe, Satoh, and Sugihara (2009) specifically formulated three kernel functions, namely the “similar” shape, equal-split, and equal-split continuous to accommodate the linear spatial configuration of the events; the latter two are recommended as they produce statistically unbiased density estimates.

Another important advance in kernel density estimation is the development of space–time KDE that estimates density distribution in both space and time. Temporal dynamics is a very important aspect of many geographic phenomena; for example, residential burglaries usually take place in daytime, implying one single static density surface cannot appropriately describe how the intensity of residential burglaries varies throughout a day. Brunsdon, Corcoran, and Higgs (2007) formulated kernel estimators as a function of geographic location (X and Y) and time (T) to estimate the probability of a crime incident at a space–time location (x, y, t).

Although a continuous field is a great way to explore spatial patterns, it does not imply statistical significance that is usually required for pattern detection. The fundamental concern of pattern analysis is to evaluate whether the clusters or areas of high risk are generated by chance or by systematic spatial processes. The Monte Carlo simulation procedure, a commonly
density estimation

used empirical inference approach in spatial
statistics, can be combined with KDE to extract
statistically significant clusters by comparing the
observed density to the simulated densities of
randomly distributed events.

Further, density estimation has been incor-
porated in popular statistical software, such as
R, S-Plus, and SAS, and geographic analysis
enabled software including ArcGIS, CrimStat III,
and STAR (Space-Time of Regional Systems).
In particular, the 3-D rendering capability of the
software provides an appealing 3-D visualization
of density distribution. Overall, the method-
ological advances and widespread availability of
new tools in both statistical and GIS software
have significantly broadened the applications of
density estimation.

Applications of density estimation in spatial
studies

In medical geography, KDE has been applied to
study spatial epidemiology, access to health-care
facilities, and service provision of health-care
facilities. Since Bithell (1990) first demonstrated
that KDE was an effective way to estimate a rela-
tive risk function, KDE has been used to examine
disease distribution and identify associated risk
factors in spatial epidemiology. To evaluate the
impact and spread of a disease, case density by
itself is often of limited use because the spatial
pattern of the disease usually coincides with
population distribution, indicating that disease
density needs to be adjusted for the density of
population at risk or a random sample from the
population (controls). In doing so, the areas of
elevated risk, which otherwise would be con-
cealed due to low population, may be disclosed.
Two measures have been suggested for assessing
relative risk: the ratio of case density over con-
trol density and the relative difference between
these two densities. In addition, KDE enables
the discovery of significant spatial variations in
relative risks of two diseases (Kelsall and Diggles
1995).

One important theme of the public health lit-
erature is concerned with social disparity of geo-
graphic access to health care. The most straight-
forward measure is the provider-to-population
ratio calculated at a predefined scale such as
metropolitan statistical areas. This measure may
be misleading because it assumes that a provider
only serves the individuals in the same area unit.
The barrier of border crossing can be overcome
by a field model, which explains why KDE has
gained broad recognition in many public health
works. Guptill (1975), for example, overlaid a
density surface of physicians with neighborhood
borders to calculate average physician density
for each neighborhood in Detroit, MI. The
density distribution of health-care providers
may be directly compared to that of popu-
lation to reveal underserved neighborhoods
or adjusted by population density to measure
relative accessibility to health care. Inequality
in geographic access to health care among dif-
ferent social groups may be further uncovered
by comparing accessibility densities of these
subgroups.

Parallel to medical geography, spatial point data
representing crimes, persons, and animals have
also been extensively analyzed with KDE and its
variants. In criminological research, KDE and
space–time KDE have become popular methods
for detecting crime-prone zones in space or
in space and time. For example, Chainey and
Ratcliffe (2005) discussed the advantages and
issues of KDE in crime hotspot analysis. In spite
of the issues faced by KDE, such as subjectiv-
ity involved in both bandwidth selection and
gray scale classification in the legend, it is a
very effective way to depict the location, size,
extent, and orientation of crime hotspots. Their
example of comparing robberies with burglaries
further suggests that the spatial structures of two geographic phenomena are different if distinctive smoothing effects are observed with the same bandwidth.

In the context of mapping people, KDE has been applied to examine geographic distributions of customers for marketing and human activity–travel patterns. Using KDE in conjunction with map algebra and 3-D geovisualization techniques, Kwan (2000) compared space–time activity density patterns of different subgroups with a travel diary dataset collected in Portland, OR. For ecological applications, KDE and time-geographic density estimation are found to be useful in defining home ranges of species (Worton 1989). Usually, a density surface is first developed with the tracking data, and then home ranges and core areas are delineated using specified contours of relative intensity (e.g., 50%).

Further, effort has been spent to develop density estimation for spatial phenomena that are restricted over a network, such as road accidents (Flahaut et al. 2003). Identifying road accident hotspots, also called black zones, is critical for developing effective strategies for the reduction of traffic accidents. Compared to the traditional approaches that focus on road segments or junctions, a density surface of accidents, or a relative risk surface if controlled on traffic volume or other factors, can better represent the dangerous spread that, in fact, should not be confined within a well-defined street network boundary.

**Summary**

In summary, the benefits that density estimation brings to the spatial studies are threefold. First, density estimation greatly supports spatial pattern analysis by smoothing discrete point data into different kinds of continuous fields, including density surfaces (e.g., crime or activity densities), risk surfaces when background is controlled (e.g., risk of a disease or relative accessibility to health care), or surfaces of difference when multiple events or groups are compared. Combined with the Monte Carlo simulation procedure, statistical significance can be tested on these resulting density or risk surfaces, with which policymakers can make informative decisions to combat crime, promote accessibility of underserved populations, or target groups for preventive health care.

Second, by depicting discrete geographic phenomena as spatially continuous variables, density estimation successfully circumvents the modifiable areal unit problem and the border-crossing issue that are raised by aggregating individual points into predefined area units. Although administrative boundaries are convenient for managing data, spatial phenomena like diseases or criminal activities do not operate accordingly. For the applications that only involve areal data, such as population counts of census tracts or disease rates of districts, different spatial smoothing techniques, including interpolation and empirical Bayes estimation, need to be applied.

Last, an important use of density or risk surface is to identify risk factors associated with the events of interest. For the problems in which risk factors are spatially continuous variables, such as air pollution or proximity to a contaminated source, the density of these variables can be directly correlated with the risk surface of the events. In other cases where the relevant factors are areal data (e.g., median household income or percentage of a particular ethnic group), the density or risk of the events may be aggregated as a summary statistic like mean or median for an in-depth analysis on relationships.

Dependency theory

William G. Moseley
Macalester College, USA

In reaction to modernization theory, a new set of development ideas began to arise in the 1950s that emphasized structure, or the global framework under which countries operated. Dependency theory was a leading example of this new type of structuralist thinking. This emphasis on structure meant that the relationships between countries were as important as, or more so than, internal policies for determining the future development of a country.

The earliest ideas about dependency are most closely associated with two economists, Hans Singer and Raul Prebisch, who published papers on the topic in 1949. They had observed that the terms of trade for the poor, tropical countries had deteriorated over time relative to those of the wealthy, industrialized nations. Their idea, known as the Singer–Prebisch thesis, was that poor countries were acquiring fewer and fewer manufactured goods in exchange for the raw materials they exported.

This idea was then elaborated upon by a number of Marxist scholars, one of the most well known being Andre Gunder Frank. Frank (1979) suggested that economies in the tropics (Africa, Latin America, Asia) were essentially “underdeveloped” during the colonial era as European countries refashioned these economies (through a combination of taxation policies and forced coercion) for their own benefit. According to Frank, elites in developing countries often colluded with the colonizers to organize primary extraction in exchange for wealth and power. In many instances, farmers in tropical countries were encouraged or forced to produce commodity crops for the European market (often at the expense of subsistence production) and/or pushed to leave their own farms to pursue wage labor on large plantations or in emerging mining sectors. These primary commodities from the tropics (the satellites) were traded for manufactured goods from Europe and other industrialized countries (the metropoles) in a global system of unequal exchange that favored Europeans. Taylor (1992) described the creation of the modern world economy as being “made by Europeans for Europeans as one great functional region centered on Europe.”

Wallerstein (1979) expanded on dependency theory through his world-systems theory, which basically gave a spatial face to dependency theory by depicting the world in terms of the core, semiperiphery, and periphery. Under this schema, the core countries represent the most developed states that are dominated by industry, financial services, and an information-based economy. The semiperiphery is an emerging group of states where high levels of cheap manufacturing increasingly take place. Finally, the periphery represents those countries whose primary role in the global economy is to provide raw materials. All three of these regions operate as a world system, with deep connections existing between the spheres.

The problem, as dependency theorists see it, is that many tropical countries will find it difficult to break out of their role of producing goods with peripheral processes, including relatively low wages, low levels of technology, and low levels of education. In other words, Rostow’s
DEPENDENCY THEORY

(1959) stages of economic growth will not occur because the least developed countries are locked into an exploitative set of relationships with countries that are more developed. This has led to the idea of an international division of labor, wherein one has unskilled laborers working on the periphery and a skilled workforce in the core countries (Baran 1957). Given this division, highly skilled workers in the periphery will be tempted to migrate to the core countries (a problem known as brain drain) because employment opportunities for them are limited in their own countries.

Dependency theory was also influential at the subnational scale via the concept of dualism. Influenced by notions of dependency, dualism refers to situations where two areas are in relationship with one another, and one area is developing at the expense of the other. This concept may be examined at a variety of different scales, including global (as is the case with dependency theory), regional (within country), urban, and rural.

Within most countries, dualisms often exist between urban and rural areas. In the United States, for example, many would argue that core areas exist where a disproportionate amount of investment and wealth accumulate. These areas, typically cities, have historical relationships with more rural zones of resource extraction that function as peripheries to the urban cores. In Nature’s Metropolis (1992), environmental historian and geographer William Cronon wrote of the relationship between Chicago and vast interior regions of the Midwest. Timber, iron ore, livestock, and grain historically came to Chicago from the Upper Midwest in exchange for manufactured items. Cronon explained that while Chicago became fabulously wealthy during the nineteenth and twentieth centuries, the regions of extraction (such as northern Minnesota, southern Illinois, and northern Wisconsin) have little to show for their exports today.

Dualism is apparent in rural areas where one may have an export-oriented commercial agricultural sector that exists alongside smaller-scale, mostly subsistence farming. The classic situation is one wherein small subsistence farmers spend the day laboring on nearby large plantations, returning to work on their own farms in the evenings and during the weekends. The linkage between the two sectors is often disadvantageous for the small farmer or laborer. For commercial farms, the advantage of laborers who moonlight as small farmers is that they need not be paid a living wage because they have their own production to cover a portion of their annual food needs. Many small farmers who end up working on larger farms may initially take on such employment in order to bridge a food production shortfall. In so doing, however, they often embark on a slippery slope of declining production as they spend critical time off the farm compromising their own ability to produce food.

A similar set of dualistic relationships exists in urban areas between the formal and nonformal employment sectors. Formal sector employers, such as large export-oriented firms, may draw on temporary laborers who are otherwise employed in the informal sector, including a wide array of undocumented full- and part-time employment in activities such as petty commerce and artisanal production. This system allows for the relatively cheap supply of labor to the formal sector, as these laborers may also rely on the informal sector for income.

Policy outcomes

At the international scale, dependency theory did lead to some real policy changes in developing
countries. Probably the most significant of these was an approach known as “important substitution industrialization,” often associated with the Argentine economist Raúl Prebisch previously mentioned. Prebisch (1959) argued that tropical countries would be forever stuck as producers of primary products (and therefore fail to develop) unless they took proactive steps to change the nature of their economies in relation to those of others. The idea behind import substitution was that manufactured goods needed to be produced at home rather than imported from the core countries (hence the name of “import substitution” for such policies). Given a lack of private capital available for industrialization, and stiff competition from producers in the core countries, the governments of peripheral states often became directly involved in the creation of such enterprises. These state-run enterprises came to be known as parastatals. Governments typically also erected tariff barriers to protect such nascent or infant industries until they could stand up to international competition.

The other policy, at least partially inspired by dependency theory, was the nationalization of some industries, often mines, that were owned and run by transnational corporations (TNCs) in tropical countries. The argument was that the foreign companies that ran these industries would not manage them in the interest of local people and development. While capital accrued from mining, for example, might normally be reinvested in industry and lead to the development of the local economy, the problem was that TNCs repatriated most of the profits. By taking over such industries (and running them as parastatals), the state could, in theory, insure that the profits from these mines were plowed back into developing other industries in the country. Good examples of countries that did this are Chile and Zambia, who nationalized their copper mines in the 1960s and 1970s.

Import substitution, and to a lesser extent nationalization, was quite popular until the late 1970s when the “third world” debt crisis struck. This crisis involved a number of peripheral countries that were on the verge of defaulting on loans owed to private commercial banks as well as public creditors. The crisis was largely brought on by government involvement with increasingly inefficient, state-run enterprises and the energy crisis of the 1970s when high oil prices were particularly challenging for oil importers.

Neoliberal and poststructural critiques of dependency theory

Dependency theory, and structuralist thinking more broadly, began to face two very different sorts of critiques in the 1980s. The first type of critique came from neoliberal economists who argued that dependency theory-inspired import substitution policies were inhibiting economic growth. These policies, they suggested, were largely responsible for the “third world” debt crisis of the late 1970s. Neoliberal reforms were initially developed and undertaken in Latin America, led by economists from the University of Chicago known as the “Chicago Boys.” These polices would then spread to other parts of the world. For example, the so-called Berg report (World Bank 1981) offered a searing critique of import substitution policies in Africa and proffered neoliberal reforms, known as structural adjustment, as the solution. This package of reforms called for reduced government, free trade, export orientation, and the privatization of state-run enterprises.

Critics of neoliberalism (largely supporters of dependency theory) suggested that this was a return to the economic policies of the colonial era (where tropical countries were encouraged
to focus on the export of raw materials). Some subsequent work in Asia (e.g., Bruton 1998) has shown that import substitution policies were critical for developing the export-oriented industries that led to the rise of the Asian Tigers (Hong Kong, Singapore, South Korea, and Taiwan). Ironically, it was the export orientation of these countries that was used as evidence in support of neoliberal economic reform (conveniently leaving out the policies that helped build these industries in the first place).

Another type of critique of dependency theory came from the poststructuralists, a group of social scientists influenced by postmodernism. This group argued that structuralist thinking (to which dependency theory is central) did not give adequate attention to “agency,” that is, the power of individuals and groups to change their circumstances through individual or collective action. This group also asserted that greater attention needed to be accorded to discourse as a form of power and influence. While the discourse on any given subject is often controlled by elite interests, and the masses have often internalized these narratives (the definition of hegemony), collective action could also lead to the production of counternarratives, or a new conventional wisdom. In many ways, the poststructuralists were not abandoning the insights of dependency theory, but they wanted to build on it to account for power of agency and discourse. Good examples of such poststructuralist thinkers include Peet and Watts (1996) who wrote about the emancipatory potential of poststructuralist thinking when applied to an older, more structuralist leaning, political ecology (a subfield of human–environment geography). The poststructuralist, feminist economic geographers J.K. Gibson-Graham also write eloquently about the limitations of dependency theory. In The End of Capitalism (As We Know It): A Feminist Critique of Political Economy (Gibson-Graham 1996), they write about how we imagine capitalism to be more powerful and ubiquitous than it is in reality. Once we begin to realize all of the noncapitalist activity around us, we can rewrite or reimagine the dominant narrative and feel empowered to act differently (or express our agency). For them, feminist scholarship is critical for recognizing the heterogeneous nature of the economy.

More recent debates, referencing ideas and intellectual offshoots of dependency theory, include claims for new regional growth in Africa, or the “Africa Rising” assertion, based on natural resource-based exports (compare Roxburgh et al. 2010 to Carmody 2011 or Moseley 2014). The question is whether this recent growth represents something new or simply a return to dependency. The notion of path-dependent growth is now also widely debated in the social sciences (Martin 2010).

Desakota

T.G. McGee

University of British Columbia, Canada

Desakota is a neologism developed after fieldwork in the Jakarta mega-urban region in the 1980s and discussion with Indonesian colleagues. (McGee 1991). The term was coined to recognize the fact that rural areas adjacent to the built-up central areas of cities were being subjected to increasing urban expansion. This process was creating areas of mixed urban and rural activity that were increasing in territorial size and population. The term desakota combines two words from the Indonesian language, desa (village) and town (kota); it captures the ideas of rurality and urbanity that have existed in Indonesia for many centuries. These areas were growing rapidly as the result of urban spatial expansion that accelerated in the large mega-urban regions of Asia from 1970 onwards.

In the period since the 1980s, these processes of urban expansion have accelerated in Asia, particularly in the faster growing economies of the region, often leap-frogging along urban corridors beyond the immediate hinterlands of the mega-urban regions to secondary urban nodes that were developed to link new industrial areas, residential estates, and retail complexes to other parts of the mega-urban regions. This process has been facilitated by the growth of digital communication that facilitates networks which link these activities to core cities in the mega-urban region, nationally, and globally. The rapid increase in the price of land in the urban cores also encouraged decentralization to the cheaper land markets located on the edge of these cities. These developments are reshaping the urban space of the mega-urban regions for which the models of the organization of urban space that have been developed in the past for developed countries are no longer valid; they are replaced by the concept of mixed urban land-uses in a form of hybridity that reflects the collapse of space and time in which these extended urban spaces are linked by networks of flows of commodities, people, capital, and information that facilitate urban expansion. Today these desakota regions are a kind of “in between” in the “rural–urban dichotomy” that have become a prevailing form of land use. Indeed, national space is now a form of rural–urban hybridity. This does mean that “rurality” and “urbanity” as concepts do not capture reality and people’s beliefs and actions, but these are still all subject to cultural, historical, and economic variations at a global, national, and local level. In the contemporary era, these developments have been complicated by the new challenges of environmental change and deterioration and rapid but uneven economic growth in many of the developing countries of Asia (McGee 2011). These challenges will continue in the next thirty years with almost 60% of all global urban growth occurring between 2010 and 2050 in Asia, much of it located in the extended urban space of large mega-urban regions. This suggests that ideas that inform the study of the organization of urban space need to be critically evaluated in this new era of “planetary urbanization” (Brenner 2014).

Desert ecosystems

Taly Dawn Drezner
York University, Canada

The world’s deserts have a unique assemblage of species, and are not the lifeless zones often envisioned. Nearly one third of the Earth’s land surface is identified as arid or semi-arid, and perhaps 15% of the world’s land areas are true desert. Characterized by low precipitation, high evapotranspiration rates, little cloud cover, high summer temperatures, and large annual and diurnal (day-night) temperature ranges, desert climates are also highly variable in rainfall receipt from year to year, and in seasonality of rainfall. Winter conditions can vary from mild in lower latitude deserts to higher latitude deserts that regularly see subfreezing winter temperatures and sometimes snowfall, such as the Gobi in central Asia. Only the coastal deserts associated with cold ocean currents (such as the Atacama and the Namib) deviate from this scheme. These deserts typically experience smaller temperature ranges, milder summer temperatures, and higher humidities associated with regular fog. Desert organisms have adaptations to cope with the extreme temperatures and limited moisture of desert environments. The focus of this review is on traditional “hot” deserts, excluding the polar deserts.

The pulse-reserve paradigm

Perhaps one of the most central theories on desert function is the pulse-reserve paradigm, proposed by Noy-Meir (1973), along with ideas by Westoby, Bridges, and colleagues credited within Noy-Meir (1973). Noy-Meir (1973) proposed that desert ecosystems are controlled by the unpredictable availability of rainfall and water, and thus behave in a pulse and reserve manner. This view suggests that a rain event produces an influx of the controlling resource (water) and triggers a pulse of production (Noy-Meir 1973). While some pulse-driven resources are later lost, such as to mortality of newly germinated seedlings, or by consumption through grazing of new biomass produced from the rain event, some of the pulse goes into carbon and energy reserves including seeds (Noy-Meir 1973). Noy-Meir (1973) develops these ideas further, such as relationships between the pulse and depth of water penetration, root systems, and differences across taxa, as well as impacts of soil texture, salinity, and the timing of rainfall events on the pulse. He even extends these basic ideas to higher trophic levels as available forage, water, and prey for animals will also depend on inputs of water both in the open (i.e., standing water) and in potential food (Noy-Meir 1973).

Reynolds et al. (2004) update and modify these ideas, such as consideration of soil moisture conditions prior to a rain event, soil water recharge, rain event size, and total seasonal rainfall. Noy-Meir (1973) discusses soil moisture, and Reynolds et al. (2004) observe that soil moisture is a better predictor of plant uptake and use than rainfall. They suggest that smaller rain events may only be biologically important when falling in conjunction with a larger storm event (rain falling in temporal isolation may be only minimally beneficial biologically), and that...
DESERT ECOSYSTEMS

Rainfall itself does not fall randomly over time, but rather, tends to be somewhat clustered over a season (Reynolds et al. 2004). Further, different plant functional types exhibit different responses to soil moisture and precipitation, and seasonality of precipitation (e.g., winter rain evaporates more slowly) may also be important, depending on the rainfall regime of the particular desert (Reynolds et al. 2004).

Primary production and food chains

Primary production and amount of biomass created by plants are strongly linked to rainfall in desert ecosystems. Primary production in arid environments is low in comparison with more humid ecosystems, but there is considerable variability in primary production within deserts, with primary production sometimes rivaling that of more humid temperate ecosystems (Whitford 2002). Deserts are also home to localized mesic environments and associated vegetation, such as riparian areas near perennial streams, and communities associated with springs and oases.

There has been some disagreement among researchers about desert food webs and linkages within the ecosystem. For example, some studies have suggested the desert ecosystems have relatively few links while others have observed many more (Ward 2009). Other points of disagreement include, for example, whether two species preying on each other (loops) are rare or not (Ward 2009). Generally, trophic level interactions and food chains are far more complex than often recognized. In some cases desert consumers may be subsidized by the close proximity of another community, such as in a coastal desert where food sources and prey species become available from the nearby marine ecosystem. Ward (2009) provides a succinct review of some of these issues.

Animal adaptations

Animals have a wide range of adaptations to the heat and aridity that typify desert environments, and in some deserts, also adaptations to protect them from cold winter temperatures. Adaptations to heat and aridity include rapid uptake of water and mechanisms to reduce water loss, to tolerate and/or escape high temperatures, and to reduce metabolism (Whitford 2002). The examples below hint at some of this variety.

Many insects, amphibians, and mammals burrow as temperatures may be 30°C cooler than at the surface. Many insects, spiders, and scorpions remain in burrows for much of their lives. Some species remain in their burrows until a relatively large rain event, when they emerge, eat, and mate before returning, such as amphibians who may use ephemeral ponds for breeding. Some toad species can remain in their burrows for more than two years without eating, typically with a highly reduced metabolism. Even snails are found in deserts, sometimes dormant during the hot months with increases in activity following rain events.

In southern Africa, the Cape ground squirrel (Xerus inauris) can lower its operative environmental temperature by 8°C by shading itself with its own tail and aligning itself relative to the sun’s position to maximize shading, which can double the number of hours it can spend foraging during the day. Kalahari lizard species maintain a nearly constant body temperature by alternating between sunny and shady spots over the course of the day, while some insects and lizards move around to different parts of a plant to find the most suitable shade and temperature conditions (Whitford 2002). Many insects and rodents come to the surface to seek food at night. Nocturnal activity is found in many mammals including commonly in small mammals, and a variety of insects, spiders, and scorpions. Even insects that
are not nocturnal may limit their activity during the hottest times of the day, and some large mammals (e.g., the Arabian oryx) may only seek food at night during the hot months.

Many small mammals in deserts are known for concentrating their urine to reduce water loss. Some amphibians secrete and cover themselves with wax to minimize water loss. In some cold current coastal deserts commonly characterized by fog, some insect and lizard species have adaptations to condense and capture fog water onto their backs and then to drink that water as it drains toward their mouths.

Perhaps the most famous desert residents are camels, which originated in North America 40–45 million years ago and include the dromedary camel (one hump, Middle Eastern deserts) and the Bactrian camel (two humps, central Asian deserts); their ancestors crossed the Bering Land Bridge into Asia about 3 million years ago. Rather than having a more even distribution of fat over their bodies, which would act as an insulating layer, camels have humps that are fat reserves concentrated in one place. Camels can go without water for two weeks, and can store that water initially in their gut, thus enabling them to consume large quantities at once without overhydrating. The camel has a wide variety of other adaptations, including highly concentrated urine, the ability to withstand elevated body temperatures of several degrees, and a specialized circulatory and breathing system that allows the brain to be kept at a cooler temperature than the rest of the animal, as has been found in other large desert mammals (e.g., eland, wildebeest). Camels and other arid land animals (e.g., ostriches) have long legs and necks that help with cooling.

There has been some debate about bird adaptations in deserts (Williams and Tieleman 2005). Research shows that metabolism is lower in desert birds, some species lay fewer eggs, and evaporative water loss is lower in desert birds than in other birds (Williams and Tieleman 2005). Desert-dwelling birds typically seek microhabitats and conditions that minimize their exposure to extreme temperatures which includes selecting shaded and sheltered nesting sites and foraging in the morning and evening. Some birds have glands that secrete salt, including the ostrich and roadrunner. A variety of birds pant to aid in cooling themselves and their eggs (Ward 2009).

Plant adaptations

Plants exhibit numerous adaptations to the high temperatures and lack of water that are typical of desert environments. Many species avoid the extreme conditions by remaining in the soil as seeds and only germinating during favorable periods, followed by a short life cycle and a return of seeds to the seed bank. Seed dormancy is discussed further below. Other species are drought tolerators, which can desiccate to extreme levels, such as the resurrection plant (*Selaginella lepidophylla*) in the Chihuahuan Desert.

Root adaptations include extensive root systems that maximize capture of surface water, deep roots that can tap to a water table or to soils that retain their moisture longer, and the production of rain roots within hours of a rain event to increase water uptake. Some plants (called halophytes) are adapted to soils with high salt concentrations. In some cases, these species do not establish in non-saline areas where they may have to compete with other species.

Leaf adaptations include fewer stomata (pores through which gas exchange and water loss occur), and their greater distribution on the shaded underside of leaves. Some species have waxy leaf surfaces, while others have pubescent leaves (e.g., with hairs, such as *Encelia farinosa*), or have lighter colored leaves (e.g., *Ambrosia dumosa*) to increase albedo (reflectance) and reduce leaf
**DESERT ECOSYSTEMS**

Temperatures and sometimes to reduce photosynthesis (Whitford 2002). In foggy deserts, some species have many narrow leaves that promote water interception and capture from fog. Some perennial plants are drought-deciduous, dropping their leaves during periods of reduced soil water, in some cases reclaiming nutrients locked up in the leaves prior to dropping them (resorption) (Whitford 2002), and some plants orient their leaves to minimize insolation during the hottest times of the day. Similar adaptations have been noted in cacti, such as prickly pears (*Opuntia* spp.) that orient their pads to minimize exposure during the hottest times of the day, while other cacti tilt equatorward to minimize receipt of solar radiation during the hottest times of the day. Other leaf adaptations include a reduction of leaf size to reduce water loss; cacti are an extreme example of this, where leaves have reduced to spines. While spines provide protection from animals, they also cast shade reducing the plant’s surface temperature, and can elevate nighttime stem temperatures by trapping heat and sometimes expanding the species’ range into cooler areas (Anderson 2001), and spines reduce surface area exposed to PAR (photosynthetically active radiation) reducing photosynthesis and growth (and water loss), among other benefits (Anderson 2001). Spines can even aid in the transport of stem segments to a new location for some species where a new plant can establish vegetatively.

Succulence, the storing of water in leaves, stems, and/or roots, is often associated with desert plants, along with CAM (Crassulacean acid metabolism) photosynthesis. While about 90% of the world’s flowering plant species engage in the traditional C₃ photosynthetic pathway, some species utilize the CAM or C₄ photosynthetic pathways. Unlike C₃ plants where stomata are open and gas exchange occurs during the day, in the CAM pathway, stomata are closed during the day and CO₂ uptake occurs primarily at night (Nobel 1988) when tissue temperatures are lower, thereby reducing water loss. As a result, the plant's ability to store carbon dioxide at night can limit photosynthesis (Nobel 1988), and thus the trade-off for this more efficient use of water is slow growth, typical of CAM plants such as cacti. When ample water is available, CAM plants can switch to C₃ photosynthesis (Nobel 1988). The C₄ pathway also improves water efficiency but is more common among monocots and grasses. Nobel (1988) reviews these pathways.

Many of the tall columnar cacti (such as the famous branched saguaro cactus of the American southwest) have an accordion-like external design of ridges and furrows. The cacti’s shallow and extensive roots help them quickly absorb rainwater, which they store by expanding the accordion-like folds. This process also regulates receipt of solar energy for photosynthesis with furrow exposure increasing the photosynthesizing surface area of the plant that increases with greater water in storage.

Cacti are perhaps the plants most associated with deserts, though cacti are native only to the Americas (one epiphytic species was probably carried by birds to tropical Africa) (Anderson 2001). Thus the Sahara and Middle Eastern deserts, the Australian deserts, and all the Old World deserts have no native cacti. Today, some introduced species persist and some are cultivated. The cactus family is also not limited to deserts in their natural range, though their richness (number of species) is relatively high in the North American deserts, particularly in Mexico, and in arid and semi-arid areas in South America (Anderson 2001). The cold hardy *Opuntia fragilis*, for example, reaches the boreal forests of Canada and northward, while other cacti are found to 50°S latitude in southern Argentina. Some cacti are found in the humid,
temperate regions of eastern North America and many species are native to the tropics (Anderson 2001). These species may be epiphytic in more humid areas, while cold-tolerant species such as those living in Canada experience acclimatization to cold as well as lower stature to increase coverage by snow which helps protect plants from extreme air temperatures, among other adaptations. Caution needs to be used to not mistake cacti with the more general characteristic of succulence, which has evolved independently in multiple groups and includes Aloe vera, some Euphorbia (spurges) species, which also include leafy, non-succulent members such as poinsettia (Euphorbia pulcherrima), and other species.

Seed dispersal in space and time

Most plants worldwide have adaptations for dispersing their seeds by animals (e.g., fleshy fruits) and abiotically (e.g., “parachutes” to carry seeds in the wind like dandelions). The benefits of dispersing seeds away from the parent plant are many, including colonizing new areas, reducing competition with siblings or other conspecifics (= of the same species), reducing reproduction with closely related individuals, and general competition for space and nutrients (Van Rheede van Oudtshoorn and Van Rooyen 1999). While dispersal away from a parent dominates in more mesic areas, this is not necessarily the case in arid environments. Ample open space eliminates space competition as a driver of dispersal, and establishment sites are not as widespread as in a mesic environment, often limited to favorable microsites with greater water or other key resources. Further, with a substantial portion of desert florals being annual plants (which would thus die before the next generation germinated and established), the best strategy may be to leave seeds at the mother site, which is necessarily hospitable as the mother plant has already been successful there (Van Rheede van Oudtshoorn and Van Rooyen 1999). Atelechory (absence of features on the diaspore to facilitate long distance dispersal) and antitelechory (features, structures, or mechanisms that hinder dispersal away from the parent plant) have been documented in deserts and soon the “mother-site” theory emerged. Ellner and Shmida (1981) question this theory as atelechorous and antitelechorous annuals are widespread across many desert areas, raising doubts about limited favorable sites, and further, many perennial species are atelechorous or antitelechorous, raising questions about these perceived adaptations in annuals (where the parent plant would not be a competitor in subsequent years). Antitelechorous species that are amphicarpic and geocarpic (produce some or all, respectively, of their seeds below the soil surface) are better represented in more mesic areas nearby (Ellner and Shmida 1981). The mother-site theory would also suggest continuity in species composition over time at microsites, but Ellner and Shmida (1981) did not find this to be the case. They propose that many of the atelechorous and antitelechorous adaptations observed are not so much for dispersal over space (or lack thereof), but for dispersal over time as water availability is more important than competition for space, and plants need to take advantage of periodic wet years. Mortality is often density-independent so adaptations to dispersal may not be needed (atelechory) (Ellner and Shmida 1981). Antitelechory adaptations such as burial can improve water uptake and shelter seeds from rodents and other seed predators, and some structures may anchor seeds to avoid being washed downstream during heavy rains, rather than simply acting to hinder dispersal as previously suggested (Ellner and Shmida 1981).

Seed dormancy is a common bet-hedging mechanism in deserts whereby germination
DESERT ECOSYSTEMS

occurs over multiple years; thus one devastating
year (such as early rains that trigger germination
that are followed by little to no rain resulting
in widespread mortality of seedlings) does not
leave the soil devoid of seeds, particularly crucial
for annuals that do not have living adults grow-
ing in the vicinity to replenish the seed bank
(Venable 2007). A certain fraction of the seeds
from a cohort delay germination to subsequent
years. The fraction of the seeds produced that
are dormant is variable (e.g., Venable 2007),
including a lower germination fraction with
increasing risk of reproductive failure. Typically,
the more unpredictable and arid the desert,
the higher the proportion of the flora that is
annual (e.g., Van Rheede van Oudtshoorn and
Van Rooyen 1999). Because of their dynamics,
annual plants are more prone to local extirpation
than perennials, as well as to invasion.

Invasive species

It has been suggested that deserts are not invaded
as successfully as other biomes as a smaller
portion of the desert flora is typically made up
of non-natives. Those non-native species that
are found in deserts are often unoffending to
the native biota. The relative lack of success of
invasion is thought to be related to the extrem-
ities of the climate and environment (Lambert,
D’Antonio, and Dudley 2010). In fact, more
mesic species from surrounding ecosystems that
invade the desert often establish in those more
mesic microsites, as many species, including
trees, typically do not succeed in establishing
in the desert because the environment is too
harsh (Ward 2009 and references therein). Not
surprisingly, some of the greatest threats to desert
biotas worldwide occur in more mesic areas,
such as along riparian corridors. Non-native
Tamarix (tamarisk) species negatively impact
native ecosystems in a variety of ways including
lowering water tables, decreasing faunal diversity,
and outcompeting many native species such as
cottonwood (Populus spp.) and willow (Salix
spp.) and reducing their presence along streams
(Ward 2009). Some of the rarest forest types in
North America have been invaded by Tamarix.

Invasive species, including grasses, such as the
problematic buffelgrass (Pennisetum ciliare), and
herbs such as Sahara mustard (Brassica tournefortii)
have outcompeted native species, and also altered
the native fire regime causing further damage
to the desert ecosystem (Lambert, D’Antonio,
and Dudley 2010). Buffelgrass contributes to the
production of combustible ground cover and
thus to fire, and causes native species to decline.
Many other species have become problematic in
a variety of arid and semi-arid areas worldwide,
such as members of the Opuntia cactus genus.
Today, Opuntia ficus-indica, Opuntia stricta,
and others are invasive and well established over large
areas in Australia, the southern African Karoo,
and the Middle East. Non-native and invasive
animal species have also established in deserts,
including the European starling (Sturnus vulgaris)
and cane toads (Rhinella marina) in Australia, a
highly toxic species that has caused declines in
larger native predators that eat the toads.

Convergent evolution

While some species or closely related species
have dispersed to many parts of the world, species
inhabiting the different deserts of the world are
typically not related, despite their similarity in
appearance (e.g., succulence, small light-colored
leaves) and that they may fill similar niches. The
nearest relatives of most desert plants are from
the more humid areas in the surrounding regions
(Ward 2009). Certain traits confer advantages
for survival and reproduction; thus desert species
have adapted to a similar suite of conditions, and as a result they have apparently similar features (adaptations). Environmental conditions are an important driving force in the evolution of continental species (Melville, Harmon, and Losos 2006). This similarity of form, ecology, and/or function (such as succulence or small leaves) that evolves independently in unrelated groups in response to similar environmental conditions is termed convergent evolution. For example, the succulent aloes (*Agave* spp.) are closely related to lilies but only distantly related to cacti. In areas where fog is common, narrow leaves have been observed convergently for water capture in unrelated species.

These parallels occur across both plants and animals. Ungulates are lighter in color in desert environments, likely related to camouflage and concealment. Unrelated lizards in North America and in Australia exhibit similar adaptations (e.g., water collection on their bodies), and convergence has been documented in many lizard species (e.g., Melville, Harmon, and Losos 2006). A classic example of convergence is that of desert rodents (and a marsupial) in form, who share many similarities such as bipedal hopping, tufted tails, and various aspects of coloring, as well as urine concentration which is well studied in small mammals and is convergently found in a South America marsupial “mouse” as well. However, no two species ever converge completely and there are also differences in all convergence examples as no two niches are exactly the same. In both plants and animals, differences in form and function persist.

**Keystone species**

Keystone species are those that play a disproportionately important role in the ecosystem and food web and, if they were to become extinct, would likely affect the survival and reproduction of other species to the point where some may become extinct by the loss of the keystone species. Keystone species are found across a variety of plant and animal groups. Small rodents have been identified as being important, as have arthropods, particularly ants and termites. Ants and termites may fill niches typically filled by other taxa, and have substantial impacts on the structure and function of desert systems. Termites and ants affect nutrient cycling, plant production, and a variety of soil properties. The saguaro (*Carnegiea gigantea*) and other columnar cacti found in the southwestern US and Mexican deserts are keystone species (Drezner 2014). A variety of leguminous trees have been identified as central species in deserts worldwide including the Sahara, Israeli, Australian, and North American deserts, sometimes by increasing soil fertility while in some cases simply through microclimate and microsite modification as nurse plants (see below). For example, in the Sonoran Desert, the leguminous tree *Olneya tesota* acts as a nurse to over 200 plant species and over 250 animal species are known to utilize the plant; in some cases, *Olneya tesota* nurses more species beneath its canopy than are found outside of it (Burquez and Quintana 1994).

**Nurse associations and the stress gradient hypothesis**

A nurse plant is one that creates a beneficial environment under its canopy or in its proximity, thus promoting the survival of other species near or under it. Extreme heat and cold temperature amelioration, protection from soil surface temperatures of over 70°C, and shelter from herbivores are common benefits, and some nurse species create fertile islands with increased soil nutrients, among other benefits.
Protégé species often produce fruits that are consumed, carried, and deposited by animals to shaded areas such as under potential nurse canopies, including birds that may defecate the seeds while perching. It has been widely documented that nurses are often woody species, though some disagreement has arisen about whether this may be the result of greater survivorship in such areas (i.e., a true facilitative effect), or whether protégé distributions are simply a reflection of the nonrandom seed dispersal by animals to such microsites (e.g., Sosa and Fleming 2002). It is possible that survivorship is higher in such areas due to reduced seed and seedling predation under nurse cover, though for some species, the abiotic climatic benefits are important, as reviewed in Sosa and Fleming (2002). Many species are nurse plants and many species are protégés in arid environments, although the reasons for the large number of such associations in these environments are still debated. Some species simply do not survive without a nurse (e.g., Carnegiea gigantea) while for other species, such associations are beneficial but not essential.

For the nurse, disadvantages of such associations range from none, particularly when protégé individuals are very small, to many. The protégé cactus Carnegiea gigantea has very shallow roots that are laterally extensive, thus sitting above its nurse’s main root system and capturing rainwater percolating down through the soil ahead of its nurse. Carnegiea effectively compete with their nurse for rainwater, and their towering size as adults enables them to take up and store large amounts of water, sometimes resulting in the premature death of the nurse. It has been suggested that a replacement cycle may occur where the protégé causes early mortality of its nurse thereby reducing nurse presence and thus potential nurse establishment sites for future protégé individuals, resulting in protégé population decline, which leads to an increase in nurse establishment, driving up protégé recruitment, and so on. However, this relationship would operate at relatively long time scales, and since many protégés are successful under a variety of different nurse species, any such dynamics are complicated. In some cases, the nurse may benefit from the presence of a protégé. For example, the grass Hilaria rigida nurses several cholla cactus species (Cylindropuntia spp.) (Cody 1993). These cacti have easily detaching jointed segments that are both difficult and painful to remove from skin, and many desert animals avoid these plants. Thus the protégé cactus provides its nurse grass natural protection from grazing (Cody 1993).

There are also drawbacks to the protégé species for establishing in close proximity to another plant. These include reduced sunlight and PAR which can result in slowed growth, and root competition not only with a nurse, but also with other plants (the same and different species) similarly clustered beneath the shared nurse. However, the extreme environmental conditions typifying desert habitats make any such disadvantages secondary; that is, the benefits (and sometimes requirements) conferred by a nurse may be so important that they outweigh the disadvantages to the protégé with regards to its survival and reproduction. It has been suggested that in communities where climate is less extreme, biotic factors are limiting and competition becomes the dominant interaction; conversely, places with more extreme abiotic conditions (e.g., high temperatures and aridity as found in the desert) limit species more than does competition (Bertness and Callaway 1994). The stress gradient hypothesis suggests that in more abiotically harsh environments, facilitation and positive plant interactions should be relatively common in comparison with less extreme environments, where competition would be far more important in shaping communities (Bertness and
A variety of studies have been done both debating and modifying the stress gradient hypothesis.

Deserts are diverse regions that are home to numerous endemic species that are unique to those regions. A wide variety of adaptations have evolved to deal with irregular and often unpredictable rainfall and inputs of water, as well as with the temperature and other environmental extremes. Many theories about desert function have been developed, including the influence of rainfall, and on positive interactions between species to assist in survival in such abiotically extreme environments.

**References**

Desertification is as much a powerful idea as it is a biophysical process. Indeed, it is the idea of desertification, rather than the processes of land degradation in arid regions, that has been more influential over the last two centuries. Many millions of dollars have been spent, and many people’s lives disrupted, around the world in order to combat “desertification” in places where dryland ecologies have been largely misunderstood and degradation has actually been limited. First coined by the French colonial forester Louis Lavauden in 1927, the word desertification has long been associated with notions of spreading deserts and of human culpability for deforestation, overgrazing, and land degradation. Lavauden, following an old Anglo-European tradition of thinking about arid lands and indigenous people, wrote that “desertification is uniquely the act of humans … [T]he nomad has created what we call the pseudo-desert zone” (Lavauden 1927, 267). From its very first use, then, the word desertification has been ideologically and politically laden with many preconceptions and misconceptions that led to the dominant view during the twentieth century that deserts are spreading and that desertification is primarily the result of human mismanagement.

Contemporary research in arid lands ecology, however, has reached a broad consensus that the extent and severity of desertification has been greatly exaggerated (Helldén and Tottrup 2012; Herrmann and Hutchinson 2005; Nicholson 2011; Reynolds and Stafford Smith 2002; Reynolds, Stafford Smith, and Lambin 2007; Thomas 1997). After years of what have come to be called the “desertification debates,” a great majority of scholars now agree that nonequilibrium dynamics dominate in arid lands around the world, that documented cases of severe arid lands degradation are relatively few, and that they are found in discrete locations associated with particular social, political, or economic problems. The limited number of cases of serious dryland degradation are found primarily in places under the strong influence of political economic forces such as capitalist expansion (US southwest), authoritarian state rule (China, USSR) or the developmentalist state (Egypt). That is to say, degradation in arid lands has certainly taken place in some areas for certain reasons, in particular from over-irrigation and plowing marginal soils, but the common claim of the global crisis of desertification has repeatedly been demonstrated to be false. In fact, a recent “greening” has been detected in many arid regions over the last two decades (Dardel et al. 2014; Helldén and Tottrup 2012; Nicholson 2011).
Most deserts are not continually expanding but, rather, they grow and shrink according to rainfall patterns more than any other single factor, and have over the last several millennia. Indeed, as noted by the geographer Andrew Goudie, many deserts including the Sahara, the Namib, the Kalahari, and the Gobi have been more or less where they are today since the beginning of the Tertiary, about 65 million years ago, shrinking and expanding with global climate conditions (Goudie 1986). Deserts, according to most scientists, are the arid and hyper arid regions covering about 20% of the globe that receive very little rainfall of a highly unpredictable nature (Laity 2008). There is now little debate that these are naturally occurring physical features. Another 20% to 25% of the Earth’s surface is variously categorized as semiarid and together deserts and semiarid areas are often called the “drylands.” Although usually thought of as sparsely populated, the drylands are estimated to contain approximately 38% of the world’s population (Reynolds, Stafford Smith, and Lambin 2007). Most of the debate about desertification concerns the semiarid zones and fears that they will become arid deserts, leaving many of these people without a means of livelihood or subsistence. Located primarily in the low humidity, high pressure zones of 30° north and south latitude, dryland environments are highly variable, ranging from sand seas to stony pavements to arid mountains to desert crusts and varnishes to steppelands, grasslands, shrublands, and savannahs.

The majority of arid and semiarid regions contain vegetable and animal life well-adapted to heat, aridity, and drought. In many drylands numerous plants, such as annual grasses and wildflowers, are only visible for short periods following rainfall while spending the majority of their life cycles as below ground biomass in seed banks and in bulbs or other forms. Although often invisible to the casual observer, most arid zones are rich in biodiversity (Laity 2008). The high interannual variability of rainfall in the majority of arid and semiarid regions, however, creates ecological conditions
of nonequilibrium that render many conventional development approaches (like eliminating grazing) and common baselines for defining degradation questionable and sometimes invalid. Moreover, many of the plants, a majority in places like the Mediterranean basin and related climate regions, are also well-adapted to fire and grazing. Indigenous systems of extensive pastoralism, moving livestock frequently over large areas, therefore, is often one of the best uses of land and resources in these regions (Adams 2009, 228–233). Given the nature of arid and semiarid lands and their biophysical components, it is not surprising that well-documented cases of large-scale desertification are relatively few.

Many arid lands scientists agree, in the words of meteorologist Sharon Nicholson, that the extent of desertification has never been adequately determined and in most cases “it is virtually impossible to separate the impact of drought from that of desertification” (Nicholson 2011, 433, 441). A large part of the problem is that there exist at least 100 definitions of desertification and no agreement has been reached on how to measure or monitor desertification (Nicholson 2011; Thomas 1997). This is not to say that degradation in arid and semiarid lands has not taken place or that degradation is not a potential risk. Many details of how degradation can occur in the drylands have been documented, and include salinization, crusting, erosion, nutrient depletion, and acidification (Nicholson 2011, 437–439). Such degradation has occurred but it is limited to relatively few discrete locations usually in the semiarid zones (Helldén and Tottrup 2012; Reynolds and Stafford Smith 2002). How permanent the degradation is and whether it constitutes desertification, which almost always implies irreversibility, is still being debated by scholars. Evidence is growing, however, that a great proportion of the drylands are more resilient and less fragile than previously believed. Many areas categorized earlier as desertified have since recovered with increasing rainfall (Adams 2009; Dardel et al. 2014; Nicholson 2011; Thomas and Middleton 1994).

The persistence of the global crisis narrative of desertification has been analyzed by a
DESERTIFICATION

number of scholars who have shown that it has remained influential because it can be very useful to various powerful actors (Adams 2009; Davis 2007; Swift 1996; Thomas and Middleton 1994). Despite the large and growing body of evidence that undermines it, the crisis narrative of desertification continues to be used by many because it is an efficient way for governments to raise development funds, to spur action, and to justify social policies that control “difficult” populations like nomads. Furthermore, it allows international agencies like the UN as well as multiple NGOs to raise funds and justify many of their programs at the same time that it helps scientists and other scholars generate grants and professional opportunities. The crisis narrative of desertification also persists because it has deep roots in our environmental imaginaries about deserts and arid lands and the histories of these regions.

The roots of our global concern about the crisis of desertification are usually traced to the drought in the African Sahel and the related famine which occurred in the early 1970s because it generated an unprecedented level of concern about desertification around the world that resulted in coordinated action. Some scholars have also highlighted the importance of earlier events such as the Dust Bowl in the United States and colonial activities in West Africa in the early twentieth century in shaping our thinking and policies about desertification. Governments, however, particularly Western colonial governments, used the idea of menacing spreading deserts to justify a host of programs, laws, and policies that facilitated state rule for a long time before the word desertification was first used in the early twentieth century. Many of these programs, laws, and policies carried over into the postcolonial period and several remain influential today. The remainder of this entry traces the history and evolution of Anglo-European thinking about deserts and desertification because it is the legacy of these notions about spreading deserts that directly informs contemporary mainstream global anti-desertification policy today.

Spreading deserts before the “age of desertification”

Deserts were not always considered the ruined or undeveloped wastes that they have been for the last couple of centuries. From antiquity to the age of European exploration, deserts and their edges were primarily considered by Europeans to be naturally dry, sometimes sandy features that presented difficulties for traveling and were known to produce strange and exotic people like the Ethiopians who were believed to be “scorched” by the torrid climate and its burning sun. Importantly, though, they were not conceived as ruined or deforested spaces, nor regions where crops could or should be grown. Early Christianity held the desert in Egypt more or less sacred as the site of ascetic perfection where the desert saints went to prove their piety. For a few, then, the desert represented a heaven on Earth. For others, like Marco Polo, deserts such as those in Central Asia, were strange and wonderful, but also sometimes home to threatening people and frightening spirits.

The “age of exploration,” when Europeans “discovered” the new world, and the rest of the old world, brought new knowledge of very different environments, especially the tropics and tropical islands, but also of other deserts. It is after the so-called Columbian exchange that we see Western perceptions and understandings of deserts and drylands begin to change in significant ways. The sixteenth century witnessed not only the development of early capitalism and colonialism, but also the beginnings of
an articulation of desiccation theory which forged the long-lasting link between deserts and forests. Desiccation theory included the idea that deforestation causes the climate to dry out and diminishes rainfall and also, the corollary, that reforestation restores lost rainfall and creates a generally more humid and healthful atmosphere. There are many problems and weaknesses with this theory and it only applies, if at all, to relatively small “micro-climates” in certain ecological settings.

Early scientific work on desiccation theory primarily focused on the beneficial effects of deforestation and desiccation. This late seventeenth- and early eighteenth-century work tended to highlight the benefits to health and agriculture of clearing forests in cool, humid, continental climates like eastern North America. It did not mention any dangers of deforestation creating deserts. By the mid-eighteenth century, however, this began to change and by the 1760s and 1770s connections began to be drawn by colonial officials like Pierre Poivre and Joseph Banks between deforestation, apparent desiccation, and the creation of desert-like conditions, particularly in tropical island settings such as Mauritius and St. Helena (Grove 1995). Grazing by livestock was frequently blamed along with deforestation for the desiccation of these island environments. The solutions that began to take shape to prevent the creation and spread of arid, infertile conditions were reforestation, elimination of grazing, and creation of forest reserves. These ideas, so well articulated by Pierre Poivre, spread rapidly among French, British, and other European thinkers to become dominant during the nineteenth century.

By the dawn of the nineteenth century, the presumed relations between deforestation, desiccation, and the creation of desert-like conditions were becoming well known and began to be paired with the political preoccupations of the time. Europeans’ notions of the “decline” of the Ottoman empire and its “despotism,” weakness, and deterioration had grown to be quite common. Many thinkers in Europe began to worry that Europe might decline in very similar ways and it stimulated much writing on the subject. Others began to put together these common fears of political/economic decline with fears of environmental decline via deforestation, desiccation, and “desertification.” The region we now call the Middle East, most of which was under Ottoman control during this period, was often used as a withering example of the dangers of deforestation and overgrazing since it was widely presumed that these were the reasons, largely due to Ottoman ineptitude, that the Middle East apparently had become a worthless desert. Many feared that European countries could suffer a very similar decline into despotism and desertification if care were not taken. The most common solutions were forest conservation, which entailed curtailing grazing, fire suppression, and mass reforestation overseen by an enlightened government. Very similar ideas and policies were applied to the arid lands of the United States in the nineteenth century.

These early notions of what came to be known as desertification were also influenced by the increasingly powerful ideas of agricultural improvement and enclosure of commons and waste land during the rise of economic liberalism in the eighteenth and nineteenth centuries. An important transformation took place that changed perceptions of wastes and commons as a “productive remainder” that could provide gathered foods, grazing, and provisions for the poor, to understanding these uncultivated lands as “wasted land” that needed to be enclosed and made agriculturally or otherwise valuable and productive. This transformation included not only the notion that waste land was not being used efficiently but also that it was actually being
DESERIFICATION

degraded by gathering wood or medicinal plants, overgrazing, and the like. For the agricultural improvers, drylands and deserts were the ultimate wastes and they needed the most improvement. Especially in France, the long battle of the improvers to stamp out itinerant grazing in order to enable enclosure over the course of the nineteenth century created widespread antipathy to herding and grazing which became important to the administration of arid lands during the colonial period.

Few European countries had arid lands within their borders, although several southern countries like France, Spain, and Italy had semi-arid regions. Most direct experience with arid lands, then, was encountered by European powers in their colonial territories in Africa and Asia. As a result, much European thinking about and managing arid lands was bound tightly to colonialism and its various goals for more than a century. By 1800 the idea of ruined desert wastes had become firmly rooted in the Anglo-European imaginary. The early nineteenth century was therefore a crucial time for these ideas to be “tested” in the colonial territories. Some of the earliest and most influential experiences were in British Cape Colony (South Africa), French Algeria, and British India.

The French were likely the first in putting many of these early ideas about arid lands into practice outside of Europe, in Algeria, where the colonial narrative of indigenous deforestation and desertification of the environment provided powerful fodder for the development of a wide array of laws and policies that expropriated the local Algerians of significant amounts of their lands, forests, and herds during the colonial period (Davis 2007). Within just a few years of conquering Algeria in 1830, many involved with the colonial project came to understand, incorrectly, the arid and semi-arid regions of Algeria as having been deforested and overgrazed by the indigenous Algerians with their “primitive” agricultural methods and their supposedly destructive nomadic grazing practices. Despite a few dissenting voices at the time, this flawed understanding of the Algerian environment resulted in policies that were said to be aimed at restoring the environment to its former fertility and prevent the desert from spreading. The ideals they aimed to emulate were the “rational” and productive agricultural fields and thick forests back home in France. The resulting policies included sedentarizing nomads, protecting forests from grazing and fire, promoting reforestation, and encouraging or enforcing intensive European farming methods. Many of these goals were supported with a legal transition to private property regimes from collective property regimes justified with the same story of environmental ruin by the “natives.”

From the nineteenth century into the twentieth, this process of arid lands “development” that restricted and criminalized native grazing and agriculture, promoted reforestation, and later built irrigation works for settled farming, intensified across the colonial world from the Maghreb to South Africa to the Middle East to India. Many of these policies have proven harmful to indigenous populations who have lost their livelihoods and also harmful to the environment. In South Africa, for example, afforestation undertaken in the name of desiccation theory in the late nineteenth and early twentieth centuries, resting on the flawed belief that local populations had deforested and desertified the environment has been shown by recent research to be a major contributor to landscape desiccation (lowered water tables). It has led the government to develop plans for large exotic tree removal programs and to formally regulate any new tree plantations (Showers 2010). In India, the Punjab was declared an unproductive desert waste in the late nineteenth century by
the British, the nomads were settled and large irrigation works were built by the administration to intensify farming. This resulted, however, in sizable areas of land suffering waterlogging and salinization and also in significant increases in water-associated diseases such as malaria.

France and Britain were the two colonial powers who controlled the most territory in arid and semiarid lands during the nineteenth and early twentieth centuries. With the dissolution of the Ottoman empire following World War I, arid lands administered by the French and British grew substantially with the creation of the Mandate territories in the Levant. The understandings of arid lands that developed in France and Britain while administering their imperial territories, have been, therefore, especially influential in global thinking about drylands and desertification. As a result, the dominant policies implemented in the drylands at the turn of the twentieth century consisted of sedentarizing nomads, eliminating or reducing grazing, fire suppression, and reforestation in various combinations. During the twentieth century, this Anglo-European dominance of knowledge and policy in the drylands grew and was enhanced with growing American influence.

The age of desertification: the twentieth century

It was within this long-standing Anglo-European imperial context, then, that the French colonial forester Louis Lavauden coined the term “desertification” in 1927 and pronounced that desertification was the result of the improvidence of nomads and the overgrazing of their livestock (Lavauden 1927). Such had been the thinking in the colonial territories of the Western world for a long time, and it built on an old European intellectual tradition of anti-nomadism (Adams 2009; Davis 2007).

Other indigenous livelihood activities were also frequently blamed for desertification, including local agricultural practices (especially the use of fire). The British forester Edward Stebbing increased fears of anthropogenic desertification with his alarmist articles during the drought years of the 1930s. He warned in dire terms of the southern spread of the Sahara desert, despite the evidence from the Anglo-French forestry commission to West Africa that the Sahara was not spreading to the south. The American Dust Bowl of the 1930s further heightened knowledge of and concern with what had become known as desertification and with it focused attention on the problems of soil erosion in dryland environments.

The events of the 1930s thus led to the internationalization of the idea of a “crisis of desertification” that raised the profile of environmental change in the drylands to a global level. The concern with erosion raised by the American Dust Bowl experience was taken up in many Western colonial territories in Africa and Asia with American-inspired policies to curb erosion in ways that were often ecologically inappropriate. All too frequently, the new anti-erosion policies, along with more well-established anti-desertification policies, led to socially repressive programs and the implementation of political goals in the name of environmental protection (Adams 2009). In Mandate Palestine, for instance, such thinking led the British-run forest department to report, incorrectly, that half of the habitable area of Palestine had become an artificial desert due to overgrazing and to implement grazing restrictions and reforestation programs with the help of Zionist interest groups.

Following World War II, as many former colonial territories were gaining, or about to
Figure 3  Camels grazing in southern Morocco. Without an understanding of arid lands ecology, scenes like these camels grazing an apparently bare landscape are easily misinterpreted to be cases of “overgrazing.” Camels are actually one of the few domesticated species able to survive arid conditions due to their unique ability to conserve water and eat plant species normally unpalatable to most other livestock. gain, independence, the newly created United Nations formed the Arid Zone Program in 1949 in its UNESCO branch. Framed as “man’s battle against the desert,” the program grew in size and influence and by 1956 it had been renamed the Arid Lands Major Project, with permanent seats held only by Great Britain, France, and the United States (Selcer 2011). A few other countries, mostly from the Middle East, were represented on a rotating basis. The Arid Lands Project became a centerpiece for UNESCO and allowed the young organization to gain an international reputation in both science and resource management. It incorporated the vast majority of earlier Anglo-European thinking and policies on arid lands and threatening deserts and further spread these ideas and policies globally with training programs and publications such as The Future of Arid Lands, the Arid Zone Newsletter, and the Arid Zone Research Series. Although it was subsumed under the International Hydrological Program in the 1960s, the Arid Lands Project set the stage in several ways for the later development of the UN Conference on Desertification a decade later.

When a serious drought hit the African Sahel in the early 1970s, attention to desertification exploded. The dramatic famine that accompanied the drought killed hundreds of thousands of Africans and their livestock and was covered sensationaly in the Western media. This particular drought appeared all the more dramatic because it followed a couple of decades of above normal rainfall in much of Africa. The “natural disaster” of drought was commonly believed to have pushed environments and burgeoning communities already weakened by decades, if not centuries, of alleged desertification through improper land use over the edge of survival. The drought also followed many decades of colonial rule in most of the region, however, that had disrupted precolonial social and agricultural
DESERTIFICATION

systems to a great degree which led to a higher death toll. As a consequence of this widely publicized disaster, the 1977 United Nations Conference on Desertification (UNCOD) was held which generated the desertification branch of the UN Environment Programme (UNEP).

Following in many ways the example of the earlier Arid Lands Program of UNESCO, the new UNEP desertification branch wrote action plans and published the Desertification Control Bulletin and the World Atlas of Desertification, which echoed much of that earlier UNESCO work. It also produced numerous reports that were highly politicized and rarely based in field research or ecological detail (Nicholson 2011). As a result, the extent and severity of desertification globally were quickly exaggerated. Just as during the colonial period, however, the “crisis of desertification” suited the purposes of many newly independent governments in their efforts at state building and controlling both agricultural development and populations perceived as unruly. UNCOD’s perspectives and prescriptions were reaffirmed in the 1994 UN Convention to Combat Desertification (UNCCD) and further institutionalized with the creation of its subsidiary body, “the global mechanism,” designed to disperse anti-desertification funds in 1997 (Adams 2009). In 2006, the UN declared the International Year of Deserts and Desertification which entailed more publicity of the global “crisis” of desertification.

Conclusion

The hegemonic perception of deserts and desertification embodied in UNCOD/UNCCD, and many other institutions, though, is profoundly flawed. Moreover, “it seems to have triggered many problems, of understanding and of action, that manifested themselves in the ways in which desertification was conceptualized, represented and approached as an environmental, social and political issue” (Thomas and Middleton 1994, 49). According to these two geographers, and many other specialists, dryland ecosystems “appear to be well-adapted to cope with and respond to disturbance, demonstrating good recovery characteristics” (Thomas and Middleton 1994, 160). In other words, most drylands around the world are resilient, not suffering significant degradation, and deserts are not expanding. A large and growing body of scientific research has reaffirmed these conclusions over the last two decades. Some researchers have even proposed eliminating the term desertification altogether to facilitate greater understanding and more sustainable development in the drylands.

Arid lands scientists Stefanie Herrmann and Charles Hutchinson have insightfully noted recently that “we have a non-equilibrium world that is saddled with an overriding equilibrium mindset and [anti-desertification] policies that reflect it” (Herrmann and Hutchinson 2005, 38). They conclude, as have many others, that “policies that affect people on the ground may be formulated largely independent of science that is current and thus may serve to degrade rather than enhance the lives of people most affected” (Herrmann and Hutchinson 2005, 38). One of the biggest points of contention surrounding desertification, then, is between the scientific/academic community and the global policy community, especially at the levels of international agencies like the UN and many national governments.

Although some agencies and programs have begun to understand and act on problems of land degradation in the drylands as intricately connected to problems of poverty and social,
DESERTIFICATION

political, and economic issues, too many projects are still implemented to “roll back the desert” which uncritically assume desertification. Such projects usually rely on some combination of sedentarization and destocking, reforestation, and increasing irrigated and non-irrigated agriculture. These old policies, derived from the long-standing assumption that deserts are the result of overgrazing and deforestation, have been shown to increase degradation in many nonequilibrium, arid environments. Other approaches exist that can enhance dryland environments when tailored for specific environmental conditions such as terracing, water harvesting, and extensive grazing, among others (Adams 2009; Nicholson 2011). The difficulty that many policymakers have in understanding and implementing these differences is strongly related to the underlying environmental imaginary of deserts and desertification that has deep roots in the colonial period and earlier. Bridging the gap between the science of drylands and mainstream policy development in these regions is crucial for building more sustainable environments and livelihoods in the world’s magnificent drylands.

Deskilling consists of simplifying the tasks of individual or collective labor. This includes lessening its technical (e.g., the amount of formal training/education) and/or its conceptual (e.g., the level of conscious planning and thought to complete a task) content both within firms and/or in the domestic sphere, as the result of either an explicit strategy or an unintended effect of changes in work organization and/or labor supply. Beginning in the 1970s, deskilling became the object of an intense debate in the social sciences over the nature of the capitalist labor process, sparked by Harry Braverman’s (1974) book *Labor and Monopoly Capital*. Influenced by Marx, Braverman argued that the introduction of Taylorism and scientific management in US manufacturing in the early twentieth century allowed the separation of conception, or the planning and organizing of work, from its execution. Conception was appropriated by a new cadre of managers and supervisors, while work formerly performed by craft workers was reduced to deskill assembly tasks. This allowed a significant increase in the intensity of work and productivity, especially when combined with the new assembly-line techniques of manufacturers like Ford. Braverman argued that deskilling had become dominant not only in manufacturing, but also in newer service employment.

Braverman’s arguments were subject to criticism by both Marxian and non-Marxian scholars, who argued that control of the labor process was only one means to capital accumulation and could often lead to the development of new products and processes, which also created new skills (Burawoy 1985). Geography scholars also stressed the uneven sectoral and spatial development of the production process (Sayer and Walker 1992) while feminist (including feminist geography) researchers noted that Braverman and much of the labor process debate had ignored the critical role of gender not only within the formal capitalist workplace but also in the domestic sphere (Cockburn 1983; Hanson and Pratt 1995). Other scholars argued that firms using Japanese production methods had reskilled employees or, more generally, that most jobs require higher levels of education and training over the long term (see Block 1990). Defenders of Braverman argued that “reskilling” strategies could be consistent with work intensification and did not challenge deskilling as a dominant long-run tendency in capitalism. The debate over skill and the pervasiveness of deskilling has continued, for example, in relation to the “creative class” (see Florida 2012) and the impact of new technology. Thus Krugman (2013), citing a McKinsey Global Institute (2013) study, argues that new technology is likely to be disruptive and displacing of employment, including that requiring high levels of education.

DESKILLING

The nature and scope of development

One of the hallmarks of contemporary global societies is that, at whatever scale we view them in terms of “levels of development,” they are almost universally characterized by major contrasts and differences. As proof, a recent 2006 study carried out by the World Institute for Development Economics Research on behalf of the United Nations (UNU-WIDER) showed that 50% of the world’s total population owned total assets of less than US$2200 and collectively accounted for only 1% of the world’s total wealth. Indeed, over half the world’s population is currently to be found living on less than just over $2 per day. Furthermore, the same study showed that one did not have to own much in the way of resources to be part of the richest group of the population on Earth. Specifically, owning assets worth $500,000 or more, or about £350,000, or more, puts one into the richest 1% of people on the planet who control some 40% of the world’s total wealth. Such widely divergent conditions, standards of living, and associated qualities of life require explanation not only because such unfairness should not be tolerated but because such inequalities belie the promises concomitant with modernization and growth theories.

It is this central developmental issue that frames this entry, which seeks to provide an overview of the evolving nature of the cross-disciplinary and interdisciplinary field(s) of development studies and of development geographies and cognate areas of social science, as well as a brief introduction to the practice of development in the global policy arena (see also Potter et al. 2012). It may be argued that, in the past, development geography and the cognate interdisciplinary area of development studies showed signs of being treated as the Cinderella of the discipline of geography in particular, and of the social sciences in general. This can no longer be tolerated because the current pace and penetrative power of globalization and the spread of the canons of the free market or neoliberal order are making the world more and more unequal and unjust. This means that it is vital to include development–related work at the core of scientific assessments of societal change and progress in this iniquitous, unruly, runaway world (Conway and Heynen 2006; Piketty 2014).

So, what exactly is implied by the word “development” in its global-developmental context? This entry proposes that development at its most basic level is about improving the life conditions that are faced by the global majority, and specifically this means reducing existing levels of poverty and inequality at local, regional, national, and global scales. A more detailed working definition of development might be adopted that stresses development as attempts to reduce poverty and world inequalities in an effort to guide the world to a situation of betterment and improvement over time (see Kothari, 2005; Potter et al. 2008). It would seem axiomatic that development should provide for the betterment
of the poor majority in the first instance, as this will add the most to what may be referred to as the common good. The essence of development is that there is a poor world and there is a rich world, and it is implicitly assumed that it is the responsibility of the latter to assist the former. In other words, there is a pressing ethical need to equalize the highly disparate conditions that currently exist in and between the poor and rich worlds, so that the tenets of Denis Goulet’s (1971, 2006) and Des Gasper’s (2004) “development ethics” are constantly at the forefront of “thinking” and “doing” development (Desai and Potter 2014).

Development, therefore, is very much a practical subject and nations, international agencies, nongovernmental organizations (NGOs), and community-based organizations are all involved in the policy-related processes of trying to promote development on the ground. Combined together, the practice of development and the concepts that underlie such practice give rise to what is referred to as the broad arena of “development studies.” Development studies, therefore, represents theoretical, empirical, and policy-related studies concerning how development has, and should be, implemented. It can be further argued that, rather than being either inter- or multidisciplinary, development studies can make a strong claim to be cross-disciplinary in nature in that it serves to bring together a large number of fields in the study of poverty and inequality. This is represented in graphical summary form in Figure 1. The central concern of development studies may be regarded as the existence and seemingly inexorable deepening of global poverty and inequality.

Development studies has its origin in the 1940s, when development became an overt aim of Western or advanced nations, specifically those of Europe and North America. In its early stages, “breakaway” economists were strongly involved in the rise of the field. Reflecting this in the core discipline, a distinct subdiscipline within economics can be recognized that is now conventionally referred to as “development economics” (see Figure 1). Geographers, with their strong tradition of regional and area studies

![Figure 1](image-url)
represented another area of involvement and interest. In the same manner as in the case of economics, the rise of development geography as a distinct field can be recognized. Other mainstream social science disciplines, such as politics and sociology, also contributed to the rise of development studies and came to be known respectively as the sociology of development and the politics of development. Attesting to the truly cross-disciplinary character of the field, subjects such as demography, international relations, anthropology and history, and urban and regional planning should also be identified as making a distinct contribution to development studies.

Indeed, cross-disciplinary theory development, and regional empirical contextualization would be fostered within this sharing of disciplinary concern for fair and just human development. Throughout the second half of the twentieth century and into the twenty-first there were a plethora of alternative perspectives, alternative visions, and alternative approaches that challenged the modernity theorizing that was at the core of the Global North’s “classical traditional” approaches (see Figure 2). The evolving nature of these alternatives is reviewed later in the entry. By way of an introduction, competing measurements and assessments of

![Figure 2](image-url)
what development should mean to the world’s majorities are first reviewed.

Assessing and measuring development

Both researchers and policymakers have sought to assess and measure development with competing approaches that directly reflect the historically contingent and evolving conceptualizations of development as a process (Desai and Potter 2014; Potter et al. 2012). During the 1950s through to the early 1980s, development was generally measured in terms of the level of economic growth achieved by countries and, in particular, the growth of production and income. From the late 1980s through to the 1990s, changes in the way development was being envisioned were directly recognized in the promotion of wider indices of human development and change. This trend toward recognizing the multidimensional nature of development has continued from the 1990s through to the second decade of the twenty-first century, whereby wider sets of factors, reflecting more subjective and qualitative dimensions, have increasingly been employed to define development. Three general approaches have characterized these trends (see Potter et al. 2012):

1 measuring development in terms of economic growth, by means of gross domestic product (GDP) and/or gross national product (GNP) per capita;
2 measuring development in terms of human development: the Human Development Index (HDI); and
3 measuring development in terms of wider dimensions, including human rights and freedoms.

Throughout, the account in this entry is strongly based on that provided in Potter et al. (2012).
labor that accompanies low levels of physical capital (natural resources), human capital (e.g., education), and technology.

HDI and wider measures of development

Development is far wider than the growth of income alone, and many development studies practitioners and scholars view GDP/GNP measures as highly limited in their ability to capture the depth and breadth of socioeconomic change. Specifically, GDP and GNP take no account of the distribution of national wealth or of output between different groups of the population or between different areas/regions. Further, such income-based measures do not take into account the broader wellbeing of people, which includes more than goods, money, and material wellbeing. Given these limitations, and the increasing recognition of the need to account for noneconomic factors in development, new or alternative measures of development came into being, starting in the 1980s.

In 1989 the United Nations Development Programme (UNDP) promoted the Human Development Index as a wider measure of development. HDI data were published for the first time in 1990 in the inaugural Human Development Report (UNDP 1990). In the original HDI, the emphasis was placed on assessing human development as a more rounded phenomenon. There was still a measure of economic standing, but this was only one of three principal dimensions identified:

1 a long and healthy life (longevity) – originally measured by life expectancy at birth in years;
2 education and knowledge – initially measured by the adult literacy rate and the gross enrolment ratio (the combined percentage of the population in primary, secondary, and tertiary education);
3 a decent standard of living – originally measured by GDP per capita in US dollars, as outlined in the previous section.

Since 1990, the Human Development Report has been published by the UNDP every year, but in the Human Development Report 2010 the formula was changed. The three dimensions of health, education, and living standard have been translated into four indicators, and these are summed to give a single HDI. The common practice, therefore, has been for HDI to be used to divide nations into what have come to be referred to as high, middle, and low levels of human development. Recently, the classification has been extended to also include a very high human development category.

It should be stressed that the HDI is a summary and not a comprehensive measure of development. For example, in the years since its introduction, various methodological refinements and spin-offs have been made by the United Nations, including the Human Poverty Indexes 1 and 2, the Gender-Related Development Index, and the Gender Empowerment Measure. These are all variations on the basic Human Development Index. In each case, additional variables were brought in to reflect the revised index. (For a more in-depth discussion, see Potter et al. 2012.)

Measuring development in terms of wider dimensions, including human rights and freedoms

While the HDI extends our measure of development into the noneconomic realm, a number of writers have stressed the importance of self-esteem, basic freedoms, and human rights
as further components of the development equation (see, e.g., Sen 1999). Such views represent specific recognition that wider aspects of development are vital, particularly those that relate to the quality of people’s daily lives, their freedom from various inequalities, and the attainment of human rights and basic freedoms. In an attempt to account for and measure progress in relation to these dimensions of development, the UNDP, starting in 2000, began developing a set of indicators and objectives through which to guide global efforts at achieving broad-based development.

The resulting Millennium Development Goals (MDG) are designed as instruments and metrics to steer the world to enhanced levels of development (Rigg 2014). By 2013, there were eight broad goals that serve as priorities for the global development project:

1. Eradicating extreme poverty and hunger – measured by the percentage of the population living on less than $1 or $2 per day (now $1.25 and $2.50 per day);
2. Achieving universal primary education;
3. Promoting gender equality and empowering women;
4. Reducing child mortality;
5. Improving maternal welfare;
6. Combating diseases;
7. Ensuring environmental sustainability;
8. Achieving global partnerships for development.

For each of the eight MDGs there are associated targets and detailed indicators (see http://www.un.org/millenniumgoals for details). The indicators can be seen as dimensions that can be employed in order to assess the progress of nations and regions toward the goals and targets, and thereby represent measures of the wider dimensions of development.

An impression of how such indicators can be used as measures of progress in development can be gained from the National Reports covering progress with the MDGs that are available on the UNDP website. The 94-page Report for India 2009, for example, shows in considerable detail the mixed success achieved on the 12 targets that apply to it. In terms of basic human rights, an interesting approach is to chart the extent to which countries have ratified the six major human rights conventions and covenants (e.g., the United Nations Convention on the Rights of the Child, the Convention against Torture; see Potter et al. 2008). In a similar manner, the United Nations Human Development Report 2010 introduced the HDI-derived Gender Inequality Index (GII). The statistics input to the GII include the national female and male shares of parliamentary seats and educational attainment. The GII also includes female participation in the labor market. The GII thereby represents a direct effort to measure the progress made by countries in advancing the standing of women in wider political and economic developmental terms.

The mainstream economic development project

Having broadly defined what is meant by development and how it can be assessed and measured, the entry now provides an overview of the changing concepts that have directed development in what has been referred to in a multitude of terms, including the “third world,” “Global South,” “developing” or “poor worlds,” or whatever other phrase is used to denote those parts of the globe which are deemed to be in pressing need of enhanced rates and levels of development. At the outset, the account considers the multidisciplinary concept
of modernity as the focus of societal development manifest in recent mainstream (Keynesian and neoliberal) approaches to achieving development. In the sections that follow, the historical record of alternatives to these top-down economic development approaches are detailed.

**Modernization, modernity, and Keynesian capitalist development**

“Modernization,” in its earliest promotional guise as “Western” modernist thought, firmly placed third world or Global South “traditional” societies as “backward” if not also “savage” and “uncivilized.” For development and progress to take place, modernization and modernist changes similar to those in play in Europe and the “West” had to occur (Power 2003). Modernity is distinguishable from modernization in terms of the new technologies and innovations that accompany capitalism’s evolutionary transformations, from early urban industrialization to advanced capitalism, and on to neoliberal and global capitalism.

Modernity brings about new modes of transport, new sources of energy, new management and communication technologies, new media forms, and the like. These, in turn, change social relations, power relations, and institutional structures and supplant or modify previous ways and means. To Giddens modernity may be defined in terms of being:

1. associated with (1) a certain set of attitudes towards the world, the idea of the world as open to transformation, by human intervention; (2) a complex of economic institutions, especially industrial production and a market economy; (3) a certain range of political institutions, including the nation-state and mass democracy. (Giddens and Pierson 1998, 94)

It was, however, the economic constructs built on modernization’s top-down tenets that had the most lasting influences during the early development decades of the 1950s, 1960s, and 1970s. More specifically, modernity and modernization both became the main conventional economic models favored by the development establishment since the second half of the twentieth century. Between 1940 and 1980, modernization (as development) was thought to be best propelled by the Keynesian model of advanced capitalism that prevailed in the developed “first world” of the United States, the reconstructed “war-torn” economies of Europe, and a rebuilt Japan. Keynesian capitalism favored governmental intervention to enable robust growth such that both social welfare safety nets and public subsidization programs were common partners to private enterprise.

Central to this economic formulation for the post–World War II “developing world” was the work of W.W. Rostow and his influential 1960s book *The Stages of Economic Growth: A Non-Communist Manifesto*. As evidenced in the title, Rostow had interwoven two major concerns, one political and strategic, the other economic and developmental. Rostow was geopolitically concerned with the international and political contexts of the process of transition in third world nation–states. His model, accordingly, was constructed in large part to further the strategic influences of the United States. Rostow’s model proposed that all societies would be able to transit through five stages: traditional society, preconditions for takeoff, takeoff, the road to maturity, and the age of mass consumption. Crucial to his takeoff and road to maturity stages were the infusion from outside (presumably the United States or its Western allies) of two factors of modern industrial success:

1. the existence of already functioning modern technology which can be made available by technology transfer from benevolent outsiders and public–private partners; and
the existence of international aid and technical assistance (including technical education and consultants) provided by the governments of developed countries and their contracted professional/technical advisers.

Neoliberalism and market-led development

Following the global recession of 1978–1983, a new capitalist model, labeled neoliberalism, brought about a dramatic turn away from Keynesian economic thinking and political-economic practices just about everywhere in the globalizing world. Accordingly, supply-side economics solutions to economic recovery – Reaganomics and Thatcherism, for example – were offered as alternatives to combat inflation, reduce government overspending, reduce public sector workforces, and roll back wages. Neoliberalism as an ideological discourse and unchallenged model of economic efficiency, fiscal austerity, and capitalist enterprise has prevailed since the 1980s, forging the contemporary era of neoliberal capitalism and globalization.

In theory, neoliberalism is about increasing the scale, scope, and pace of the movement of goods, commodities, resources, and commercial enterprises so that cheaper resources can be accessed to maximize profits, enhance efficiency, and increase income per capita worldwide. Neoliberal strategies seek to achieve these objectives through the removal of various controls (e.g., tariffs, quotas, capital regulations) and restrictions on capital flows and investment across national boundaries. Beyond its transnational implications, neoliberal ideologies and policies also advocate for or promote the following within nation-states:

- the rule of the market – freedom for capital, goods, and services, where the market is self-regulating – allowing the “trickle-down” notion of wealth distribution; it also includes the de-unionizing of labor forces and removal of any impediments to capital mobility, such as regulations (the freedom is from the state or government);
- reducing public expenditure for social services, such as health and education, by the government;
- deregulation, to allow market forces to act as a self-regulating mechanism;
- privatization of public goods, resources, and services (ranging from water, power, and transportation to information dissemination and exchange, Internet use, and communication);
- changing valuations of public and community worth to privilege individualism and individual responsibility.

With respect to development issues in the Global South, the International Monetary Fund (IMF) and World Bank have been the stalwart “enforcers” and promoters of neoliberal policies, notably through their Structural Adjustment Programmes (SAPs), Poverty Reduction programs, and austerity and “stabilization” measures designed to reduce public spending, remove subsidies on basic foods and other commodities, privatize state-owned enterprises, reduce the government’s wage bill, and devalue or free-float domestic currencies. In addition, neoliberal initiatives promote market-led forms of public service provision (e.g., through public–private partnerships) and economic liberalization measures which remove tariffs and trade barriers and deploy tax reductions and subsidies to encourage local entrepreneurship and inward foreign investment by transnational corporations. The World Bank, IMF, and the regional development banks (e.g., Asian Development Bank, Inter-American Development Bank) often place “conditionalities” on development loans to ensure that such
policy measures are enacted and that developing countries are opened up to more international trade and foreign corporate investment.

All told, while neoliberal initiatives have fostered GDP growth in some countries, particularly those rich in natural resources such as minerals and oil, there is little or no evidence to suggest that widespread wealth distribution is on the rise, that inequality is decreasing, and/or that economic diversification (à la Rostow’s stages) is occurring on a large scale. In essence, the contemporary circumstances seem remarkably similar to those observed in the colonial and early postcolonial period where surplus extraction by Western states and corporations and South-to-North dependencies stifled widespread human development in the Global South. As Harvey effectively summarizes, the contemporary neoliberal project fails to adequately or justly address pressing questions of inequality and redistribution:

The world is broadly polarised between the continuation (as in Europe and the United States) if not a deepening of neoliberal, supply-side and monetarist remedies that emphasise austerity as the proper medicine to cure our ills and the revival of some version, usually watered down, of a Keynesian demand-side and debt-financed expansion (as in China) that ignores Keynes’s emphasis upon the redistribution of income to the lower classes as one of its key components. (2014, xi)

Alternative, radical, and people-centered theories of development

Revolutionary and radical ideas concerning societal development were commonplace during the second half of the twentieth century. As if the end of World War II signaled that dramatic, nonviolent change needed to be brokered differently, from the 1950s onward, societal upheavals, popular resistances, elite power-brokering, militarism, pacifism, colonial oppression, and postcolonial independence movements occurred throughout the world. Writings that enflamed passions, ignited revolutionary (or radical) ardor, and cried out for social justice for all — not just for the wealthy and privileged — were as much at the heart of violent revolutionary action as they were central to the development of radical approaches to development.

This section focuses attention on people’s ideas and writings on “radical” or “alternative” approaches to development and social progress in the underdeveloped third world/Global South. Early on, radical critiques and “antidevelopment” arguments were leveled at Westernization, imperialism, modernization, and neocolonialism by third world spokesmen (Brookfield 1975). Following on from such critiques, the remaining sections detail a representative set of critical, alternative models that their advocates felt could, or would, bring about “development from below.” These alternative approaches culminate in people-centered development models, which combine development ethics, sustainability, capacity building, and community empowerment as progressive means for the poor majority to achieve development (see Figure 2 for an overview).

Marxist critiques and models of (under)development

Anti-imperialist, radical approaches which were offered as alternatives to the Western, Eurocentric, modernity-based models were idealistic geopolitical works, often written by Soviet scholars. Often, translations of Lenin’s writings, as well as those of Karl Marx and Frederick Engels, were used as theoretical and ideological guidance by local revolutionaries and radicals. Some
academically trained political leaders of newly independent countries, such as Tanzania’s Julius Nyerere and Ghanaian Kwame Nkrumah, wrote their own nationalistic manifestos advocating socialist, revolutionary models.

Other radical authors penned socialist and Marxist critiques that became well cited authoritative texts for decades. For example, Paulo Freire’s Pedagogy of the Oppressed (1970) became an extremely influential text for educators interested in improvements in literacy in third world territories. Another seminal work was Frantz Fanon’s The Wretched of the Earth (1967), a devastating critique of colonialism’s damaging impacts on the psyche of colonized societies’ new political elites. Particularly perceptive was Fanon’s portrayal of the imitative attitudes of the new generation(s) of third world leaders, which would lead them to continue on similar paths of servitude and deference to “outsiders” in their postcolonial relations with their ex-imperial masters.

Perhaps most influential of the radical critiques came from a group of scholars based or working in Latin America in the 1950s and 1960s. In his influential 1957 anticapitalist treatise, Marxist economist Paul Baran “explained” Latin America’s underdevelopment as a consequence of Western nations forming special partnerships with powerful elite classes in the continent’s underdeveloped countries. These special partnerships perpetuated the ability of advanced capitalist, core countries to maintain traditional systems of surplus extraction and ensured that the periphery’s domestic resources would be continuously available. By such means, they made economic development unlikely, since any surplus generated was appropriated by these client-elites. This would then enable core countries to keep their own monopoly of power over cheap primary resources (Baran and Sweezy 1966).

Notably, these alternative anticapitalist ideas on uneven exchange, surplus redistribution, and expropriation would be further developed by a chorus of voices from below: Latin American political-economy scholars, collectively known as Economic Commission for Latin America (ECLA) structuralists, and later as dependistas, or the “Dependency School” (Brookfield 1975). Although their neo-Marxist critiques differed in theoretical detail, all argued that Latin America’s historical marginalization and resultant underdevelopment were perpetuated by unequal commercial arrangements with core countries (particularly, the neighboring United States) who benefited at the expense of Latin America.

André Gunder Frank would soon become the main advocate for the dependistas. Focusing on the dependent character of peripheral Latin American economies, Frank coined the term “development of underdevelopment” to characterize the capitalist dynamics that developed core countries while at the same time ensuring underdevelopment and dependency within Latin American countries. Frank’s conceptual framework therefore explained the dualistic capitalist relations which had occurred, and which he felt would continue to occur between Latin American and core counties. In line with other anticapitalist critiques, Frank (1966) argued that any change for the better would be possible only through revolutionary action, which would install socialist ideals within the political systems of Latin America’s dependent countries and usurp the client-elites’ special relationships.

Another highly influential and passionate third world voice was that of Samir Amin, who expanded on the notion of dependencia in his critical examinations of the dependent economic relations of Africa since European colonization, and found them to be the destructive and disastrous consequences of that continent’s peripheral
development of capitalist condition. His writings, spanning the 1970s to the present (and dying in 2005), are voluminous and provide a highly persuasive case for the failure of the “development project” all over Africa (Adil 2007). Amin goes so far as to propose extreme measures to overcome the decades of failed Eurocentrism and its modernization approaches, such as “delinking” from Europe and starting afresh (Amin 1990).

Broadening the global scope of this Latin American-based construct, Wallerstein (1974; 1980) adapted dependency notions to comment on the commercial relations between the core countries and Latin America, and examined world historiography in terms of the dominant and subordinate relations that successive emerging cores, their peripheries, and semiperipheries experienced. Wallerstein’s account starts with the long sixteenth century and passes through successive eras of capitalism to arrive at the present neoliberal era of globalization (the post-1980s). His world-systems theory complements and expands on Frank’s ideas, providing a more comprehensive global stage appropriate for understanding the wider reach and more diverse spatial realignments of commercial capitalist relations in contemporary times. More recent world-systems explanations of geopolitical eras detail the transformations of the world’s hegemonic relationships of core–periphery relationships to the present global era in the second decade of the twenty-first century (e.g., see Sparke 2013).

Alternative approaches: development from below, empowerment, and capacity building

Western modernity’s externally driven strategies to bring about economic, social, political, and cultural changes in the underdeveloped client states of the third world came to be characterized as development from above by its radical critics. They criticized its import-substitution form of industrialization and its monolithic and uniform value systems, which lauded capitalist entrepreneurialism, urban living and intellectual “modernity.” In contrast, development from below sought to replace such externally driven dependent and subordinate relations and to increase equity rather than inequity across regions. It sought the creation of dynamic development impulses within regions that were less favorable to urban industrial growth and “growth pole” development, such as rural peripheries and remoter hinterlands.

From its inception in the 1970s, development from below was an activist agenda with a progressive message on the need for radical change in policy formulation and implementation. Succinctly, it argued that economic growth from above needed to be supplanted by development from below so that the basic human needs of all people could be met, rather than just those of elite minorities and the powerful classes. Development policy needed to be reoriented toward basic needs service provision at the territorial scale. Rural and village development should be as much a focus as urban-located development. Labor-intensive activities and micro-economic small businesses and projects should be favored over high-technology entrepreneurialism. Such territorially integrated development should aim to provide full employment, and regional human, natural, and institutional resources should be mobilized. Following Schumacher’s vision that Small Is Beautiful (1973), it was argued that intermediate technologies, small- and medium-sized projects, and participatory and locally designed and executed projects should be integral parts of the mix of development strategies (Chambers 1997). For the next three decades, from the 1970s to the 1990s, a mix of alternative approaches,
most seeking similar objectives for their humanistic development paths, would be launched in academia and in policy circles.

A key contemporary successor to development from below alternatives is the notion of people-centered development (Eade 1997). People-centered approaches explicitly blend concerns about societal and environmental sustainability and promote capacity building and community empowerment as progressive means through which the poor majority may achieve development. Saliently, civil society, NGOs, and other grassroots philanthropic organizations are embracing this notion. Proponents of people-centered approaches maintain an ethical position that is aligned with Goulet’s (1971) development ethics, and which seeks to make the real-life economy of people more human and humane, as well as ecologically sustainable (Korten and Klauss 1984). Decrying the roots of the current “global problematique” – Western modernity, scientism, and developmentalism, the nation-state’s political limits – Ekins (1992) sought a new world order of “democratic popular mobilisation” in which “real-life economics” was to be a radical alternative to positivist development economics. Given the structural rigidity and persistence of the stark global problems presented by war, insecurity, and militarism; the persistence of poverty; the denial of human rights; and the occurrence of environmental degradation, Ekins believed this radical option would be better able to bring about peace, human dignity, and ecological sustainability for all.

At the same time, “real-life economics” was never offered as a complete alternative to conventional political-economic orthodoxy. The structural geoeconomic forces at work globally pose so many diverse problems that such a local-level perspective can scarcely be viewed as an all-encompassing equivalent. Rather, the approach was an intellectual, theoretical alternative, and the basis for a new interpretation of people’s day-to-day economic strategies. In support, Ekins and Max-Neef (1992) marshaled a community of like-minded scholars to offer their alternative views on “living economics” in which real-life economics, ethics, environmentalism, and sustainable development should be considered inseparable dimensions in tomorrow’s thinking about human life and livelihoods. They warned that the market, the state, and civil society, singly or in combination, are all potential creators or destroyers of wealth. They cautioned that monetary concerns are not the only motivations for economic choice, and that livelihood behaviors do not have to be rational. Rather, habits, intuition, and bounded “satisfying” rationality guide human decision-making. Love, altruism, duty, respect, dignity, and obligations are all meaningful influences equal to economic rationality and wealth accumulation.

Gender and development debates also drew on this discourse, but with a focus on the issue of women’s empowerment, which subsequently became important for development institutions such as the UNDP and Oxfam, and for Global South government agencies and NGOs (Momsen 2004). Driving this initiative was a growing concern that gender equality would not be achieved unless women could challenge patriarchy and global inequality. Most importantly, scholar-activists from the Global South raised crucial questions as to how this objective might be attained, with a rising tide of female advocates supporting its goals. While women’s greater representation in government circles was seen as an achievable objective (and successfully accomplished in time), the plight of poor women and their empowerment and representation in decision-making processes were viewed as much more difficult to achieve. It was also clear that the reality of many poor women’s
struggles for empowerment and local communal authority required the analysis of local complexities within their regional, national, and global contexts. It was eventually realized that empowerment projects and their local advocates needed to pay attention to the ways institutional structures and discursive frameworks shaped the possibilities and limits of individual and group agency and choices. Furthermore, the inclusion of men and masculinity is a welcome expansion of the empowerment project and a key to more comprehensively addressing gender empowerment in our contemporary globalizing world (Parpart, Rai, and Staut 2002).

Bringing NGOs and the wider plural, civil society into the picture, Friedmann (1992) viewed “alternative development” as an expression of militant and activist civil society, also known as NGOs. Upholding universal human rights had to be the prime political objective, especially the rights of the disempowered poor majority of the Global South. For Friedmann, the empowerment approach is fundamental to such an alternative approach because it places emphasis on autonomy in the decision-making of territorially organized communities. It thereby brings about local self-reliance (but not unrestricted power), direct (participatory) democracy in communal affairs, and experiential social learning. With people empowered by participatory democratic involvement at the local level, they will become engaged in the larger processes of representative governance, and experience progressive “alternative development.”

The central idea behind local institutional capacity building is about how outsiders such as NGOs and private–public partners in development projects can help foster community authority and managerial expertise in the provision of social capital, social welfare and services, agricultural extension services, urban neighborhood community projects, and the like (Eade 1997). With governmental involvement as an enabler, rather than an active participant, or as leader and manager, this people–centered strategy seeks to strengthen institutional and social capacity to support greater local control, accountability, transparency, initiative, and self-reliance for urban and rural communities of the Global South (Korten and Klauss 1984).

A reflective assessment by Oxfam GB summarized the potential of this current development mantra: “The concept and practice of capacity building has to be tested against whether it can contribute to creating the synergy between different actors which can confront and challenge existing imbalances of power” (Eade 1997, v)

All told, people–centered approaches seek to keep hope alive in the face of the seeming impossibility of achieving human development for all, utilizing current paradigms. They seek progressive change, and a path forward that builds self-reliance, empowers men and women, and puts the first last in terms of which people are the most deserving: principally, the poor (mostly rural) majority who have been left out of the development project to date (Chambers 1997). They challenge conventional economic thinking and seek humanistic solutions, in which development is conceived in terms of people’s sovereignty. Succinctly put, peoples’ participatory involvement in controlling resources, thereby, gives rise to individual, familial, and communal empowerment. Furthermore, and with reference to his conceptualization of development ethics, Goulet (1971) also recognized three social freedoms as crucial quality-of-life components of a people–centered development that follows ethical tenets: (i) life sustenance and the provision of basic needs; (ii) self-esteem acquired through self–respect and independence, or autonomy; and (iii) freedom for people to determine their own future.
Transnationalism and the migration–development nexus

At the global scale, both temporary and relatively permanent international cross-border movements have taken on more diverse and complex characters, with migrants undertaking what has come to be labeled “transnational migration” (Vertovec 2009). Conceived as a transformative spatial and mobile option for an increasing number of international migrants, transnationalism constitutes the social, economic, and cultural experiences and practices of living “in and between two worlds, or sometimes three or more” (Conway and Potter 2009, 227). Over time and through their life course, transnational migrants undertake repetitive mobilities, circulate regularly, maintain close global social contacts with family and friends, and exchange information, knowledge, monetary remittances, goods in kind, technologies, and innovations via information technology and other communication media, or personally through visits. Such mobilities, exchanges, and circulations can contribute in significant ways to livelihoods and other development outcomes at the household and community scales.

Serving to greatly alleviate poverty in the Global South, monetary remittances are overseas migrant donors’ transfers that meet the immediate needs of family recipients, but also contribute to savings and investment when sustained. With remittances being spent locally to buy goods and services, this has multiplier effects in the recipients’ communities. Remittances represent a direct investment in human capital as well as needed consumption, and, with further migration being financed as well, the reproduction of flows of remittances can be assured. Remittances can also be altruistic transfers to community and family to fulfill obligations, without repayment. On the negative side, however, remittances may create migration dependency, encourage the conspicuous consumption of luxury imports, and contribute locally to wealth inequalities, where among recipient communities the haves and have-nots are distinguished by their overseas connections and their family members’ propensities, not their own industry and work efforts while staying home (Newland 2007).

Diasporas, however, do contribute far more to development than just the monetary support they send home to families and communities. Diaspora donors’ collective flows are a major source of foreign direct investment (FDI), market development (both for exports and for the outsourcing of production), technology transfer, philanthropy, tourism, political development, and more intangible flows of knowledge, new attitudes, innovations, and cultural influences. Consequently, recognition of return migrants’ considerable stocks of social and human capital has developmental implications, as so-called social remittances can serve as vehicles for people-centered organizational management and capacity building in the Global South. Migration–development relationships such as these that occur at microscales, therefore, appear to show promise for migrant families and local communities, although regions and more geographically marginal areas may not be so fortunate (Newland 2007).

Sustainable development

The notion of sustainably balancing economic growth with environmental protection and resource conservation emerged out of growing concerns about the pace and scale of the destructiveness of modernization in the latter half of the twentieth century (see Adams 2009 for a detailed review). With their early roots in more radical perspectives on limits to growth and deep ecology, such concerns manifested themselves in mainstream development objectives with the
DEVELOPMENT

now famous World Commission on Environment and Development’s (WCED) Brundtland Report, *Our Common Future* (WCED 1987). At the core of the mainstream sustainability agenda was the notion that economic growth should be managed in a manner that facilitates development while ensuring that there will be sufficient resources available for future generations to achieve their own development objectives. Achieving sustainable development thus entails balancing growth with environmental and social considerations through technological, market, and institutional changes that improve the efficiency and distribution of resource use and access, incentivize environmentally friendly behavior, and protect vital ecosystem services (e.g., hydrological cycles) such that these are able to sustain and enhance socioeconomic development. At its core, however, such a view maintains a *weak* perspective on sustainability in that it does not fundamentally question the paradigm that growth equals development, but calls instead for incremental, largely technocratic, adjustments to the capitalist system.

In contrast, *strong* perspectives on sustainability challenge directly the often used conflation of development and growth as if they were the same process. Ecological economists and limits-to-growth proponents argue that it is untenable to pursue a capitalist hard-growth strategy, but that a soft-growth path should be followed instead, in which environmental and quality-of-life concerns are fully integrated and prioritized. *Hard* (quantitative, physical) *growth* involves an increase in the size and scale of consumption and production, intensifying the exploitation of natural resources and pressure on the natural resource base. Conversely, *soft* (qualitative, nonphysical *growth*) is based on improvement, social efficiency, and the qualitative “unfolding of potentialities” (Daly 1996). While the first type of growth is severely constrained by natural limits; the second would be potentially sustainable (Daly 1990).

Given the North/South divide, strong sustainability proponents argue for limits to growth and a global “steady-state economy,” but acknowledge that poverty need to be addressed for sustainability at the global scale to be possible. To balance the global account, therefore, Goodland, Daly and El Serafy (1992) propose that an increase in hard economic growth for the poor be offset by a corresponding decrease for the rich, who predominantly reside in the Global North. Once the offset is rectified, a steady-state sustainable system can then be maintained through economic and ecological tradeoffs that carry the world “beyond growth” (Daly 1996).

**Beyond development? Postcolonial, postdevelopment, and antidevelopment thinking**

Since the 1980s, the shortcomings of modernization theories, as abstract and ahistorical depictions of developed and underdeveloped societies, have been contested through postmodernist and poststructural deconstructions and sociocultural critiques. Generally speaking, these approaches offer alternative humanistic interpretations of self, identity, and plurality of meaning, and reject the objectivity and scientific rationality of modernism and structuralism. In doing so, it critically examines the systems of knowledge that produce human and societal objects that need to be “developed” or that represent or lack “development.” Such perspectives privilege agency and subjectivity, and often ignore or decenter structural factors such as those derived from political-economic relations, hierarchies and other power relationships, markets, and class systems. This postmodern or poststructuralist turn in the social sciences inspired three
reconceptualizations of development theory and thinking – postcolonial, postdevelopment, and antidevelopment theory (see Power 2003; McEwan 2009).

Postcolonial theory is more than “after colonialism”; it seeks to critique the complexity and ambiguities of the imperial encounter in crucial ways. It shares with the postmodern critique a focus on relationships between the colonizers and the colonized, and challenges the legacies of Western Enlightenment discourses that promoted the prevailing modernist (and Western) histories of progress and advancement. Moreover, a postcolonial discursive lens contributes to the development discourse by enabling us to understand the material and cultural geographies of colonialism (and neo-colonialism) and the politics of identity and belonging as it varies across spaces (Power 2003). Postdevelopment and antidevelopment thinking share similar concerns and approaches, albeit with a more conscious intent to promote alternative means to achieve distribution, progress, justice, and equality through grassroots social movements based in the Global South (Escobar 1992). The wider point of these approaches is to overcome the constraints imposed by the mainstream development project and to develop alternative, egalitarian, and perhaps radical means by which communities might prosper and progress. As Escobar argues (1992, 48–49):

> In the long run, it is a matter of generating new ways of seeing, of renewing social and cultural self-descriptions by displacing the categories with which Third World groups have been constructed by dominant forces, and by producing views of reality which make visible the numerous loci of power of those forces; a matter of “regenerating people’s spaces” or creating new ones, with those who have actually survived the age of modernity and development by resisting it or by insinuating themselves creatively in the circuits of capital and modernization.

While many welcome such perspectives, others have criticized postcolonial, postdevelopment, and antidevelopment theories as being overly abstract, academic theorizations and as radical reactions to the hegemonic notion behind the modernization construct that a Western middle-class lifestyle is not at all a desirable or realistic goal for the majority of the world’s population (Pieterse 2000). Moreover, some have argued that any concern for the relationships between such theories and the political economy of development under contemporary globalization omits considerations of the historiography of European colonialism and US neocolonialism, and instead serves as umbrella terms for the experiences of decolonialization (Power 2003).

The contemporary impasse: neoliberal capitalism as antidevelopment

Just as Keynesianism prevailed as the dominant political, economic, and industrial mantra during the post-1945 era, the ensuing era of globalization that followed the deep recession of the early 1980s continues to be dominated by neoliberal capitalism and its free-market ideological faiths. The elimination (in 1999) of the venerable Glass–Steagall Act, devised in the Great Depression era to separate American commercial and investment banking, allowed for the centralization of financial institutions and for corporate mergers to flourish. Further deregulation and rollbacks allowed finance capital to tighten its control over global financial markets and to usher in an era of so-called casino capitalism (Stiglitz 2013; Strange 1986). There was extensive refashioning of the United States and global regulatory regimes, driven by US geopolitical expediency and leadership as an “American project” to foster globalization (Agnew 2005), such that the
international mobility of finance capital became free and unfettered. This enabled finance capital to play a dominant role in the global economy, and raised its rates of profit, while Global South and North capital stocks, sovereign funds, and financial profits were channeled into sustaining US and European fiscal and balance-of-payment deficits. The exponential expansion of this global financial credit economy created debt peonage within advanced capitalist countries and mounting debt burdens internationally. International debt combined with the absence of capital controls accentuated boom and bust cycles of debtor countries, leading to recurrent international debt crises which are still with us today (Verick and Islam 2010).

Despite its crisis tendencies, and the precariousness of an increasingly financialized global economy, neoliberalism persists, extending its global reach and scope, and remaining extremely powerful as an organizing logic for contemporary capitalism. Viewing the 2008–2012 global crisis and its aftermath from a progressive perspective, Peck, Theodore, and Brenner (2012) find that neoliberalism not only survived but that it subordinates collective, communal rights to the dominant power of market exchange and individualistic accumulation of wealth, even underwriting the justification for excessive militarism and warmongering (Amin 2007). For his part, Harvey critically condemns neoliberalism’s structural power as:

creative destruction, not only of prior institutional frameworks and powers (even challenging traditional forms of state sovereignty), but also of divisions of labor, social relations, welfare provisions, technological mixes, ways of life and thought, reproductive activities, attachments to the land and habits of the heart … It holds that the social good will be maximized by maximizing the reach and frequency of market transactions, and it seeks to bring all human action into the domain of the market. (2005, 3)

While the neoliberal era arguably represents a particularly problematic period in world history, it also highlights the continued failure of capitalism as a system to deliver development widely, justly, equitably, and in the broadest sense of the term. Reminding us of the repetitive flaws of capitalism’s economic outcomes, John Maynard Keynes observed that “The outstanding faults of the economic system in which we live are its failure to provide for full employment and its arbitrary and inequitable distribution of wealth and incomes” (1935, 372). In other words, capitalism still divides and conquers, extracts surplus from labor, and accumulates at the expense of those still too powerless to democratically negotiate for social justice and basic human rights. A radical overhaul of the system is past due (see Harvey 2010, 2014), one that can redirect national and global economies such that they are fairer, more just, and sustainable.

Dedication

While writing this entry, my dear friend and co-author, Rob Potter died at the age of 64. Rob was an eminent geographer and the founding editor of Progress in Development Studies. As his ideas remain central to this assessment of the field of development studies, I feel it is only proper that this final work of ours be dedicated to his memory (Dennis Conway).

Developmentalism is a theory of economic development targeting developing nations that proposes the intervention of the state in economic and social institutions in order to achieve “development.” Developmentalism is an approach to understanding economic differences between countries based on the idea of a ladder of growth and progress (Taylor and Flint 2011). While developmentalism generally refers to a set of practices that involves the cultivation of a strong domestic market and local industry, and the development of social institutions amenable to capitalism, there is considerable divergence on the genealogy and application of the term.

Watts (2009) identifies four philosophical roots of developmentalism: Keynesian-style state planning, free markets and property rights, Marxist critique of capitalist accumulation, and development institutions’ agendas. It is generally agreed that contemporary forms of state developmentalism emerged after World War II, when aid to newly decolonizing nations was consolidated around the objective of addressing the “underdevelopment” of these states. New institutions, such as the International Bank for Reconstruction and Development, were directed to helping impoverished former colonies emulate the economic success of Western countries. Countries that have adopted varying strategies of developmentalism since the 1950s include India, Singapore, South Korea, Taiwan, Botswana, and more recently Thailand and Vietnam. Also known as developmental states, these states are characterized by their ability to regulate capital and class power to meet long-term social, economic, and strategic goals (Olds and Yeung 2004).

A model that best exemplified postwar developmentalist thinking was Walt Rostow’s Stages of Economic Growth. Countries move through a linear sequence of stages from “traditional society” through “take-off” phases before reaching the stage of “high mass consumption.” Advanced economies such as that of the United Kingdom are presumed to occupy the top of the ladder, while developing countries attempt to catch up from the bottom rungs by transforming subsistence agrarian societies into export economies. Modernization theories have been seriously challenged by Immanuel Wallerstein and other world-systems theorists. World-systems approaches view developing countries as locked in dependent relationships with industrialized countries, resulting in cycles of poverty and economic stagnation rather than economic advancement. Critiques have also been lobbied from postdevelopment and postcolonial scholars such as Escobar (1995), who argues that development aid perpetuates linear views of progress while maintaining unequal power relations between giver and receiver. Postcolonial geographers argue that developmentalist thinking is rooted in colonial projects and in the very language we use for describing countries and cultures (McEwan 2003; Robinson 2003). More recently, the spread of neoliberalism as economic doctrine through the mechanisms of the Washington Consensus of the International Monetary Fund and the World Bank has led some to argue that neoliberalism...
DEVELOPMENTALISM

has become the latest strand of developmentalism (Harvey 2005).

Diaspora

Elaine Lynn-Ee Ho
National University of Singapore

Diasporas are formed when people move from one part of the world to settle elsewhere but retain a deeply felt sense of belonging to their place of origin, often referred to as the homeland. Derived from Greek etymology, the label “diaspora” in its earlier usage referred mainly to populations that were exiled and dispersed in other lands, such as the Greek, Jewish, or Palestinian diasporas. But, over time, “diaspora” has been increasingly used to describe other types of emigration. Opinions differ on the criteria that should be used to delimit whether an emigrant population can be described as a diaspora. This is partly because of different disciplinary approaches to the study of diasporas but diasporas as an object of study are also protean-like and evolve dynamically over time. The journal *Diaspora: A Journal of Transnational Studies* was established in 1991 as a publication dedicated to this topic, attesting to not only its wider scholarly significance but also the proliferation of views concerning the study of diasporas. Several other journals exploring diaspora as a subject of inquiry have also emerged since then.

The political scientist William Safran (1991) suggested that a diaspora community would have experienced dispersion from or loss of a homeland, but its members retain a collective identity and desire to return to the homeland because they believe that they are not or cannot become fully integrated into their host society. For Safran, members of a diaspora feel a sense of ethno-solidarity with their homeland and are committed to its welfare. This rather narrow definition of diaspora, however, belies the variety of ways in which the label is applied loosely to different types of emigrant populations now. Robin Cohen, a prominent scholar in diaspora studies, proposed a broader typology of diasporas in his book *Global Diasporas*, which was first published in 1997. This influential book has been reprinted multiple times and translated into several languages. For Cohen, diasporas are characterized by the shared link their members have with a certain migration history and by their solidarity with those in the homeland. In the latest edition of the book, Cohen (2008) classifies diasporas in the following ways: (i) victim diaspora; (ii) labor diaspora; (iii) imperial diaspora; (iv) trade diaspora; and (v) deterritorialized diaspora.

Interlinking analyses of nation, diasporic identities, and homeland

Notions of belonging and collective identity situated in a national homeland are commonly invoked whenever the label “diaspora” is deployed. Diaspora revolves around imaginative and material links to a home and homeland, framed in terms of belonging to and identifying with a nation. These tenets of diaspora are capable of mobilizing emotive feelings of patriotism among diaspora populations. Critical race scholars argue that diasporas should not only be treated as a descriptive typology but also examined conceptually. Among them is Brah (1998) who suggests that the “homing desire” underlying diaspora demands critical interrogation from a historically informed perspective rather than
be accepted as a primordial condition. This is because the genealogies and social relationships underpinning diaspora contribute to subjectification and identity-making. These in turn create categories of inclusion or exclusion in conceptions of the nation and diaspora.

Another group of scholars in diaspora studies, influenced by the writing of cultural theorists such as Paul Gilroy (1993), emphasize how diasporas function as sites of hybridity, creativity, and even resistance. Gilroy’s signature book, *The Black Atlantic*, argues that transnational bonds in the case of the African diaspora foment hybrid cultures that destabilize the hegemony of indigene claims. In contrast, other scholars dispute the hype of hybridity or resistance associated with diasporas. Historian Arif Dirlik (2004) argues that, inasmuch as diasporas can be celebrated for countering parochial framings of “race,” ethnicity, and nation, diasporic imaginaries are also vulnerable to reification and appropriation by chauvinist agendas. Scholars like Dirlik caution against essentializing the ethnic markers contained within diasporas.

For example, portrayals of Chinese capitalists as “flexible citizens” strategizing their immigration pathways in exchange for citizenship rights (Ong 1999) sideline the heterogeneous class backgrounds of members in the Chinese diaspora. Also contributing to distinct homeland identities within the Chinese diaspora are the geopolitical relationships of countries with majority (e.g., China or Taiwan) and minority Chinese populations (e.g., Southeast Asia). Likewise, what is commonly referred to as the South Asian diaspora is in fact made up of distinct homeland identities associated with the geopolitical entities of Bangladesh, India, Pakistan, or Sri Lanka. Within any of these South Asian diasporas, there are further nationality, religious, ethnicity, class, and gender divisions. Intersecting axes of identity such as those related to gender, class or nationality divisions thus differentiate between subgroups contained in diasporas. The intersectionality of these identities can reinforce domination or subordination, affecting resource allocation and life chances.

There is growing recognition of the internal divisions and contradictions within diasporas. Diasporas do not exist a priori but are constituted by the interplay of power relations internally and externally. The external influences that contribute toward how diaspora claims are mobilized by different groups at the community, national, and international levels are significant for understanding diaspora formation in space and over time. Brah (1998) proposes the term “diaspora space” to draw attention to not only border crossings by migrants but also their copresence with those that stay put. This underlines the multiple power relations between and within social groups in spaces of diaspora.

**Spaces of diaspora, territory, and extraterritorial reach**

Diasporas identify with a spatial center considered the homeland. The metaphor of “homeland” situates diasporic identities and belonging in actual or sought-after territorial space. Narratives associated with particular landscapes situated in the homeland can become intertwined with personal memories or family stories of migration. Migrants recreate home and homeland identities during their diasporic journeys through the use of oral histories, visual cultures, and material artifacts. The intersection of geographies of home and spaces of diaspora reflects contested and multiply refracted notions of identity, belonging, and diaspora. As such, nationally framed portrayals of diasporas can be complicated by not only the dual affiliations that diaspora populations have with their countries of origin and arrival but, in the
context of postcolonial migrations, wider colonial and postcolonial histories that also inflect on diasporic identities and belonging.

While the anchoring of diaspora in homeland space and the recreation of homeland in spaces of diaspora are already prominent themes in geographical research, the concept of diaspora also intrigues geographers because of the way it destabilizes the fixity of territory that has become ensconced with nation and nationhood. The dispersal of populations identified or identifying with a national territory evokes spatial imaginaries of deterritorialization, referring to how territory is decoupled from its presumably stable links with nation, identity, and community. Classical diasporas are often portrayed as enclosed social formations characterized by homogeneous culture and identity. But contemporary conceptualizations of diasporas are more likely to emphasize their fluid nature, internal tensions, and hybrid identities that in turn trouble homogeneous portrayals of diasporic space or territorial delineations. Diasporas can be studied both as a social condition and as a social process that plays out in space and across geographical scales and networks.

Inasmuch as the territorial imaginary associated with nation can be destabilized through diaspora formation and deterritorialization, reterritorialization takes place alongside deterritorialization processes. Examples are of political mobilization and lobbying by diaspora actors aimed at influencing developments in the homeland, or remittances sent to the homeland for family support or development purposes. These practices by diaspora populations reinforce the interlocking of nation and territory. While some of these activities are initiated by the diaspora, migrant-sending states are increasingly asserting extraterritorial claims on their emigrant populations. Their goal is to reinforce national belonging and to solicit contributions from the diaspora to the homeland. These state-led policies extending the reach of the nation-state over diaspora populations are collectively referred to as diaspora strategies.

**Diaspora strategies and geographical inquiry**

The “intrinsic and contradictory” (Dirlik 2004, 491) relationship between diaspora and nation is widely acknowledged today, but entangled with it are the impacts of globalization and late capitalism. Whereas the mobilization of diaspora populations for development purposes have long been associated with poorer countries that tap their diasporas for remittances or small-scale investments, today such state-led policies are just as likely to be implemented by economically advanced countries. Nation-states looking to gain a competitive advantage in the global economy are tapping on their diaspora populations for highly skilled human capital, international networks, and global capital.

While diaspora studies emphasize the homeland orientation of emigrants, transnationalism approaches recognize that migrants are simultaneously anchored in their countries of immigration and emigration. Transnationalism and diaspora can thus be read as an analytically distinct phenomenon. But migrant-sending states are enacting diaspora strategies to capitalize on the transnational attachments and mobilities of their emigrant populations. International institutions such as the World Bank and the Asian Development Bank, as well as migrant-receiving countries like the United States or European Union countries, also promote diaspora strategies as a means to further development in poorer migrant-sending countries. Their interest in using diaspora strategies to effect development elsewhere is prompted
partly by a global leadership role but also out of national interest. Promoting development in countries where their immigrant populations originate is a means of deterring further economic migration that could strain the social stability of the migrant-receiving country. The joint international and national interests in diaspora strategies have triggered a global dialogue for the knowledge sharing of best practices through international nongovernmental organizations like the International Organization of Migration and the Migration Policy Institute.

This policy trend has influenced the direction of geographical research on diaspora strategies in several ways. One approach critically interrogates the neoliberal ideology underpinning the “development” agenda of diaspora strategies (e.g., Larner 2007). Such analyses posit that new forms of global governance and subjectivities are culturally constructed through diaspora strategies that constitute certain ways of participating in the global economy. Another approach considers how political institutions and governance mechanisms evolve as migrant-sending countries deploy diaspora strategies to connect with their emigrant populations (e.g., Gamlen 2008). Citizenship is one such political institution that has become redefined spatially when membership, rights, and responsibilities are selectively extended beyond the national territory to diaspora populations. This reconstitution of citizenship creates sites where some emigrants are privileged over others, leading to the marginalization of certain diaspora groups and even contestations of the state’s portrayal of identity and belonging (e.g., Ho 2011). Diaspora strategies can trigger spaces of uneven development when diaspora strategies entrench capital and other accumulation in particular sites, resulting in greater dispossession elsewhere.

When migrant-sending states portray emigrant populations as diasporas that belong to them, the claim exerted by the nation of departure is privileged over the nation of immigration. In this way, diaspora strategies can have politically debilitating effects if they cast doubt over the attachment and commitment of immigrant groups to their countries of reception. Tensions between ethnic, national, and diasporic identities can be heightened by the demands of diaspora strategies when they are juxtaposed against the parallel onus of assimilation or integration borne by immigrants in their countries of reception. The following section expands this discussion by highlighting the geographical implications of overlapping national claims experienced by diasporas when migrants undertake transnational sojourning between countries of origin and countries of reception.

Multiple diasporic identifications and proliferating emigrant mobilities

Increasing migration flows and more complex geographical trajectories are likely to engender multiple diasporic identities among emigrants or their descendants as they journey between the different countries they simultaneously consider home. Geographers have studied transnational sojourning trends that indicate that, even though migrants embark on return migration, they intend to subsequently remigrate back to the immigration country they have left (or to another country). Diasporas are thought to long for return to their places of origin but during transnational sojourning there can be several forms of “return,” thus challenging the premises of diaspora identity and belonging. Migrants may have naturalized in the immigration country and developed legal and emotional attachments to it. As immigrants they were considered the diaspora
of the country of origin, but during return migration they adopt an additional diasporic identity and form the secondary diaspora of the immigration country they have left. They identify as the diaspora of more than one country, thus complicating nationally framed definitions of diaspora membership.

Such diaspora populations are able to capitalize on their transnational affiliations if the countries in question view their national interests as complementary, which may even trigger the coproduction of diaspora as both countries leverage their diaspora populations to mutual advantage. But, should the countries of origin and immigration have conflicting interests, then either or both of those countries can view their diaspora populations suspiciously and question where their loyalty lies. Proliferating emigrant mobilities present fruitful avenues for geographers to explore the tensions wrought when different migrant-sending states, whether the country of origin or country of secondary migration, assert overlapping claims in relation to what they both consider are their diaspora populations.

Also of interest to geographers is the reverse migration of diasporic descendants to their ancestral homelands. These studies illuminate the structural pressures placed on the children of immigrants to assimilate or integrate into immigration countries. Yet their ethnic identities, family migration histories, and transnational ties set them apart from mainstream society. In some cases, experiences of discrimination or nonbelonging in immigration countries precipitate nostalgia for the ancestral homeland and a desire to be among coethnics whom they perceive to be more similar to them. In other cases, diasporic descendants have been compelled to leave their settlement countries because of conflict situations or ethnic persecution. Ancestral homelands that prioritize shared ethnicity and kinship obligations could implement ethnically privileged migration policies to give coethnics in distress preferential rights to entry and resettlement. Ethnically privileged migrations may even intersect with development agendas, such as manifested by diaspora strategies that target coethnics and diasporic descendants abroad.

When diasporic descendants relocate to the ancestral homeland they are presumed to cohere more easily with the resident population because of assumed ethnic similarities, but this is usually not the case. Diasporic descendants are likely to find that the expectations they had of life in the homeland are different in reality. This is because the ancestral homeland has changed compared to the memories and family stories shared with them by an earlier generation of emigrants. Moreover, when diasporic descendants live in proximity with coethnics in the ancestral homeland, they become conscious of differences in habits, mindset, language, or accent. Likewise their coethnics may treat them as insiders because of their shared ethnicity but simultaneously view them as outsiders because of cultural differences. This could bring about another layer of social segregation that multiplies the spaces of exclusion experienced by diasporic descendants even if they are in their purported ancestral homelands.

Diaspora is, as Clifford (1994, 302) describes it, “a traveling term.” Not only does it denote human mobility; it is also a practice and concept that takes on certain emphases in different spaces. Intrinsic to the social processes and relationships constituting diaspora is its relationship to the nation and state. Diasporas can be protective of their perceived homeland identity, and the homeland, equally, can mobilize the diaspora for the benefit of the nation. Geographical approaches to the study of diasporas thus contribute to identifying how diasporas change the meanings associated with places and territoriality, and further the impact of such spatial concepts on diaspora formations.

**Difference**

Deborah P. Dixon  
*University of Glasgow, UK*

As with all manner of key concepts, difference has been used to underpin a wealth of geographic thought, analysis, and writing while eluding precision, in terms of a circumscribed definition, and specificity, in terms of what it appropriately illuminates. What is more, this geographic engagement itself rubs up against explorations and deployments of the term within other disciplines in the natural and social sciences, as well as the arts and humanities. Difference is itself differently understood as an object of analysis, but also (and often implicitly) as a means of sorting and ordering other objects such that they lend themselves to analysis. As such, these differences are themselves indicative of much broader conceptual and methodological shifts in geography and beyond.

Prior to the emergence of spatial science in the mid-twentieth century, difference as a concept had largely been wrapped up in regional geography. Geographers sought to lay out the singular collection of spatially overlapping physical and social phenomena that, taken together, both differentiated regions from each other, and allowed an understanding of their holism. With the arrival of spatial science – an approach that very much took the world as there for all to see – an objectivist gaze was coupled with an abstract, isotropic, and rectilinear spatiality, one that relied on both subject/object separation and the unambiguous location of objects of analysis. While there were certainly diverse understandings of space and spatiality at work in spatial science (e.g., topographic versus topological), this approach became firmly associated with difference as a matter of both variation across a gridded, Euclidean space, and the positing of objects and events as discrete entities. For critically minded geographers, both of these assumptions have been problematic. Numerous lines of inquiry have sought not only to bring to light an underlying essentialism and transcendentalism within spatial science, but also to proffer alternative understandings of what difference is and how it matters.

Though difference has certainly been implicated in geographic inquiry for centuries, its importance as an analytic concept was subordinate to human–environment relations. Spatial science was the first geographic approach to place difference squarely at the forefront of analysis as a means of sorting and ordering phenomena in the form of objects and events. Here, objects/events are distinguishable from one another in ways that permit scientists to measure variation between them, and to construct elaborate systems for analyzing and explaining such variation. This distinguishability is itself made possible through a particular understanding of difference as discreteness. That is, objects/events are presumed to have an essential core of attributes (size, weight, color, duration, intensity, etc.) that afford them stability and fixity, and on which a host of powerful scientific analyses can be constructed and carried out. These attributes are crucial constitutive components of the object/event under analysis, but, importantly, their presence and intensity can be compared and contrasted between phenomena because they lend themselves to being observed by an objective observer and
measured according to universally applicable criteria. Within spatial science, this approach to difference is most explicit in the construction of data matrices, wherein various measured attributes – systematic, temporal, and spatial variables – are taken to be representative aspects of the real-world object/event under investigation. It is also apparent in topographic accounts of objects/events that seek to map the putative influence of discrete objects on each other as relations that unfold across space. The methodological rationale for this approach to difference, wherein everything has its place, is rigor, which guards against any ambiguity that might undermine scientific analysis of cause and effect.

The most significant implications of this ontology revolve around the presumed discreteness of objects/events. At one level, such sharp-edged distinctions permit the separation of academic disciplines into categories charged with understanding the systematic (e.g., biology or economics), temporal (history), and spatial (geography) characteristics of objects/events. At another level, these distinctions mean that scientists do not have to approach the world as an undifferentiated, chaotic, and interconnected jumble that requires that each new study reconceptualize that reality. By assuming that objects/events are distinguishable, and that their characteristics are divisible into the three dimensions, scientists can direct most of their conceptual efforts into devising the most appropriate concepts and measurements for these dimensions.

Although spatial science still underpins a great deal of geographic inquiry, particularly with regard to the earth sciences, human geography has been radically transformed by a more critical accounting for scientific knowledge and associated practices, combined with a philosophical interest in the crisis of representation. That is, and in contrast to the above, Marxism, feminist theory, postcolonial theory, and poststructuralism have largely worked to a pluralist epistemology, wherein the distinctions drawn between objects/events are not taken for granted as the starting point for analyses, but are positioned as socially constructed. None of the distinctions – or differences – between individuals and groups, made and natural objects, types of experience, and aspects of meanings, are understood to be naively given as unmediated parts of reality. These are positioned, rather, as compartmentalizations that allow the world, as well as the place of human beings within it, to be made sense of. Compartmentalization relies on the use of rigidly fixed and policed boundaries around the meaning of objects/events, such as natural and cultural, masculine and feminine, human and animal, and the putative relations between them.

Geographers working within several conceptual approaches have developed numerous lines of inquiry that address the larger discourses within which such distinctions are posited, brought to bear, and challenged. In the process they have drawn inspiration from a range of social theorists from Roland Barthes and Michel Foucault to Jean Baudrillard and Jean-François Lyotard, each concerned, although with varying emphases and intent, with the production of knowledge. Although discourses are enabled and reproduced through language, to geographers interested in the making of distinctions “discourse” is a term more complicated than its everyday use as “mere words,” for it refers not only to the processes of categorization but also to everyday social practices – from raising children to dancing – that, like language, are imbued with meaning and hence also signify something about the world. Through discourse human subjects come to understand where things fit in the world, literally and figuratively. They also come to comprehend the relationships between
cultural motivations behind these, have been taken up by geographers working across the discipline’s subfields. And, in the process, these concerns have led geographers to consider the utility of literatures on psychoanalytic issues, emotion, and affect, in conjunction with methodological treatments of reflexivity and situatedness.

This move from difference as a given ordering of the world to difference as socially constructed has had three broad implications for geography. First, and at the level of the discipline’s objects of analysis, constructivism suggests that geographers scrutinize the ways in which discourses, and in particular binary logic frames, predetermine their conceptualizations of objects of analysis. Indeed, it has been pointed out that binary thought seeps through epistemology and into the discipline’s ontological categories, as can be seen in the distinctions between social and physical phenomena, or between individual agency and sociospatial structures, just two of the more prevalent. Second, and at the level of geographic thought more generally, these two approaches provide contrasting views of the history and development of the discipline. On the one hand there exists a “paradigmatic” view that posits distinct bodies of inquiry shaped by different philosophical frameworks, methodologies, substantive domains, research questions, and methods. Paradigms are predicated on the assumption that they can be compared and contrasted – for example, environmental determinism versus regional geography – as if they were discrete bodies of thought. And, by implication, paradigmatic thinking also assumes that there exists a body of thought external to others, from which the historian of geographic thought might evaluate the rise and fall of paradigms. On the other hand, a constructivist approach sees these as embedded in a relational field of methodological constructs that have been sorted and afforded significance, such as pattern versus
DIFFERENCE

process, science versus art, truth versus fiction, nomothetic versus idiographic, objectivity versus subjectivity, quantitative versus qualitative, explanation versus understanding, and mapping versus writing. The borders between these concepts are not given, but are maintained by various discourses that center paradigms and their competitors. In poststructural accounts, for example, modern-day geography emerges as a metaphysical enterprise whereby seemingly secure ontological categories, such as presence, essence, existence, cause, origin, substance, subject, truth, God, and man, are pivotal in the formulation and development of geography’s paradigms (Doel 1999). Third and finally, since compartmentalization relies on excluding those objects/events that do not fit easily into place, the very construction of such an edifice is made possible by what lies outside of the category. Thus, as many geographers working with post-colonial theories argue, the outside, or other, is always already constitutive of the inside, leaving its trace within the boundary of the category (Nash 2002). Certainly, in many human geographic syllabi, a key pedagogic component is now to make students aware of the need to acknowledge otherness in the formation of often taken-for-granted social categories, such as “European” or “white,” the everyday operation of inclusion/exclusion, and the ethical appeal of diversity (McLeay and Chalmers 2011).

Taken as a whole, the drive to query difference as socially constructed has led geographers to engage in all manner of epistemological debate, and to practice a linguistically driven, power-sensitive deconstruction of meaning that has often been referred to as the “cultural turn.” And the dangers of assuming difference to be a matter of the essential (discrete, static, and fixed) attributes of phenomena are well signposted. Over the past two decades, however, the discipline has also been witness to a variety of efforts to ontologize difference in a manner that does not fall back into such an essentialism. That is, efforts have been made to pay attention to difference not as a social construct, but as a fundamental part of the world, much of which lies outside of human purview. What is at stake here is the charge of transcendentalism, whereby the criticism is made that geographers, including those working within the critical traditions noted earlier, have tended to prioritize analyses that simply ignore (as inaccessible or as unimportant) the workings of a world outside of human understandings of it.

Confronting this ontological challenge, geographers inspired by the work of Derrida, Gilles Deleuze and Felix Guattari, and Bruno Latour especially have mapped out an immanent ontology bereft of socially constructed, organizing concepts such as scale. Immanent here refers to a self-organization, as opposed to the work of some form of external, organizing agency. This ontology is characterized by what has been termed a “radical alterity,” wherein phenomena are understood not as discrete, static, and fixed, or as the end products of a process, but as existing, rather, in a continual process of becoming (Dixon, Woodward, and Jones 2009). Becoming is made possible by the entanglement of phenomena with a host of others, each affecting and being affected by the rest. What is of interest in such an approach is not the current material configuration of an object/event, which might be summed up as a series of attributes, but the relations that bind and cleave phenomena. These relations are in turn understood as a reference for various forces that, with varying speeds and intensities, constitute (as opposed to direct or emanate from) the material composition of phenomena. Difference thus becomes a matter of differentiation, wherein phenomena are refashioned time and again through their connections with other phenomena.
Geographers interested in difference as an ontological condition of the world have explored a variety of concepts, such as network, assemblage, folds, and strata, that more usefully capture this sense of connectivity between phenomena and their ongoing co-constitution. Each of these takes space not as a dimension across which variables can be measured and events unfold, but as a fundamental component of the objects/events in question. Often referred to as a “counter-topographic geography,” spatiality becomes here a capacity, alongside other capacities, that helps to constitute phenomena and which, as those phenomena are refashioned, is also caught up in a continuing process of differentiation. Geographers have also turned to concepts such as queering and hybridizing to emphasize something of the momentum that takes place as differentiation occurs. Nevertheless, although there is a shared concern to understand how phenomena are refashioned, politically and ethically, there are debates over how refashioning is to be accomplished, insofar as the theories brought to bear do not add up to provide a correct or universally relevant accounting for an immanent ontology. Such conceptual approaches must be considered, rather, as in a productive dialogue that highlights some continuing problematics for geographers, such as the manner in which a human/nonhuman boundary is composed and blurred, and the nature of relations that compose as well as undercut such boundaries, but that also offers up new lines of geographic inquiry. Currently, there are three broad areas of debate.

First and foremost, while there is a concern in the immanent approaches noted above to emphasize the self-organizing of phenomena, and to map out how self-organization is materially differentiated, there is also a concern to recognize the various limits of this movement. For some geographers, the danger inherent in such approaches is that they lend themselves to an understanding of phenomena as always connected, and always fluid and malleable, such that they are constantly in the process of transforming into the new. Taking a cue from Deleuze’s (1994) notion of “difference with repetition,” these geographers have sought to emphasize in turn the blockages, fractures, displacements, and antitheses that characterize ontology time and again. To date this effort has been particularly manifest in work that situates geography as the analysis of sites (Woodward, Jones, and Marston 2010) that are considered dynamically composed aggregates constituted from emergent and self-organizing processes, and that can be “mapped” according to their own internal logics of composition. In disciplinary terms, spatiality is one such logic. We should not be surprised, therefore, to find that the spatialities of sites rub up against each other; indeed, this polycentrism may well be a defining characteristic in understanding how a site works.

A second and related debate concerns how the “becomingness” of phenomena is to be understood. Some geographers have alleged a tendency, despite the emphasis on phenomena as self-organizing, to read objects/events as the end products of a combination of processes. The worry here is that in attending (often implicitly) to the connections between phenomena as processes there is an accompanying assumption that their sum operation, which must extend beyond the materiality of the phenomena in question, are generative of a material recomposition. For critics, the holism underpinning such an approach is an unwarranted distribution of causality. In part, this is because, it is argued, this conflation of process with causality glosses over the “thingness” of the very phenomena under scrutiny. Often resorting to “object-oriented” philosophies to work through what is taken to be a backdoor transcendentalism, geographers...
have emphasized differentiation as the work of “force-full” phenomena (Shaw and Meehan 2013). While scholars may speculate over the capacities of such phenomena, there is simply no final accounting for such capacities; a lingering reticence must be accorded the objects/events that draw so much attention.

Third, and taking the emphasis on the materiality of phenomena, and their connections (and nonconnections) noted above, there is considerable debate as to how the human subject is to be constituted in such analyses. Geographers working under the rubric of a posthumanism have looked to illustrate the problematic character of differences that promised to render the human subject unique – such as reason, sense-making, and even artistry – and have emphasized the transfers of energy and matter between and among bodies and environments in the form of, for example, affect. The question remains, however, as to whether certain capacities are to be accorded the status of a fundamental human/nonhuman distinction (Dixon, Hawkins, and Straughan 2012).

Regardless of such conceptual debate, future work on difference is likely to track back and forth across the iterative construction of difference, and the ontologizing of difference, in the pursuit of new lines of inquiry regarding how particular phenomena are composed and afforded significance, and how they work both materially and discursively within a particular context. In the process, one concern that has so far remained submerged and will no doubt come increasingly to the fore is the tendency for geographers working with and on difference to assume that doing so is an inherently productive endeavor. Long skeptical of the political inequalities forged and maintained by homogenization, stasis, and sameness, geographers have turned time and again to difference as a means of querying and even disrupting such dynamics.

In large part, this normative impetus explains why difference has remained a key concept in geography. And, yet, there remains much more reflective work to be undertaken on the question of why critical analyses should help to proliferate difference as an output of the research process; and, moreover, why the difference posited by the inaccessible is the most appealing of all.

**Digital divide/digital divides**

The term “digital divide” has existed for some decades and was perhaps most famously defined by Pippa Norris in 2001 as “a multidimensional phenomenon encompassing three distinct aspects. The global divide refers to the divergence of Internet access between industrialized and developing societies. The social divide concerns the gap between information rich and poor in each nation. And finally within the online community, the democratic divide signifies the difference between those who do, and do not, use the panoply of digital resources to engage, mobilize, and participate in public life” (Norris 2001, 4).

Journalistic shorthand sometimes refers to the so-called haves and have-nots of the digital world. This binary is, however, empirically and conceptually flawed, first, because access and use opportunities differ for different digital media and 2.9 billion people now have some form of access to the Internet (ITU 2014a). Thus many people’s reality situates them somewhere on a digital technologies continuum. Second, some “not-having” is based on a deliberate choice by users and can thus be better described as “not-choosing-to.” Therefore, instead of “digital divide” (singular), “digital divides” (plural) has been proposed (Warschauer 2004) and this is conceptually a more accurate term.

**Identifying the gap**

At the 2003 UN World Summit on the Information Society (WSIS) in Geneva, the member countries endorsed a set of 67 principles, indicating their commitment to “turning this digital divide into a digital opportunity for all, particularly for those who risk being left behind and being further marginalized” (Principle 10, WSIS 2003). Namely, the WSIS declaration identified those at risk as those living in rural areas or marginalized urban areas, poor, elderly, or indigenous people, women, people with disabilities, “marginalized and vulnerable groups of society, including migrants, internally displaced persons and refugees, unemployed and underprivileged people, minorities and nomadic people” (Principles 11, 12, 13, 14, 15, and 16, WSIS 2003).

Institutions such as WSIS view “universal, equitable and affordable access to ICT infrastructure and services” as a central development objective for all stakeholders building the information society (WSIS 2003). As a consequence, universal access has become a key policy objective in most countries’ national ICT strategies, and in some countries, such as Finland, France, and Estonia, legislation has been passed which makes access to the Internet a basic right.

However, social scientists have frequently pointed out that the digital divide per se is nothing new but often another manifestation
of existing social inequalities along education, gender, income, class, or ethnicity lines. The relationship with age is far more complex, as many studies have shown that young people are frequently skilful adopters of new digital technologies if they have access to them.

The digital divide is measured, at a relatively basic level, as numbers of people with access to the Internet or a mobile phone, households with Internet access, or subscribers to mobile phone providers, captured by counting subscriber identity module (SIM) cards or devices. Yet, this is frequently criticized for not taking into account that many people with low incomes hold multiple SIM cards and that increasing numbers of digital devices in households will soon make the counting of devices problematic as an indicator. At international level, there have been longstanding efforts to measure ICT and country development and trace the digital divide (see Figure 1). The UN’s International Telecommunication Union (ITU) has developed the ICT development index (IDI) which has evolved from previous indices developed by ITU, Orbicom–UNESCO (United Nations Educational, Scientific and Cultural Organization), and the United Nations Conference on Trade and Development (UNCTAD) and has been published annually since 2009. The IDI relies on 11 indicators across three components: access (lines and subscriptions), use, and skills (literacy, secondary and tertiary education enrolment). Other agencies collect data on specific themes; for example, UNCTAD collects data on “information economy” indicators such as the relative size of a country’s ICT sector. The data have significant limitations, and yet it is through these statistics that the “digital divide” is most commonly measured.

Beyond the indicators and indices, however, there are theoretical debates about the nature of access and which dimensions should be taken into account. Some of these dimensions are not directly visible in the indicators.

Dimensions of access

Access can be conceptualized in three dimensions: (i) availability of Internet connectivity, (ii) affordability of access, and (iii) skills needed for use (Gerster and Zimmermann 2003). Other aspects include having content that is relevant, meaningful, and in a language that the relevant user group can read (Warschauer 2004); being
able to create content (Van Dijk and Hacker 2003); and having access to content without censorship or paywalls causing a “data divide” (Gurstein 2011).

Other axes of exclusion affect other dimensions of access. Regarding gender, how different members of the family “ought to use their time” and social norms on the use of space may impact on girls’ and women’s ability to use the Internet (Kleine 2013). Studies have explored key cultural factors that may be sustaining the gender gap in ICT or mobile phone access, ownership, and usage. For instance, Buskens and Webb (2009) indicate that male relatives may be surveilling/prohibiting the ICT/mobile use of their wives and daughters. According to the 2012 GSMA mWomen report, “82% of married BoP [base of the pyramid] women who own mobile phones [agreed that] ‘it makes my husband suspicious’” (3).

Initiatives to combat the digital divide

Initiatives have evolved along with the pace of technological change and the understanding of the divide. A new field of research and practice, ICT4D (Information and Communication Technologies for Development), emerged to explore the use of ICTs in development work (Unwin 2009). Typical initiatives in the 1990s and 2000s were telecenters, or communal Internet access spaces, for example in schools or libraries, which provided access at subsidized rates or free of charge. Efforts here are ongoing, however, because as home and mobile Internet access increases (see Figure 2), telecenters have had to reinvent themselves as multipurpose community hubs which combine the access to information and communication with services and advice. This is provided by intermediaries and can in some cases create

Figure 2  ICT-related indicators globally over the last 15 years. ITU 2015, 2. Reproduced by permission of ITU.
DIGITAL DIVIDE

opportunities for collective empowerment, which is an aim stressed by the Community Informatics movement.

Another front for digital inclusion has been IT training, or more in-depth, critical digital literacy training. Although IT skills have instrumental value, researchers have been emphasizing the need for critical thinking to promote meaningful uses that support people’s own empowerment. On content, there are organizations such as the Wikimedia Foundation or the World Wide Web Foundation, who campaign to keep the Internet publicly accessible, while human right groups, such as FreedomInfo and the Open Rights Group, campaign against government censorship.

Diverging visions for the future of the Internet

Basic connectivity is improving. Technological innovations such as the battery-based Internet router BRCK by Ushahidi offer new possibilities, especially for rural communities that still lack basic electricity. Also, in 2009, underwater fiber-optic cables skirting the African continent docked at the Kenyan coast. According to Graham and Mann (2013), this process is producing significant effects in “cost, speed, and the ability to access information and communicate” in East Africa, due to a combination of technological improvements and people’s powerful optimism which impacted policies, practices, and expectations. However, structural factors governing national economies and the global trade system continue to limit the transformative power of such access.

While Internet backbone lines will still be cable-based, Internet use is increasingly taking place on mobile devices such as smartphones and tablet computers. Mobile applications, such as Facebook Zero, provide optimized speed and zero data charges as a way to attract more users in low-income countries. These initiatives, and a reduction in mobile data costs in low-income countries, would make it likely that first-time Internet users in these countries encounter the Internet on mobile devices rather than via a stationary computer.

Globally, the current prevailing business model allows free access to content in exchange for collecting and exploiting user data for commercial purposes. Commercial search engines (such as Google or Bing), email or social media platforms (such as Facebook and Twitter), and others allow easy and simple ways in which ordinary users can generate and share content, which then is held and regulated by the platform. The risk is that most users lack critical understanding of, or feel helpless to resist, the imposed data gathering, as well as surveillance by firms or governments.

The digital divide debate, which started as the question of how the poor might gain access to the Internet, is increasingly overshadowed by the global struggle between different visions of the future Internet. The discussions around open access to data and content online are set to continue, and have received a significant impetus by some governments committing to open data policies for their own work and government research councils, for example in the United Kingdom, making open online access to research outputs compulsory from 2016. Open access and digital rights activists fear that, if a vision of the internet as a largely privatized and commercialized space, rather than as a global public commons, prevails, then, by the time some of the last currently digitally excluded people gain access, the Internet itself will be much impoverished.

Digital Earth

Changlin Wang
Institute of Remote Sensing and Digital Earth, Chinese Academy of Sciences

Digital Earth is an evolving global initiative in which spatially referenced information – historical, present, and modeled – is integrated to create a three-dimensional representation of the Earth’s physical and social environments for use by researchers, decision-makers, and citizens (Craglia et al. 2012). Digital Earth extends beyond the visualization-centric virtual globes of the early twenty-first century, for example, Google Earth, to include connected infrastructures and participative information resources needed for people to compute, manage, and communicate big Earth data. The Digital Earth concept is promoted and developed globally by public, private, and third-sector organizations, usually within the contexts of sustainability and earth system science.

The concept of a computer-driven, virtual globe is not a recent development. Buckminster Fuller’s Geoscope is an early example. In his 1962 book Education Automation, Fuller described “a large two hundred-foot diameter (or more) lightweight geodesic sphere ... a miniature Earth. Its entire exterior and interior surfaces will be covered with closely packed electric bulbs, each with variable intensity controls” (Fuller 1962). The lights on the globe, controlled by computers, could display a variety of data, including simulated “consequences of various world plans.” The concept has also been described in science fiction. In the novel Snow Crash, Neal Stephenson imagines a digital globe “about the size of a grapefruit, a perfectly detailed rendition of Planet Earth, hanging in space at arm’s length in front of his eyes ... It is a piece of CIC software called, simply, Earth. It is the user interface that CIC uses to keep track of every bit of spatial information that it owns – all the maps, weather data, architectural plans, and satellite surveillance stuff” (Stephenson 1992). He describes it as having very high resolution with an ability to zoom in on specific areas.

Former vice president of the United States, Al Gore (1992), first proposed the idea of setting up a Digital Earth program in his book Earth in the Balance: Ecology and the Human Spirit. It would help organize and interpret the enormous volumes of Earth observation data, turn raw data into understandable information, build a new global climate model capable of receiving data from different sources, and improve the quality and usefulness of the models by comparing predicted results based on information from known climate records and what has actually happened. The concept of Digital Earth was then popularized by Gore’s speech, “The Digital Earth: Understanding Our Planet in the Twenty-First Century” (Gore 1999). He defined Digital Earth as a multiresolution, three-dimensional representation of the planet into which vast quantities of georeferenced data could be embedded. Gore’s vision predicted that with technological innovations and advances in information acquisition and processing, unprecedented amounts of information about our planet and a wide variety of environmental and cultural phenomena could be captured, stored, processed, and displayed digitally. He sketched a scenario where a young girl in an immersive environment would be able to
don a head-mounted device, and enter a virtual environment that would offer a “magic carpet ride” over the Earth’s surface, zooming to a sufficient resolution to explore and learn about the Earth and its human and physical environments from global to local scales over the Internet.

Although there is no singular definition of Digital Earth as it is understood today, Digital Earth in a very broad sense is an extensive integration of other advanced technologies including Earth observation, geographic information systems, global positioning systems, communication networks, sensor webs, electromagnetic sensors, virtual reality, and computational grids. Digital Earth can be generally understood as putting a representation of the Earth, and activities on the Earth, including temporal and spatial changes in the environment into a networked computer system, thus enabling information to be stored and transmitted as a service. This kind of digital replica of the planet can potentially reproduce all that is known about the real Earth. It could be presented as one of a class of services termed Digital X, a digital mirror of some complex system X, embedded in space and time, including a detailed representation of X, and software for acquiring, storing, manipulating, visualizing, and archiving that representation (Goodchild 2012). This notion of a digital world could be used to describe all digital types and forms – digital countries, cities, land, oceans, heritage, or events – showing a variety of applications of digital technologies for modeling, simulating, predicting, and representing the Earth globally and locally. The implementation of Digital Earth is highly associated with global and national information infrastructure development. The global, regional, and national development of Digital Earth may vary in different forms, such as improvements in spatial data infrastructure (SDI), and e-government initiatives. Furthermore, Digital Earth is seen as a potential global strategic contributor to scientific and technological developments and is promoted as a catalyst in finding solutions to international scientific and societal issues.

At the end of the last century, the vision of Digital Earth seemed almost impossible to achieve due to the limitations of the required high-resolution imagery, high-speed computer processing, broadband Internet, interoperability of systems, and – above all – data organization, storage, and retrieval. Today, however, the Digital Earth concept has come closer to reality. Vast, unprecedented quantities of spatiotemporal data are increasingly available at ever-accelerating rates due to the rapid development of Earth observation technologies, the increasing sophistication of new airborne and spaceborne sensors, new ground-based sensor networks, and crowd-sourced information. Achievements in computer technology, data processing, multimedia, and data storage and retrieval capabilities make it possible to realize 3-D presentations and descriptions of the Earth at multiple resolutions, scales, times, and categories.

Digital Earth initiatives

In 1993, the Clinton administration of the US government started construction of the “National Information Infrastructure” (NII), or as it was called the “Information Super Highway” for building an “Information Society.” In April 1994, President Clinton signed Executive Order 12906 for coordinating geographic data acquisition and access, establishing the National Spatial Data Infrastructure (NSDI) and paving the way for nascent Digital Earth initiatives.

In response to Al Gore’s 1998 speech, NASA and its federal partners initiated the Interagency Digital Earth Working Group (IDEWG) in 1999, in which 17 government agencies were
coordinated, including the National Oceanic and Atmospheric Administration (NOAA), Federal Geographic Data Committee (FGDC), US Geological Survey (USGS), Environmental Protection Agency (EPA), and National Science Foundation (NSF), to sustain development of applications for the Digital Earth enterprise. The initiative attempted to accelerate technological developments in standards, protocols, and tools toward the full realization of the Digital Earth vision.

NASA’s leadership for Digital Earth had waned by 2001, however, owing to a change in the US administration. The coordination of related activities was taken up by the Geospatial Applications and Interoperability (GAI) working group, a part of the US FGDC. Several outcomes were achieved in this three-year effort, including the development of interoperability standards for geospatial data sharing, the Web Map Service (WMS), the Digital Earth Reference Model (DERM), the NASA Digital Earth Testbed, the SRI International Digital Earth project, and a series of “Digital Earth prototypes,” such as Digital Earth alpha version applications for climate and weather tailored to four audiences: museums, education, governance, and journalism. An early academic example of Digital Earth research was the Alexandria Digital Earth Prototype Project (ADEPT), a “virtual learning system” developed at the University of California, Santa Barbara (UCSB), between 1999 and 2004. Further studies of Digital Earth at UCSB have since focused on analyzing Google Earth’s functionalities in comparison to the Digital Earth vision, and defining a Digital Earth system (Grossner, Clarke, and Goodchild 2008). Under the Obama administration, Digital Earth–related issues have been represented by the e-government initiative and US Group on Earth Observation with the vision of enabling a healthy public, economy, and planet through an integrated, comprehensive, and sustained Earth observation system.

Outside of the United States, Digital Earth concepts have attracted the attention of decision-makers, scientists, and entrepreneurs, and have been followed by worldwide discussions on this important topic. An INSPIRE (Infrastructure for Spatial Information in Europe) initiative was commenced and operated by 28 countries of the European Union to support environmental policy and overcome barriers affecting the availability and accessibility of relevant data (Annoni et al. 2011). The Digital Asia project was launched by Keio University in Japan to develop geospatial infrastructure for data sharing via the Internet and to provide people and communities in the region with easy access through the collaboration of potential agencies who participate on a voluntary or best-effort basis. Virtual Australia and New Zealand (VANZ) is an ambitious long-term vision to gradually create a post–Google Earth “system of systems” to monitor and simulate both countries’ environmental and social conditions. Scientists in China have paid much attention to building “Digital China” and have designed its framework.

China has been particularly active in its pursuit of Digital Earth, including the development of a digital country, digital cities, digital oceans, digital heritage, and other digital representations. It has proposed to build China’s digital resource platform by integrating and harnessing a vast variety of data, information, and knowledge by taking the whole of China as an object with geospatial coordinates as its base. “Digital China” would have features such as georeferenced layers of socioeconomic and environmental data; remote sensing imagery base maps; interface features such as virtual reality, seamless contiguity, smooth zooming, accurate querying, and measurability; and mechanisms for rapid or real-time updates and sharing of information. Digital provinces and cities have already been developed in China. “Digital Beijing” and “Digital Fujian”
DIGITAL EARTH

are examples of provincial Digital Earth projects initiated by the Beijing municipal government and Fujian provincial government, respectively.

In November 1998, the Geoscience Division of the Chinese Academy of Sciences (CAS) organized a high-level scientific forum in Beijing on “Environmental Resource Information and Digital Earth,” and then submitted “A Proposal for Developing China’s Digital Earth” to the state council in January 1999. The First International Symposium on Digital Earth (ISDE), themed “Towards Digital Earth,” was initiated by CAS and held from November 29 to December 2, 1999, in Beijing, thereby providing a venue for extensive international cooperation in implementing the Digital Earth vision. Approved by some 500 participants including scientists, engineers, educators, managers, and industrial entrepreneurs from 20 countries and regions, the 1999 Beijing Declaration on Digital Earth called for close cooperation and collaboration between governments, public and private sectors, non-governmental organizations, and international organizations and institutions to ensure equity in the distribution of benefits derived from the use of Digital Earth in developed and developing countries. The declaration also proposed that a symposium should be organized and held biennially in rotating locations by interested countries or organizations.

Guided by this declaration, a nonpolitical, nongovernmental, and not-for-profit international organization called the International Society for Digital Earth (also abbreviated as ISDE) was established in May 2006 in China. ISDE principally promotes academic exchange, scientific and technological innovation, education, and international collaboration on Digital Earth in order to further enhance the understanding of Digital Earth’s evolution, to keep pace with the progress of science and technology, and to advance Digital Earth worldwide.

In March 2008, ISDE in cooperation with Taylor & Francis based in the UK, launched an official journal named the International Journal of Digital Earth. The journal was accepted by Thomson Reuters for the Science Citation Index Expanded in August 2009, and reached an impact factor of 3.291 for 2014, ranking it fourth among the 28 journals in remote sensing. It was the first journal dedicated to the field of Digital Earth, and has become one of the world’s leading journals in geospatial information.

At the ten-year anniversary of Digital Earth, a group of scientists gathered together under the Vespucci Initiative in 2008 to re-evaluate Digital Earth in light of the many developments in the fields of information technology, data infrastructures, and Earth observation that had taken place. The group published “Next-Generation Digital Earth” as a position paper inviting comments and feedback.

The 2009 Beijing Declaration on Digital Earth was another milestone for advancing Digital Earth, evaluating the progress of Digital Earth’s development and recommending the use of integrated technologies to construct Digital Earth applications in the fields of global climate change, disaster prevention and response, alternative energy source development, agriculture and food security, and urban planning and management. In November 2009, ISDE was accepted by the Group on Earth Observations (GEO) as a participating organization, so as to jointly work together on implementing a ten-year plan to build a Global Earth Observation System of Systems (GEOSS).

In March 2011, ISDE organized the “Digital Earth Vision 2020 Workshop,” the outputs of which were “Next-Generation Digital Earth” and “Digital Earth 2020: Towards the vision for the next decade,” respectively published in the Proceedings of the National Academy of Sciences (Goodchild et al. 2012) and in the International
Journal of Digital Earth (Craglia et al. 2012), providing a big-picture outlook for Digital Earth’s development.

By the end of 2013, ISDE had organized eight international symposia and four summits on Digital Earth worldwide; additional details about these events are available on the ISDE website (www.digitalearth-isde.org). In addition, nine Taipei International Digital Earth Symposia have been held since 2003 by the Digital Earth Research Center, Chinese Culture University.

Components of Digital Earth

Digital Earth is a framework comprising conceptual and technological components that together form a system of geographically linked research and applications in the physical and social domains of the Earth, a digital modeling platform to monitor, measure, and forecast natural and human activity on the planet, and a visualization of the world. It is at least three-dimensional, four-dimensional if a temporal monitoring component is added, and five-dimensional if scale is treated as a variable instead of a set of discrete steps.

The vast availability of digital resources around the planet is the most basic component of the Digital Earth paradigm. Specific key technologies needed to build a Digital Earth are: computational capacity, mass storage, satellite imagery, broadband networks, interoperability, and metadata. Numerous techniques such as image fusion and automatic image interpretation are also used to facilitate the realization of Digital Earth. The NASA Digital Earth Office has identified four components of the Digital Earth system, including digital resources, interoperability, tools and technologies, and applications. National spatial data and information infrastructures, and Earth observations are also fundamentals for building Digital Earth.

The interoperability of the Digital Earth system defines the standards, terminologies, and protocols for communication between heterogeneous data sets. People from public and private sectors using desktop geobrowsers are also a component of Digital Earth, communicating with an infrastructure of high-performance servers over a high-speed communication network. They collect data and utilize the other components to enable communities to better understand and model the Earth.

Digital Earth platforms

A Digital Earth platform is a system that embodies a vision of Digital Earth. Taking spatial information as a theoretical basis, Digital Earth platforms aim to build a manageable system for visualization, quantitative analysis, and simulation of the Earth. Virtual globes and their portals (geobrowsers) are specific kinds of Digital Earth platforms. Virtual globes allow interaction with a 3-D representation of Earth (or another world), and provide the user with the ability to freely move around in the virtual environment by changing viewing angle and position. Compared to a conventional globe, virtual globes have the additional capability of representing many different views of the surface of the Earth. These views may be of geographic features, man-made features or abstract representations of, for example, demographic quantities.

A geobrowser, first developed in 1993, is a client in a web browser or a stand-alone application that is capable of accessing georeferenced data and providing multidimensional visualizations to end users. The advent of the Digital Earth vision has advanced web mapping technology and has propelled geobrowser research to a completely new phase characterized by applications that strive for greater realism through the
use of 3-D globes and immersive environments. The Digital Earth conceptual framework model (Foresman 2008) consists of a foundation of standards, disciplinary content and applications, and the aggregation of the three pillars for sustainable development (economic, social, and environmental) through 3-D geobrowsers. In December 2002, the Chinese Academy of Sciences hosted the first International Workshop on Digital Earth 3-D Geobrowsers at the Institute of Remote Sensing Applications, and the second 3-D geobrowser workshop was convened at the University of California, Santa Barbara, in March 2003.

The emergence of Web 2.0 (including volunteered geographic information) feeds virtual globes with rich, user-controlled information, including images, videos, sounds, and written content. Virtual globes use a variety of hierarchical tiling structures known as discrete global grids (DGG) to enable rapid zooming, and tiles pre-computed on servers to avoid extensive local computation. Sophisticated level-of-detail management allows the field of view to be refreshed at video rates (Goodchild et al. 2012). DGG systems usually contain increasingly finer resolution grids that represent the Earth with a tessellation of nested cells designed to ensure a repeatable representation of measurements that are better suited to today’s requirements and technologies than our legacy coordinate systems that were designed for repeatable navigation and manual charting. For example, the PYXIS Digital Earth Reference Model is such a system for geometric coordination and digital indexing on an optimized discrete global grid. Another example is from GeoFusion, Inc., whose technology includes features such as a fast and versatile rendering engine, dynamic terrain tessellation on unique global grids, high-quality image and terrain processing, and an application programming interface (API).

On March 12, 2014, the Open Geospatial Consortium announced the formation of a new Technical Committee Standards Working Group to explore and propose terms for a standard to enable interoperability through the use of Discrete Global Grid Systems (DGGS), which would better serve the design of virtual globes used to interact with Digital Earth.

Generally speaking, Digital Earth systems could be classified into two types: scientific and commercial. Scientific systems mainly contain information about research from different fields and present analytical results to the public. NASA World Wind, released in 2004, is both a geobrowser for public-domain scientific data, as well as a platform for land, sea, air, and space mission operations. It provides graphic access to terabytes of imagery and elevation models for planets and other celestial objects including satellite and other data of the Earth, moon, Mars, Venus, and Jupiter, as well as astronomical data made available through the Sloan Digital Sky Survey. The Eyes on the Earth software of the NASA Jet Propulsion Laboratory allows users to travel in time and explore NASA satellite visualizations in 3-D. It presents recent data on air temperature, carbon dioxide, carbon monoxide, sea level, ozone, ice, and water. It follows NASA satellites and provides information about how they collect critical data about the Earth’s atmosphere, land, and oceans, and also provides views of Earth from space, with daily updates. NASA Hyperwall, first developed in 2002 by NASA’s Advanced Supercomputing Division, is now capable of rendering one quarter billion pixels. The system helps researchers display, analyze, and study high-dimensional datasets in meaningful ways, allowing the use of different tools, viewpoints, and parameters to display the same data or datasets. The CAS Digital Earth prototype system released in 2006 is a platform for conducting applied research in Digital Earth.
Digital Earth

Sciences and demonstrating results in a virtual reality environment (Guo, Fan, and Wang 2009). The Earth Simulator developed in Japan consists of a 640-node super-computer that is used in various fields of research including climate change projections and modeling solid Earth interior dynamics. The Earth Simulator has enabled scientists to run weather forecasts and climate projections at more than 1000 times the resolution of conventional simulations. In addition to the above, Australia initiated the BLUELink program for creating a global ocean forecasting system that provides information on ocean conditions to help manage Australia’s diverse area of maritime operations, and a Glass Earth project for using 3-D visualization and geological modeling technologies to unveil 1-km sections beneath the Earth’s surface. The new “UNCOVER” initiative is underway to help Australia’s geosciences community understand the Australian crust and its mineral systems beneath the regolith – the under-explored layer of unconsolidated rocks and soil covering about 80% of that continent.

Many commercial virtual globes are available today. Most of these globes share similar functionalities, although they differ in some features. Digital Earth systems with general applications are often free to the public; however, enhanced versions with more powerful functionalities must be purchased. Popular software has included Google Earth, Skyline Globe, Bing Maps (formerly Microsoft Virtual Earth 3D), ArcGlobe, Leica Virtual Explorer, Yahoo Maps, Marble, Unidata’s Integrated Data Viewer, Diginext’s VirtualGEO, EV-Globe, GeoGlobe, GeoBeans, and SuperMap GIS. Among these systems, the most well-known is probably Google Earth. Released in 2005, Google Earth’s innovative techniques for organizing and presenting data have enabled hundreds of millions of people of all ages worldwide to view and share scientific information about the planet Earth, without the need for prior GIS training or software purchase. It allows access to geospatial information, with the ability to show fine-scale features in high-resolution images. Its functionality for zooming from space right down to the street level, flying over terrain and structures, and showing a high level of detail – even individual people – is very reminiscent of the “magic carpet ride” found in the 1998 Gore speech. With Google Earth, people are able to explore the Earth, moon, Mars, sky, ocean, and 3-D buildings, as well as landscapes of the past with historical images. Google’s other widely used geobrowser product is Google Maps. The publication of the Google Maps API has enabled users to become producers of geographic information and contributors in the development of Digital Earth initiatives.

Many countries use virtual globes as their portal for managing national spatial data. In April 2007, Geoportail was developed on the basis of Skyline Globe and launched by the French government as its national geospatial information network and distribution system through a 3-D virtual globe platform. Although similar to Google Earth, it provides much more detailed information for France with higher resolution images than those provided by Google Earth. Such national geoportals can be found for Finland, Ireland, China, India, Luxembourg, Italy, Philippines, and several other countries. Each of these geoportals contributes to the development of their national spatial data infrastructure.

At a global level, the Group on Earth Observations developed a portal (GEOPortal) for GEOSS. The GEOPortal, an operable Digital Earth, offers a single web-based access point for users seeking data, imagery, and analytical software packages relevant to all parts of the globe. It connects users to existing databases.
and portals and provides reliable, up-to-date, user-friendly information that is vital for the work of decision-makers, planners, and emergency managers. It also allows users to search datasets or contribute to the portal’s resources and data discovery tools, and link worldwide communities practicing in the nine societal benefit areas defined by GEO: disaster, health, energy, climate, water, weather, ecosystems, agriculture, and biology.

These virtual globes have contributed enormously to the practical implementation of many features of the Gore vision, but whether Digital Earth has been realized through the achievements of various virtual globes has been questioned in the literature. Goodchild (2008) provides an analysis of the uses of Digital Earth with comparison of the content of Gore’s speech and the features of Google Earth. Google Earth has a passing resemblance to the vision of Digital Earth and has realized some functions of Digital Earth (Grossner 2007), however, it is only a simplification and approximation of Digital Earth. Virtual globes can “embed” information and media for visualizing data from various sources, but the mechanisms for collective discovery are largely absent. In geobrowsers there is a lack of ability to analyze and process integrated data, and there has been a failure to harness grass-roots efforts toward generating the “vast quantities of georeferenced data” that should be available in a Digital Earth. Furthermore, the functions of reconstructing past scenarios and predicting the future in Gore’s vision have not been realized.

Digital Earth prospects

Gore’s Digital Earth aimed to develop a single geoportal that would present an integrated view of everything that is known about the planet’s surface and near-surface, along with views of the past and predictions about the future (Goodchild 2012). The next generation of Digital Earth would be distributed, with multiple connected infrastructures based on open access and participation across multiple technological platforms to address the needs of different users (Goodchild et al. 2012). In addition, Digital Earth in five to ten years would have the following features: dynamic and interactive exploitation of the full range of information flows from sensors and people; synthesis of heterogeneous information; metrics of quality and trust of both data inputs and outputs; mechanisms for being more participative as people become geoinformation providers and analysts; ease of use with different levels of functionality available to different audiences; and a ubiquitous frame of reference with information to be continuously updated (Craglia et al. 2012). Newly emerging citizen science, such as crowd-sourcing and volunteered geographic information, encourages people to become actively involved in the acquisition of data on many aspects of Earth-related phenomena, such as disasters or disease outbreaks. The use of citizens’ data to complement official data on forest fires in Europe, for example, has already been undertaken (Craglia, Ostermann, and Spinsanti 2012). In the future, citizens will more likely improve their understanding of the forces that shape society, such as measures that ensure global environmental sustainability.

The literature on the future of Digital Earth also addresses ethics and education. Ehlers et al. (2014) developed a set of guiding principles for realizing Digital Earth: (i) All humankind must have unrestricted access to Digital Earth; (ii) Digital Earth must be developed to improve the welfare of humankind as a whole; and (iii) Digital Earth must always be “on” – immediately accessible, with known precision and accuracy, comprehensive, fully interactive, and available anywhere at any time. In addition, it is foreseen that a set of underlying principles, that
is, Digital Earth ethics, to guide the development, implementation, and application of Digital Earth should be proposed so that Digital Earth can deliver its anticipated benefits for all humankind. Digital Earth education has been put on the agenda in Europe (www.digital-earth.eu). A Digital Earth curriculum has been proposed to promote the Digital Earth vision to the general public, and the idea of Digital Earth as a “knowledge engine” makes it particularly relevant to education.

References

A digital elevation model (DEM) is one of the most important spatial datasets in many geographical information systems (GIS). It is defined as an ordered or unordered digital set of ground elevation (spot height) for terrain representation. In literature, there are three commonly used terms related to this, namely, digital elevation model (DEM), digital terrain model (DTM), and digital surface model (DSM). The distinction among the three terms is not clear and universally agreed, but some common tenets may apply, as follows.

- A DEM is a “bare” land surface model, which is supposedly free of trees, buildings or other “nonground” objects.
- A DSM is an elevation model that includes the tops of everything, including buildings, treetops, and ground where there is nothing else on top of it.
- A DTM is a more generic term referring to a DEM with one or more types of terrain information, such as terrain morphological features, drainage patterns, and soil properties. When dealing with only one terrain information type (i.e., height), this is a DEM. Obviously, DEMs is a subset of DTMs (Li, Zhu, and Gold 2005).

Tasks of digital terrain modeling

A few major tasks can be identified in the study field of DTM, namely, terrain data capture, DEM generation, DEM manipulation, DEM interpretation, DEM visualization, and DEM application (Hutchinson and Gallant 1999). The objective of data capture, DEM generation and manipulation is to achieve digital representation of terrain. The ultimate outcome from these tasks is an error-free and “hydrologically sound” DEM at the right scale. The rest of the tasks, DEM interpretation, visualization, and applications, can be categorized in a general field of terrain analysis, which aims to derive terrain parameters, morphological features, and other terrain-controlled environmental factors from DEM. The overall relationship between the DTM tasks is illustrated in Figure 1.

Topographic data and topographic map

The foundation of a DTM is the topographic map. A topographic map is a tool for the transformation and dissemination of geographical information of a region, and has a long-standing and ascendant place in human history. One reason for this is that a topographical map is an image of the real world. Without leaving home, a person can read the map of a region of interest and understand its natural environment, society, economic conditions, and terrain. Another reason is that the natural and social conditions reflected in the topographical map can, through
the interpretation and discovery of numerical and graphic data, form a basis for inferring further information not directly displayed on the map.

Traditionally topographical data are acquired through field survey, by measuring horizontal and vertical positions. The outcomes of such field survey are typically represented as contour maps. In the digital era, the large collections of contour-based topographical maps naturally become the major source for generating a DEM, typically through time-consuming high-cost digitization processes. More advanced technologies have been developed to acquire digital elevation data, including digital photogrammetry, satellite remote sensing, LiDAR (a portmanteau of “light” and “radar”) and InSAR (interferometric synthetic aperture radar), and so on.

Digital elevation data acquisition techniques vary in performance, cost, time, and accuracy, with advantages and disadvantages in different aspects. A simple comparison between the techniques is shown in Figure 2.

**Figure 2** Comparison between different DEM data acquisition techniques (the color shows the speed of data acquisition, the darker the slower) (adapted from Zhou and Liu 2006).

**Digital terrain representation**

Whatever the data acquisition method employed, the resulting data are merely a set of discrete sample points (spot height). They are independent of each other without any inherent relationships among them. In order to fully represent the terrain surface, a model has to be established to define the relationships between these points so that a continuous surface can be formed in a 3-D space.

Three data models are commonly used to construct a DEM:

1. regular grid structures (grid, lattice, raster);
2. triangulated irregular networks (TINs);
3. contour structures.
Regular grid

With the regular grid data structure, a terrain surface is represented by a matrix of spot heights, assuming there are slopes between these spot heights, thus forming a continuous surface (Figure 3, Figure 4, Figure 5). The position of any location is specified by its relative position to the origin in terms of column and row numbers, thus the positional accuracy of a given DEM is directly linked to the grid resolution (Figure 3).

Regular grid data structure is currently widely used for DEMs. It is simple to structure and compute, facilitating the automatic generation of photogrammetric and remote sensing imagery. Its structural characteristics, such as its fixed resolution and regular arrangement of data points, however, limit its flexibility and accuracy in representing topography. At the same time, producing the grid with randomly distributed sample data (e.g., samples acquired by ground survey, analytical aerial mapping, and map digitization) requires interpolation technologies. This not only causes the loss of terrain features by the smoothing effect but also results in non-natural phenomena, such as pseudo-depressions, increasing the complexity of later applications.

Triangulated irregular network

Triangulated irregular networks (TINs) use non-crossing, nonoverlapping triangular networks to simulate topographical surfaces. The size and shape of the triangles depend on the position...

</table>
and density of randomly distributed samples. The horizontal and vertical positions of the three vertices of a triangle determine the extent and orientation of a triangular facet in the 3-D space (Figure 6) and the interconnected facets then forms a representation of the terrain surface (Figure 7).

The advantage of a TIN model is that it allows stratified sampling of ground elevation. Where the terrain surface is flat, less sample points can adequately represent the surface. In rugged terrain, on the other hand, more sample points may be used to preserve details of the terrain features. Additionally, a TIN can take into account various topographical feature points (e.g., peaks, pits, and saddle points) and lines (e.g., ridges, valleys, and cliffs), allowing it to accurately approximate complex topographical surfaces from relatively few sampling points. A TIN, however, has its drawbacks. Its storage and management, and data manipulation process are relatively complex, costing significantly higher in computation compared with grids, particularly when a large dataset is used.

**Contour**

A contour-based DEM is composed of a set of contour lines that are “tagged” with their corresponding elevation values. The contour lines are stored by ordered coordinates and can be thought of as polygons or polygon-arcs containing elevation values (Burrough and McDonnell 1998). The contour and flow path (i.e., the normal of the contour line) can be used to divide the topographical surface into irregular polygons (Figure 8), which can simplify the analysis and computation of hydrological models. This type of structure is, therefore, relatively common in hydrological modeling and related analytical geosciences.

The various topographical factors and features in DEM applications can be produced from each of the three DEM structures, although the grid DEM is the simplest, and relatively more efficient. Because of this, at present, DEMs have been commonly defined as grid structures (Theobald 1989) and many countries provide DEM data only in the regular grid matrix format. Advantages such as the high degree of
automation of data collection, the simplicity of computation and database management, and the ease of integration with remote sensing and raster GIS have given grid DEMs a dominant position in applications (Tang 2000). Nevertheless, digital terrain modeling data structures are not static and a large number of algorithms allow for conversion between different structures of DEM. Therefore, in selecting data structures for digital terrain modeling, the data source, technical requirements, and the application aims must all be considered.

Figure 8  A contour-flow path network.
Digital terrain analysis

Digital terrain analysis (DTA) is defined as the information extraction method and technique that derives terrain parameter computation and feature extraction from DEMs. The DTA is also termed “geomorphometry” in literature (Hengl and Reuter 2009). The core task of DTA is to find a balance between the influencing factors in the course of complex real-world geography and simple, clear, efficient, and easy-to-understand abstractions through computer realization. There are many parameters that can be used to describe terrain features and spatial distribution, and the classifications of terrain attributes vary across different disciplines and fields. Within the scope of the earth sciences, terrain attributes can be separated into ordinary terrain attributes (e.g., elevation, slope and aspect) and hydrological attributes (e.g., terrain structure recognition, watershed segmentation). In terms of the relationship between topographical elements, there are single attributes and compound attributes. The single attributes are derived directly from DEM, whereas compound attributes are functions of several single attributes, often used to describe spatial variation, and usually constructed by modeling empirical relationships or simplified natural mechanisms. In terms of computation, terrain attributes can be divided into local terrain attributes and nonlocal attributes.

Based on the relationship and computation characteristics of terrain elements, the terrain attributes can be grouped into four types: surface parameters (parameters), morphological features (features), statistical attributes (statistics), and compound attributes, as summarized in Tables 1–4 (Wilson and Gallant 2000; Zhou and Liu, 2006).

Terrain surface parameters (Table 1) have clear mathematical expressions and physical definitions, such as slope, aspect, and curvature, and can be directly calculated on a DEM. The results of parameter calculations have actual physical meaning and are scalar quantities, and can be directly assessed by the measurements in the field or on a topographical map. The calculation of parameters is usually realized through differential or surface fitting techniques in a local window of a grid DEM.

Terrain morphological features (Table 2) are qualitative expressions of surface morphology and characteristics, and can be directly extracted from a DEM. The distinguishing quality of features is that while their definition is clear, their boundary conditions have ambiguous qualities, making them difficult to represent using mathematical expressions. An example is the division of watershed units, as it is often difficult to define the watershed boundaries. In accordance with the spatial features and relationships in surface morphology, the surface’s morphological features can be extracted and used to determine terrain elements, such as topographical feature points, geomorphological feature units, hydrological elements, topological structure lines, and visibility. Terrain morphology features are commonly extracted in accordance with simplified models of the analysis of spatial distribution relationships between elevation points or the motion mechanisms of surface material, through simulation algorithms and realizations, such as the water-path algorithm used to determine hydrological elements. Results obtained through terrain morphological features are commonly expressed in the form of categorizations; statistical methods can be used to undertake testing of these categories.

Terrain statistical attributes (Table 3) refer to the statistical properties of the terrain surface in a region. Statistical methods are applied to the DEM to derive measurements of terrain nature, such as correlation, regression, trend surfaces, and spatial clustering. The statistical attributes are

also used to find the variation patterns or implied links between factors, and to select appropriate factors or parameters to construct geographical models, so that the spatial patterns governing the evolution of terrain can be explored at a deeper level.

Compound attributes (Table 4) are typically computed based on surface parameters and terrain morphological attributes, using models of relevant applied science (such as hydrology, geomorphology, or soil sciences). Unlike the surface parameters and terrain morphology characteristics previously mentioned, compound terrain attributes are not directly computed or extracted from a DEM, hence they are named “secondary topographic attributes” (Wilson and Gallant 2000). Compound terrain attributes have practical significance to a number of fields of application, but it is difficult to test the results of their practical applications. Their physical implications also require professional measurements and interpretation within the field of application.

Tables 1–4 show the direct and indirect links between compound attributes and surface parameters such as slope, aspect, catchment area, and specific catchment area (SCA). These parameters have broad applications in such analytical geosciences as hydrology, geomorphology, or soil sciences (Zhou, Lees, and Tang 2008). For example, slope can be used to calculate flow direction, which can be used to calculate SCA. The SCA can further be used to discern geomorphological structure lines (ridges and valleys), and used with slope as the input parameters of topographical wetness indexes, flow strength, and so on.

Besides numerical analysis, another important area of DTA is the DEM visualization. DEM visual representation is perhaps the most impressive task of DTM, and it is clearly a focus of development for commercial GIS software. In addition to rapid, realistic, accurate, and clear visual presentation of original DEM or derived data, the visual analysis in DTA is also focused on enhancing the visual impact of terrain features of interest, and conveying information on surface parameters, morphology, and compound attributes.

**Summary**

Digital terrain modeling is an important component of GIS. Almost all current GIS software has some kind of DTM function in its functional capability specifications. In recent years, the rapid development of elevation data acquisition techniques has been witnessed. Numerous public-accessible global and national DEM databases have become available at various spatial scales. These advancements will certainly encourage more advanced applications in a broader application domain.

DTM, in a broader sense, is not only the data representing terrain surface but also the provider of geographical analytical functions that derive and extract geographical/geomorphological parameters and features from digital elevation data. In many GIS application projects, particularly those dealing with environment, natural resources, and urban lives, use of DTM data and analytical functions has been a common practice.

In the foreseeable future, it is expected that DEMs will progress in the following aspects:

- more rapid and cheaper acquisition of high-resolution digital elevation data;
- more advanced generalization/extraction methods and algorithms in constructing multiscale DEMs from very large elevation datasets;
- broader adoption and integration of DTM data and techniques in applications of specific application fields;

Digital soil mapping and pedometrics

Bradley A. Miller
Iowa State University, USA
Leibniz Centre for Agricultural Landscape Research (ZALF), Germany

Digital soil mapping (DSM) is the computer-assisted production of maps that present either a single soil property or specified combinations of soil properties, based on a defined classification system. Digital soil maps differ from soil maps traditionally produced on paper by being a visualization of a geographically referenced database. Although a digital soil map can be directly generated from a paper map, digital soil maps are increasingly being created from digital data by processes that are explicitly defined. The format of the spatial data created by DSM is particularly useful as model parameters for precision agriculture, land management, and other environmental issues.

Due to the extent and complexity of the soil landscape, creating soil maps requires some form of spatial prediction and generalization. Methods of prediction commonly utilize the concepts of spatial association and spatial autocorrelation. DSM applies the data and tools of geographic information systems (GIS) to improve the accuracy and efficiency of soil landscape models. GIS can quantitatively utilize data from digitized legacy maps, field samples georeferenced by global positioning systems (GPS), and data products from remote and proximal sensing to model the soil landscape.

Predictor variables (base maps)

DSM makes use of parameters from a large variety of sources, each of which has strengths and weaknesses. With the current state of technology, however, they all have roles in the calibration and validation of digital soil landscape models.

GIS can utilize legacy maps through digitization, but spatial accuracy is a major concern when utilizing maps that were not initially created for the GIS environment. One of the reasons for this is that the meaning of cartographic scale has changed between maps produced on paper and those produced digitally. With paper maps, the display size is fixed, meaning that the map audience is most likely viewing the map at the same scale that the mapper did. This limitation creates a natural linkage between map detail, accuracy, and cartographic scale, which is no longer the case in GIS environments. In a GIS environment, the user is able to freely change the cartographic scale by zooming in or out, allowing the map to be viewed at a greater (or lesser) level of detail than the map maker intended or than is supported by the original data.

Another source of information for DSM is direct points of observation. Soil samples from the field can have their location recorded accurately by GPS. The attributes of that location can be based on field observations or lab analysis. These point observations are commonly coupled with the strategies of spatial association or spatial autocorrelation to fill in the areas between observations for a more complete coverage of the map area.

Proximally and remotely sensed datasets are collected by noninvasive methods that provide
DIGITAL SOIL MAPPING AND PDEOMETRICS

greater areal coverage than data collected by point sampling. Proximal sensing commonly uses geophysical techniques such as electromagnetic induction. Remote sensing uses aerial sensors to detect the spectral distribution of electromagnetic radiation being emitted or reflected by the soil surface. Both of these technologies detect characteristics that can be directly correlated to soil properties, and thus, enable DSM. Because proximal sensing tends to detect belowground features and remote sensing tends to detect surface features, they sometimes offer different perspectives on the soil environment.

In addition to model variables that are directly measured, useful information can be generated from the analysis of variables to create new parameters. Land-surface derivatives, for example, are parameters that are beneficial to DSM. Elevation alone can be used as a predictor of soil properties. However, calculated derivatives of elevation, such as slope gradient, slope curvature, and location on the slope (Ruhe and Walker 1968; Walker and Ruhe 1968), can all provide even more and potentially better information about contextual characteristics of the soil environment.

Apparent soil patterns differ due to analysis scale (i.e., modifiable area unit problem), unique combinations of processes, and the soil attributes of interest. For example, a continental scale map of soil organic carbon shows that carbon relates broadly to climate and the associated ecological communities (Figure 1a). At more local scales, climate is modified by topography, which produces patterns of soil organic carbon that are better distinguished by terrain parameters (Figure 1b). However, the influence of topography can be diminished in some landscapes where parent material or climate characteristics negate topographic processes, for example when the erosion of soil material is suppressed due to high infiltration rates, or in arid climates where all soils are low in organic matter. Additionally, contextual parameters can be calculated at virtually any scale. Depending on the phenomenon being modeled, certain analysis scales will be better suited for the spatial prediction of soil properties. The vast quantity of parameter options and unique conditions at different sites make DSM a challenging, stimulating, and potentially enlightening endeavor.

DSM models

Traditional soil maps are made by synthesizing information gathered in the field with a variety of pre-existing maps, such as topographic maps, geology maps, and aerial photographs. These pre-existing maps are called base maps because they provide spatial reference for the mapper to transfer their mental model of the soil landscape into a graphical representation of the soils they see. However, in addition to spatial reference, the base maps can provide information about the environmental context or other attributes that are spatially associated with soil properties. Due to human limitations, only a few base maps can be layered at a time. Also, when the maps are overlain, there is a potential for misalignment. DSM improves upon this process by enhancing spatial accuracy, quantifying the synthesis of base maps, and increasing the number of base maps that can be synthesized at once, all in a more time-efficient manner. The quantitative synthesis of a series of base maps is particularly important as it allows for a fully documented inclusion of many data layers. The analysis of different spatial datasets (aka maps) together is accomplished digitally within a geographic information system. The challenge is to know how and which layers to synthesize, in order to make the best map for the desired purpose.
Figure 1  (a) Global map of soil organic carbon generated from the Harmonized World Soil Database version 1.2 (FAO/IIASA/ISRIC/ISSCAS/JRC 2012). (b) Local scale map (approx. 40 km²) of soil organic carbon generated by digital analysis of remote sensing data. The local scale map is shown in a three-dimensional perspective to illustrate the relationship with terrain. However, the modifying effect of land use is also affecting the spatial pattern at this resolution. Source: (a) FAO/IIASA/ISRIC/ISSCAS/JRC. 2012. Harmonized World Soil Database (version 1.2).

Recognizing the value of the vast body of knowledge that has been accumulated by field soil scientists using traditional soil mapping methods, expert knowledge models attempt to capture and convert the logic in the expert's mental model into digital techniques. Expert knowledge capture includes the selection of model parameters and analysis structure.
DIGITAL SOIL MAPPING AND PEDOMETRICS

Strategies for capturing expert knowledge range from directly questioning the expert, to analyzing the map produced by the expert. Asking the expert to explain their mental model is problematic, however, because tacit knowledge is not always completely quantitative or explicit. Conversely, analysis of the expert’s map is complicated by the multitude of considerations that were used to construct it. For example, different map units can be based on different soil attributes as determined by perceived value, or unique soil areas could be omitted due to issues of scale.

Whether based on tacit knowledge, driven by sample data, or some combination of the two, some type of synthesis of the available data is always needed to accurately model the soil landscape. Popular modeling approaches include regression, kriging, cluster analysis, decision trees, and machine learning (Scull et al. 2003). Because DSM is a rapidly evolving field, new versions of these approaches are continually being developed. Although there is constant innovation in DSM, modeling approaches generally apply the concepts of spatial association, spatial autocorrelation, or some combination of the two.

Fundamental strategies of DSM

Spatial association is the similar distribution of attributes within geographic space. In cases where there are known spatial associations, the spatial distribution of a measured attribute can be used to predict the distribution of an unmeasured attribute. This is particularly useful when certain attributes are more easily measured than the desired attribute. For example, soils in prairie or steppe ecosystems tend to have a thicker horizon of topsoil enriched with organic carbon. Also, the soil particle size distribution can be used to predict soil hydraulic properties. In soil science these relationships are commonly referred to as pedotransfer functions (Bouma 1989). Computer models that utilize this concept are generally referred to as soil inference systems. A challenge for DSM strategies utilizing spatial association is the selection of the optimal parameters and models for the soil properties of interest. Not only is there an ever-increasing variety of measurements available, many of those measurements are scale dependent, which multiplies the number of parameters to choose from.

A classic example of spatial association in soil mapping is Dokuchaev’s (1967/1883) factors of soil formation: climate, organisms, relief, parent material, and time. Because each of these parameters describes the environment affecting soil development, this approach to soil mapping can be described as environmental correlation. The majority of parameters used in DSM models can be categorized under these factors. However, related soil properties that are more easily measured than the property of interest are also commonly used. Some examples of these kinds of pedotransfer functions are the relationship between clay content and electrical conductivity, or predicting soil erodibility from the combination of particle size and organic matter content data.

Spatial autocorrelation is the covariation of properties within geographic space. For DSM, spatial autocorrelation relies on the increasing similarity of soil properties with increasing proximity. Most spatial interpolation methods utilize this concept to predict attributes between measured observations. Various versions of kriging, a type of spatial interpolation based on a Gaussian process, have become popular in DSM because of their internal quantification of spatial variability. Because many soil properties and conditions are difficult to observe at all locations, especially those below the surface, some form of interpolation is often needed to estimate attributes between points of observation. The challenge to this problem lies in the requirement of adequate sample density or support for interpolating
across the desired area. Different soil properties have different ranges of spatial autocorrelation, requiring different sampling densities for properly constructing an interpolation model.

**Representation**

A digital soil map needs to be stored and visualized in one of the data models available in GIS. The most common of these are the vector and raster data models. Vector data models are the most similar to traditional soil mapping and are thus most often used for digitizing legacy (paper) maps. Raster data models can store data more efficiently, but are restricted to a grid of rectangular delineations, or cells (Figure 2). Raster data models are becoming increasingly popular in DSM for two reasons. First, better data storage efficiency allows for faster data processing and soil maps of larger extents, which are particularly needed for environmental models. Second, increasing the resolution of the raster (decreasing the cell size) brings the map representation closer to the theoretical concept of soil as a continuous surface.

An additional strategy to represent the soil landscape as a more continuous surface is fuzzy logic (Burrough 1989). With fuzzy logic, a location can have partial memberships in multiple attribute classes, that is, a map may contain delineations that have partial membership in soil A and B, whereas on a traditional map the delineation would have been forced to be either soil A or B. Typically the degree of similarity of a location to a class is expressed on a numeric scale from 0 (nonmembership) to 1 (complete membership). Classes can then be created from the data (e.g., fuzzy k-means) or based on predefined classification systems. Fuzzy memberships can be used throughout the DSM process and can be simplified at any time. The process of converting fuzzy memberships into a Boolean classification is referred to as hardening.

**Uncertainty (error)**

Uncertainty is an important aspect of digital mapping and modeling that will need to be added to future soil maps. In this context, uncertainty is a quantified expression about the limit in precision for the map data. Information about uncertainty must be sufficient for the user to determine the fitness of the soil map for the intended purpose. Uncertainty in a soil map can propagate from measurement inaccuracies as well as from spatial and temporal variation (Heuvelink 1999). Errors in spatial position and soil property analysis both contribute to measurement error. To simplify the problem, spatial position is commonly assumed to be correct, allowing the error to be more concisely expressed as the difference between the modeled value and the measured value at particular locations. For soil attributes, this error can be communicated stochastically or summarized for the entire map area with statistics like the coefficient of determination ($R^2$) or root mean square error (RMSE). Because soil classification is a categorical attribute, tests of digital mapping accuracy in this case tend to express error as percent agreement with validation points, a confusion matrix, or a kappa statistic. Geostatistics (e.g., kriging) has recently become popular because of the need to quantify uncertainty and its ability to model error across the map area.

Spatial heterogeneity is also an important consideration for determining the fitness of a spatial dataset for a given use. Generally, interpolation methods estimate an attribute value for a central point within a map delineation and assign that value to the entire delineation area. For this reason, spatial interpolation approaches
Figure 2  Example of (a) a traditional soil map (Dideriksen 1986) side by side with (b) a digitized version of the same map in a polygon (vector) data model (Soil Survey Staff 2013). In (c), these data have been converted to a raster data model. In the digital format, the spatial soil data can be easily incorporated into models for a variety of purposes. The goal of digital soil mapping is to leverage new digital data and techniques to improve the soil map. Source: (a) Reproduced from Dideriksen 1986. © US Government; (b) and (c) Produced from data provided by the Soil Survey Staff 2013. © US Government.
seek to increase the resolution to as high as can be supported by the data and computational constraints. However, it is difficult to have a sufficiently high density of data points covering large spatial extents, and there are few technical restraints for interpolating a resolution finer than that supported by the data. In contrast, traditional soil mapping uses spatial association to divide the landscape into as many pieces as possible. The size of map delineations is limited by the resolution of the base maps, thus the size of the delineations reflects spatial uncertainty. Attribute uncertainty is then expressed by a range of values associated with the unique combination of predictors observed within the delineation area.

Pedometrics

Pedometrics is the application of mathematical and statistical methods for the study of the distribution and genesis of soils, often with a focus on quantifying uncertainty (De Gruijter, Webster, and Myers 1994). The establishment and growth of pedometrics in the early 1990s followed the post-quantitative revolution study of pedology. As digital techniques of soil mapping are by definition based on quantified datasets and procedures, DSM is nearly synonymous with pedometrics. However, pedometric analyses tend to focus on the use of geostatistics. Those who study pedometrics advocate for the use of geostatistics because it is based on random function theory, which enables the modeling of the uncertainty associated with spatial estimation. Like pedology, in addition to soil mapping, pedometrics includes the study of soil formation.

Although the spatial distribution of soils and their formation factors are intimately linked, they do not necessarily have to be studied together. For example, geostatistics can interpolate between sample points without regard to pedogenesis. Conversely, soil research can focus on vertical processes in the soil profile without regard to the horizontal dimension. However, each research concentration benefits from the consideration of the other. This is illustrated by the use of Dokuchaev’s soil formation factors, which began as a tool for spatial prediction, later applied as a method to reduce independent variables in pedologic research (e.g., Jenny 1941).

Information about both individual pedons and their place in the soil landscape is essential for understanding the soil system. The innovation of geographic information systems and other geospatial technologies has reinvigorated interest in soil geography, leading to a recent explosion in ideas and research for improving soil maps.

Disability

Edward Hall
University of Dundee, UK

Disability is generally understood as a physical or mental impairment that constrains an individual’s participation in the activities and sites of “normal” society; this biomedical definition is now challenged by a social constructionist conceptualization that locates the “problem” of disability in the exclusionary landscapes and attitudes of mainstream society. Human geography’s long-standing engagement with disability reflects this shifting debate: from studies of the spatial distribution of medically defined conditions, such as multiple sclerosis, to identifying the physical and attitudinal barriers to the accessing of public space, and from mapping the everyday social geographies of people with intellectual disabilities to, more recently, examining the role of online environments for those on the autistic spectrum. In short, disability geography studies the interactions between people with impaired bodies and minds and social and spatial contexts; a spatialized perspective has made a unique and incisive contribution to the understanding of disability and the lives of disabled people.

Disabled people have experienced much positive change since the mid-1990s, with an increasing presence in public spaces, workplaces, education, sport, and the media. Antidiscrimination legislation in many countries and United Nations support for the human rights of disabled people, along with a growing disability political movement, have contributed to this gradual transformation. The emergence of an aging and increasingly chronically ill population in the Global North has emphasized the growing commonality of the experience of disability; however, many disabled people continue to experience discriminatory attitudes and inaccessible environments, and hence limited opportunities, in many spheres of life; there is also a growing awareness that in the Global South, where the majority of disabled people are located, everyday lives remain extremely challenging.

The study of disability in the discipline has its roots in medical geography; indeed, geographical analyses of disability have, perhaps unsurprisingly, reflected changes in social science and popular conceptualizations at large. Medical geography understood disability to be within its remit as a set of clinically defined conditions, and applied the techniques of epidemiology to map and study its incidence and to examine causation; examples are studies of multiple sclerosis and schizophrenia and their possible environmental causes. While such studies are now questioned for their uncritical adoption of a medical model of disability, they did succeed in identifying the unequal spatial distribution of disabled people, and emphasized the importance of location for the production of disability. Another quite different research strand that emerged from a broader social geographical concern with welfare and the “crisis” of urban deprivation was the deinstitutionalization of disabled people (including people with mental health conditions and intellectual disabilities) from asylums and other large care sites in the 1970s and 1980s. This research focused attention on the role of spatial context in shaping the lives of disabled people, including barriers to access in urban
environments and transport systems for people with mobility problems (Hahn 1986); and the discrimination targeted at people with mental health conditions, together with the absence of care and support services, in local communities (Dear and Wolch 1987).

The phrase “asylum without walls” was coined to reflect the experiences of many disabled people, now spatially included yet remaining socially excluded, in community settings. Important historical geographical work was also undertaken in this period on “lunatic” asylums, which described how their location and internal spatial organization reflected both a medical demand for classification and treatment and a social fear of those with impairments. The interaction between disabled people and urban spaces was also studied, most notably through descriptions of inaccessible streetscapes and the possibility of using tactile maps (and, later, GPS systems) for people with visual impairments in negotiating city environments. Humanistic research, prominent in geography in the 1970s and 1980s, also touched on disability, with studies of the sensory “life worlds” of people with impairments.

The geographical study of disability has reflected broader academic and sociopolitical developments. The discrimination, exclusion, and lack of services experienced by the many disabled people now living in mainstream communities inspired political activism in the 1970s, drawing on other rights-based movements. In the United Kingdom, for instance, the Union of the Physically Impaired Against Segregation (UPIAS), one of the first disability rights organizations, defined the principles that would later inform the social model of disability: “What we are interested in are ways of changing our conditions of life, and thus overcoming the disabilities which are imposed on top of our physical impairments by the way this society is organised to exclude us” (1976). UPIAS and other emerging groups, allied with a small but influential group of disabled academics in the social sciences, including Mike Oliver, Vic Finkelstein, and Jenny Morris, identified and sought to dismantle the dominant impairment-determined biomedical model of disability and to establish in its place a social constructionist model, disentangling the experience of impairment from the “disabling” nature of “normal” social and spatial environments. The broad acceptance of the social model in policy and practice is testament to the tenacity and political empowerment of some disabled people.

The emergence of the social model encouraged social (and later cultural) geographers to consider disability as a topic of study. An exchange in Transactions of the Institute of British Geographers (1993–1996) marked the emergence of the “geography of disability” as a subdiscipline. Ruth Butler (1994), Rob Imrie (1996), and Brendan Gleeson (1996) critiqued the impairment-focused work of Reginald Golledge (1993), advocating instead a concern with the exclusionary nature of everyday environments and the role disabled people should play in the design and practice of academic research.

Three themes emerged. First, building on earlier work on barriers to access in urban spaces, critical studies identified the discriminatory attitudes and structures in public spaces, workplaces, institutions, and other sites, and further how such environments were inherently “disablist” in their design and operation. Second, a series of studies considered the experience of bodily impairments and the everyday social geographies of disabled people. Significantly, this work saw a critique of the social model of disability, arguing that its focus on social structures and environments had distanced it from the realities of pain and discomfort, and
the challenges of visual impairment and mental illness, experienced by many disabled people (Hall 2000). Through these studies, geography made a significant contribution to the development of an embodied model of disability. Third, there was the development of methodological approaches to include the voices and interests of disabled people to ensure that research is both ethical and empowering. Significant challenges remain, however, including developing appropriate means of gaining permission from those unable to give conventionally understood informed consent.

While the foregoing research strands continue, the study of disability in geography has taken a series of new directions, both broadening its scope and adding further complexity to its conceptualization. An edited collection *Towards Enabling Geographies* (Chouinard, Hall, and Wilton 2010) argued for the extension of the concept of disability – and the insights of disability theory – to include other “non-normal” bodies “disabled” by dominant sociospatial practices, such as older people, “fat” people, and young people with emotional and behavioral problems; in addition, the inclusion of research on people with chronic illness hinted at a fruitful reconnection between disability geography and medical geography. However, to some activists and scholars, the inclusion of other bodies of difference in disability geography is a potentially controversial move because of the risk of undermining disability politics and the social model. A counterargument is that a truly emancipatory politics of disability will be inclusive of all forms and experiences of disablism, whatever the nature of impairment. There is also much to be gained analytically: studies of the everyday geographies of people with intellectual disabilities (a group long excluded from the social model of disability and geographies of disability), for example, reveal the intensely relational nature of the construction, maintenance, and contestation of disabling spaces and attitudes, in particular the central role of friends (with and without a disability), family and supporters, and particular sites. Recent studies of the use of online spaces by deaf people and people on the autistic spectrum (many of whom choose not to adopt a disabled identity) have shown the empowering potential of relationships with others with the same impairment, and the enabling value of being able to interact in spaces separate from the mainstream (online and otherwise). In addition, in studies of participation in the creative arts, cultural geographers have revealed the importance of disabled people’s embodiment and emotions in the ongoing relational production of “disability.”

Together, these studies constitute the emergence of a contextual model of disability, placing material embodied experiences of impaired bodies of all forms within the varied and dynamic landscape of social, cultural, and political constructions of disability. This sharpens the critique and insight offered by disability theory into the experiences of disabled people (broadly defined), the disabling (and enabling) nature of local spaces, the discrimination of institutional and state policies, and the meaning of “disability” itself.

The emotional lives of disabled people, in particular people with mental health problems (broadened to include those with phobias and anxiety), have been the subject of recent studies. Building on earlier geographical work on mental health, these studies argue that becoming attuned to emotions permits a fuller understanding of how people with mental ill-health seek to locate themselves within often challenging everyday environments and, further, how identities characterized by difference can be developed. This work has made three key
contributions: first, it has challenged the binary construct of mental health/mental illness, revealing the widespread experience of mental health problems in contemporary society; second, it has shown how mental wellbeing is, at least in part, a product of an individual’s emplacement within local contexts and sets of relations (and, in turn, can shape these contexts); and, third, it has revealed the limitations of the dominant notion of social inclusion for those who cannot fulfill the ideals of active citizenship and paid employment.

The geography of disability has also contributed to the recent expansion of the debate around care and caring. As with the focus on impairment, this debate has generated some negative reaction from disability campaigners who view “care” as part of the disabling biomedical institutional structures that have taken so long to (partially) dismantle. However, it can be strongly argued that care and support are integral to many disabled people’s lives, and, as we include more people with impairments into the disability realm, including older people, we can see that the spaces and relations of care must be central to geographical study (Power 2008). For many disabled people, in particular people with intellectual disabilities and older people, the support of family members, friends, voluntary helpers, and professional carers is often crucial to their wellbeing and their ability to live an independent life. In addition, the continuing deinstitutionalization and personalization of care in many countries in the Global North, for example the closure of adult daycare centers in the United Kingdom, has raised questions of where caring should take place (in an institution, in a community facility, or in an individual’s home) and who should be responsible (family and friends, voluntary organizations, or the government). For many disabled people this period of transformation has caused anxiety; for others, new possibilities for more informal, empowering, and ethical caring have opened up in local community contexts. There is the opportunity here for dominant discourses of social inclusion to be contested by embodied and emotional senses of belonging founded on connections with others in local places, shared activities (e.g., creative arts) and friendships. Further, the assumption that inclusion in the mainstream spaces of education and employment is best for the wellbeing of disabled people has been challenged by geographers, who reveal the benefits for some of separation, at least for part of a person’s everyday life.

There are a number of directions for future research in the geography of disability. First, spatially informed scrutiny of disabling barriers must continue; despite legislative protection and marked cultural change in attitudes in many countries, disabled people still endure significant discrimination in many realms of society. This work can be strengthened by the recognition of the intersecting characteristics of disability identities (i.e., ethnicity, gender, sexuality, and age). Second, a broadened concept of disability to include older people and people with chronic illness can encourage a productive (re-)engagement between the geography of disability and medical and healthcare geography, kept apart for many years by the constructionist underpinning of the social model. Critiquing the social care of older people from a geography of disability perspective, and a medical geography-informed analysis of the wellbeing of people with intellectual disabilities, could prove equally enlightening. An engagement with medical geography would also provide an opportunity to critique the ongoing expansion of genetic medicine that, through improved testing, offers the possibility for the elimination of impairment, a development seemingly widely welcomed by many (yet contested by some
disabled people). Third, as many governments in the Global North make radical changes to welfare provision, the category of “disability” and the status of disabled people have come under intense scrutiny; at the same time, the disabled population continues to grow, with increasing numbers of older people and people with chronic illness. Geographers can play a central role in critiquing the consequent shifts in sites and practices of care and support, and the place of disabled people in the spaces of everyday life. Fourth, there remains a significant absence of work on disability in Global South contexts, despite the majority of disabled people residing in developing countries. The conceptual debate in the Global North, in particular the widespread adoption of the social model, has arguably marginalized the experiences of many disabled people in developing countries, where medically framed attitudes and policies remain dominant. Western geographers should establish enduring connections with academics and organizations in countries in the Global South to ensure that the experiences of many more disabled people in a wider range of contexts are represented. Fifth, the geography of disability has, arguably, been an early adopter of empowering and participatory research methods; indeed, the ethics of research were central to the social model of the 1990s. Innovative techniques, such as “photovoice,” “go along” interviews, and participatory mapping, have emerged in an attempt to better convey people’s experiences. There remains much to be done, however, to rework the relations of research into that of true coproduction, and further to ensure that the outcomes of research are effectively communicated and acted on, in collaboration with people with disabilities to ensure positive outcomes for people’s lives.

Further reading

The term “discourse” is very much dependent upon “the disciplinary context in which the term occurs” (Mills 1997, 3). Mills explains how the “term ‘discourse’ has become common currency in a variety of disciplines [including]: critical theory, sociology, linguistics, philosophy, social psychology and many other fields, so much so that it is frequently left undefined, as if its usage were simply common knowledge” (Mills 1997, 1). While the term “discourse” is ubiquitous, it can be argued that the academic signifier and signified have a specific history that has developed through a large number of (sometimes interlocking) theoretical disciplines. Four schools are salient to the discipline of human geography: (i) a critical theory school; (ii) a neo-Foucauldian school (or what we might call a practice and performativity school); (iii) a critical linguistic school; and (iv) a discursive psychology (or reification) school.

The critical theory school

In the field of critical theory, studies of discourse are often related to what Jørgensen and Phillips have described as “critical research … [which] investigate[s] and analyse[s] power relations in society” and which “formulate[s] normative perspectives from which a critique of such relations can be made with an eye on the possibilities for social change” (Jørgensen and Phillips 2002, 2).

As a starting place it can be argued that theories of discourse in this tradition actually owe their beginnings to neo-Marxist reinterpretations of the concept of ideology. The work of the French neo-Marxist Louis Althusser (1918–1990) and his discussion of ideology has had an impact on a range of critical theories of discourse. Althusser suggests that ideology in a capitalist society is produced through the state and its institutions: what Althusser called ideological state apparatus (ISAs). Althusser also suggests that “ideology works through constituting (‘interpellating’) persons as social subjects, fixing them in subject positions, while at the same time giving them the illusion of being free agents” (Fairclough 1994/1992, 30).

Without a doubt, these early ideas of ideology had a major impact on a range of poststructuralist thinkers who developed new theories of power, discourse, and identity. One major commentator influenced by Althusser’s ideas was the French poststructuralist philosopher Michel Foucault (1926–1984). As opposed to viewing power as emerging from a singular source, Foucault argued that power is dispersed and is tied up with institutions. For Foucault, institutions refer to historical blocks of knowledge or epistemes. Foucault contends that an episteme is a system of knowledge or more appropriately a site (or framework) of discursive production. In short, epistemes, or discursive frameworks, define what can be understood as knowledge in a particular time period. Moreover, epistemes produce multiple discourses (as opposed to ideologies) that cannot be read as sites or conduits of bourgeois hegemony, but are sites of production and reduction. Thus, Foucault contends that power is not only a weighty force – it is not only a force
that prohibits – it is also a force that produces, such as knowledge and pleasure.

Foucault outlines a theory of power as dispersed and heterogeneous. In the first volume of *The History of Sexuality* he contends that “power is everywhere; not because it embraces everything, but because it comes from everywhere” (Foucault 1987/1976, 93). Thus, and moving away from foundationalist ontologies that locate power in one or a specific number of sites, power emerges from “innumerable points, in the interplay of non-egalitarian and mobile relations” (Foucault 1987/1976, 94). At each of these points (or discursive formations), then, discourses locate, position, and produce subjects. In developing this theory, Foucault is interested in the way subjects are located in historical frames or discourses. Like Althusser’s concept of ideology, discourses are not simply linked to the production of ideas; rather, they are also linked to the process of producing subjects, or subject positions.

**Foucault and geography**

Foucault’s ideas of discourse have had a very strong influence on geography, and geography’s poststructuralist turn in particular. During the late 1980s and early 1990s, Foucauldian ideas of discourse, and particularly Foucault’s genealogical work, had a reflexive influence on the way geographers began to look back at the history of the discipline. During this period scholars began to examine the role of imperialist, sexist, racist, and competitive discourses in the construction of the human geographical field. Commentators such as Jonathan Crush also explored discourses of progress in human geography and began to unpack the writing formulas that geographers operationalized in their texts.

By the early 1990s, more and more geographers began to utilize Foucauldian notions of discourse to reread ideas of space, place, and landscape. In the seminal *Writing Worlds* (1992), Barnes and Duncan began reframing ideas of landscape through Ricoeurian notions of text and Foucauldian notions of discourse. Importantly, the editors note that “Texts, in the broadest sense that we construe them, are constitutive of larger, even more open-ended structures termed discourses” (Barnes and Duncan 1992, 8). Arguably Barnes and Duncan’s textual-discursive readings of landscape set a precedent for a new era of human geographical work. Alongside these textual concerns, Foucauldian theories of discourse also had a large impact on development studies. Notably, the Colombian-American anthropologist Arturo Escobar views the concept of development itself as a discourse, as a “system that allows the systematic creation of objects, concepts and strategies; it determines what can be thought and said” (Escobar 1995, 40). In his text, *Encountering Development*, Escobar views development as a socially constructed knowledge which has maintained the hegemonic power of Western nations.

Foucauldian approaches to discourse (and particularly Foucauldian genealogical epistemologies) have also had a broad impact on the terrain of historical geography. Implicitly Foucauldian discourse analyses of modern English landscapes were a strong feature of research by historical geographers in the late 1990s, including the writings of David Matless and Catherine Brace. In the field of geopolitics a series of writers have sought to map out Foucauldian definitions of discourse to analyze foreign policy and/or political disputes. In the field of economic geography, Foucauldian methods of genealogical discourse analysis have developed in relation to the work of Gibson-Graham and the seminal text *The End of Capitalism (As We Knew It)*: A Feminist Critique.
of Political Economy (1996). Gibson-Graham traces the historical formation of discourses that enforce and maintain the capitalist system. Moreover, in the arena of spatial and environmental policy, Foucauldian discourse analysis (and particularly the idea of governmentality) has played a major role in understanding the way in which spatial and environmental texts are produced and constructed.

Foucauldian discourse analysis and geographical methods

Foucauldian definitions of discourse analysis have also played a part in the development of methodological discussions in contemporary geography. Notions of discourse analysis have featured as a discrete method in a number of geographical methods books. One innovative use of Foucauldian discourse analysis can be found in the work of Gillian Rose and her book Visual Methodologies, where Rose explicitly unpacks two forms of Foucauldian discourse analysis that she believes are pertinent to the practice of geography. The first of these, discourse analysis 1, she describes in terms of the “notion of discourse articulated through various kinds of visual images and verbal texts” (Rose 2016, 192). The second form of analysis, discourse analysis 2, Rose describes as analysis that pays “more attention to the material practices of institutions than it does to visual images and verbal texts. Its methodology is usually left implicit. It tends to be more explicitly concerned with issues of power, regimes of truth, institutions and technologies” (Rose 2016, 192). While many geographical methods textbooks gloss over Foucauldian discourse analysis in a vague way, Rose can be credited for sketching out the nuances of the analyses and the ways in which these theoretical tools can be applied to geographical and visual contexts.

Neo-Foucauldian schools: practice and performativity

Foucault’s ideas on discourse continue to be taken up by scholars in philosophy and the wider social sciences today. But of all the theorists who have utilized Foucault, Ernesto Laclau and Chantal Mouffe are regarded as key interpreters of Foucault’s original project. First, like Foucault, Laclau and Mouffe challenge traditional Marxist notions of ideology and reject the idea that society can be divided into “a surface or appearance of society [ideology] and an underlying reality [the truth of the capitalist system]” (Laclau and Mouffe 1985, 22); second, Laclau and Mouffe also reject the traditional Marxist contention that economic relations “determine political and discursive processes” (Howarth 2000, 100). Drawing upon Foucault (and Derrida and Lacan), Laclau and Mouffe define a discourse as “the fixation of meaning within a particular domain” (that is, the fixation of meaning in a field of meanings or truths) (Jørgensen and Phillips 2002, 26).

In this regard, “discourse is a reduction of possibilities. It is an attempt to stop the sliding of … signs in relation to one another and hence to create a unified system of meaning. All the possibilities that the discourse excludes Laclau and Mouffe call the field of discursivity” (Jørgensen and Phillips 2002, 27; emphasis in original). But, as Laclau and Mouffe contend, it is exactly “because a discourse is always constituted in relation to an outside, [that] it is always in danger of being undermined by it, that is, its unity of meaning is in danger of being disrupted by other ways of fixing the meaning of the signs” (Jørgensen and Phillips 2002, 27). Laclau and Mouffe suggest that discourse has a relational side: dominant discourses are always dependent upon other discourses (binary others), which unwittingly allows for openness, multi-meaning,
and instabilities in social and practical situations. But, discourse always works continually to try and close elements: these “are the signs whose meanings have not yet been fixed; signs that have multiple, potential meanings (i.e., they are polysemic)” (Jørgensen and Phillips 2002, 27).

Second, if the idea of a field of discursivity is important in Laclau and Mouffe’s theory, so is the notion of practices; indeed, in explaining Laclau and Mouffe’s ideas, Howarth has referred to the example of Thatcherism. Thatcherism represents a discursive set of ideas but, importantly, Thatcherism also refers to “a set of practices (‘strong leadership’ and ‘entrepreneurship’) and involved attempts to transform institutions and organizations, such as the British Conservative Party and the British state” (Howarth 2000, 103). Finally, and drawing upon Lacanian theory, Laclau and Mouffe also view subjects as split. That is: “The subject is fragmented or decentred; it has different identities according to those discourses of which it forms part” (Jørgensen and Phillips 2002, 43). As Jørgensen and Phillips contend, in Laclau and Mouffe’s ontology subjectivity is contingent: that is, subjects always have “the possibility to identify differently in specific situations” (Jørgensen and Phillips 2002, 43).

### A theory of discourse and performativity

If Laclau and Mouffe develop Foucauldian analysis through the idea of practices, the work of Judith Butler (2007/1990) has also been important to another very popular reading of Foucault’s work, and the idea of discourse in particular. Like Laclau and Mouffe, Butler also draws upon wider thinkers including Freud, Lacan, Kristeva, and Austin. In her classic work *Gender Trouble* (2007/1990), Butler critiques the idea of heteronormativity, a hegemonic discourse which prohibits, denies, or renders nonheterosexual sexualities as “illegitimate” or even polluting. In her study of the reproduction of heteronormativity (or compulsory heterosexuality), Butler suggests that discourses of gender intertwine with compulsory heterosexuality to reinforce the concept of heterosexuality as the only “natural” or “normal” form of sex.

Importantly, however, Butler argues that while heteronormative ideas of gender and sexuality are very powerful, they are haunted by sites of “disorganization and disaggregation … [which] disrupt the regulatory fiction of heterosexual coherence” (Butler 2007/1990, 185). Because of the continual instability of the fiction of gender coherence, Butler claims that subjects are always already involved in a never-ending drama of repetition and re-inscription whereby gendered identities must be continually performed. Rather than the hailing of a subject into a position, the subject in Butler’s ontology is always trying to maintain the idea of an “internal” (or essential) “core” or substance by continual acts of performativity, repetition, and “ritualized” legitimation (Butler 2007/1990, 191). Like Laclau and Mouffe, Butler also transforms Foucault’s original concept of discourse through the idea of practices, more specifically performativity.

### Practices, performativity, and geography

In recent years more and more geographers have moved beyond standard Foucauldian discourse analysis. Theories of discourse proposed by Laclau and Mouffe have featured in writings on qualitative geographical methods and geopolitics. In his article on “The disciplinary effects of communicative planning in Soufriere, St Lucia,” Pugh utilizes Laclau and Mouffe’s discursive approach to unpack “the importance of the Contingent articulation of a discourse in specific places at specific times” (Pugh 2005, 310). Here, Laclau and Mouffe’s utilization of the concept
of contingency allows Pugh to pay attention to the way “in which language brings into being signed differential subject positions, partially, but never completely, fixing identity around nodal points” (Pugh 2005, 311).

Butler’s notions of performativity have also had a huge impact on cultural geographers as well as geographers in the fields of gender and sexuality studies. Articles in the journals Gender, Place and Culture, Environment and Planning D, and Progress in Human Geography have often taken up discussions of performative theory in relation to issues of gender and sexuality; however, more recently discussions of performativity have also entered into debates concerning the nonrepresentational (and more than representational) in cultural geography; thus, writers such as Catherine Nash and others have pointed to the relevance of performative theories in reorienting “cultural geography towards practices rather than representations” (Nash 2000, 660).

The critical linguistics school

So far we have examined the field of critical theory and have drawn attention to a series of Marxist, poststructuralist, and performative theories. A third school of discourse theory and analysis belongs to those writers who have drawn upon the writings of scholars within traditional linguistics and the critical social theoretical schools discussed above (schools 1 and 2). Loosely speaking, in traditional linguistics the idea of discourse refers to the way subjects utilize the knowledge they already possess about language. Critical linguistics (CL), or the critical discourse analysis (CDA) school, has close links to these traditional linguistic concerns, but often charts its critical social theoretical influences back to the writings of Russian theorists such as Valentin Voloshinov (1895–1936) and Mikhail Bakhtin (1895–1975) who sought to conceptualize language in terms of wider social processes. Moreover, commentators in the CDA school also refer to the Frankfurt school and the work of Antonio Gramsci as influences on their work.

The CDA school began to take shape and develop in the late 1960s and 1970s, and can be associated with the work and writings of Michel Pêcheux, Roger Fowler, Bob Hedge, Gunther Kress, Toney Trew, Norman Fairclough, Teun A. van Dijk, and Ruth Wodak, among others. Like the critical theorists of the Frankfurt school, the CL or CDA school aims to unpack the relations between language and power and to understand the way hegemonic groups normalize their own interests within language. Also, like the Frankfurt theorists draw inspiration from, the CDA school advocates a transformative approach to contemporary society and the hegemonic institutions within society. For writers in the CDA school, the critical discourse analyst must provide alternative solutions to dominant discourses and hegemonic society. One influential theorist in this school is Norman Fairclough, whose version of CDA often focuses on a technologization of discourse: that is, in a very Foucauldian way, a reading of discourse (and, importantly, of language and words) as a mechanism of social control in the “engineering of social and cultural change” (Fairclough 1994/1992, 8). Fairclough is often concerned with the naturalization of discourse and its “widespread acceptance” in the social world (10). In this regard, Fairclough’s research has often investigated the commonsense nature of language and the way institutions such as the media construct their texts as neutral (or objective) (see Fairclough 1994/1992, 108).

Critical linguistics and geography

Geographers have also started to explore the work of writers and thinkers in the CDA school.
Commentators pointed to a “linguistic” turn in urban studies inspired by the work of Fairclough, Wodak, and Van Dijk. In her article, “Urban Geography: Discourse Analysis and Urban Research,” Lees talks about a distinct “discursive turn” based upon poststructuralist Foucauldian theory and Gramscian notions of discourse. In relation to the latter, Lees maintains that the Gramscian school (which we have called the CDA school) constructs the idea of discourse as being “almost synonymous with ideology itself in so far as it functions to conceal the power of vested interests and to induce the consent of the dominated to their own domination” (Lees 2004, 102). What she suggests here is that often this research has “emphasized the role of ‘discourse coalitions’ in urban politics and policy” which draws upon a CDA style methodology; that is, research that “involves the close semantic scrutiny of rhetoric and turns of phrase to discover particular narrative structures, issue framings and how storylines close off certain lines of thought and action at the expense of others” (Lees 2004, 102).

The discursive psychology (or reification) school

A final large school in the field of discourse theory emanates from the discipline of discursive psychology. This school can be associated with the work of Michael Billig, Jonathan Potter, Margaret Wetherell, and Derek Edwards, among others. While a number of key writings have been associated with this approach, Jonathan Potter and Margaret Wetherell’s Discourse and Social Psychology: Beyond Attitudes and Behavior (1987), has been regarded as a seminal text. Like traditional ethnomethodologists, Potter and Wetherell draw upon the idea of language as a form of action or commitment; however, where ethnomethodologists and conversational analysts see language as a tool to refer to entities in the “real world,” Potter and Wetherell start from the Foucauldian notion that language is discursively generated. In a form of ethnomethodological logic, Potter and Wetherell are interested in processes of reification: that is, the reality-generating aspects of discourse. Rather than simply analyzing the psychology of language, Potter and Wetherell explore the way in which reality becomes solidified and reified by subjects. As they state at the end of Discourse and Social Psychology, discourse analysts ask questions such as: “What procedures are used to authorize factual accounts? How are factual accounts used to perform a specific act? How is the effect of ‘mere description’ generated in discourse?” (Potter and Wetherell 1987, 182). Furthermore, as commentators have suggested, their work is not only concerned with the construction of reality and the authorization of factual accounts, but it is also concerned with the undermining and unsettling of reifying discourses.

The discursive psychology “reification” school and geography

It might seem that the discursive psychological school has made little impact on human geography, where figures like Foucault, Laclau and Mouffe, and schools like the CDA school have made significant inroads; however, a closer examination of a range of papers within the field, over the last 20 years, demonstrates that the discursive psychology school has indeed appeared in a number of geographical papers and writings. References to the work of Potter and Wetherell have been taken up by numerous authors in various subdisciplines of the subject. In their article, “Naming as Norming,” Berg and Kearns utilize Potter and Wetherell’s approach to
discourse because it allows for “a double movement between styles of reading that emphasize the constitution of subjects and objects, and those that emphasize the ideological work of discourse” (Berg and Kearns 1996, 103). Berg and Kearns have shown that in their ideological and reality-producing guise, Potter and Wetherell’s insights are really valuable to human geographers who have sought to look at commonsense notions around race, gender, and sexuality.

Discrete global grid systems

Perry R. Peterson
The PYXIS Innovation, Canada

Discrete global grid systems (DGGS) are spatial references that use a hierarchical tessellation of cells to partition and address the entire globe. Figure 1 shows an example, using the ISEA3H (icosahedral Snyder equal area aperture 3 hexagonal) grid of nested hexagons. DGGS are designed to portray real-world phenomena by synthesizing digital values on a common discrete geospatial data structure. They are commonly used to create virtual globes. The adoption of an optimized DGGS is considered a favorable choice for the establishment of distributed Digital Earth information systems (Goodchild 2000).

DGGS differ from conventional geographic coordinate reference systems. A DGGS is designed to be an information grid, not a navigation grid. Conventional coordinate reference systems address the globe with a continuous lattice of points suitable for repeatable point-to-point navigation and analytical geometry. DGGS, however, address the entire planet by partitioning it into a hierarchical tessellation of nested cells, thereby providing a reference frame for repeating the location of measured Earth observations, feature interpretations, and extrapolated predictions.

A DGGS provides a digital framework for geospatial information. Conventionally referenced geospatial information is quantized or sampled into a discrete, aligned, discontinuous representation of the source information. This analog to digital conversion provides benefits exemplified by other digital signal technologies such as digital imagery, digital audio, and digital video. Data values are independent of the original data source – spatial reference system, spatial scale, or data type – vector or raster imagery. Information integration, decomposition, and aggregation can be optimized in the hierarchical structure, which can be exploited to support data processing, storage, discovery, transmission, visualization, computation, analysis, and modeling.

Formal development of DGGS began in the 1980s with the promising value of global analysis coinciding with the increased use of geographic information systems and availability of global mapping data and positioning systems. DGGS are characterized by their tiling designs, cell address, quantization strategy, and associated mathematical functions. The tessellation of cells provides discrete, nearly uniform fixed areas to assign values that describe the Earth – from backyard birdbaths to entire continents.

Spatial resolution is explicit as every item of information in a DGGS is associated with an area. The grid resolution can be designed to represent arbitrarily sized locations. Properly indexed and processed, data stored as a multilevel global grid can integrate geospatial data layers captured at different scales and resolutions at appropriate degrees of accuracy. Meaningful use of data stored at different resolutions can be accomplished without the need to conflate between scales. For the end user, combining or integrating layers becomes a free operation because items of information are automatically aligned. Topology is explicitly defined within the relationship of cells and their values within a DGGS.
There are early records of using grid patterns to organize measurements of land parcels, astronomical observations, and cartographic information. Most charting and map projections rely on transforming a grid on a globe to a plane. Artillery surveys provide accurate targeting on grid quadrants. Requirements for digitally organizing national maps produced innovation in map tiling and spatial data indexing systems that now drive spatial databases and web maps. At a global level, computational grids developed for fluid flow models supported climate, weather, and ocean current predictions. However, none of these approaches to Earth gridding evolved directly into the information-centric Digital Earth reference of a DGGS.

In 1986, Waldo Tobler and Zi-tan Chen identified an opportunity to create a global grid, the primary purpose of which was information storage. Tobler – of Tobler’s first law of geography: “Everything is related to everything else, but near things are more related than distant things” – argued that as geographic information systems are primarily for planning, analysis, and inventorying of geographic phenomena, it follows that “coverage must be uniform and that every element of area must have an equal probability of entering the system. This suggests that the world should be partitioned into chunks of equal size” (Tobler and Chen 1986). Tobler suggested an approach with a cube as a base polyhedron and dividing it into rectilinear quadtrees to create successive subdivisions with unlimited resolution. Tobler’s paper referenced Geoffrey Dutton, a software researcher working at the Laboratory for Computer Graphics and Spatial Analysis (LCGSA) at Harvard Graduate School of Design, who had done similar work, first using squares, then triangles.

Harvard’s LCGSA was a fertile birthplace of ideas related to digital thematic mapping, spatial analysis, and what is now called geographic information systems (GIS). Early work at LCGSA set some groundwork for using discrete models to characterize geospatial information. From 1967 to 1972, under the direction of William Warntz, LCGSA produced a series of papers on geography and the properties of surfaces that would lay a foundation for digital mapping, including several notable papers examining the properties of mixed hexagon tessellations to represent central places and networks. In 1967, Carl Steinitz, then an associate professor at Harvard’s Graduate School of Design, applied LCGSA-developed computer mapping software – SYMAP (Synteny Mapping and Analysis Program) – to an aggregation of various vector maps to facilitate an urban planning study of the Delmarva Peninsula. Steinitz found while integrating the various vector-based data sources...
that gridding the data was more efficient. A new raster-based module to SYMAP, coined GRID, resulted. GRID went on to become IMGRID – the basis of work by another Harvard student, Dana Tomlin, the originator of Map Algebra, whose raster-based analysis software would be integrated into ERDAS (Earth Resources Data Analysis System) Imagine and the US Army Corps of Engineers’ Map Analysis Package (MAP) in GRASS (Geographic Resources Analysis Support System).

Geoffrey Dutton came to Harvard for a master’s degree in urban planning in 1966 and worked as a research assistant at LCGSA until 1989. Dutton focused much of his attention on raster-based data structures and three-dimensional (3-D) terrain visualization. Using a time series of 2.5-D gridded surfaces he created the first animated holographic map. In 1984, Dutton published his work on assembling and managing global terrain data on a triangular global grid. His global geodesic elevation model (GEM) started with a cuboctahedron connected into a rhombic dodecahedron and recursively divided the initial 12 triangular faces into refinements of nine partially nested equilateral triangles. Elevations were assigned to the faces of each successive triangle.

Dutton’s paper did more than lay out the mathematics for a global grid; it emphasized why he felt such an effort was necessary: “we live on one planet, a world which may be regarded as an organic entity. The wholeness of the Earth – self-evident to many non-western cultures – largely escapes the western culture of science, even the so-called earth sciences. This peculiar myopia is reflected both by our disciplinary specialization and by territorial concerns.” Dutton believed assembling relevant data in a holistic, globally useful framework could act as a unifying model: “[it is] only through using technology that we have any hope of comprehending the nature of the problems we have wrought for the planet” (Dutton 1984).

A few years later, Dutton modified the GEM model to a simpler structure called quaternary triangular mesh (QTM). QTM was based on an octahedron embedded in the Earth with a vertex at each pole and four vertices at the equator.

In 1975, Denis White, who had been a computer scientist at the Massachusetts Institute of Technology, joined LCGSA at Harvard to co-design and develop the vector-based GIS, Odyssey. During that time, White learned of Michael Woldenberg’s work on mixed hexagonal hierarchies and collaborated with Geoffrey Dutton. White was familiar with Dutton’s vision for a global data structure when he left Harvard to work at the US Environmental Protection Agency’s (EPA) ecological research lab in Corvallis, Oregon.

A cluster of research offices in Corvallis, Oregon, which included the University of Oregon, US-EPA, and US Department of Agriculture-Forestry Service, fermented and fostered the next concerted development to formalize global grids into a system. The basic idea was driven by a need to develop an integrated approach to monitoring aquatic and terrestrial resources in the United States, the objective of the EPA’s new Environmental Monitoring and Assessment Program (EMAP). The concept of using an area frame as the basis for a survey design was proposed by Scott Overton, a statistical ecologist at the University of Oregon. Statistically valid sampling was a very important criterion for EPA. White, working with Overton, proposed that EMAP use a global system of hexagonal cells. They shared their plans with Jon Kimerling, a professor of geography at Oregon State University who had extensive experience with map projections. Kimerling suggested a global grid that started with a truncated icosahedron (White, Kimerling, and Overton 1992).
By June 1989 the three convened a meeting in Corvallis to discuss the geometry of sampling designs for EMAP and included Tobler, Dutton, Hrvoje Lukatela, a Canadian scientist who had developed a global model using Voronoi areas, and Tony Olsen, a statistician at the Pacific Northwest Laboratory. Design criteria for a DGGS began its formalization. Michael Goodchild, of the National Center for Geographic Information and Analysis (NCGIA) and University of California, Santa Barbara, had met Dutton when he presented QTM at an NCGIA specialist meeting on spatial accuracy at Montecito in 1988. Goodchild could not attend the Corvallis meeting, sending instead a paper authored with his student Yang Shiren suggesting modification to Dutton’s QTM labeling. Dutton would later collaborate with Shiren to show, as is often the case with DGGS indexing methods, that their respective models were isomorphic, permitting mappings between the two numbering systems.

The choices of three regular tilings for a global grid – quadrilateral, triangular, and hexagonal cells – were represented at the 1989 Corvallis meeting with the challenges for a further decade of global grid research established.

Discrete global grid system design

The Open Geospatial Consortium (OGC) proposes a formal definition for a DGGS “as a spatial reference system that uses a hierarchical tessellation of cells to partition and address the globe. Discrete Global Grid Systems are characterized by the properties of their cell structure, geo-encoding, quantization strategy and associated mathematical functions.” For an Earth gridding system to be compliant with the OGC’s standard definition of a DGGS it must be a fixed tessellation with its cells covering the entire Earth at multiple levels of granularity. The system must include a method of addressing each cell, a mechanism for sampling data values into the cells, and known algebraic operators for expressing and transforming these values.

There are many possible DGGS, each with their own advantages and disadvantages. Criteria for choosing an appropriate tessellation include properties of shape, adjacency, connectivity, orientation, self-similarity, and decomposability, as well as packing properties. There are only three shapes that provide regular tiling of the plane: quadrilateral, triangle, and hexagon. All methods must deal with the fact that a perfect regular partition for the surface of a sphere does not exist, except in the form of the five Platonic solids, each with a single level of granularity: the tetrahedron, cube, octahedron, dodecahedron, and icosahedron.

Quadrilateral cells are an attractive choice as they are in common use within raster imagery and textures, hardware devices, and image-processing algorithms. They are widely adopted in raster data structures. Triangular cells can be rendered very efficiently and are supported by many built-in graphic mesh functions. As a lattice they provide an efficient network connectivity for interpolation of values such as elevation models. Hexagonal cells are favored for their statistically optimal sampling, close packing, and uniform adjacency. They are a preferred shape for modeling dynamic environmental systems. Quadrilaterals and triangles can be decomposed or refined into self-similar congruent shapes to form hierarchical structures. Triangular lattices and hexagonal tessellations form Delaunay/Voronoi duals and so transformations between them provide dual utility. Essentially, squares are familiar, triangles are fast, and hexagons are the finest fit. Each has its own
advantages within the context of DGGS (Sahr, White, and Kimerling 2003).

The generation of a tessellation on a spheroid is mathematically intensive. Most methods start with a regular polyhedron and then project the cells to the spheroid. Preserving cell size or shape is an inevitable compromise in spherical geometry because projected shapes cannot be both of equal area and conformal. Preservation of cell area is a preferred trait when a DGGS is intended to represent information consistently across the entire globe at the same resolution. There has been some work developing voxel-based 3-D DGGS; others rely on the attribution of data values to extend an elevation or time dimension.

Each cell must have a unique identifier. Hierarchy-based, space-filling curves, and axes methods of indexing have been used to uniquely address cells. Hierarchical data structures that provide the basis for nearest neighbor, fast linear ordering, and parent–child relationships are the most common. Though choices can be limited by the type of tessellation, geocoding types can generally be transformed from one to the other (Mahdavi-Amiri, Samavati, and Peterson 2015).

Strategies for sampling content into cells are an important aspect of encoding information to a DGGS. There is normal loss when quantizing a continuous signal to a discrete digital signal. This principle also applies to DGGS. Some DGGS choices are therefore optimized for high fidelity and statistically valid sampling. For example, one cannot assume that quadtree indices will be more accurate with each additional refinement; centroidal points used to define vector geometries (lines and polygons) can move further away from a real value with a refinement. However, when centroids of child cells align with a parent’s vertices, as they do on some hexagonal tessellations, the resulting hierarchical indices will converge monotonically as it refines. This gives those tessellations the characteristics of a Cartesian coordinate lattice where each decimal place can indicate a level of accuracy. Similarly, the finer the change in cell area between resolutions the generally more efficient the sampling rate can be to meet the Shannon–Nyquist theorem on digital representation of an analog signal.

DGGS provide a uniform environment to integrate and visualize both vector geometry and raster-based geospatial data sources in much the same way that information within a computer graphics pipeline becomes the pixels on a computer screen. Efficiencies are gained as operations and algorithms can be created on the data structure itself, independent of the data sources. Typically, a DGGS will include Boolean, relational, and image algebra, mathematical morphology, frequency transforms, and other image processing operations. The structure of the DGGS provides opportunities to simplify most spatial relationships into set theory operators. Topological relationships between two regions can be described within an efficient binary matrix such as the Dimensionally Extended 9 Intersection Model. Predictive modeling techniques such as finite element, agent-based, or cellular automaton can rely on the cell structure, operations, and data integration characteristics of the DGGS.

The common conceptions of a grid can lead to misidentifying any general gridding schemes as a DGGS. As an example, single resolution computational grids cannot be considered to qualify as DGGS, although a DGGS could serve the dual purpose of a computational grid. Similarly, spatial data indexing used to organize map tiles or optimize rapid spatial analysis cannot be considered to qualify as a DGGS in and of itself; although DGGS often utilize hierarchical indices to identify a cell, the primary feature of the DGGS is the cell geometry, not the optimization of a spatial query.
DISCRETE GLOBAL GRID SYSTEMS

A decade of development

In March 2000, the pioneers of DGGS convened at the 1st International Conference on DGGS in Santa Barbara. Notable additions to the main group included Tony Olsen, Kevin Sahr, and Dan Carr.

Tony Olsen came to the EPA in 1990 to lead the statistical design of EMAP. Dan Carr, a statistician from George Mason University, had developed innovative data binning techniques using hexagons and contributed to the cartography of hexagonally partitioned data. White and Olsen worked closely on implementations of the original EMAP grid system, but after several years the disadvantages of the truncated icosahedron hexagonal grid encouraged further research and development. The importance of an equal area cell had become apparent, so Kimerling turned to John P. Snyder, the clever self-taught geodesist and author of the definitive text on map projections, for a method of projecting equal area cells from the face of a polyhedron to a sphere (Snyder 1992). Subsequent work at the EPA and Oregon State then focused on the icosahedron as the preferred solid model upon which to develop global grids.

Funding was made available to add a computer scientist to compile and test the ideas that were being generated for a truly global equally valid sampling grid. Kevin Sahr had completed his master’s degree in computer science from the University of Colorado in 1995. Sahr was an admirer of Buckminster Fuller, his Dymaxion technology, and his global vision of “Spaceship Earth.” Kevin had picked up on the military use of hexagonal tessellations while serving in the Reserve Officers’ Training Corps in Army intelligence and was a keen champion of a hexagon Earth. Sahr coined the term “discrete global grid” and would become a passionate advocate and technical expert on DGGS. “The term ‘discrete global grid’ was proposed by Kevin Sahr to identify the types of global partitioning systems based on continuous coverages of polygons. It was first used in print in a draft technical report from the OSU Geosciences Department Terra Cognita Laboratory, where the EPA funded projects on biodiversity and global grids were located. Kevin wrote the report, dated 30 May 1996, entitled ‘Terra Cognita Technical Report 96001: Discrete Global Grid.’ In September 1996, Kevin and others wrote a description of 14 desirable properties of discrete global grid that were proposed by Michael Goodchild in the 1994 meeting in Santa Barbara” (White 2014).

In 1988, the US National Science Foundation established the National Center for Geographic Information and Analysis to conduct basic research to advance geographical information systems. Many technical impediments existed. The geographer Michael Goodchild, serving as one of the NCGIA’s founding co-directors, produced a prolific series of papers, reports, and vision documents that earned him the reputation as the pre-eminent thought leader within geographical information science. In 1994, Goodchild had constructed a list of criteria describing a global grid.

The EPA research team at Corvallis had advanced significantly by the 1st International Conference on DGGS in 2000. At Oregon State University, Kimerling had received the Milton Harris award in 1996 for his exceptional achievement in basic research on developing global grids. A number of research areas had been explored and the preferred solution was identified as the ISEA3H grid (Sahr and White 1998). Dutton had advanced QTM and completed a doctoral degree at the University of Zürich with a dissertation thesis on the subject (Dutton 1999).

Goodchild’s research into DGGS systems followed Dutton’s QTM approach; however, his interest aimed at a more generalized and
lofty utility than Dutton’s original objective of global terrain modeling. Goodchild could envision an Internet subsystem for organizing and aligning all geospatial information which was sufficiently simple that a child could use it to explore the Earth. His vision was articulated in a 1998 speech, *The Digital Earth*, written with substantial input from Goodchild, that was to be delivered by Vice-President Al Gore (Gore 1998). For Goodchild, *The Digital Earth* provided the actionable requirements needed to respond to Al Gore’s vision of a digital replica of Earth proposed in his 1992 book *Earth in the Balance* (Gore 1992). Goodchild articulated the connection between DGGS and Digital Earth at the 1st International Conference on DGGS: “[Digital Earth] can clearly benefit from developments in discrete global grid, which can provide the georeferencing, the indexing, and the discretization needed for geospatial data sets. They have properties, in particular hierarchical structure, uniqueness, explicit representation of spatial resolution, and consistency, that make them superior to any single alternative” (Goodchild 2000).

Keith Clarke, a geographer at the University of California, Santa Barbara, prepared and presented at the conference a comparison of criteria for assessing a DGGS (see Table 1).

### Applications for discrete global grid systems

The growth of the web as a primary source of information dissemination has naturally led to the evaluation of different approaches to efficient online cartography and spatial analysis. Microsoft, as an example, used Dutton’s QTM as a base structure for their early digital mapping program Encarta and by 2003 they had investigated other DGGS as central data structures for a web-based media geocoding standard they called the Worldwide Media Exchange (WWMX). However, the opportunity for fast display of global maps on the web led Google to adopt a much more simplified approach to digital mapping. In 2005, Google Maps was released using Web Mercator — a spherical variant of the Mercator projection suitable for partitioning and indexing map tiles for rapid transmission and display. Despite its controversial nonconformance, it has become the de facto standard for web maps. Similarly, speed and visualization trumped analytical capacity when Keyhole (now Google Earth) introduced a virtual globe that used mip-map to create mapping tiles for fast rendering of a multiresolution 3-D globe.

Trends indicate emerging requirements that cannot handle these solutions. Geoscientific data and mass-market location data of petabyte scale are rapidly heading toward the exabyte-scale range. Decision-makers expect fast access to big, distributed, and dynamic geospatial data archives in a form that answers their geospatial questions without the assistance from a middle data integrator. Combining multiple sources of geospatial information — a necessary and expensive step in the geospatial intelligence cycle — is not solved by these advances. Traditional approaches to the acquisition, management, distribution, and application of mapping data are not able to meet the Digital Earth vision that presupposes a young child searching and exploring a virtual globe for meaningful insights on demand.

The deployment of DGGS is providing a more comprehensive and scalable solution for distributed Digital Earth information systems. By conversion of traditional Earth observation data archives into standardized DGGS, massive amounts of data are made available to scientists as timely decision-support products in a transparent and repeatable fashion. Very large multiresolution and multidomain datasets are aligned and ready for distributed and/or high-performance
### Criteria for DGGS characteristics proposed by both Goodchild and Kimerling, à la Keith Clarke 2000.

parallel-processing computer environments. Geospatial data integration on demand is a grand challenge that DGGS have solved.

A recent survey of DGGS indicated that there are at least 10 DGGS in active development and use. PYXIS WorldView, developed in collaboration with Natural Resources Canada and Defence Research and Development Canada, is one example. The web-based client application uses the ISEA3H DGGS to enable complex spatial queries over multiple geospatial data streams on demand. SCENZ-Grid DGGS, developed by Landcare Research New Zealand, is a rectangular DGGS based on 3×3 tessellations of the six faces of a hierarchical equal area iso-latitude pixelated ellipsoidal cube (HEALPix) designed for use in high-performance computing and cloud architectures for interdisciplinary environmental modeling.

DISCRETE GLOBAL GRID SYSTEMS

Disease and illness, political ecology of

Ezekiel Kalipeni

Joseph Oppong
*University of North Texas, USA*

Political ecology is an analytical social theory framework that focuses on the relationships between political, economic, and social factors and environmental and health issues (Peet and Watts 1996, 6). It was developed to examine a wide ranging set of phenomena spanning the human–environment nexus and interactions and has led to better systemic understanding of health and disease. This framework has become an increasingly attractive approach because of its capacity to handle specific questions that deal with complex historical and contemporary issues at varying scales of analysis. Its power lies in its ability to combine the concerns of ecology on the one hand and political economy on the other. As such, political ecology can be defined as cultural ecology plus political economy. Steward (1972) defined cultural ecology as “...the study of the processes by which a society adapts to its environment.” Indeed, it is the study of the ways in which different human groups interact with, and relate to, their environment in order to survive and/or change. Culture is viewed as the primary mechanism by which human societies adapt to the environment. With reference to disease, different cultures develop different adaptations to their environment that produce or prevent the spread of disease.

Examples of such cultural adaptations might include “eating bush meat” and the onset of the HIV and/or Ebola epidemics, the drinking of hot tea in India to prevent outbreaks of cholera, or houses in Indonesia built on stilts to keep malaria-causing mosquitoes at bay. In Africa, bush meat is meat from wild animals hunted in the forests and consumed for sustenance. The wild animals are from a range of species, which include great apes, bats, porcupine, African squirrels, and so on. Many of these animals are known to harbor various pathogens, including the simian virus and Ebola. Research has shown that human immunodeficiency virus (HIV), the virus which causes AIDS, originated from a similar virus in primates called simian immunodeficiency virus (SIV); researchers believe that HIV probably initially jumped into humans after people in Africa came into contact with infected bush meat. Similarly, Ebola is believed to have spread from bats to humans through the consumption of Ebola infected bats. This is an example of a case of disease exposure due to human consumption of wild meat. The second example of cultural adaptation is the customary drinking of hot tea in China and India. Because water is often contaminated with cholera-causing bacteria, drinking hot tea is safer. The health benefits of drinking hot tea have made it popular in India today and definitely increased longevity by keeping cholera, dysentery, and typhoid at bay. In Southeast Asia, particularly Indonesia, stilt houses built primarily as a protection against flooding also serve to keep out vermin and insects such as mosquitoes. Living in a raised house is...
DISEASE AND ILLNESS, POLITICAL ECOLOGY OF

a cultural adaptation that lowers the risk of mosquito bites and the associated risk of malaria.

These are examples of cultural adaptations that may result in the spread or control of the diseases in question. On the other hand, political economy is the study of the interaction of politics and economics to explain how political institutions, the social and political environment, and economic systems influence each other. The central argument of political economy is that resources should be distributed based on social, economic, or environmental justice. Thus, people deserve a share of resources because of long-standing property claims/customary use, the prior investment of labor, and/or citizenship status. Those few members of society that control the means of production do well while most of the poor suffer from the effects of poverty, including ill or poor health. With reference to political economy and how it relates to disease, the behavior and dynamics of visible and invisible actors within the health-care sector can only be understood in terms of their power and class position in the larger social system (Meade and Emch 2010). Those who apply the political economy approach to health-care problems often look to the political, economic, structural constraints, and historical contexts to explain changes to health and social issues. Indeed, for the less fortunate such as poor farmers, health problems and poverty intersect and create complex causal chains with synergistic effects. For example, diseases such as schistosomiasis, tuberculosis and Ebola may result in debilitation or even the death of the main provider in the household, resulting in poor human nutrition. On the other hand, poor human nutrition and poor soils will undermine productivity, which may undermine the household economy and the ability to afford medical treatment, with spiraling deleterious consequences on the household and its well-being. It is in this regard that political ecology of disease is defined as political economy plus cultural ecology. In a nutshell, political ecology of disease is the study of how power relations and political and economic factors (political economy) impact environmental and health-care issues (ecology) and the ways people interact with the environment (culture).

Terminology of public health, epidemiology, and medical geography

Researchers that employ the political ecology approach to explain both distal and proximate causes of epidemics and diseases usually place their research within the disciplines of medical geography, public health, and epidemiology. Meade and Emch (2010) define medical geography as a discipline that uses concepts and techniques of geography, an integrative, multidisciplinary, and holistic discipline that deals with human–environment interactions. There are many facets of medical geography that examine the geographical patterns of health and disease from geographic and population points of view, including health geography, disease ecology, epidemiological geography, public health geography, and so on. As a matter of fact, medical geography can be considered the spatial side of public health but with emphasis on population, place, and time. Nevertheless, medical geography distinguishes itself from public health and epidemiology by acknowledging the distinctiveness, uniqueness, and importance of “place,” integrating its research at multiple scales and addressing the core questions of geography, that is, “where” and “why there.”

The World Health Organization (2014) defines public health as all organized measures (whether public or private) to prevent disease, promote health, and prolong life among the population as a whole. Its activities aim to provide conditions
in which people can be healthy and focus on entire populations, not on individual patients or diseases. As such, public health is concerned with the total system and not only the eradication of a particular disease. Further, the World Health Organization defines epidemiology as the study of the distribution and determinants of health-related states or events (including disease), and the application of this study to the control of diseases and other health problems. In essence, epidemiology is the cornerstone of public health; it informs policy decisions and evidence-based practice by identifying risk factors for disease and targets for preventive health care. While medical geography is intricately related to public health and epidemiology, its emphasis is on spatial or geographic aspects of disease. It is, therefore, important to define briefly several public health, epidemiology, and medical geography terms that are used to illustrate how the political ecology framework is applied to diseases.

The three disciplines, public health, epidemiology, and medical geography, use several medical and environmental terms to illustrate the different ways that diseases and interrelated health conditions, such as malnourishment, are transmitted or acquired. The case studies and ensuing discussion in this entry make reference to some of these medical terms, which need to be defined in advance, for example, the terms communicable or infectious disease, infectious agent, host, vector, reservoir, zoonosis, waterborne and airborne, toxic exposure, endemic, epidemic, and pandemic. A vector is a living agent that transmits pathogens, for example, arthropods such as ticks, mites, fleas, and lice and insects such as mosquitoes. On the other hand a fomite is an inanimate object that can transfer pathogens to a host when contaminated (e.g., surgical instruments). A reservoir of pathogen or disease agent can be a geographic site (natural nidus) or an animal host that carries the pathogen but does not get the disease. Once identified, natural reservoirs provide the complete life cycle of infectious diseases, providing effective prevention and control. For example, raccoons, foxes, and bats are natural reservoirs for rabies while rats and squirrels are natural reservoirs for bubonic plague. Another related term is zoonosis, which is a disease that occurs primarily in animals but can be transmitted to humans, for example, swine influenza virus (swine flu) transmitted from pigs to humans or Ebola transmitted from bats and other wild animals.

The transmission of several other diseases does not depend on vectors; rather they are waterborne and airborne or generated through toxic exposure. Waterborne diseases are caused by pathogenic microorganisms and most commonly transmitted in contaminated water, with infection occurring through bathing, washing, and drinking. A good example of a waterborne diarrheal disease is cholera. Airborne diseases are caused by pathogenic microbes that can be discharged from an infected person via coughing, sneezing, and close personal contact. Examples of such diseases include severe acute respiratory syndrome (SARS) and tuberculosis. Environmental pollution due to toxic chemicals and respiratory irritants can lead to poor health
through inhalation of the irritants. Toxic chemical compounds and aerosols can cause harm by a variety of different mechanisms, and the extent of injury can vary widely, depending on the degree of exposure and on the biochemical properties of the inhalant. People exposed to toxic chemicals are likely to develop varied ailments, including cancer, bronchitis, pulmonary hemorrhage, nasal inflammation, and pneumonitis.

Finally, endemic implies a disease is constantly present in a given locality, usually in low numbers, for example, chicken pox. But it can also be in sizable numbers, such as malaria in sub-Saharan Africa. An epidemic is when the occurrence of the disease is unusually high in a localized population. A pandemic is when a disease becomes a worldwide epidemic or epidemic that has spread to new geographic areas such as HIV/AIDS and the 1918 influenza outbreak. Emerging and re-emerging diseases, in contrast to endemic diseases, are those diseases that have recently appeared in a population or have existed but are rapidly increasing in incidence or geographic range (emerging). Re-emerging diseases are those diseases that once were health problems, and then declined, but are again health problems for a large proportion of a population, for example, tuberculosis. As Meade and Emch (2010) note, emergence is about changing and expanding spatiotemporal patterns of diseases.

Examples of the Aral Sea in Asia Minor and schistosomiasis in Senegal

Demonstrated in the remainder of this entry are how social, economic, and political influences have shaped land-use patterns, human–environment interactions, and disease emergence and spread in specific locations using the political ecology approach. We weave together a story of examples from different regions of the world that demonstrate clearly the workings of political ecology of disease. Two notable examples include the impacts on disease of dam building in Senegal and the disappearance of the Aral Sea in Asia Minor. During the mid-1980s, the Senegalese government decided to increase the production of rice by building the Diama dam at the mouth of the Senegal River. It had tragic ecological consequences, culminating in the outbreak of schistosomiasis (Bilharzia), a water-based disease. In Asia Minor, the Aral Sea Basin has seen its waters dwindle by 90% because of irrigation for cotton, a situation exacerbated by the five countries that find themselves in this basin. These countries have different sizes, political orders, conflicting political and economic interests, particularly in natural resource use.

These two examples offer two different case studies, one straightforward in its application of political ecology and the other more complex. The case of schistosomiasis in Senegal is a seemingly more straightforward example, with a single disease that has a well-defined mechanism for transmission, which is enhanced by a single development intervention (the dam). It illustrates clearly both proximate and distal causes of the disease, and the related potential solutions to the problem. By contrast, the second example of the Aral Sea is more complex in the sense that it does not highlight a single health problem at all; nor are the mechanisms of transmission all so straightforward. Instead, a macroscale environmental intervention produces a suite of complex often interrelated health problems due to environmental exposure. The proximate and distal cause distinction holds, but the epidemiological story is more complex. It is for this reason that we begin with the simpler story and deliberately move to the more complicated one. These two examples are discussed briefly before
moving to a general discussion and application of this framework.

**Schistosomiasis and the Diama Dam in Senegal**

Schistosomiasis, also known as Bilharzia, is a disease caused by a helminth (parasitic worm) of the *Schistosoma* type. Three types of these helminths are responsible for this disease, namely, *S. mansoni*, *S. haematobium*, and *S. japonicum*. Schistosomes are waterborne parasites that require aquatic snails as important intermediate hosts. The snails release free-swimming schistosomes into water; these are then attracted to the human skin. They often infect the urinary tract or intestines and symptoms include abdominal pains, diarrhea, bloody stool, or blood in the urine. In those who have been infected a long time, liver damage, kidney failure, infertility, or bladder cancer may occur. More than 700 million people are at risk of schistosomiasis worldwide, mostly children in poor, rural villages; Africa contains 97% of the world’s infected population (Hunter 2003). An estimated 200 million people worldwide are infected with the disease and over 20,000 deaths annually are associated with the severe consequences of infection.

There is convincing evidence that dam construction increased the habitat for, and decreased native predators of, the intermediate host snails in Senegal, contributing to the epidemic emergence of human schistosomiasis (Kuris 2012). In order to increase rice production, the Government of Senegal embarked upon the building of a dam at the mouth of the Senegal River in the early 1980s. The Diama Dam drastically changed the ecology of its water upstream, which resulted in the reduction of salinity and change from acidic to alkaline environment, promoting the growth of freshwater snails and affecting their natural predator, the prawns which all but disappeared. Creation of new irrigation canals and expansion of the rice fields provided new habitats for the snails, intermediate hosts of the schistosomes, to colonize; hence, a schistosomiasis epidemic in the affected areas.

The ecological damage caused by human activity in Senegal has unquestionably influenced the rise of schistosomiasis and adversely impacted human health. With reference to scale, decisions taken at the national level have impacted the rise of disease at the local scale. In spite of the knowledge that the disease outbreak was caused by ecological damage of the environment, public health campaigns rarely turn to ecological solutions to mitigate infectious disease risk, instead favoring traditional approaches such as vaccine development or drug treatment. The case of Senegal is an excellent example of how the political ecology approach can explain the rapid proliferation of disease and inform policy with reference to novel approaches to disease control strategies for schistosomiasis, one of the most significant parasitic diseases in Senegal today. It is possible to devise a strategy to mitigate the ecological damage caused by dam building in Senegal, thereby reducing the transmission of this disease that emerged and spread to epidemic levels following dam completion. Indeed, experiments are ongoing in Senegal to develop an ecologically sound intervention strategy that combines bio-economics, aquaculture, social science, ecology, and epidemiology to reverse the spread of schistosomiasis. As Jullien (2013) indicates, a harvestable native crustacean (prawns) suffered dramatic declines in the Senegal River ecosystem due to dam construction. These very same prawns also happen to be the natural predators of snails. Scientists are in the process of environmental re-introduction of the native prawn, using village-based aquaculture, as
a socially and economically sustainable control strategy for schistosomiasis (Jullien 2013).

Aral Sea

These two examples illustrate clearly the issue of scale and history in political ecology and set health issues within a broader social and economic context. Health problems at a local scale need to be connected to national and global decisions about health policies, funding allocation, land use and management. In other words, there is a need to examine carefully the effects of state policies on land-use change/management by starting at the “micro” or local scale and examining the historical context and local impacts of global and national level policies. Let us examine the case of the Aral Sea using the political ecology lens. The often asked question is what happened to the Aral Sea? If we go back to 1960, the Aral Sea was the world’s fourth largest inland water body. Although from the start the water environment was brackish and inhabited by mostly freshwater species, the lake supported major fishery operations and offered a key regional transportation route for the five countries that surround it, that is, Afghanistan, Kazakhstan, Tajikistan, Turkmenistan, and Uzbekistan.

By 2003, the Aral Sea had lost approximately 90% of its volume. Salinization caused massive loss of biodiversity and species. The Aral Sea Basin countries were part of the former Soviet Union before it broke up and during Soviet rule the allocation of water was based on the development master plan instituted in 1987 by the former Soviet Union’s Water Management Ministry. The intention of the former Soviet Union was to use the waters of the two major rivers (Syr Darya and the Amu Darya) that drain into the Aral Sea for irrigation purposes to increase cotton and food production (Kasperson, Kasperson, and Turner 1995). While in the Soviet era peace and calm was maintained from Moscow, the break up has resulted in rising tension regarding water allocation, water delivery, and sustainable development. There is no interstate agreement between the countries with regard to the Aral Sea Basin to address water use and regulation.

The countries are ravaged by drastic economic problems and the primary interest is to increase agricultural production, which it is hoped will have a major impact on the economy. As such, each one of the former republics is striving to expand irrigation, mainly to meet food needs for a growing population. This has necessitated heavy application of insecticides, pesticides, herbicides, and defoliants on irrigated farmland. It is estimated that about 150 000 tons of toxic chemicals are used annually, making it hard to find clean drinking water because of the contamination by agricultural chemicals (Ataniyazova 2003). Ecological consequences include the collapse and disappearance of the fishing industry as a source of food and income. In addition, the soil is so salty that crops cannot easily be grown, and agricultural output has declined by 30–50%. An estimated 40 000 km² of the heavily saline sea bed is now exposed and is blown out by frequent winds, resulting in the air becoming salty and dusty, leading to respiratory illnesses (Micklin and Aladin 2008). Also, the local climate is becoming hotter and drier as the effect of the Aral Sea is reduced. Health has also been affected in numerous ways with diseases increasing, particularly rates of anemia, tuberculosis, kidney and liver diseases, respiratory infections, allergies, and cancer (Ataniyazova 2003). Rates for these diseases in this region far exceed those of the former USSR and present-day Russia. Average life expectancy in the Kzyl-Orda region of Kazakhstan has declined from 64 to 51 years and one in every 20 babies is born with a birth defect, a statistic five times higher than European countries.
DISEASE AND ILLNESS, POLITICAL ECOLOGY OF

In short, the Aral Sea perfectly illustrates the use of political ecology to explain ecological damage and disease proliferation. Historically, the former Soviet Union put in motion a strategy of agricultural development that relied on the waters of the two major rivers to increase cotton production. Once the former Soviet Union broke up, the new independent states began to pursue their own resource use interests, which often were in conflict with those of the other states in the region. This has resulted in ecological consequences that have had a major impact on health issues in the Aral Sea Basin. Thus, the political ecology framework is useful for explaining the fate of the Aral Sea with reference to issues of scale (decisions taken by the former Soviet Union at higher levels with disastrous effects at the local scale) and the historical and economic contexts.

General discussion of the application and usefulness of the political ecology framework

As these two examples illustrate, understanding newly emerging and re-emerging diseases demands a political ecology approach. The traditional human ecology model of disease can tell us what conditions a disease requires to develop, but it cannot explain why conditions have changed. To draw out causative factors the political, historical, and economic story must be told. We can add little to the vast literature on the human ecology of tuberculosis; however, the reappearance of the disease in the Ukraine after 50 years requires researchers to address the effects of Soviet rule, man-made disasters, structural adjustment policy, cultural tension between east and west, inadequate private health care, and rising rates of HIV/AIDS due to neglected family planning programs and sex trafficking. Thus, from a political ecology perspective one of the oldest known human diseases still has a rich and exciting story to tell.

Emerging diseases are diseases that were previously unknown, either globally or locally (Wang et al. 2013). These may be diseases that appear in a new geographic area, that have adapted to new hosts, or which have never been seen before. The most obvious example is the human immunodeficiency virus (HIV). Virtually unknown before the late 1970s, HIV is now the sixth leading cause of death worldwide (World Health Organization 2013). On the other hand, re-emerging diseases are those diseases that were once eradicated or controlled but have since reappeared (Wang et al. 2013). Re-emerging diseases usually come about when the environment conducive to disease spread is recreated, either biologically, physically, socially, or behaviorally. Many of these realignments come from economic and political forces beyond the individual’s control, but some develop at the local level. Wherever a re-emerging disease is present a political ecologist is sure to find something fascinating to explore. In the modern world most of our changing disease patterns are anthropogenic; humans learn to control diseases but then the diseases bite back, exploiting many of the projects intended to make human life better as the case of dam building in Senegal testifies.

One way humans create and enable disease spread is through physical changes to the environment, such as dam construction, deforestation, agriculture, and wetland drainage. These environmental changes are usually a direct result of ongoing government policy or neglect. Furthermore, economic challenges resulting from government economic policy and global and regional economic fortunes fuel the environmental changes, which ultimately result in the proliferation of certain diseases. Global climate change is sure to contribute to disease spread by making previously uninhabitable areas attractive
to disease vectors such as mosquitoes. For example, Kyasanur forest disease is a tick-borne hemorrhagic fever that was endemic only to 300 square miles (777 km²) of forest in South India in 1957. However, in the 1980s a major epidemic occurred in villages that had recently been cleared within previously undisturbed forests. Currently about 100 people are infected a year and the number continues to increase. Similar origin stories exist for Leishmaniasis in Latin American rainforests, and perhaps even Ebola outbreaks in Uganda and the Democratic Republic of the Congo (Yale, Bhanurekha, and Ganesan 2013). Of course, people are moving deeper into the forest because large-scale agriculture and limited land require people on the fringes of society to venture farther into the forests to eke out a living. In the Indian case most of the land had been cleared to produce cashew, a cash crop. Cash crop farming has been particularly detrimental in the developing world because it breeds reliance on outside goods, services, and funds. In most cases, it is the poorest people who have the fewest resources who endure the first waves of emerging and re-emerging diseases caused by the changing physical environment.

One more example of how political ecology contributes to our understanding of emerging diseases is through the increasing mobility and interconnectedness of modern life. Some of these changes are purely recreational. When an American citizen with multidrug resistant tuberculosis wished to attend a wedding in Europe he evaded the CDC quarantine directives, possibly spreading an uncontrollable and highly infectious disease to people in the airports, planes, and venues he attended. Many more population migrations are economically and politically forced, however. Refugee camps have notoriously poor health outcomes and can lead to re-emerging diseases like cholera from poor infrastructure, but also to emerging psychological illness such as shared night terrors caused by fear of ethnic cleansing (Kalipeni and Oppong 1998). Migration into large cities creates slums, where every disease caused by unsafe water, poor ventilation, malnutrition, and overcrowding will flourish if given the chance. These diseases do not stay in the slums and can create epidemics throughout the region. This migration is due to the same forces that push poor people deeper into the forest primarily due to economic desperation.

Likewise, the spread of HIV in Africa is largely driven by the massive numbers of migrant laborers who must trek to cities and mines to make a living, leaving their families at home for many months at a time. Once infected, many do not have access to anti-retroviral treatment and the pandemic continues to spread unabated. Indeed, the historical and geographical context of Africa is critical to the understanding of the economic conditions, migration, and spread of the HIV/AIDS epidemic. Colonial powers were attracted to southern Africa because of the presence of rich soils and minerals, which included gold and diamond. As the European powers carved out colonies and began to settle they also created pockets of economic development that, in turn, triggered migration of labor from economically depressed areas such as rural parts as well as land-locked countries such as Malawi to resource-rich areas such as South Africa. This, in turn, contributed towards the spread of diseases, including sexually transmitted diseases (Sawers and Stillwaggon 2010). It is pertinent here to reiterate the distal and proximate causes of epidemics and diseases. Globalization has so shrunk the world that a disease can be transported from a distant part of the world to some far-away place in a matter of days, for example, from Africa to the United States. Proximate causes of the disease like Ebola might include people eating bush meat such as infected bats and contracting Ebola by doing so. A distal cause might be an
infected person in Liberia traveling by air to Nigeria bringing with them the infection and spreading it among the populace in Nigeria.

Take the case of Malawi, for example, a country that is no exception to the severity in HIV prevalence although recent estimates indicate a declining trend. The first case of AIDS was diagnosed in 1985 and in 1998 the country reported a prevalence rate of 26%. USAID estimates that at the end of 2007 there were 930,000 adults and children in Malawi living with the HIV. It is currently estimated that about 10% of the adult population aged 15–49 in Malawi is infected with the virus (World Health Organization 2013). Among the population group affected by the AIDS crisis, young women seem to be disproportionately affected. Nearly 50% of all new infections occur among women between the ages of 15 and 24 years. This age group also reports a prevalence rate of 9%, which is substantially higher than the 2% reported for males within the same age group.

In Malawi, migration from rural areas to urban areas and international migration to other surrounding countries, such as South Africa, Zimbabwe, and Zambia, facilitates HIV transmission. Migration is in response to lack of sustainable economic conditions in rural areas. The migrant population includes truck drivers, female sex workers, traders, fishermen, mine workers, military personnel on peacekeeping missions, refugees, and seasonal workers. These population groups tend to engage in high-risk behaviors, which increase their vulnerability to infection. In general, many of these migrants have limited education and training, and thus have few marketable skills; as a result, they represent the country’s marginalized population who are subject to discrimination.

It is also important to note that an individual’s vulnerability not only depends on the economic conditions but also social position. Women in Malawi tend to have limited entitlements, generally earn low wages, and do not benefit from international aid programs. Furthermore, women in general have less access to education beyond the primary level, which restricts them in their choices of occupation, formal sector employment, and sustainable wages. According to the political ecology approach, the history of labor migration and the inequality among men and women influence the power structure and vulnerability to HIV and other equally important diseases in Africa and elsewhere.

Disease diffusion

Daniel J. Exeter

Clive E. Sabel  
University of Bristol, UK

Spatial diffusion theory seeks to explain the movements through time and across space of goods, people, innovations, or ideas. A diffusion process involves numerous events on all spatial levels from intercontinental transport and climatic variations to the micro level of homes, workplaces, schools, and hospitals. In geographical terms, a diffusion process involves a place of origin (a source) and one or more receiving locations, pathways, and modes of diffusion, as well as a force driving the diffusion.

Applied to disease, diffusion theory can help describe how, where, and when the spread of infectious disease occurs. Studies of the diffusion of infectious disease draw heavily on the work of health geographers and spatial epidemiologists who are interested in how a disease spreads and where cases are likely to occur. The potential for spatial diffusion depends on the character and ecology of the causative agents, such as their transmission modes, mobility, reach, and viability, as well as various determinants. Exposure (i.e., the contact between causes and susceptible individuals) is crucial for transmission and the start of a pathological change in a human or other living being.

Disease diffusion depends on exposure – the innumerable microscale events that bring individuals in contact with health hazards. Occupational conditions, daily personal routines, and attitudes may be decisive for exposure. Social norms and cultural practices play an important role for either spreading or barring infections. For example, promiscuity or fidelity, polygamy, circumcision, and other practices can influence the spread of sexually transmitted diseases (STDs).

Like other geographical phenomena, sources of disease diffusion may assume point, line, or area shapes. Infected wells or minor ponds, perhaps food stores, or even kitchens could be considered point sources. Line-shaped potential sources could be rivers or riverbanks where mosquitoes breed. Area sources of disease diffusion may be endemic regions and natural reservoirs in lakes, swamps, forests, or paddy fields.

Early models of disease related to the impacts such ailments had on the demographic structure of society, or dealt with the rates of disease transmission. These models included the classic three-compartment Susceptibles-Infectives-Recovereds (SIR) model and the use of neural network models that “learn” the underlying processes of the phenomena. These temporal models typically resulted in logistic growth curves, showing the accumulation of cases (events) over time, or normal bell curves for frequency of disease over time.

The examination of phenomena moving through space over a period of time was conceptualized by Hägerstrand (1968), whose work focused on the acceptance of new innovations...
DISEASE DIFFUSION

within a community. He contended that different spatial patterns arise due to the different methods of transportation/communication that carry information regarding the innovation and the barriers that restrict the flow of such information. When a new innovation is publicized, early adopters will begin using the technology. They share their experience with their friends and colleagues, and with continued publicity the number of people adopting the new innovation increases. As this process continues over time, information about the innovation travels to new communities – through different sectors of society, between cities and countries – until the innovation becomes “mainstream.” The speed at which the innovation spreads is dependent on the way information travels from person to person (and indeed place to place). Additionally, other factors such as the cost of purchasing the innovation, which is also governed by supply and demand, are also influential. Consider the spatial diffusion of condom usage and compare its evolution to the uptake of tobacco cigarette smoking. They each experienced spatial diffusion, although the communication networks, barriers, and associated costs were very different!

To health geographers a disease or illness (e.g., measles) is typically defined as the innovation and the time an individual is exposed to the illness represents the acceptance component of Hägerstrand’s model. Contagious diffusion processes are driven by proximity, and typically spread out from the source of infection to adjacent locations. As the epidemic progresses over time, contagious diffusion could be thought of as a band of concentric circles spreading out from the core. By contrast, hierarchical diffusion epidemics often “bounce” from the origin to (often) nonadjacent locations based on spatial interactions of importance. For example, a disease may spread from one city to a very distant city as a person with measles travels from London to New York. Although the distinction between contagious and hierarchical diffusion is made for modeling purposes, in reality, diseases are spread through a combination of these processes, especially as populations become increasingly mobile. In addition, epidemics of infectious diseases often occur in cycles in which the incidence of disease increases and wanes over a period of time. Although these “waves” tend to occur with relative frequency, different waves may behave differently or display both “contagious” and hierarchical phases simultaneously or sequentially as parts of a larger diffusion process.

In order to investigate the diffusion of measles and influenza, Iceland has been considered as a natural laboratory in the sense of being a large, effectively “closed” island population (Cliff et al. 1981). Epidemic models have been linked with spatial theory (notably spatial autocorrelation) to help better describe the flow or movement of contagious disease through time and space. Patterns of both contagious and hierarchical diffusion are evident in the modeling of Iceland’s measles epidemic of 1950–1952 and movement of disease from the capital, Reykjavik, to outlying districts around the island along transportation networks.

Understanding the geographical diffusion of diseases assists long-term prediction and containment of diseases. Adequate prediction and surveillance is necessary for public health intervention in emergencies. Vigilance and early detection of disease epidemics are important for national and global security in cases of serious infectious epidemics, regardless of whether they follow natural “waves” (e.g., measles) or hypothetically result from deliberate terrorist-induced attacks. In the past 20 years, there has been an alarming re-emergence of infectious and vector-borne diseases, such as tuberculosis (TB) and malaria, which are returning to parts of the world in which these diseases have been absent
or confined for decades. Furthermore, there is concern that some diseases such as TB have mutated and become resistant to existing medical treatments. In addition, emerging diseases such as severe acute respiratory syndrome (SARS) and avian influenza have prompted many national and international initiatives to improve surveillance and control of communicable diseases.

The influenza virus regularly appears in new strains, preventing lifelong immunity in the population, while the measles virus remains stable. Current health threats are mutations giving rise to new varieties and drug-resistant forms of causal organisms, for example, methicillin-resistant *Staphylococcus aureus* (MRSA) and TB.

Mapping disease epidemics provides a visual summary of their progression, but often these maps are not prepared in a timely manner, or estimates of the disease distribution are crude and inaccurate; however, tools have been developed for monitoring, surveillance, simulation, and prediction, based on better understanding of the spatial and temporal behavior of diseases. Geographical information systems (GIS) can be usefully applied to aid disease surveillance, simulation, and analysis, provided that cases and risk factors can be mapped with high spatial and temporal accuracy. Remote sensing can be used for surveillance of ecological conditions and habitats for disease agents and vectors. GIS-supported simulation has been used to forecast the diffusion of HIV/AIDS (human immunodeficiency virus/acquired immune deficiency syndrome) and legionnaire’s disease. With sufficiently accurate data, simulation can be applied on any level down to blocks and workplaces. Cluster detection software such as SaTScan™ has been extensively developed in order to be integrated with spatially referenced infectious disease notification registers and other health databases to either prospectively or retrospectively identify clusters of disease efficiently and rapidly.

There will no doubt be increased use and sophistication of spatial technologies such as GIS, remote sensing, and Global Positioning Systems (GPS), and the integration of such technologies with disease infection models in the future. Obtaining the detailed information regarding where individuals move, who they interact with, and for how long, on a daily basis required to better understand the spatial diffusion of disease is extremely complex and difficult. However, it is now possible to both model and use GPS sensor technology to understand social processes and diffusion of disease progression.

Place effects on health emerge from complex interdependent processes in which individuals interact with each other and their environment, and in which both individuals and environments adapt and change over time. Traditional epidemiologic study designs and statistical regression approaches are unable to examine these dynamic and interactive processes. Agent-based models (ABMs) and other system-dynamics models may help to address some of these challenges, including within the infectious disease epidemiology field (Yang and Atkinson 2008). ABMs are microsimulation models where individuals in a population are called “agents.” ABMs allow researchers to change the characteristics of agents, such as their age, gender, ethnicity, and socioeconomic position, or whether they are carriers of a disease. By running the microsimulation and allowing the agents to interact with other agents in the population, models of diffusion or indeed the impact of immunization programs may be developed to inform policy.

In summary, this entry has described the processes used by health geographers and spatial epidemiologists to model the spread of disease across space and through time, with a particular focus on infectious diseases. Disease diffusion modeling has been influenced by Hägerstrand’s (1968) time-geographic work, with most
DISEASE DIFFUSION

models representing hierarchical and/or contagious diffusion processes. Understanding these processes is invaluable in disease surveillance and in the detection of infectious disease clusters. While attention has historically focused on the eradication of infectious diseases associated with the poverty and squalor of the nineteenth century such as cholera and plague, there has been a recent emergence of new diseases and significant developments in the way people travel across large distances, such as by high-speed train and air-travel, increasing population mobility. Together, such developments will challenge our ability to model diffusion processes and to respond in a timely and appropriate manner.

We have focused on biomedical approaches to modeling diffusion in this entry; however, it is important to stress that applying our knowledge of spatial processes such as human interaction and mobility is vital to increasing our understanding of the diffusion process. Consider, for example, the rise in measles cases, and deaths, in the United Kingdom in 2008 due to insufficient population-wide vaccinations rates, to understand this. While measles is well understood medically, clearly there are social factors contributing to its diffusion which can result in diseases remaining endemic or even re-emerging in the future as epidemics or global pandemics.

Dispersal, diffusion, and migration

D.F. Greene

Concordia University, Canada

Until a few decades ago, the movement of animals or plant propagules, especially long distance dispersal (LDD), remained a sideshow in ecology, of little interest except to a few specialists. Although the process of distant dispersal was clearly important in, for example, the new biogeography pioneered by MacArthur and Wilson in 1969, as well as in our understanding of the history of taxa at large temporal and spatial scales in a world of moving plates, it nonetheless garnered little attention from geographers and ecologists. Recently, however, LDD has earned considerable interest because of two applied issues (Nathan 2006). The first is related to fast climate warming and poses the question of whether species can migrate sufficiently rapidly to keep pace with the projected velocity of climate change induced by greenhouse gases. The second issue concerns invasive species: are there traits that allow us to distinguish potentially noxious invasives from those that would either be very unlikely to establish in a new area or else will, if established, have small populations with little effect on the native biota? If so, we could make our border control protocols far more efficient.

Migration has been defined in two ways. First, many animal species migrate diurnally (e.g., most plankton species have predictable vertical movement within the water column) or annually (famously, many bird species) in response to changes in environmental stimuli. This meaning will not be dealt with here. Instead we focus on migration as a dramatic alteration of range limits at a time scale of thousands of years, a spatial shift imposed by sustained, directional climate change. The primary driver typically is change in temperature rather than in precipitation. In particular, the migrations that have been studied most intensively are the poleward range shifts of the Holocene at higher latitudes and elevations, with most of the research in mountains also occurring well away from the equator. The primary reason for this focus on the higher latitudes is merely that the main empirical tool available for studying population dynamics in the distant past – ancient pollen grains in lake sediments or deep mosses – is useful only for wind-pollinated plant species, and aside from grasses and sedges these are quite rare near the equator.

Climate-induced migration has been studied for a century (Faegri and Iversen 1989). After early geomorphologists such as Agassiz in the
mid-nineteenth century made clear that much of the landscape of Europe and North America made sense only with an assumption of recent, widespread glaciation. Scandinavian investigators argued that the pollen grains in bogs showed predictable changes vertically, with the deeper layers of course indicating the species composition at earlier times, and further, that the plant species presently well to the north of a site had shown up lower within the core. For example, willow (**Salix**; an important constituent of tundra vegetation) pollen being replaced locally by aspen (**Populus**) and pine (**Pinus**) pollen was clearly an indicator of sustained warming. At first, there was little interest in the species themselves; they were proxies for measuring the kind of radical climate change that had caused the waning of Agassiz’ glaciers. Until radiocarbon dating became common in palynological work in the late twentieth century, no dates and therefore no velocities could be assigned to temporal changes at a site or to spatial changes among a network of sites.

By the 1990s there was a sufficiently dense constellation of palynological sites with dated cores in the higher latitudes that one could chart the migrational velocity of the northern or southern range limit for wind-pollinated species. Generally, beginning about 18 kya, species in the northern hemisphere moved rapidly in a northward direction until approximately 3–9 kya at which point the great majority of plant species had approximately reached their present northern range limits (Delcourt and Delcourt 1991).

Within the last two decades four generalizations have emerged from this dense literature. The first was that when a species arrived at a site, the pollen abundance increased in a logistic manner, with doubling times on the order of 50–200 years, values broadly similar to those seen in studies of contemporary invasive populations undergoing fast increases in abundance. Presumably, this represents the competitive advantage enjoyed by the invader as it keeps pace with its realized climate niche while the other species who have been there longer are no longer well-adapted to the recently emerging combination of precipitation and temperature. Subsequently, at this site the same species declines in abundance as its climatic niche moves further poleward and thus it becomes less competitive.

The second conclusion, and far more surprising, was that species moved independently of one another; species that presently have more or less coincident ranges typically began the migration 18 kya with far less overlap in ranges, and moved at different rates and along different axes. In short, each assemblage of plant species at a place was ephemeral, and seldom corresponded to our expectations of the floristic composition of “tundra” or “boreal forest” or “deciduous hardwood forest.” This finding effectively ended the still-popular assertion of F.E. Clements from a century previously that organisms within a climax association were so finely co-evolved that they must have remained together as a discernable unit for millions of years.

The third finding – quite unexpected – was that migrational velocities seemed to be far too fast – on the order of 50–200 m per year. Given that for example trees with ample light do not begin to produce large numbers of seeds until they are several decades old, these seeming rates mean that we are actually imagining that each generation of trees has long distance dispersal (LDD) events on the order of a few kilometers. Given that most contemporary studies of seed dispersal have been limited to a few hundred meters from a focal plant, and found vanishingly small numbers of seeds at even this modest distance, it seemed extraordinary that tree species could routinely manage this magnitude of LDD over the course of a few decades. This issue
remains unresolved – because of the logistical problem of finding needles in distant haystacks – and ultimately has been dealt with only via models. Encouragingly, it is becoming clearer from these models that dispersal of small seeds on the exterior of animals and of larger seeds within the intestinal tract of animals could easily permit a dispersal distance of several kilometers for a non-negligible fraction of a seed crop. We note that some authors, mainly in Europe, have argued that refugia at hypothetical ice-free alpine sites would have greatly aided poleward migration, and thus the required LDD events need not be as high as a few kilometers per generation to explain observed migrational velocities; this contention, however, has not led to any consensus on the existence or importance of the putative pockets of survivors among the glaciated landscape.

The final result was also a surprise: all species, regardless of whether they were dispersed by animals or wind, seemed to migrate at roughly similar rates. How could this be? The obvious explanation was that the limiting factor was not LDD but rather the rate of climate change. That is, the recent Holocene example was as if a set of runners of varying abilities were all simultaneously pushing up against the same slowly yielding barrier. Testing this hypothesis has proved difficult given that invariably the plant data are used to reconstruct the rate of change of climate. In any case, there is now a burgeoning literature based on the speculation that species may not be able to track CO₂-induced warming because (i) the required migrational velocity will be far more rapid than what was experienced in the early Holocene, and (ii) species will move more slowly than previously because they must migrate through intensely fragmented terrain. In turn, this notion of a potential migrational deficit has led to arguments for “assisted migration” – that is, moving propagules from likely genotypes well-north of their present range limits because their dispersal capacity is presumed to be incommensurate with the task.

The capacity of the more mobile animals (large mammals; birds) to track migrating plants is not doubted. But for smaller animals such as herbivorous insects it is not clear if they invariably lag near or very far behind the plants. A crucial question is the ability of pollinators and frugivores to keep pace with the plant species upon which they are dependent. There is a potentially important link: the migrational velocity of the dependent plant may be limited by the velocity of the fastest symbiont for the guild of pollinators or fruit dispersers upon which it is dependent. Unfortunately, there is as yet no dense spatial network of insect macrofossils using, for example, moss cores, and thus the question must remain unanswered at present. Nonetheless, there are studies at single locations using insect head capsules and in some cases distinctive feces to examine temporal changes in abundance. An eventual network of similar sites will, of course, as with the analogous data for pollen, be limited to those species that are most commonly represented in the moss cores in a region, and unfortunately these species may seldom be important mutualists but rather high-abundance herbivores such as pine beetles or spruce budworm.

We limit the meaning of diffusion in this entry to the spread of a species across new areas, with the range change induced by a driver other than climate. Thus, here the focus is on invasions promoted by the paucity of parasites and other enemies in the new area; the rate of climate change imposes no limit on the rate of spread. Borrowing from chemistry the argument for a random walk of particles, J.G. Skellam (1951) and others had by the mid-point of the twentieth century developed simple models of species’ spread across landscapes. In particular, such models tended to focus on the rate of spread at the range margin, and, while not explicit, it
was understood that the spread rate was greatly controlled by the capacity for LDD. While the very simple diffusion model of Skellam, for example, featured local exponential population growth and predicted a constant rate of range expansion, more recent models have included selection for enhanced dispersal capacity among range edge populations. There is no shortage of good empirical data sets of species spread rates from the last 100 years available for model testing, especially for animals (e.g., muskrats in Europe or starlings in North America).

The Convention on Biological Diversity defines invasive species as those spreading outside of their normal range and causing substantial harm. Globally, the damage caused by invasive species has been estimated as £1 trillion per year – close to 5% of global Gross Domestic Product (GDP). In developing countries, where agriculture accounts for a higher proportion of GDP than elsewhere, the negative impact of invasive species on food security, as well as on economic performance, can be even greater. Indeed, invasive species are typically viewed as primarily an economic issue rather than a biological one (despite the frequently dire effects of invasives on native species, especially on small islands).

Much work has been invested in enumerating the traits that predict invasion probability. For both plants and animals an essential characteristic of successful invaders is, relative to other members of the taxon, rapid individual growth rate. An equal role for dispersal capacity is less clear. Where dispersal traits can be at least modestly quantified with commonly available metrics (e.g., for wind or water dispersal by plant seeds, the ratio of propagule mass to propagule area is key), better dispersed species are indeed more likely to be successful invaders (e.g., Moravcova et al. 2010). But for many other kinds of plants, for example, those dispersed inside the intestinal tracts of animals, there is no such simple measure. Thus, while the more complex diffusion models make clear that LDD is a crucial determinant of invasion success and subsequent spread rate, nonetheless the empirical evidence remains largely unhelpful.

Uninformed by any but the simplest kinds of biological reasoning about dispersal, governments have developed policies for reducing invasions, and here they focus upon humans as the dispersal vector. For example, one cannot bring firewood into the United States as it might contain saprophagous insects such as pine beetles. Additionally, voluntary certification protocols have begun to play a role in reducing invasions. For example, there is now a certification program in North America governing the sale of “clean” nursery stock for gardens. A certification approach is of course highly useful as it capitalizes on the interest and education of the potential dispersal agent.

The term distance decay has been used to describe the effect of distance on interactions between two separate locations. Although the term might also be used in ecology or habitat of plant and animal species, the description here is confined to human activities in the disciplines of urban, economic, and cultural geography, that is, a concept linking geography and the occurrence or frequency of a pattern of activity. Distance decay is an important precept of spatial analysis, especially for spatial interaction models and notions of cultural diffusion; it is inherent in various applications of gravity models (Hanks 2011).

As a term that describes the decline of influence as distance increases, the term is related to Waldo R. Tobler’s first law of geography that “All things are related but near things are more related than far things.” Two terms need to be qualified: distance and decay. Traditionally, distance means the physical map and, more realistically, topographic surface distance. Assuming a flat surface where accessibility from a center point to all directions is equal, lines of equidistance will display a circular pattern around that point. This was the key assumption in the von Thünen rural land-use model and in Christaller’s central place theory at the time when the road network was not yet well developed and animal transportation was still dominant. The term decay refers to the diminishing influence of a phenomenon, attribute, or activity when two locales are far away from each other. For example, there is less interaction between distant places because accessibility and land value tend to decrease from a center.

Distance decay is commonly represented graphically by a curving line that swoops concavely downward as distance along the x-axis increases. It can be mathematically represented by the expression $I = 1/d^2$, where $I$ is a measure of spatial interaction and $d$ is distance (The Stands4 Network 2013). Borrowing the idea of Isaac Newton’s equation defining gravitational force, distance decay bears a strong relationship to the gravity model in that a precise mathematical relationship exists between the strength of a spatially expressed phenomenon and the distance over which it is distributed (Hanks 2011). For instance, a superstore tends to have a lower distance-decay function than a neighborhood convenience store (Figure 1). Geographers using gravity theory in their work attempt to construct a similar model analyzing labor or trade flows; transportation; shifts in population; and diffusion of languages, religions, and technologies.

The bid–rent theory is an important element in the gravity model, in which the concept of accessibility plays a decisive role. The rationale is that due to land-use competition in a free market, the land will be allocated to the highest bidder that is able to derive the greatest utility from the most accessible land. The saving in transportation cost can be traded off for extra rent payment. As the distance from the city center increases, the accessibility decreases, resulting in the decrease in derivable utility and rent. Hence, distance and land rent bear a negative
relationship termed as distance decay. Different functions have different bid–rent curves due to differences in height (a measure of the utility) and gradient (an indicator of sensitivity to accessibility). Commercial land use, especially for high-order retail business and service, earns the highest bid, as it is supported by a large market threshold with longer range. Industrial land use has smaller utility, as the return per unit area is low due to its large space requirement. Residential land use has the least utility, so its bid–rent is the lowest. The distance-decay curve, therefore, turns out to be steepest for commercial use and the gentlest for residential use. In urban geography, a city or town center is usually explicitly defined, from which all attributes, such as population density, land value, and quality and quantity of services, decline as the distance from it increases.

Although the distance between two places need not necessarily include such a center, it bears the same underlying assumption that declining accessibility will lead to reducing interactions for places farther apart. In many cities, the highest land values occur in the city center, but prices drop off rapidly with increasing distance. Local increases to the prevailing trend occur at outlying subcenters, forming secondary peaks, which are probably also major freeway and arterial highway locations, forming ridges of higher land value (Figure 2). Values at suburban downtown locations again reach the peaks found in the downtown areas, but drop off rapidly at short distances.

It has always been controversial whether the concept is universally applicable and the relationship is quantified correctly. With the advent of transportation and communication technologies, the frictional effect of distance has largely been reduced. Personal or social group interactions need not be actually meeting one another at the same place and at the same time. Besides, speculation for high-class residential blocks in space-limited cities has drastically raised its bid–rent ability. It may be more accurate to conclude that physical or topographic distance is no longer a prime determinant of the degree of interactivity between places and people. Yet, they still dictate a spatial variation of interactivity between places, whether at the local, regional, national, or global level.
A new perspective of distance decay

Interactions between places and people are still very much dependent on available connectivity and the efficiency in transporting people and goods or transmitting information. It can be a passenger-traveling network for land, sea, and air transport, a walking path network for short-range travelers, or even a wireless network for mobile communication. As such, the term “distance” needs to be defined with a new perspective. Empirical studies have shown that the following have become key variables instead of mere physical distance.

1. **Time distance** – with a road network for driving by car or walking as a pedestrian, the time taken to travel between two places normally increases in proportion to distance; but additional factors, such as waiting at traffic lights, the number of stops, number of lanes, density of cars or commuters, and speed restrictions, will all affect the travel time. This also varies temporally for day and night, normal and rush hours, weekday and weekend, low season and peak season. Time is an important determinant for everyday life activities, public administration, and commercial decisions. A 5–10 minute longer travel may stop people from buying daily necessities from shops that are further away. It is uncommon to spend over three hours’ journeying to enjoy just an hour’s hiking in the countryside in a day; postal delivery is less frequent the greater the distance from the post office; shopping malls and business activities will orientate themselves toward the biggest potential markets.

2. **Cost distance** – this includes fuel cost, toll fee, or even administration cost at custom borders. Despite the general truth that it is more costly to travel a greater distance, in most cases cost in monetary terms is not proportional to distance. In particular, for public transport, fare is nonadditive. Zonal fares, section fares, concessionary fares at selected stops can apply in many different ways for different modes of transport in different cities. These may alter the pattern, in that people may be willing to travel a little further distance for greater benefits or leisure. In Hong Kong, ever since the government introduced a subsidy for senior citizens to travel anywhere for just HK$2 (equivalent to one US quarter), mobility for this age group has increased significantly. Such spatial expansion is especially obvious for people who rate fare more importantly than time.

3. **Convenience in terms of alternatives** – this refers to reaching a place directly or having to make one or more transfers. The proximity to car parks, terminals, stops, or transport nodes can also affect the desire to travel.

4. **Behavioral preference** – despite shorter time and lower cost, some prefer to travel on certain modes of transport or to certain destinations for leisure or business activities due to other nonquantifiable reasons, such as security, fame, or personal preference.

**Rate of decay**

Traditionally, the rate of decay – or distance lapse rate in some literature – was plotted inversely with one variable distance, with the gradient dependent on the phenomena and studied area being considered. From a strictly normative path set by the original retail gravity models in the 1930s, consumer behavior was considered predominantly uniform and deterministic until the 1960s. For instance, land value has a steeper downward sloping curve for cities with less developed transportation or more rugged
DISTANCE DECAY

terrain. Today, distance decay may still hold for long distances. With the advent of transportation and communication technologies, the increasing diversity of means of transportation, the introduction of various fare structures, and the increasing demand for better living conditions, the effect of distance on human interactions has become less and, thus, the curve deviates significantly from the traditional trend. Models explaining human activities between places should take into account not only typical normative criteria but also other environmental and people-based factors. One of the major problems associated with traditional gravity models is lack of parameters on intuitive understanding of interaction behavior.

Many studies have, therefore, worked on computing mobility patterns to see the extent of distance or other factors in governing human behavior. In particular, with the advent of geoinformation technology, mass data can be collected and analyzed. To compute or predict the number of interactions between two spatially separated places, one way is to evaluate their accessibility with various types of activity, facility, or service. The impact of distance on a particular activity may be linear or nonlinear and can be modeled with a distance-decay function. Computation accuracy is enabled with network analytical functions in a number of commercial geographical information systems (GIS). The accessibility of each origin or center is computed with regard to a number of destinations or service points, for example, school from residential blocks, supermarkets from housewives’ residences, resorts from potential sources of visitors. On the side of origins, both distance (including also traveling parameters such as time and cost) and attractiveness can be taken into consideration. Together with the demographic data of the service points, potential trips or interactions are predicted.

When evaluated by empirical data, the effect of distance decay can be assessed. However, to accurately model the degree of interactions between places, it is necessary to formulate very clear objectives. The type of interaction, for example, working, schooling, or shopping, and whether it is a single or multipurpose trip has to be identified first. Much essential data have to be collected including:

1. places of origins and destinations, which can be scaled from a building to a city level or even national level;
2. demographic composition and characteristics (e.g., certain age groups, income level or socioeconomic status) at origins that are essential to the type of interactions;
3. services at various destinations, which can be a long and complex list, such as the type and order of services, cost, popularity, and so on, from which an index of attractiveness is computed;
4. individual trip data obtainable from the more traditional but reliable questionnaire survey and activity log sheet to the more advanced and automatic mobile tracking data and credit/debit card records; traffic flow data in between places might also reflect the degree of interactions made at a generalized level.

On the other hand, to find out if these activity patterns are related to distance or other variables, data on the journeys made are important. These include not only the more quantifiable and objective parameters of the above-mentioned physical distance, time distance, and cost distance, but also the more subjective behavioral issues like safety and familiarity, road quality, and scenic value. The latter are perhaps overriding but not accounted for very well in traditional path-finding models. The main
reasons are that these spatiotemporal variants are not easy to quantify and precompute and are perceived differently from individual to individual.

The collection, manipulation, and analysis of voluminous data have become feasible with advances in positioning technology, CCTV image capturing, and geoinformation technology. The current way forward is to develop appropriate techniques for big data mining and to generalize patterns for developing reliable models, especially in the area of human behavior, of the activity patterns.

Distance

Anthony C. Gatrell
Lancaster University, UK

Distance is surely one of the defining variables in geographic inquiry. Indeed, 60 years ago the Scottish geographer Wreford Watson referred to geography as a “discipline in distance.” As location theory (whether concerned with agriculture, settlement, industry, or retail) took hold on the discipline in the 1960s (ushering in a preoccupation with the relative location of agricultural land use, central places, firms, or shops) distance as a variable assumed a crucial role. The relative location of consumers and producers mattered. And despite writers such as Cairncross (2001) asserting the “death of distance,” it still structures much behavior and interaction. People do still want to meet in geographic as opposed to virtual space; people do still want to shop in stores on the high street or in the shopping mall, despite the massive growth of online retailing; and many consumers care that their food is grown locally rather than shipped across the globe and thereby eating up many “food miles.”

We can conceive of distance, or spatial separation, in a number of different ways. For example: as a straight line or perhaps “great-circle” distance that we can measure once we know the locations of two places, given by their respective latitude and longitude; the route length that is measured along a set of roads, streets, or paths; the time it takes to get from one place to another; the monetary cost incurred in making a trip; and, perhaps, the sense we have of how far one place is from another. Such “distances” can be both precise and absolute (given identifiable and fixed or stable locations), but also sometimes vaguely specified and perhaps having a frequency distribution. A train journey from one station to another might be scheduled to take 81 min. if there are no stops, but if the train is delayed or requires a connecting journey it will take longer. The flight will cost more at particular times of the year, and depending on the carrier. If engrossed in a good book or movie the flight may seem a lot shorter than on other occasions, while if we ask a set of people to estimate the distance between, for example, Paris and Berlin we will get a variety of estimates. And while we may measure distance on an interval scale (kilometers, minutes, dollars) we often use nominal or ordinal scales (“it’s close by,” “it’ll take you quite a while to get there,” “it’s closer than you think,” and so on).

Distances are structured by economic and social factors, some of which are under individual control, some of which are not. Such factors change over time. While the great-circle distance between Paris and London remains fixed, journey times and costs do not. While the physical distance between Chicago and Los Angeles is the same for the wealthy and the disadvantaged traveler, the cost in monetary terms may be very different if one travels business class and the other relies on a cheap, last-minute deal. Conversely, the real cost to the traveler on a low budget might seem considerably more than that for the business traveler who can either easily afford the trip or has someone else covering that cost. Social factors matter too; if accompanied on a flight by an intimate partner the journey may appear much shorter than if traveling alone.
or with small children who require frequent attention and amusement.

Distances are invariably thought of as measures of the spatial separation of two discrete locations on the Earth’s surface. To measure, for instance, the distance from Los Angeles to Miami requires us to specify where each city is located; but since cities have no fixed “center” the distance is somewhat arbitrary. Further, while it is not unreasonable to ask “how far is it from California to Florida?” the answer will depend on what we take to be their respective “locations”: the geographic centers of each state, the state capitals, the largest cities, the east-most point on the boundary of California and west-most equivalent in Florida, and so on.

It should be clear from the above that distance can get quite complicated, conceptually and empirically. Distance is more than a simple variable that matters only to those pursuing a spatial analytic approach to geographic inquiry. Some of these conceptual and measurement issues are explored below before considering how distance has been used in some branches of geography.

**Formalizing distance**

In a very general sense, distance can be defined as a measure, often (though not necessarily) quantitative, of the space that separates two points in that space. It is a relation between those two points. This is a sufficiently general definition that it takes into account different types of spatial separation and also recognizes that while we may make precise measurements, we can also think of distance in qualitative terms.

More formally, consider two urban locations (i and j) that have known coordinates; denote these locations as \((x_{i1}, x_{i2})\) and \((x_{j1}, x_{j2})\) respectively. Simple geometry gives the distance between these points as:

\[
d_E(i,j) = \left[ (x_{i1} - x_{j1})^2 + (x_{i2} - x_{j2})^2 \right]^\frac{1}{2}
\]

This is the straight-line or Euclidean distance (hence the subscript “\(E\)” in the equation) between the two points, determined by Pythagoras’s familiar formula. Euclidean distance is useful in many contexts but it is of little use if measuring distances that have to take into account the curvature of the Earth’s surface. In this case, assuming the latitude and longitude of each point are given it is quite straightforward to calculate the length of the shorter arc on the great circle that joins these locations.

Euclidean distance forms what is known in mathematics as a metric. Formally, this means that \(d_E(i,j)\) has the following properties: it cannot be negative; it can only be zero if the locations are identical; it is symmetric (the distance from \(i\) to \(j\) is the same as that from \(j\) to \(i\)); and it obeys the triangle inequality (this means that the distance from \(i\) to \(j\) must be less than or equal to the sum of the distances from \(i\) and \(j\) to another location, \(k\)). Note further that the locations are assumed to be in a two-dimensional space; a third dimension will require another coordinate.

Euclidean distance is, however, not the only metric. Imagine a city whose streets are set out in a grid. Measuring the straight-line distance (distance “as the crow files”) from one location to another might help the crow but it will not help someone walk or drive from one location to another. But the equation above is readily modified:

\[
D_M(i,j) = [(x_{i1} - x_{j1}) + (x_{i2} - x_{j2})]
\]

and the subscript \(M\) is used to denote this as the “Manhattan” metric. This replaces the square of the coordinate differences, and the square root of their sum, by unity. More generally, an entire family of metrics (so-called Minkowski metrics) arises if these differences are raised to the power \(“p”\) and, after summation, raised to the power...
1/p. Some of these ideas were explored by Gatrell (1983), though Miller and Wentz (2003) provide a more recent perspective.

Proximity is the converse of distance. Locations are proximal if they are near to, or close to, each other. But proximity can also refer to areas or regions; for example, California is closer to Arizona than it is to Oklahoma. This proximity relation can be represented as a topological graph in which two states are connected directly if they are adjacent (contiguous). Such a simple representation of spatial separation (as adjacency) has often been exploited in spatial analysis, particularly in creating spatial weights matrices as used to construct measures of spatial autocorrelation.

While distance is considered above in terms of spatial separation it can also be conceived in terms of the difference or dissimilarity in the characteristics or attributes of particular locations or places. For example, if two countries share identical or similar languages, religious and ethnic composition, and so on, they can be thought of as “close” in terms of cultural “distance.” In this case we could construct a matrix of countries and attributes and assess the extent to which pairs of countries were similar or dissimilar across a range of attributes.

Relative distance

Distance, therefore, can be conceptualized in ways other than as physical distance. These include measures of cost, time, cognition, and social separation. None of these is fixed, so instead of speaking of the absolute distance between a pair of fixed locations we refer to relative distance instead (Abler, Adams, and Gould 1971). More recently, a relational, as opposed to a relative view of space, has emerged, asserting that objects can be understood only in relation to other objects. Yet while the relations matter, it is material things (people, stores, parks, hospitals, and so on) occupying specific locations that usually give rise to such relations.

Cost distance

Since distance is a constraint on some forms of activity (the so-called friction of distance) there is a cost incurred in overcoming such distance. Classical location theory (such as that of Von Thünen) posited an isotropic or uniform plane in which cost distance and physical distance were interchangeable. But since geographic space is not homogeneous or uniform in character the straight-line distance across such space ignores any underlying landscape heterogeneity or even – in flight – the variable pressures that may be encountered. As a result, geographers have sought to identify “least-cost” paths that seek out regions of low cost and avoid zones that “cost” more to traverse (Gatrell 1983, 52–53; Miller and Wentz 2003, 582). A simple example would be route construction, where constructing a road or rail track across marshland or steep terrain would be prohibitively expensive compared with drier, flatter land. To take a very different example, the perceived “cost,” to personal safety, of taking a direct route through a park at night might be very high and it may well be a safer option to take a longer, better-lit route home. Cost does not always have to be monetized.

Economists interested in international trade have shown that physical proximity matters: about one quarter of trade flows are between countries sharing a common border, and half is between countries separated by less than 3000 km. Giuliano, Spilimbergo, and Tonon (2013) look at the costs of freight transport among European countries using data from the International Monetary Fund’s Direction of Trade Statistics. They correlate these cost distances with a measure of genetic distance – the
DISTANCE

extent to which the populations of pairs of countries are genetically similar (Figure 1). More generally one can think of the economic distance – the disparity in wealth or economic size between countries or regions.

Time distance

Time distance can be considered as the average journey time from \( i \) to \( j \), or perhaps the fastest travel time between two places. As a measure, it does not meet the definition of a distance metric (see above) since it is unlikely to be a symmetric relation (the travel time from \( i \) to \( j \) may well be different from that of \( j \) to \( i \)). Travel time is shaped by material factors, such as mode of transport and level of technology. Further, any trip involves time spent in situ. For example, a short-haul flight takes perhaps an hour to get from one landing strip to another. But this bears little relation to the time taken to get from the origin (perhaps home) to the destination (a downtown hotel, perhaps), when the relatively unproductive waiting times (for passport control, security, luggage, taxis, and so on) add greatly to the real time-distance (and, of course, its perceived cost).

Journey times from one place to a set of other locations can be displayed graphically as a set of isochrones, lines joining points of equal travel time from a chosen location. In an urban context the spatial configuration of the street network generates isochrones that are quite convoluted, perhaps with inversions which suggest that locations that are geographically further apart are, in terms of time distance, somewhat closer. At a regional, or even international, scale there may be a broadly linear relation between travel time and geographic (or network) distance but there will be inversions here too, and no single time distance from one location to a set of others. A compelling historical example, due to the German geographer Eckert in the early twentieth century, showed time distance from Berlin to parts of Africa and the Middle East in 1900; while the travel time to the south coast of Africa might have taken 25 days by boat, it would have taken over 40 days to reach inland parts of North Africa (Figure 2).

Geographic space is therefore warped by travel time. But it is a one–many relation, showing time distance from one location to several. In order to represent travel time between many pairs of locations geographers have used multidimensional scaling (MDS) to create maps depicting the relative location of places in time space. More recently “spatialization” is a set of techniques where cartographers have played a prominent role. The underpinnings are essentially the same as MDS, although they seem to favor self-organizing maps (SOM) over MDS methods. MDS is often referred to as “ordination” in other disciplines (such as ecology).

Of considerable interest is that time (and cost) distances themselves change over time, as transport technologies and routes improve or are upgraded. Locations therefore “move” relative
Figure 2 Travel time from Berlin to Africa in 1900. Source: Gatrell (1983). Reproduced by permission of Oxford University Press.
to others. This process is called time–space convergence. Such convergence is not a simple linear, or even continuous, process since it is shaped by the introduction of new technologies that may result in a sudden and dramatic reduction in travel time. For example, the introduction of diesel trains, and then high-speed trains, dramatically reduced journey times in the United Kingdom during the latter half of the twentieth century, while transatlantic journey times by air have reduced sharply over the last 60 years, reflecting new engine technologies. But such convergence is itself geographically differentiated; while some places get brought closer together, others are bypassed, with potentially serious effects on their economic prospects.

Cognitive distance

Cognitive distance is the implicit or explicit judgment made about the spatial separation of locations that are not directly observed. For example, respondents might be asked to estimate distances between a set of landmarks in a city or the spatial separation of world cities. Judgments of distances between multiple pairs of places may, via MDS, be used to construct cognitive maps. As “behavioral geography” developed as a subdiscipline in the 1970s a substantial literature emerged – both in geography and psychology – that examined the relationship between cognitive and physical distance (invariably shown to be nonlinear) and what the correlates were of cognitive distance. Such correlates depend on the spatial scale of analysis but in a within-city context might include whether places are linked directly by major routes, or if there are spatial barriers (such as rivers). Other variables affecting distance estimation relate to the properties of the places themselves and how these are assessed. If one pair of places is “valued” more than another then distances are underestimated, and vice versa.

There is an inverse relation between “emotional involvement” and cognitive distance, neatly captured in German research which showed that distances between cities in the former East and West Germany were over-estimated by those opposed to German reunification – an effect poignantly labeled a “mental wall” (Carbon 2010).

Sociocultural distance

Intuitively we can think of the cultural and social distance between countries or social groups and individuals. Two countries made up of predominantly different religious or language groups are culturally and perhaps politically distant even though they might share a common border (India and Pakistan, or Israel and Jordan). Such differences, whether in religious beliefs, language, or ethnicity, can create distance between two countries. Trade among countries with common language is, other things being equal, three times the volume of those without, and countries linked as colonizer–colony (and therefore politically “proximate”) see trade increased nine-fold. And, of course, trade and tariff barriers create distance between potential partners.

The distance between social groups or individuals can be thought of in terms either of volumes of interaction or their social difference. At an individual level there are sets of interpersonal distances according to whether the interaction is intimate, personal (e.g., conversation between two colleagues), social (perhaps within a small group), or public (e.g., an address to a small audience). These sorts of interactions are mediated by culture, gender, physical setting, and other factors. More generally, an entire subdiscipline of social network analysis exists (and is expanding rapidly) that looks at the structure of interpersonal contact networks and the relations that define such networks (whether simple knowledge of each other, acquaintance, friendship,
and so on). Clearly, it is also of interest to know whether such networks are also structured by geographical proximity.

Despite the huge growth in social media, where it matters not a jot whether interaction is with a near neighbor or with someone the other side of the globe, distance does still structure human interaction. People often want to meet in real space, not only cyberspace. An important family/social occasion such as a wedding or a civil partnership, or even a funeral, usually expects or requires copresence. In both cases, distance still matters but is socially structured; an invitation to attend will depend in part on the social relationship to the couple or the deceased.

Despite the huge growth in online shopping (retailing) many consumers want to visit stores in person, while charges for local delivery to the front door will, in some cases, depend on distance from the store. In addition, social media themselves may call for spontaneous interaction in real space (flash mobs) while there are many examples of meetings that are assemblies of concerned citizens protesting about political issues. Think, for example, of the “Arab Spring” uprisings in countries such as Egypt, where crowds have gathered on many occasions (in Tahrir Square, Cairo, for example) to call for changes in government.

Examples

As noted in the introduction, distance was the crucial variable in classical location theory. For example, Von Thünen’s agricultural location theory expressed rent as a function of distance (cost of transport) to the market; Alonso’s urban land-use theory took the same stance; Weber’s industrial location theory relied on measuring distances between sites of extraction and of consumption, while central place theory (due to Christaller and Lösch) was concerned with the spacing of settlements at different levels of the urban hierarchy.

Distance also became the defining feature in classical studies of movement – whether of human beings, freight, or information. In the late nineteenth century, studies of migration by Ravenstein suggested that most migration (at least, in England and Wales, his area of study) comprised short distance moves, often between neighboring counties, and that longer-distance migration was to larger towns and cities. Such an acknowledgment of the role played by population and distance prefigures work 40-50 years later by researchers (such as William J. Reilly, John Q. Stewart, and William Warntz) into “social physics.” Here, the fundamental principle (Abler, Adams, and Gould (1971) was that spatial interaction is shaped by factors operating at the origin and destination but, crucially, by the distance separating them. This became enshrined in the notion of a “gravity model” that borrowed directly from Newtonian physics, where attraction is directly proportional to the product of masses of “bodies” and inversely proportional to the square of the distance separating them. Later reformulations and generalizations of such modeling (leading to classes of “spatial interaction” models rather than simple gravity formulations) offered much greater sophistication, though the importance of distance as a variable that constrained human interaction was still crucial. It remains an important component of any attempt to measure spatial accessibility (for example, to schools or health centers) though more sophisticated analyses use likely travel time along street networks as a measure of spatial separation, while other studies use route distances rather than travel times and some question the added value of using travel times rather than simple Euclidean distance. Distance also remains an attractive variable to economists attempting to model international trade flows as a class of
Distance

Spatial interaction (with national income used as a measure of “mass” and intercountry distance in the denominator). Income and distance explain a good deal of the variation in international trade.

At much the same time as social physics was developing, the Swedish geographer Torsten Hägerstrand was embarking on another classic study of spatial interaction, namely, the spread or diffusion of agricultural innovations. The key feature of his model was the “mean information field,” a construct which proposed that the ability of one farmer in rural Sweden to influence others was constrained by physical distance. Farmers who lived close to one another were more likely to meet and exchange ideas and information than those who lived further away. To the modern reader this may seem quaint, but the historical context (1940s rural Sweden) and Hägerstrand’s own empirical research in the 1950s bore witness to the fact that distance did indeed impede social interaction. The mobile phone, the tweet, and Facebook may well have eroded the importance of such interaction, but such devices and media were undreamt of 60 (even 25) years ago.

Distance in contemporary spatial analysis and GISci

The development of geographic information systems (GIS) and its accompanying scientific underpinnings (GISci) over the past 25 years has reasserted the importance of distance and location. The basic building blocks here are the accurate recording of locational data, and these data, coupled with the measurement of (usually physical) distances between objects, permit a considerable array of spatial analyses to be performed. A basic GIS procedure is the definition of “buffer zones” around point, line, or area objects and these require the setting of a distance limit; for example, a buffer zone of 50 m either side of streets in order to assess air quality, or circular regions of, say, 250 m around a set of schools in order to count the number of fast-food outlets within such catchment areas.

Geographers in the early 1960s drew on work by ecologists on the spatial distribution of plant species. These ecologists had devised a method called nearest neighbor analysis which sought to assess whether plants were distributed randomly in geographic space, or instead showed a tendency to cluster or alternatively display a more regular spatial pattern. Since empirical testing of central place theory was required, an obvious use of such methods was to detect departures from nonrandomness in settlement distributions. This required the measurement of distances from one settlement to its neighbors. More recently, much more sophisticated techniques for exploring spatial point patterns have become available, including the estimation of K-functions (to detect clustering) and kernel smoothing (to create an estimate of the density or intensity of the point pattern) – in effect, a continuous surface (O’Sullivan and Unwin 2010). These still require distance calculations. Such methods are now widely adopted in spatial epidemiology and spatial analysis of crime data. A critical issue is that these methods assume that the point locations (in human geographic applications, often residential locations) are fixed and meaningful. But people occupy activity spaces rather than being rooted to fixed locations, the distances between which may have little or no intrinsic significance. And other concepts of distance may mean more.

Physical (Euclidean) distance also features strongly in the problem of spatial interpolation. Given attribute data (perhaps precipitation, mineral ore content, or particulate air pollution, for example) sampled at a set of discrete locations it is often of interest to construct a best estimate of the continuous field from which these samples are taken, and in some cases to predict attribute...
values at locations which were not sampled. There are a variety of methods or techniques for doing this. The simplest case is to lay a regular grid over the study region and estimate values at grid points based on a weighted average of known values, where the weights are a function of distance; intuitively, it makes more sense for locations nearby to “contribute” more to the estimates than samples taken further away. More sophisticated methods of interpolation, such as kriging, make use of spatial autocorrelation in the given data, and also permit estimates of the uncertainty that attaches to each of these (O’Sullivan and Unwin 2010).

The classic work by Hägerstrand on the spatial diffusion of innovations was highlighted above. Other geographers have used some of these ideas in order to understand the spread of disease. Imaginative research on the spread of cholera in nineteenth-century America (Pyle 1969) showed how in 1832 disease spread was constrained by distance from the point of entry (New York City) but that a later epidemic in 1866 spread in a way that was structured more by distance in a space shaped by the recent rapid expansion of the rail network. In epidemiology distance, either in absolute or relative terms, remains relevant today, as seen by the spread of diseases such as SARS (severe acute respiratory syndrome) and new strains of influenza. SARS emerged in Guangdong, China in 2002, almost certainly having crossed the species barrier from civets to human because of the close proximity of animals to human populations and the keeping of animals in cramped conditions (Gatrell 2011, 142–144). The disease spread at a microscale within a Hong Kong hotel, but given Hong Kong’s location as a hub in the international airline network it was almost inevitable that the disease would diffuse quickly to other world cities (such as Toronto) that are either directly or indirectly connected to the source. Physical proximity still matters, certainly at a very localized scale, as on an airplane (Baker et al. 2010; see Figure 3). Yet distance in spaces that are structured by social and economic relations, and particularly by the nature of transport networks, matters more.

Distance matters in other public health-related contexts as, for example, in studies of the “walkability” of urban neighborhoods. Neighborhoods are “walkable” if they have good levels of street connectivity, a mix of land uses and residential densities, and facilities such as urban parks that make walking more attractive. A key element of walkability is the distance between residences, shops, and workplaces and geographers have made use of GIS to analyze variations in walkability and consequent variations in walking behavior. Given the rising levels of obesity in many countries this research is important.

Conclusion

Seen simply in terms of physical separation on the Earth’s surface, distance, both as a key geographic concept and as a factor in human life, has weakened over the years. Forty or fifty years ago, when the dominant paradigm in human geography was positivist spatial analysis, distance was perhaps the key variable that exercised the geographer’s interest. In general, and excepting the study of geographic information science, this is no longer the case. Relatively few contemporary students of geography engage with location theory, spatial interaction, spatial diffusion, and other subjects that were once part of a core geographic curriculum.

In part, this declining role in academic inquiry reflects its lessening importance as a factor influencing human behavior and socioeconomic life. Fifty years ago authors spoke of the “tyranny of distance” (Blainey 1966); now, others speak of the “death of distance,” though Cairncross
DISTANCE

(2001, 5) is quick to assert that while “the death of distance loosens the grip of geography ... it does not destroy it.” Blainey’s book referred to how the relative isolation of Australia – its distance relative to other parts of the world – had shaped its history and development. Now, cities such as Sydney and Melbourne are truly world cities that are connected into a global network. But they are still far away from Europe and North America and journeys to those continents are not a trivial undertaking. Despite the rapid, recent growth in communications technologies, if face to face meetings are required, or people wish to visit real places, distance still matters.

Over 40 years ago Waldo Tobler invoked geography’s first “law”: that everything is related to everything else, but near things are more related than distant things. It still holds. But we must acknowledge that there are alternative concepts of distance, and these matter a great deal – to geographers and many others working in different disciplines. The physical separation of places does not imply separation in other kinds of space. Given the complexity of modern communications and travel networks, simple conceptions of distance are unlikely to tell the whole story; physical separation is not always a good proxy for social, cultural, economic, or other kinds of separation.

Earth system science

Noel Castree
University of Manchester, UK

Earth system science (ESS) goes back 30 years and today has considerable momentum. As one commentator puts it, ESS “embraces chemistry, physics, biology, mathematics, and applied sciences in transcending disciplinary boundaries to treat the Earth as an integrated system and seeks a deeper understanding of the physical, chemical, biological, and human interactions that determine the past, current and future states of the Earth” (Ruzek 2013). ESS thus has grand intellectual ambitions. As a science it uses evidence, logic, and physical laws to identify patterns, trends, and explanations that aspire to accurately represent the interactions between the components of the Earth surface (namely, the atmosphere, hydrosphere, lithosphere, cryosphere, and biosphere). However, unlike the specialist sciences (such as marine biology), ESS aims to “join the dots” by identifying relations and feedbacks between Earth surface phenomena often studied in relative isolation. Because the Earth surface comprises a set of interlinked “open systems” existing at a range of spatiotemporal scales, ESS’s quest to be interdisciplinary has faced some formidable intellectual challenges, as this entry will explain (see Environmental uncertainty). Geologist Richard Alley (2000, 7) likened it to creating the world’s most detailed ever “operator's manual” for a “machine” of unequalled complexity.

In its early years, ESS was global physical geography by another name – although relatively few geographers were actively involved in promoting it, for reasons explained below. Before and immediately after the millennium, ESS tended to bracket the human causes of global environmental change and focus largely on biophysical effects. More recently, however, its ambitions have broadened (see Global environmental change: human dimensions). Today, ESS looks more like the sort of environmental geography that, for some of academic geography’s founders (such as Halford Mackinder), defined the discipline’s mission as a “bridge” between the physical sciences (on the one side) and the social sciences and humanities (on the other) (see Geography and the study of human–environment relations). ESS increasingly considers two-way human–environment interactions rather than only humans’ biophysical impacts on Earth. However, again few geographers have championed ESS in its current form, although several have been involved in parts of its grand research agenda.

The why and how of this involvement is detailed in the final part of this entry. Before this, the history, institutional configuration, and evolution of ESS is described in three sections. Along the way some evaluative comments will be offered on successes and challenges. Thereafter, ESS’s relations and nonrelations with research by physical and environmental geographers is explored. Because this entry includes a great many acronyms, Box 1 itemizes them alphabetically to aid the reading process.
The origins of ESS

The precursor to Earth system science was the idea of an “operator’s manual for spaceship earth” formulated in 1968 by the remarkable American architect-inventor Richard Buckminster Fuller. Fuller criticized academic specialization and challenged his readers to aspire to “total knowledge” of a world they were fast-changing. He wrote at a time when humans, courtesy of the Apollo space missions, had seen their planet from space for the first time. The term Earth system science originated seventeen years later with a British mathematician and modeler of ocean and atmosphere dynamics, Francis Bretherton (1985). A University of Wisconsin professor, in 1983 he was appointed by the United States’ National Aeronautics and Space Administration (NASA) to chair a committee convened to consider how the Administration could most effectively fulfill its mission to observe the Earth surface. The committee comprised 16 members covering meteorology, atmospheric chemistry, marine biology, plant ecology, soils and vegetation interactions, agronomy, and geophysics (among other fields).

After a series of meetings in 1984 and 1985, the committee produced a report entitled *Earth System Science Overview* (NASA 1986). Page one described ESS’s goal as “understanding the entire

Earth System on a global scale by describing how its component parts and their interactions have evolved, how they function and how they might be expected to continue to evolve on all time scales.” On the same page, ESS’s “challenge” was to “predict those changes that will occur in the next decade to a century, both naturally and in response to human activity” (NASA 1986). The report included a diagrammatic presentation of the Earth system that would subsequently circulate widely in the research communities devoted to understanding global environmental change (Figure 1). The diagram expressed the holistic view recommended twelve years earlier in a (now quite famous) scientific paper. That paper proposed that Earth is seen as a self-regulating system and was authored by James Lovelock and Lynn Margulis (1974). Lovelock, a former NASA employee, went on to promote the so-called “Gaia hypothesis.” One aspect of this, which few took seriously in the early 1970s, was that humans’ combined activities might be sufficiently powerful to set in train alterations to the Earth system as a whole, not just one or other component of it.

As this diagram made clear 30 years ago, a number of important ingredients would be required if ESS was to become more than a grand, possibly idealistic, research idea. First, mechanisms for fostering cross-disciplinary exchange among the various geosciences would be essential. Second, high-resolution data about Earth surface patterns and processes at a range of spatiotemporal scales would be required. Third, there would be a need to ensure international academic cooperation among researchers in all parts of the world. Finally, there would be a need for computational and analytical techniques able to portray (and predict) complex Earth system dynamics across geographical space and through time. Recognizing this, NASA quickly used the Bretherton committee report to involve the USA’s National Science Foundation (NSF) and the National Oceanic and Atmospheric Administration (NOAA) in its aspiration to make ESS a reality.

One result of this outreach was the creation of the federal Global Change Research Program (GCRP) in 1989, underpinned by the 1990 Global Change Research Act. This program, involving multiple federal government agencies, committed considerable financial resources to promoting integrated environmental research. Its original strategic vision was threefold: “1. Establish an integrated, comprehensive monitoring program for Earth system measurements on a global scale, 2. Conduct a program of focused studies to improve our understanding of the physical, chemical, and biological processes that influence Earth system changes and trends on global and regional scales; and 3. Develop integrated conceptual and predictive Earth system models” (Committee on Earth Sciences 1989, 11–12). This trio of aims was framed by the overarching desire to “establish the scientific basis for national and international policymaking related to natural and human-induced changes in the Earth System” (Committee on Earth Sciences 1989, 9). Because of the United States’ leading role in academic and applied research globally, the creation of the GCRP had an almost immediate impact on research programs into anthropogenic environmental change elsewhere. For instance, the UK’s Natural Environment Research Council (NERC) announced an ESS initiative of its own from 2001. Around the same time, leading German physicist Hans Joachim Schellnhuber (1999) made Earth system analysis central to the Potsdam Institute for Climate Impact Research (founded 1992 and today a “hotspot” of ESS). Meanwhile, the term “Earth system” is routinely found in the latest strategy documents and research funding streams associated with the GCRP (National Science and Technology Council 2012).

ESS’s international evolution

The Bretherton committee report was more-or-less coincident with the creation of four global research programs focused on anthropogenic environmental change. These were the International Geosphere-Biosphere Program (IGBP, launched in 1987), which followed the World Climate Research Program (WCRP, created 1980), and which, in turn, was followed by the International Human Dimensions Program (IHDP, created in 1990, re-launched in 1996), and DIVERSITAS (launched in 1991, focusing on global biodiversity and biogeography). The four programs enjoyed support by numerous governments and became a vehicle for collaborative research among geoscientists across international borders. They emerged because of a widespread concern, articulated in the 1987 Bruntland Report on Sustainable Development, that humans were instigating planetary-scale environmental changes. That concern was expressed politically in 1992 at the United Nations “Earth Summit” held in Rio de Janeiro. Of all the programs, the IGBP took the Bretherton report’s aspirations to heart the most. From its inception, it tried to develop models – based on physical laws and mathematical logic – that could represent accurately the intricacies of the Earth system.

Despite their professed commitment to “integrated environmental analysis,” members of all four programs soon realized that some key issues were falling between the proverbial cracks. Well aware of the ESS goals articulated by Bretherton, senior members agreed to form a partnership in 2001 – the Earth System Science Partnership (ESSP). They also enrolled a capacity building and networking initiative designed to reach researchers in the Global South (called the Global Change SysTem for Analysis, Research and Training: START). Program resources were then used to co-design and implement a set of joint research projects, such as Global Environmental Change and Food Systems (GECAFS) (Table 1). Running for a decade (2001–2011), GECAFS’ aim was to “to determine strategies to cope with the impacts of global environmental change on food systems and to assess the environmental and socio-economic consequences of adaptive responses aimed at improving food security” (www.gecafs.org/). As this objective indicates, it sought to link research into climate change, soils, and vegetation to social scientific inquiry into farming, food storage and distribution systems, and much else besides. It was, in short, “intersectional” in focus. The system concept proved useful for enabling interchange between researchers from a diversity of disciplinary backgrounds. At the same time, researchers benefited from more numerous and higher resolution Earth observation technologies. This and other joint projects were eventually steered by an ESSP science committee (from 2007). The partnership also created a peer review journal, Current Opinion in Environmental Sustainability. Under its auspices, two manifestos-cum-bibles of ESS were published in 2004: one was the jointly authored Global Change and the Earth System: A Planet Under Pressure (Steffen et al. 2004); the other was an edited book Earth Systems Analysis for Sustainability (Schellnhuber et al. 2004).

Despite progress being made in GECAFS, specific separate projects within the IGBP, WCRP, IHDP, and DIVERSITAS have also contributed to the ESS aspiration for holistic analysis of global environmental change and its regional components. For example, the IGBP’s AIMES (Analysis, Integration and Modeling of the Earth System) project made great strides in representing computationally the dynamic interrelations between atmosphere, water, and land. Unlike the traditional image of a system as closed and self-regulating (unless externally forced beyond...

operational boundaries), AIMES has made use of wider scientific thinking about complexity, nonlinear behavior and irreversible tipping points. The new incarnation of AIMES aspires to incorporate human behavior and responses, and to help decision-makers anticipate serious socioenvironmental problems before they appear (van der Leeuw 2013).

This aspiration leads back to the original inspiration for the creation of the ESSP. Many projects within the four global change research programs have arguably advanced “narrow” interdisciplinarity rather than “wide” interdisciplinarity. For instance, computer models of the sort used in many WCRP and IBGP projects have thus far left out many social scientists whose research into “human dimensions” of environmental change focuses on politics, social power, societal resilience, and community capacity building as they relate to avoiding, or adapting to, biophysical hazards. This is, perhaps, consistent with the externalization of those dimensions evident in the 1985 Bretherton diagram (to the right in Figure 1). Even the joint projects conducted under ESSP auspices have had their limits. Consider the Global Carbon Project (established in 2001. Its professed aim is to offer a “complete picture of the global carbon cycle, including both its biophysical and human dimensions together with the interactions and feedbacks between them” (www.globalcarbonproject.org/). However, it has been dominated by geoscientists and, among the social scientists involved, economists have loomed large. This means that other disciplines focused on other human dimensions of carbon acquisition and use have been rather side-lined. Meanwhile, some nationally funded ESS projects have remained unapologetically focused on physical dimensions – such as the QUEST (Quantifying and Understanding the Earth System) project funded by the UK’s NERC. What is more, some have wanted to take ESS in an applied direction by treating coupled human–environment systems as objects for a new generation of engineering and management approaches. For instance, in his manifesto for ESEM (Earth Systems Engineering and Management), Brad Allenby argued that “the anthropogenic Earth is a difficult, highly complex, tightly integrated system that challenges society to rapidly develop tools, methods, and understandings that enable reasoned responses. Engineers in general, and civil and environmental engineers in particular, must be a critical part of any such response” (Allenby 2007, 7961). This chimes with Richard Alley’s earlier mentioned notion of ESS as providing an “operator’s manual” if it achieves sufficient analytical precision and predictive accuracy.

Why the limited focus on human dimensions, going back to Bretherton – notwithstanding the creation of the IHDP? Arguably, it reflected the wider, long standing “divide” between the natural sciences and the disciplines studying people – a divide British novelist and scientist CP Snow (1959) famously described as academia’s “two cultures problem.” In essence, the divide reflected the ontological differences between the biophysical world and the world of people. Unlike rocks and rivers, people are creatures of both reason and emotion, able to be proactive and reactive in relation to nature and other humans. Consequently, “scientific” approaches are not wholly appropriate to understanding human thought and behavior. As far back as the 1960s, the German social theorist Jurgen Habermas (1968; English translation 1972) argued that “hermeneutic” and “critical-emancipatory” approaches were equally important. The former elucidates various human values, beliefs, feelings, and desires using methods like ethnography, interviews, and focus groups. These methods do not aim for objectivity and precision in the same sense as most
natural science research techniques. The latter highlights the inequalities rife in various societies and reveals the values and goals associated with marginalized or oppressed social groups (with a view to achieving them in practice). Again, where natural science aims for objectivity, critical-emancipatory research is overtly political and researchers may align their own activities with those of the disadvantaged people they are researching (see Participatory action research).

The limitations in applying a scientific approach to understand human dimensions help us understand why ESS, on the international stage, is now morphing into something less dominated than heretofore by climatologists, oceanographers, and other geoscientists. This mirrors changes in the way research into climate-society interactions has changed since the Intergovernmental Panel on Climate Change published its fourth global assessment in 2007. The most recent report (published in 2014) makes a considerable effort to focus on human responses to climate change and policy options for better mitigation and adaptation measures.

However, the intellectual and practical barriers to success in broadening ESS’s intellectual reach remain extremely high. Despite (i) improvements in the quantity and quality of available Earth surface data, (ii) increased computational power and sophistication, and (iii) success in international cross-disciplinary team working, problems remain. First, most geoscientists are interested in identifying what has happened and will happen to the Earth’s environment. However, many social scientists (and humanists) are concerned with normative issues – that is, with debates over what could and should happen, depending on the values and institutions that might influence human decision making looking ahead. Normative questions can be logically debated; but they are not amenable to measurement and modelling. They speak to humans’ capacity to change the way they think and act, perhaps dramatically so in the face of perceived existential threats. Large – perhaps unprecedented – societal changes would radically alter the future course of the Earth system.

Secondly, practical issues arise in trying to synthesize knowledge among researchers who have different “worldviews.” For instance, where environmental economists might be keen to put a price on carbon dioxide emissions, an anthropologist might want to focus on the ensemble of institutions, social relations, and cultural norms that dispose whole societies to burning fossil fuels on a mass scale. Finally, practical issues also arise in assembling data on current patterns of human behavior. Such behavior cannot be monitored by satellites in way Amazonian forest cover can. Instead, different sorts of data from a myriad of sources (governmental and academic) need somehow to be synthesized to better understand patterns, variations, and transitions in how people influence and are influenced by global environmental change. One complication here is that past and present human behavior is not governed by a universal rationality; instead, it is profoundly conditioned by the norms, relationships and power dynamics of different societies. Added to this, predicting such behavior is very difficult when compared to the challenging, but more tractable, problem of predicting future environmental change in light of current biophysical knowledge.

ESS today: the Future Earth framework for global change research

As noted already, ESS is now transitioning into a more transdisciplinary endeavor. A recent definition by some of those involved captures an intellectual broadening that is central to this. According to Leemans et al. (2009, 5), ESS today
EARTH SYSTEM SCIENCE

aims to “observe, understand and predict global environmental changes involving interactions between land, atmosphere, water, ice, biosphere, societies, technologies and economies” (emphasis added). The ESSP has come to an end, along with the IHDP. With the three other global change research programs and START, the ESSP has fed into a new initiative called Future Earth (www.futureearth.org/). Future Earth (FE) was launched at the 2012 Earth Summit (otherwise known as Rio+20). It has high level support globally. It is sponsored by the Science and Technology Alliance for Global Sustainability comprising the International Council for Science (ICSU), the International Social Science Council (ISSC), the Belmont Forum of national funding agencies, the new Sustainable Development Solutions Network (SDSN), the United Nations Educational, Scientific, and Cultural Organization (UNESCO), the United Nations Environment Program (UNEP), the United Nations University (UNU), and the World Meteorological Organization (WMO).

Several joint projects and separate projects from the ESSP and the four global change research programs are rolling forward under FE auspices. However, more than in previous research, FE aims to foster “wide-angle and relevant” inquiry that speaks more to (i) human dimensions (including development in the global South) and (ii) the needs of decision makers (in politics, commerce and civil society) and stakeholders. To quote from its strategy document, FE places “a strong emphasis on full integration among scientific disciplines, on engagement with societal partners in co-designing and co-producing knowledge, on international collaboration, on producing knowledge that is valuable to decision-makers, and on generating the solutions that society needs” (Future Earth 2014). Indicative of this, only the first of its three overarching themes speaks to the “pure research” interests of many geoscientists (the themes are, respectively, “dynamic planet,” “global sustainable development,” and “transformations towards sustainability”). This said, it will be several years before projects more focused on the human side of the human–environment relationship come to fruition. In turn, such fruition will only be possible if sufficient funds are made available to pay for the time and travel needs of myriad researchers from all parts of the globe. Additionally, the intellectual and practical challenges of achieving “wide interdisciplinarity” – noted previously – will remain. In the meantime, various environmental scientists aspire to deepen the complexity and predictive power of their Earth system concepts and models (Liu et al. 2015).

To summarize, ESS is not so much a single coherent research approach as a set of approaches to research, supported by various funding streams and institutions. These approaches, sometimes overlapping, sometimes sharing a family resemblance, together aim to provide a holistic analysis of Earth surface change (including prediction of future states in some cases). For many years dominated by geoscientists favoring large-scale Earth observation technologies and computational models, it can be seen that ESS is now broadening out. In the process, the notion of an Earth system is likely to serve as little more than a metaphor for many social scientists (and humanists) who are less disposed than some geoscientists to see humans as one (albeit important) “component” within a wider set of parts and connections.

This is evidenced by the recent world social science report (WSSR) sponsored by the International Social Science Council (2013). Entitled Changing Global Environments, it does not foreground the Earth system concept, even as it accepts the need for “joined up” analysis across the natural sciences and the “people disciplines.” Instead, it accents the diversity of human values and ambitions, the need for radical change to
our fossil-fuel driven way of life, and the role of social science in such change through fostering democratic debate about alternative future pathways for humanity. (A similar emphasis attaches to recent social science discussion of “socio-environmental resilience,” thereby complicating a concept – resilience – that began its life in ecology: see Social resilience and environmental hazards). Where the “Earth system” idea invites the image of an omniscient engineer “fixing” the machine, the WSSR promotes the idea that any “fix” will need to be socially negotiated between diverse cultures, governments, NGOs, researchers, and so on. In this context, geoscientists will be servants of diverse political agendas not “value free” experts presenting “objectively” relevant facts and “neutral” technological solutions. The seeds of this alternative approach were already sown in some projects sponsored by the IHDP, notably the Global Environmental Change & Human Security Project (1999–2010) (O’Brien and Barnett 2013).

ESS and geography

How have geographers responded to ESS over the 30 years or so since NASA’s Earth System Science Overview was published? It might be assumed that geographers were, if not ESS pioneers, then at least enthusiastic followers and contributors in the years after the Bretherton report. After all, as geographer John Wainwright noted, “ESS sits in the nexus of the physical and human worlds, which was the traditional definition of the discipline” (Wainwright 2009, 162). Indeed, one non-geographer said of ESS some years ago that it “… is actually twenty-first century geography: it encompasses the study of the environmental physical and life sciences and engineering, coupled with an analysis of human constructs and political and economic policies. It employs space-age technologies to identify, measure, and manage diverse global databases that serve as a framework and foundation for a coherent discipline.” (Ernst 2000, 520). However, as will be seen below, only a relatively small number of geographers have been actively involved in the various ESS developments detailed above. The question then arises: What explains the “missing geographers”? The answer lies with the particular evolution of Anglophone academic geography after 1945.

Briefly, once the World War II finished, Anglophone geography began to become a more internally fragmented discipline, albeit with aspirations to specialize topically using a shared “scientific” approach across the discipline as a whole (see the entry Nature). One result of this was that physical geography moved away from large-scale landscape studies and focused more on in-depth local scale research into Earth surface processes and forms. Another result was that a great deal of human geography began to bracket environmental issues, focusing on the locational aspects of economy, politics, society, and culture with little reference to the things physical geographers investigated. Consequently, despite landmark volumes such as Man’s Role in Changing the Face of the Earth (Thomas 1956), relatively few practitioners occupied the “middle ground” between human and physical geography by the mid-1970s. One underlying reason for this was the embarrassment of pre-1939 “environmental determinism” in geography. For several decades, leading geographers had tried to explain the relations between diverse human societies and their environments. For instance, in the United States, practitioners like Ellen Semple and Ellsworth Huntington were apt to argue that certain physical environments produced human “races” less intellectually or physically capable than Europeans. These arguments were
presented as descriptions of “historical accidents” that had blessed some races but not others. Indeed, both Semple and Huntington on occasion claimed that even “Europeans” would “decline” if they had transplanted a region like West Africa. After 1945, many English-speaking geographers were understandably determined to fashion a more precise and less contentious geography that had no truck with unverifiable generalizations about environmental causation (see Environmental determinism).

As a result of all this, by the mid-1980s academic geography had many capable specialists in the various branches of human and physical geography. However, relatively few “environmental geographers” existed, let alone ones working at a global scale on complex society–nature dynamics across space and through time. Interestingly, some leading geographers had – in the late 1960s and early 1970s – used systems thinking to provide a common analytical approach for human and physical geography alike (Chorley and Kennedy’s 1971). However, this approach gained little traction outside parts of physical geography. One reason is because “humanism” became influential in parts of human geography, and focused on the feelings, norms and values of diverse human agents – thereby challenging the idea of a universal “rationality” (see Humanistic geography); another reason is that the rise of Radical geography produced criticisms of system thinking as a means of controlling not only environmental phenomena but human behavior (Olson 1972). As a result, the idea that there are objectively knowable socioenvironmental systems had been called into question by the time ESS was “launched” in 1986.

Even so, several geographers have played a role in ESS since its inception, working alongside researchers in various other disciplines. Some are physical geographers involved in the IGBP, such as Quaternary scientists Frank Oldfield and John Dearing. Oldfield was co-author of among the first educational fruits on an ESS approach, the earlier mentioned book Global Change and the Earth System: A Planet Under Pressure (Steffen et al. 2004). Meanwhile, Dearing was an active researcher in the long-standing past global changes (PAGES) project of the IGBP, which continued under Future Earth auspices. Its stated aim was to “support research aimed at understanding the Earth’s past environment in order to make predictions for the future” (the IGBP has now been terminated). Meanwhile, others are human–environment geographers focused on contemporary environmental changes. Examples are Eric Lambin, Billie Lee Turner II, and Diana Liverman. All three have been key figures in developing Land systems science, an attempt to systematically understand the drivers and effects (on nature and humans) of alterations to terrestrial vegetation, soil, water, and so on. Turner was (with Oldfield) co-author of the above mentioned book by Steffen et al. (2004), while Lambin coedited a major synthesis book about land use and land cover change (Lambin and Geist 2006). During the same period, Liverman was chair of the scientific steering committee of the earlier mention ESSP GECAFS project. She coedited a major edited collection entitled Food Security and Global Environmental Change (Ingram, Ericksen, and Liverman 2010).

These are just a few examples of those geographers directly involved in the joint and single projects organized by the ESSP and the various global change research programs. Others have undertaken theoretical and empirical research that resonates with the ESS agenda without much formal involvement. Sometimes their research has been funded by the national research councils mentioned earlier in this entry. A good example is Tim Lenton, a natural scientist who models ocean–atmosphere interactions and is now based
in geography at the University of Exeter. Lenton has, among other things, advanced the idea of “planetary boundaries” (see Anthropocene and planetary boundaries).

Through these sorts of involvements, a set of physical and human–environment geographers have made honorable contributions to the evolution of ESS. Others, however, have either pursued similar projects by others means or else expressed misgivings about the aims of ESS. Perhaps the best example of the former is the Sustainability science advocated since the late 1990s by American human–environment geographer Robert Kates. It emerged formally in 2001 out of the same academic conference (held in Amsterdam) that inspired the creation of the ESSP. Kates was frustrated that more progress had not been made in integrating knowledge across the “human–physical” divide in research among the environmental disciplines. In the original manifesto for sustainability science, it was described as seeking to “encompass the interaction of global processes with the ecological and social characteristics of particular places and sectors. The regional character of much of what sustainability science is trying to explain means that relevant research will have to integrate the effects of key processes across the full range of scales from local to global” (Kates et al. 2001, 641). The overt reference to sustainability gave it an applied, normative feel that was rather muted in the early statement about the aims of ESS (see Sustainable development). Today sustainability science attracts a number of devotees from across the disciplines, although is rather dominated by science and technology-minded researchers.

In contrast to Kates and those directly involved in ESS, some geographers have questioned it keenly. This may seem odd given that ESS, as noted, shares the integrative, holistic ambitions many attribute to the discipline of geography. However, not everyone in geography approves of the particular vision of integration found in the first 20 years of ESS. For instance, the physical geographers Nick Clifford and Keith Richards (2005, 379) argued in that “In its appeal to a combination of abstract generalization and complex modelling, and to a technocentric fusion of the physical and social worlds, ESS may yet prove to be a re-invention of scientific privilege and practice, with both a language and mode of expression which are restricted rather than general, and where the claims to apprehend the real and complex are, once more, by the few on behalf of the many.” In their view, geographers should resist the siren-song of ESS and aim for more plural forms of “joined-up” analysis alive to geographical variability and the role of things not exclusively amenable to “scientific analysis”. They make a particular pitch for local scale knowledge integration on the basis that anthropogenic environmental change unfolds in geographically varied and particular ways that are felt differently by various stakeholders (Richards and Clifford 2008). They called this LESS (local environmental systems science) as opposed to ESS.

In the years since they published this critique, a number of geographers have contributed to the broadening of ESS described earlier in this entry. Among the most prominent is Karen O’Brien, a human–environment researcher at the University of Oslo, Norway. She now sits on the science committee of Future Earth. In a series of powerful articles (e.g., O’Brien 2011), she has enjoined geographers to show how predicting the future of the “Earth system” opens crucial questions about the sort of world we want our descendants to inherit. For her, there is not one “correct” way to manage a planet under pressure from unprecedented human impacts. Instead, she argues, geographers should illuminate the diverse ways that different communities might want to fashion a new Earth less burdened by endless commodity.
production, consumption, and disposal. For her, human and physical geographers can combine their knowledge of biophysical phenomena and society in ways that resist the notion of single “fixes” at any one spatiotemporal scale. This speaks to a conception of the “unity” of geography as a discipline rather different to those fed to geographers in print by senior figures down the years (on which see Castree 2015). It calls for plural forms of “intradisciplinarity” that see human and physical geographers collaborate to analyze a range of socioenvironmental challenges mindful of the various ways those challenges can be interpreted culturally and politically. However, there are risks. For example, some might worry that research findings will be seen as less credible if value questions and normative concerns are brought into the heart of the exercise.

**Summary**

ESS is today a term that circulates far and wide among the various geosciences, reflecting its origins in the Bretherton committee “wiring diagram” of 1986. There are nowadays various programs, professorships, and even departments that have ESS in their titles, usually in faculties of earth and environmental science. There are also several introductory level science texts with “Earth system” or ESS in their main or subtitles. The language of the “Earth system” now peppers publications by, and discussions between, researchers involved in the global change programs that have fed into Future Earth. However, ESS is now expanding beyond the geosciences and trying to better connect with the various “people disciplines.” This not only reflects its holistic intellectual aspirations but also the important fact that people are arguably the most important “component” at stake if the Earth system is to be managed more sustainably. As ESS broadens, questions arise about whether social scientists participating in it, so too humanists, will be comfortable retaining the ESS label to describe their collaborations with geoscientists.

Several geographers, while not always lead players, have played an important role in evolving ESS. That more practitioners have not joined them reflects the particular condition on academic geography when the NASA report was released in the mid-1980s. Even so, geographers continue to enter the fray, most recently those outside physical geography concerned that a richer conception of “human dimensions” informs initiatives like Future Earth. Geography is well placed to make more substantial contributions that challenge the assumption that there is one way to describe, explain, and predict the behavior of the Earth system. As such it can help democratize the essential question of what sort of Earth we should bequeath our successors, including nonhumans.

Earth’s energy balance

Tristan S. L’Ecuyer
University of Wisconsin–Madison, USA

The Earth’s weather and climate are strongly influenced by the exchanges of energy (fluxes) between the sun, the atmosphere, and the surface. Collectively referred to as Earth’s energy budget (EEB), these energy flows and their geographic variations establish the long-term average temperature structures of the atmosphere and oceans, drive global wind patterns and ocean currents, and define where clouds and precipitation are most likely to occur. Most other aspects of our climate follow from these basic quantities. Quantifying the factors that influence Earth’s energy balance is, therefore, of paramount importance to understanding the climate system and predicting and mitigating the effects of global climate change.

In the broadest sense, “Earth’s energy balance” refers to the balance between the incoming energy from the sun and the thermal energy emitted by the planet. The sun closely resembles a blackbody at a temperature of approximately 5778 Kelvins (K). At an average distance of 149.598 million kilometers from the sun, this amounts to an energy density of 1360 Watts per square meter, a value now known with high precision thanks to measurements from the Total Irradiance Monitor (TIM) on the Solar Radiation and Climate Experiment (SORCE) (note that fluxes of energy in the Earth’s climate system are generally reported in units of Watts per square meter, or Wm$^{-2}$, that represent the amount of energy that flows through a 1 m$^2$ surface in 1 second). Because the Earth is approximately spherical, this energy illuminates a surface area four times larger than the area intercepted by a flat disk of the same radius. The resulting energy density at the top of the Earth’s atmosphere is, therefore, 340 Wm$^{-2}$. About 29.4% ($\pm 0.3\%$) of this incoming energy is reflected, primarily by clouds and bright surfaces such as deserts and the polar ice caps, while the remainder is absorbed to heat the planet.

Thus the Earth receives a total flux of 123.5 PW (1 PW = 1 petaWatt = $10^{15}$ Watts) from the sun. For perspective, this flux produces more energy in three days than has been consumed by human activity since the dawn of civilization based on International Energy Agency (IEA) estimates. This incoming solar energy is largely balanced by 123.2 PW of thermal emission such that the Earth appears to an outside observer as a blackbody with a temperature of $-18^{\circ}$C. The 0.3 PW residual represents the excess energy trapped by the atmosphere as it adjusts to higher concentrations of greenhouse gases from anthropogenic emissions and associated climate feedbacks. Tracking the fate of this excess energy is a more challenging problem. Measurements of changes in ocean heat content from a large network of buoys known as the Argo Array suggest that approximately 90% of this excess energy is absorbed in the upper layers of the world’s oceans while the remainder contributes to melting ice sheets, warming and moistening the atmosphere, and heating the deep ocean.

The global balance between incident solar radiation and Earth’s emission is only a small part of the story. Local imbalances owing to variations in the amount of solar radiation received, thermal radiation emitted, and the partitioning
of energy between the atmosphere and the surface in different regions are responsible for the different climates encountered on Earth. Over the course of a year, the tropics receive about six times more solar radiation than the poles but only emit about twice as much thermal radiation. The stronger latitude-dependence of incoming sunlight leads to a surplus of radiation near the equator and a deficit of radiation at the poles. These imbalances induce large circulations in the atmosphere and oceans that redistribute heat and restore local equilibrium on multiyear timescales. Peak poleward heat transport occurs at the latitude where the annual mean incoming solar radiation exactly balances the thermal emission. This occurs at 36.9°S in the Southern Hemisphere and 35.0°N in the Northern Hemisphere (Stephens and L’Ecuyer 2015). Between these latitudes, the atmosphere and oceans transport approximately equal amounts of heat out of the tropics while large storms, called extra-tropical cyclones, transport heat poleward at higher latitudes. The resulting zones of convergence and divergence in the tropics and storminess at mid-latitudes define the typical weather conditions experienced around the planet. Beyond sea level rise and melting ice sheets, altered global weather patterns that could result from the changing regional energy gradients that accompany climate change (whether natural or human-induced) have profound implications for life on Earth.

**Historical perspective**

Characterizing energy exchanges between the surface, atmosphere, and space from observations has been the subject of vigorous research for more than a century. Hunt, Kandel, and Mecherikunnel (1986) summarize many early efforts to reconstruct Earth’s energy budget from ground-based observations at a number of locations scattered around the Northern Hemisphere and carefully thought-out balance arguments. It wasn’t until the development of weather satellites as part of the space race in the latter half of the twentieth century, however, that we obtained a true global picture of the EEB. New space-based observations acquired in the 1960s revolutionized our understanding of Earth’s radiative balance by providing a unique global perspective on the spatial distribution of incoming and outgoing radiation at the top of the atmosphere. In just a few years following the flight of the first radiation budget instrument aboard the Explorer VII satellite we learned that the Earth was darker and warmer than previously believed and that the gradient of absorbed solar energy between the tropics and the mid-latitudes was much larger than earlier estimates (Vonder Haar 1994). In the decades that followed, satellite observations with improved calibration, increased spatial and temporal resolution, and increased sensitivity to surface and atmospheric properties led to regular refinement of Earth’s energy budget.

The launch of three satellites that collectively comprised the Earth Radiation Budget Experiment (ERBE) from 1984 to 1986 marked another important milestone in our understanding of the Earth’s energy balance. Each ERBE instrument collected observations of solar, thermal, and total fluxes radiating from the top of the Earth’s atmosphere with sufficient accuracy to establish (with the aid of ancillary cloud information) the partitioning of fluxes between the surface, troposphere, and stratosphere. At the same time, rapid increases in computing power enabled the development of complex numerical models capable of representing the dynamic and thermodynamic processes that govern the three-dimensional flows of energy around the globe. These early climate models and the observation-integrating models (termed
“reanalyses”) that evolved from them in the 1990s simulated all components of Earth’s energy balance, including surface turbulent heat fluxes, enabling complete reconstructions of Earth’s energy budget and explicit calculations of the amount of heat transported by atmospheric circulations and ocean currents.

The influence of clouds on Earth’s energy balance

New observational and modeling tools developed near the end of the twentieth century also spawned several new areas of investigation devoted to quantifying the factors that influence Earth’s energy balance. These include aerosol particles, ocean surface temperature, snowpack and sea ice, vegetation, surface winds, and variable trace gases such as water vapor. Of particular significance is a large branch of research that centers on quantifying the role of clouds in modulating regional energy imbalances and, in turn, atmospheric circulations and ocean currents. Clouds are especially important players in the EEB since they influence both the amount of solar radiation the Earth absorbs and the amount of thermal radiation it emits. Since clouds are generally brighter than the Earth’s surface, they increase the amount of sunlight reflected back to space, cooling the planet in the same way they provide us with relief on a hot sunny day. High ice clouds, on the other hand, can be several tens of degrees colder than the average emitting temperature of the Earth, thus reducing the amount of thermal energy emitted to space. In this way clouds can also be thought of as blankets that trap heat and keep the planet warmer. This is the reason cloudy nights tend to be much warmer than clear nights in winter.

The net effects of any particular cloud on the Earth’s energy budget depend on numerous factors including its height, the amount of condensed water it contains, whether it is composed of liquid or ice, the position of the sun in the sky, and the brightness of the underlying surface. Since no two clouds are exactly alike, quantifying the effects of clouds on Earth’s energy budget is a challenging problem that only became possible in the satellite era. Harrison *et al.* (1990) demonstrated that when the effects of all clouds around the globe are summed over the course of the full year, clouds approximately double the amount of sunlight the Earth reflects from about 15% in clear skies to the observed 29.4%. This represents a reduction of incoming solar energy of 49 Wm$^{-2}$. Similarly, clouds reduce the amount of energy emitted by the Earth to space by about 28 Wm$^{-2}$ (equivalent to an 8°C change in the Earth’s emitting temperature relative to a cloudless planet). Thus, on aggregate, clouds cool the Earth by approximately $21 \pm 4$ Wm$^{-2}$ relative to the cloud-free atmosphere.

It should not come as a surprise that the influence of clouds varies significantly with location and atmospheric conditions. Figure 1 shows a map of the annually averaged cloud influence on radiation at the top of the atmosphere from the successor to ERBE, the Clouds and the Earth Radiant Energy System (CERES) instrument that flies aboard multiple Earth observing satellites (Wielicki *et al.* 1996). This figure highlights the vastly different effects clouds have on the environment in different regions, including their much stronger cooling effect over subtropical oceans and their warming effects over bright surfaces such as deserts and ice sheets. It also highlights a somewhat counterintuitive fact about the role of clouds in Earth’s energy budget: although the deep cumulonimbus clouds (thunderstorms) that occur in the tropics are the most impressive and imposing cloud systems on
the planet, these clouds do not play as important a role in defining the climate as their much more benign, shallow counterparts that reside in the stratuscumulus decks off the west coasts of most continents. This puzzling result can be understood when one considers that while cumulonimbus clouds are bright and reflect a lot of sunlight back to space, they also grow very deep and trap a considerable amount of thermal emission owing to their high, cold cloud tops. From a top-of-atmosphere energy balance perspective, these effects approximately cancel one another, limiting the influence of these intense cloud systems on the net radiation balance. Shallow clouds, on the other hand, tend to be much warmer and are often composed of liquid droplets that reflect solar radiation very effectively but emit almost as much thermal radiation as the surface. These clouds are, therefore, primarily responsible for cooling the Earth relative to cloud-free conditions.

Earth’s energy budget at the start of the twenty-first century

With the successful launches of numerous Earth observing satellites in recent years, it can be argued that the early twenty-first century was a golden era of Earth’s energy budget measurements. The combination of radiative fluxes from CERES and cloud information from three new cloud sensors, the Moderate Resolution Imaging Spectroradiometer (MODIS) and, more recently, CloudSat and the Cloud-Aerosol Lidar and Infrared Pathfinder Satellite Observation (CALIPSO), for example, provides unprecedented data for determining the role of clouds in radiative exchanges between the Earth and space. Observations in the microwave region of the electromagnetic spectrum have provided new insights into the global distribution of latent heat release in precipitation, while algorithms designed to infer near-surface temperature and humidity have facilitated the inference of evaporation and sensible heat fluxes from the surface through bulk formulas. Growing networks of surface-based radiation measurements and recent advances in computing power have also provided substantially better constraints on surface radiative and turbulent heat fluxes and atmospheric heat and moisture transports.

Together, this combination of satellite observations, in situ measurements, and models are providing the most comprehensive description of Earth’s energy budget to date. A depiction compiled by L’Ecuyer et al. (2015) from state-of-the-art National Aeronautics and Space Administration (NASA) Earth Observing Satellite (EOS) data sets is presented in Figure 2. These estimates invoke new techniques to impose known closure relationships and derive associated error bars that represent our current level of understanding of each component of Earth’s energy budget. Figure 2 shows that every square meter of the Earth’s surface is warmed by $164 \pm 5 \text{ W}$ of solar energy and an additional $341 \pm 5 \text{ W}$ of thermal energy emitted by the atmosphere to the surface. These sources of surface heating are offset by $81 \pm 4 \text{ W}$ of latent heat
Figure 2 A global energy budget reconstruction derived from satellite observations over the first decade of the twenty-first century (adapted, with permission, from L’Ecuyer et al. 2015). All fluxes are expressed in Watts per square meter (Wm$^{-2}$). The value of each flux represents the aggregate from all surfaces around the globe, but longwave and shortwave fluxes are plotted over land and ocean regions, respectively, for convenience. Alternative reconstructions based on satellite observations, ground-based measurements, and global model reanalyses can be found in Trenberth, Fasullo, and Kiehl (2009), Stephens et al. (2012), and Wild et al. (2013).

Transfer from the evaporation of water (primarily from the oceans), 25 ± 4 W of sensible heat transfer (heat mixed into the atmosphere by the wind blowing over the surface), and 399 ± 5 W of cooling by thermal emission from the surface. Thus the energy absorbed at the surface is very nearly balanced by heat transfer to the atmosphere. Independent estimates of changes in ocean heat content from buoy measurements suggest that the Earth’s surface is currently absorbing about 0.5 Wm$^{-2}$ of energy due to the trapping of thermal energy owing to the increases in carbon dioxide and water vapor concentrations in the atmosphere that have occurred since preindustrial times. While this may not seem like a lot of energy, when multiplied over the entire area of the global oceans it amounts to about 300 trillion Watts, or almost 17 times the world’s annual energy consumption estimated by the IEA. Careful efforts to track this energy suggest that 90% is absorbed in the oceans while the remainder is taken up by melting of the large Greenland and Antarctic ice sheets, melting of sea ice, and warming of land and the atmosphere.

Future challenges

While our accounting of the energy flows that make up Earth’s energy balance has improved considerably in the last century, there remains a lack of consensus among the recent energy balance reconstructions, indicating there is room for improvement (e.g., Trenberth, Fasullo, and Kiehl 2009; Stephens et al. 2012; Wild et al. 2013; L’Ecuyer et al. 2015). Furthermore, uncertainties remain in satellite observations of reflected solar and emitted thermal radiation at the top of the atmosphere as well as in buoy measurements of ocean heat content. As a result, the magnitude of present-day energy imbalances owing to increased greenhouse gas concentrations is only known to an accuracy of about 50% (Trenberth, Fasullo, and Balmaseda 2014). Better absolute calibration of satellite-based measurements of thermal and reflected solar fluxes and longer, more accurate estimates of ocean temperature structure are required to more precisely establish the magnitude of energy imbalances owing to human-induced climate change.

The primary influence of energy flows on the climate is through the regional gradients that drive the large-scale circulations that transport heat from regions of surpluses to regions of deficits. Assessing the influence of changing energy imbalances on the climate therefore requires a detailed accounting of local thermodynamic processes and feedbacks including evaporation, precipitation, and cloud cover. These processes are difficult to observe globally yet they represent the aspects of global climate
models that are most important to improve. As a result, the spread of predicted regional climate sensitivities to human activities in today’s climate models remains unacceptably large and continues to be linked to differences in the way models simulate cloud responses to temperature, humidity, and aerosol concentrations. Accurately representing these so-called cloud feedbacks in climate models is a long-standing concern of the climate community, and documenting model biases continues to be the focus of a large body of research. In fact, the Intergovernmental Panel on Climate Change has stated that uncertainty in simulating cloud feedbacks in response to increasing greenhouse gas concentrations likely remains the largest obstacle for accurately projecting future climate with today’s climate models (IPCC 2013).

Based on these considerations, the World Climate Research Program (WCRP) identifies clouds and their role in the Earth’s energy balance as one of the “Grand Challenges” or major areas of scientific research required to advance climate science in the coming decade. To address this challenge and improve climate model predictions, the WCRP further identifies three questions that must be addressed to gain a better understanding of the central role clouds play in defining Earth’s energy balance:

1. How do clouds couple to circulations in the present climate?
2. How will clouds and circulation patterns respond to global warming or other forcings?
3. How will clouds feed back on climate through their influence on Earth’s radiation budget?

Meeting these challenges will require a combination of improved modeling, observations, and analysis techniques. Given the important role satellite observations have played thus far, it is likely that continued refinement of space-based observing systems will play an instrumental role in advancing our understanding of Earth’s energy balance. Continued support for future missions with new technologies for improving the precision to which individual component energy fluxes are measured and quantifying the factors that modify them is critical. Particular attention should be given to quantifying biases in component fluxes on regional scales, and it is anticipated that analysis of data from the Global Precipitation Measurement (GPM) mission, Soil Moisture Active Passive (SMAP), and Suomi NPP (National Polar-orbiting Partnership) satellites will facilitate progress toward this goal. Proposed future satellite missions dedicated to observing cloud and precipitation processes on global scales with sophisticated, multifrequency, Doppler radars offer perhaps the greatest potential for revolutionizing our understanding of the factors that define Earth’s energy balance in the future.

Ecogeography/macroecology (range and body size)

Marta A. Jarzyna
Brian A. Maurer
Michigan State University, USA

Patterns of biodiversity have intrigued scientists for centuries and, since the 1980s, there have been significant advances in describing and explaining species distributional patterns, their geographic ranges, and their statistical distributions. Historically, these issues have been approached by many scholars, resulting in the creation of several different subfields such as geographical ecology, areography, dynamic biogeography, ecography, and ecogeography, to name a few. While somewhat disparate in their focus, these different domains of interest largely center on the issues of what today is called “macroecology,” and frequently overlap. Macroecology is a nonexperimental, statistical investigation of patterns of abundance, distribution, and diversity of species in order to understand the processes and mechanisms controlling the structure and dynamics of regional and continental biotas (Brown and Maurer 1989).

The foundation for macroecology was provided by some genuinely transformative insights from the fields of ecology, evolutionary biology, and biogeography. Near the end of his career, R.H. MacArthur laid the groundwork for macroecology by discussing the mechanisms underlying species distributional patterns across geographic space. The equilibrium theory of island biogeography, developed independently, first by Munroe (1948) and then by MacArthur and Wilson (1976), provided the starting point for the theory of the assembly of discrete biotic communities. Later, Rapoport (1982) developed a comparative approach to geographic ranges, while Price (2003), among others, examined patterns of the distribution and abundance of organisms in light of evolutionary processes.

The intent of this entry is to examine prominent macroecological patterns found in nature and to discuss the processes and mechanisms that act as primary drivers of these patterns. Species–area relationships, latitudinal diversity gradients, range size and abundance relationships, and patterns in the distribution of body size among species are some of the most general and widely studied patterns of biological diversity.

Biodiversity patterns

Species–area relationship (SAR) is one of the best-known generalizations in ecology. In its simplest form, SAR states that larger regions tend to contain more species than smaller regions (Figure 1). The study of SAR dates back to at least the mid-nineteenth century and the work of H.C. Watson, whose species–area curve of vascular plants in Great Britain was the first known illustration to be published of the species–area relationship. Currently, SAR is probably the most widely researched pattern in macroecology, encompassing thousands of studies of a wide variety of taxa and geographic extents. Despite the fact that many mathematical functions can estimate SAR, the power law (and its log-linear transformation) remains the most commonly used model both for fitting species–area curves.
ECOGEOGRAPHY/MACROECOLOGY (RANGE AND BODY SIZE)

and for the development of mechanistic theories of species diversity. It has been observed, however, that the log-linear SAR is not maintained across all spatial scales. For instance, the log-linear relationship can often be obtained only for the intermediate (i.e., regional) scales, but it does not hold for small or very large (i.e., continental or intercontinental) scales, where the increase in the number of species with area is much faster. Such triphasic SAR implies that potentially different mechanisms underlie the species–area relationship at different spatial scales. For very large areas, the steep SAR is likely a result of evolutionary dynamics, while smaller regions will lack species that are ecologically similar and evolutionarily distant, thus resulting in a flatter SAR. At very small scales, the increase in species richness is faster again because of the higher likelihood of encountering new habitats, and thus new species, as the area increases.

Latitudinal diversity gradient (LDG), another strikingly general pattern in macroecology, refers to the increase in species richness that occurs along the latitudinal gradient from the poles toward the equator. In other words, regions at lower latitudes generally contain more species than locations at higher latitudes. The LDG seems to hold for different spatial extents, habitat types, and various taxonomic groups (e.g., marine and terrestrial groups, ectothermic and endothermic animals). Yet, despite the ubiquity of the pattern, a universal explanation for the latitudinal diversity gradient has yet to be found.

The statistical distribution of abundance among species within a taxon has also received substantial attention in the macroecological literature. Comprehensive datasets on the relative abundances of species indicate that most species abundance distributions have long and positively skewed tails, indicating that communities usually consist of many rare species and only a few common species. Mathematical functions proposed to describe this species abundance pattern include Fisher’s log series and the most frequently used Preston’s log-normal, though recent theoretical work suggests that the log-normal distribution fails to properly account for the asymmetric shape of many species abundance distributions (Hubbell 2001).

Within a species, abundance tends to be the highest in the center of the species’ geographic ranges and declines steadily toward the margins of its range boundaries (e.g., Maurer 1999). It has been suggested that such pattern reflects the response of populations to local environmental conditions. Environmental conditions tend to be spatially autocorrelated (i.e., locations in close proximity tend to have more similar abiotic and
Thus, the abundance will also vary across space from high values, where the conditions are the most appropriate, to zero, where conditions preclude survival and reproduction. From a multispecies perspective, the abundant species tend to have broader geographic ranges, whereas the rare ones tend to be narrowly distributed. This pattern is the most apparent for closely related or ecologically similar species, pointing to the importance of both evolutionary processes and ecological constraints as mechanisms shaping macroecological patterns.

Another common pattern in macroecology is the tendency of species’ geographic ranges to increase with increasing latitude, formally known as the Rapoport’s rule (Rapoport 1982). Unlike the previously discussed patterns, the generality of the Rapoport’s rule has been much debated, with some studies finding convincing empirical evidence for the pattern, while others argue that it is a local rather than a global phenomenon.

In addition to patterns of species distributions, abundance, and range, macroecology also concerns itself with distributions of body size. Quantifying patterns of body size is of utmost importance because practically every aspect of the ecology of individual organisms (e.g., metabolic rates, life expectancy, range size) is related to body mass (e.g., Maurer 1999). The frequency distributions of body masses of North American terrestrial mammals vary with the spatial scale. At the largest spatial extents, body mass distributions tend to be positively skewed (i.e., medium-sized species are the most common, while there is a long right tail containing the largest species), whereas this distribution flattens with decreasing spatial scale. At local extents, the species–body size distributions are on average statistically indistinguishable from log-uniform distributions. Similar patterns have been found for other groups of organisms (e.g., Maurer 1999).

### Processes and mechanisms

Patterns of species diversity arise from mechanisms that tie evolutionary adaptations of species with the variation in environmental conditions. Because of the complex interaction of these different processes, explanations of specific biodiversity patterns continue to be conceptually challenging. However, several mechanisms have been proposed to explain the patterns discussed, and these include: (i) ecological niche theory, (ii) ecological neutral theories, (iii) metabolic theory of ecology, and (iv) phylogenetic constraints.

Ecological explanations of species distributional patterns are based on the assumption that species are limited by a unique set of environmental and biotic factors, which taken together constitute a species’ ecological niche. This ecological niche theory captures the uniqueness of each species. In contrast, ecological neutral theories consider communities to be open, continuously changing, nonequilibrium assemblages of species, in which species presence, absence, and abundance are governed by random speciation, dispersal, ecological drift, and extinction (Hubbell 2001). Neutrality means that all species are ecologically symmetrical, that is, they have identical ecological properties. Several neutral theories have been proposed to date, including MacArthur and Wilson’s theory of island biogeography and Hubbell’s unified neutral theory of biodiversity and biogeography (MacArthur and Wilson 1976; Hubbell 2001). While controversial, neutral theories have been successful in predicting some of the most fundamental patterns of biodiversity. For example, Hubbell’s neutral theory is able to successfully generate species abundance distributions as well as explain the triphasic species–area relationship as consequences of the speciation–dispersal–extinction
process rather than a manifestation of ecological niche (Hubbell 2001).

Distribution of body size among species (i.e., intermediate-sized species are the most common) has in the past been explained by invoking physical constraints and energy requirements, both of which increase as species depart from the medium body size (Maurer 2003). This notion has served as a precursor to the metabolic theory of ecology (Brown et al. 2004), which links the variation in the rates of metabolism between different kinds of organisms to the structure and dynamics of populations, communities, and ecosystems. In addition to distributions of body size, the metabolic theory of ecology provides an explanation for other common biodiversity patterns. For example, the theory attributes the latitudinal diversity gradient to the kinetic effect of higher temperatures (e.g., Brown et al. 2004). The implications of this theory have yet to be fully realized, but may lead to new insights into the complex set of processes that underlie patterns of species diversity.

Recent work has cast the study of macroecological patterns in a macroevolutionary framework. The macroevolutionary perspective argues that evolved traits of different organisms (i.e., morphology, behavior, life history) influence their ecological relationships, and thus patterns of species distribution and abundance. For example, a phylogenetic constraints hypothesis (Price 2003) argues that certain sets of characters, common to closely related species, limit the major adaptive developments in a taxon, and thus its ecological options. Minor adaptations within the phylogenetic constraint are allowed, and those have ecological consequences that are reflected in patterns of distribution, abundance, or population dynamics (Price 2003). Incorporating phylogenetic information into macroecological explanations synthesizes ecological and evolutionary concepts into a framework for understanding how the ecological properties of species evolve within higher taxonomic levels (Price 2003).

What is on the horizon for macroecology?

Macroecology has provided a synthesis of perspectives from ecology, evolutionary biology, and biogeography that has helped generate new explanations for widespread patterns that large continental biotas exhibit. A great deal of effort has gone into generating data on a variety of groups of species, and there are opportunities to develop more rigorous general explanations for these patterns. The recent activity to develop explicit theories for macroecological phenomena using models that assume ecological symmetry between species is a promising start. However, these theories don’t go far enough, because it is unlikely that species can be assumed to be ecologically equivalent. The evolutionary adaptations that drive population dynamics of different species across geographic space are ultimately responsible for ecological asymmetries between species. For example, closely related species often have different geographic range sizes that are directly tied to how their different ecological adaptations interface with available resources across geographic space. Theories based on ecological symmetry may explain how the “average” species behaves dynamically, but are ultimately unlikely to explain the range of macroecological attributes found within real groups of species.

The incorporation of evolutionary information via well-supported phylogenies can help with the development of more general theories for macroecological variation within species assemblages, but this is only part of what is needed. One of the strengths of the metabolic
A key approach to macroecology is that it has the potential to link fundamental design constraints imposed on the evolution of attributes of species with the ecological consequences that those design constraints impose on species assemblages across space. These insights may yet provide the basis for generating more general theories that can be used to understand the growing body of data accumulating in studies of assemblages of species at continental scales.

Ecological footprint

Andrea Collins
Cardiff University, UK

Ecological footprint analysis was initiated in North America in the early 1990s by William Rees and Mathis Wackernagel (see Wackernagel and Rees 1996). The ecological footprint is an aggregated indicator which provides a measure of the global ecological impact of human resource consumption, and is analogous to gross domestic product (GDP) as a representation of the dimensions of the financial economy (see Wackernagel and Rees 1996). The starting point for the concept is that there is a limited amount of bioproductive land on the Earth to provide for all human resource demands. Sustainable development requires living within the carrying capacity of the Earth, allowing our economies to develop, but also ensuring that human needs are being met.

The ecological footprint adds together the uses of six types of bioproductive land (carbon, grazing, forest, fishing, cropland, and built-up land) required to provide the resources consumed by a reference population and assimilate their waste. The ecological footprint’s unit of analysis is the global hectare (gha) and is usually expressed in global hectares per capita for a given population (gha/capita). The measure is based on a strong sustainability position, as it considers the ecological limits to resource consumption and economic growth. By comparing the area of land required to support a certain level of consumption with what is currently available, the ecological footprint is considered a valuable approach for assessing whether or not consumption is ecologically sustainable.

The ecological footprint has been advocated by the World Wildlife Fund for Nature (WWF), and since 2000 has published through its biennial Living Planet Report the “state of the environment.” The 2012 edition reported that, in 2008, the Earth’s available biocapacity was 1.8 gha/capita. In comparison, the ecological footprint was 2.7 gha/capita and so exceeded the Earth’s available biocapacity by 50 percent, thereby indicating a situation of ecological “overshoot” as consumption patterns were not sustainable and resources were being used at a rate faster than they could be generated (WWF 2012). Over- shoot may reduce the Earth’s ecological capacity permanently and this is a key concern for sustainability.

Traditionally, national ecological footprint accounts have been calculated based on a nation’s domestic production and imports and exports of primary and secondary products. Recently, however, Wiedmann et al. (2006) developed a method whereby national ecological footprints can be disaggregated to provide information by industry sector, final consumption categories, subnational area and socioeconomic groups. This approach uses input–output tables (supply and use tables) to allocate footprints to consumption categories. The strengths of this methodological development is that it permits greater consistency across footprint estimates; the footprint results can be used to provide better-quality information for scenario development and policy formation on sustainable development patterns; footprint results can be allocated to different final consumption categories and so can highlight consumer responsibilities more clearly;

and footprints can be more easily estimated at subnational level.

The first academic article on the ecological footprint concept was published in 1992 (see Rees 1992). Since then the concept has spread rapidly around the world. At the end of 2013, Google delivered almost 3 million hits and Google Scholar 73,500 hits for the term “ecological footprint.” As a source of information on environmental impacts the footprint has traveled relatively quickly, and, within the space of 20 years, studies have related to five world continents. The rapid transfer of environmental ideas on resource use and its impact, and growth in the application of the ecological footprint, have followed a similar patterns to how ideas on environmental impact assessment spread from the United States in the late 1960s to other developed countries such as Canada, the United Kingdom, and Europe in the 1970s and 1980s, and then to developing countries such as Africa and South America in the 1990s. There are three main reasons for the level of interest generated by the ecological footprint. The first is its contribution as a method for measuring biocapacity and assessing the environmental impacts of natural resource use. Second, it is often considered as providing an innovative approach to communicating messages about the ecological impact of current resource consumption. Finally, it has potential value as a policy tool and link to practice.

Despite the ecological footprint’s popularity as a measure of ecological impact, it has received a number of criticisms: it does not reflect the full impacts of consumption activity; it provides inadequate material for use in policy formulation, although improvements led by Wiedmann et al. (2006) to link footprints with industrial sectors and final consumption categories have gone some way to address this problem; the algorithms used to link production and consumption with notional global land areas may not be appropriate or sufficiently transparent; the method does not allocate the responsibilities for negative impacts correctly; in terms of deriving policy foresight, there is a strong underlying assumption that an equal distribution of global resources is a desirable outcome; and, finally, few studies have attempted to deal with the underlying uncertainty surrounding footprint estimates.

Although the ecological footprint has received criticism, it has continued to be popular and has received a wide range of interesting and novel applications including individuals, households, products, services, organizations, educational institutions, energy and fuel, food and agriculture, tourism, travel, and major events. These academic applications have helped to enrich debates on the environmental impact of resource use and also to provide alternative perspectives and a more comprehensive assessment of the impacts of resource use. However, in more recent years, with increased policy attention being paid to resource limit issues such as peak oil and peak food, and debates around climate change, the ecological footprint has been increasingly sidelined by the carbon footprint owing to the latter’s direct relevance to policy debates on climate change.

The term “ecological imperialism” comes from Alfred Crosby’s book of that title. The book was hailed by some as a landmark text in environmental history when first published in 1986. It followed Crosby’s earlier, rather more discursive exploration of an equally big idea, The Columbian Exchange (1972). In that volume, he had discussed the movement of biota between Europe and the Americas in the centuries after Columbus. Ecological Imperialism represents a conceptual shift from exchange to empire. It sought to address the question of why Europeans and their descendants are found “all over the place” and to ask, in characteristically vivid prose, what “is the reason that the sun never sets on the empire of the dandelion” (Crosby 1986, 7)?

Many years later, Ecological Imperialism reads as a fairly conventional Eurocentric history, and one that did not actively engage with work in other disciplines. Nonetheless it contained a seductively constructed argument, and was innovative in its broad sweep, global focus, and introduction of the role of biological agents in the imperial incorporation of what Crosby called the “neo-Europes,” that is those lands thousands of kilometers from Europe but with majority European populations. As a result, the term ecological imperialism has entered the academic lexicon, but more often than not without critical assessment. It deserves scrutiny both in its own terms and from the perspective of later work by a range of scholars, including geographers, whose insights question important aspects of Crosby’s argument.

Precursors

People have long carried biota around the world for sustenance, trade, and settlement. Captain Cook’s expeditions landed pigs, goats, wheat, potatoes, and many other European vegetable and root crops on islands in the Pacific as well as accidentally allowing ship rats to escape. The consequences of lack of intentionality were often noticed. A famous example was Charles Darwin’s observation of “the invasion of the cardoon,” or artichoke thistle (Cynara cardunculus), on both sides of the Andean cordillera, in Chile, as well as the pampas of Uruguay and Argentina (Darwin 1839, 151). Brought to the New World as part of the Columbian exchange in the late eighteenth century, cardoon was a fairly popular vegetable in European gardens. In their new habitat, the plants quickly escaped cultivation and reverted back to their wilder and spinier forms.

The language of “invasion” permeates the various interpretative literatures that have developed since Darwin’s time to explain the sort of phenomenon that he observed in South America. To ecologists and biogeographers, invasive species are taxa that have or are spreading rapidly into habitats and places in which they were previously absent. Normally these are alien species introduced from another place or part of the world, although many introduced taxa never become invasive, just as there are native species that invade, that is, expand their distributions as happens in response to environmental change (Blumler 2011). The first full-length treatment
of these processes was Charles Elton’s book *The Ecology of Invasions by Animals and Plants*. He opened by proclaiming that “Nowadays we live in a very explosive world,” giving then topical examples such as the influenza virus, a fungus like potato disease, a plant such as prickly pear, and an animal like the gray squirrel (Elton 1958, 15).

Elton’s argument was that in the mid-twentieth century “the mingling of thousands of kinds of organisms from different parts of the world [was] setting up terrific dislocations in nature” (1958, 18). He used a series of well-mapped case studies, such as the spread of chestnut blight, *Endothia parasitica*, brought from Asia on nursery plants that progressively infected American chestnut trees in the first half of the twentieth century, and of the European starling which in about sixty years established itself across much of the United States from an initial stock introduced into New York’s Central Park in 1891. The book illustrated a range of “successful species” in different geographical contexts, such as continents, islands, and the sea. But he argued that “there are enormously more invasions that never happen,” that is introductions that never become well established or spread (Elton 1958, 109). He addressed the question of why this might be, notably with the hypothesis, never since clearly verified, that species-rich communities will be more resistant to invasion than less diverse ones.

Elton’s ecology was strongly humanized, both in his concern for conservation of richly varied landscapes for economic and social reasons, but also in its portrayal of the human context of species explosions due to trade and travel. Even so, he was criticized for assuming that humans will eventually take all species everywhere, while there has since been much less focus on “the actual historical geography of invasion” (Blumler 2011, 515). There was, however, an American geographical tradition of research into the intentional spread of agricultural species, in the New World and Old, led by Carl Sauer at Berkeley, whose best known work was *Agricultural Origins and Dispersals* (1952). One of Sauer’s doctoral students, Andrew Hill Clark, undertook his field research in New Zealand, publishing the results as *The Invasion of New Zealand by People, Plants and Animals* in 1949. New Zealand was also to be used as a case study by both Elton and Crosby.

Clark’s historical geography was concerned very much with intentionality. He described it as focusing “on a revolutionary change in the character of a region,” with one of the key factors in this being “the invasion of the area by armies of plants and animals, which, with the help of man, mingled with or displaced the native flora and fauna” (1949, v). Unlike Elton, he was mainly interested in the settlement of people and their agricultural plants and animals, such as potatoes, wheat, grasses, clovers, sheep, and cattle. But he did not ignore animals that had become destructive of farmed as well as natural landscapes, such as rabbits and deer, nor invasive plants such as gorse and blackberry, the seeds of which were originally sold for hedging and fruit respectively. *Invasion* was intended to be the first of a series of studies “dealing with similar problems of the development of patterns and practices of land use in mid-latitude areas overseas which were settled by folk from the shores of the North Sea” (Clark 1949, vi). Although Clark subsequently published two volumes on Atlantic Canada, others projected for Australia and South Africa were never completed. He did not use the term neo-Europes but in his systematic interest in those parts of the world he was an intellectual forerunner of Crosby.

**Crosby’s ecological imperialism**

Alfred Crosby retired from the University of Texas at Austin in 1999 as professor emeritus
of geography, history, and American studies. By his own account, he was a radical in his early career, being involved in the civil rights movement, teaching black studies and leading anti-Vietnam War demonstrations. It was this background that shaped his interest in the histories of peoples who were invaded and exploited by European imperialism. It did not, however, lead to a clear political economy framework for the argument developed in *Ecological Imperialism*, even though the book begins with a quote, among others, from Marx and Engels’s *Communist Manifesto*. The book therefore does not connect with work in human geography at the time, and it also neither discusses nor references the work of Elton or Clark. It is best portrayed as standing to one side of other literatures, although in spirit it displays rather more of an interdisciplinary inclination than is usually the case in historical writing. It was republished in an unchanged second edition in 2004, its appeal underlined by translations over the years into nine European languages, including Turkish, as well as into Chinese, Japanese, and Korean.

This appeal reflects the quality of Crosby’s writing and use of metaphor in a field that, as the work of his predecessors shows, is prone to this. But the key was the way in which he pulled together a range of evidence about the purposive spread of people, plants, animals, and diseases in the service of the development of the neo-Europes. His was a grand narrative that convincingly inserted the role of biological factors into an explanation of the effects of imperialism at the same time as it effectively sidestepped any encounter with the economic. And while colorfully portraying “invasions” as ecological, it did not attempt to engage with the complexities of ecological processes. Hence it embodies the characteristics of all grand narratives, being simultaneously plausible and partial.

Central to Crosby’s ecological imperialism was what he called the “portmanteau biota” with which the neo-Europes were colonized. This is a more analytical category than Clark’s invading armies, but serves a similar purpose. He traced it to the Old World Neolithic Revolution and the assemblages of people, plants, and animals — including those that people did not want, the weeds and vermin — that developed in close proximity, initially in Mesopotamia but then spreading through the Middle East and into Europe. Crucially, the synergistic effect of these different species existing side-by-side produced new diseases and variants of old ones. Then, continuing the military analogy, he analyzed the fate of “the full platoon of the Old World Neolithic” (Crosby 1986, 37) taken by the Norse to Iceland, Greenland and beyond, as well as by the Crusaders into the Levant. These early geographical lunges were unsuccessful: supply lines were tenuous, migrant numbers small, and environments unsuited for crop plants. Isolation rendered small Norse settlements prone to diseases evolving in Europe, and there were never enough Crusaders to acquire immunity to those such as malaria.

The core of Crosby’s analysis, however, concerned colonies at a greater distance, once Europeans began to discover the sea: with this the “seams of Pangaea were closing, drawn together by the sailmaker’s needle” (Crosby 1986, 131). He employed this analogy to describe how the continents and their biota, isolated in deep geological time by plate tectonic boundaries, were knitted together with the new technologies of shipping and navigation. In a detailed analysis of the impacts of European settlement, cropping and diseases in “the Fortunate Isles,” the Azores, Madeira, and Canary Islands, he argued that these “were the laboratories, the pilot programs, for the new European imperialism” (Crosby 1986, 100). The lessons learned were, first, that
simplified versions of the portmanteau biota could flourish—wheat, pigs, goats, honeybees, sugarcane too—and, second, that indigenous peoples could be subjugated, as in the Canaries by epidemics of European disease and the use of the horse in contests for territory.

Crosby concluded that the essential conditions for successful European colonies of settlement were that, first, land and climatic conditions had to be similar to some part of Europe; second, remoteness from Europe would mean few predators or diseases adapted to prey on Europeans; and, third, such remoteness would also ensure that indigenous inhabitants would be without defenses to introduced diseases and lack “servant species” such as horses or cattle. The tropics did not meet the second condition, and the lands of East Asia met neither the second nor third and were too well populated and organized. The neo-Europes on the other hand are all in similar climatic zones to Europe, but with biota that had evolved separately on the other side of the “seams of Pangaea.” Drawing on work about waves of extinctions of large land animals and birds that coincided with the first movements of people into the Americas and Australasia in pre-history, Crosby suggested that when Europeans followed millennia later, they found vacant ecological niches ready to occupy with their tame and feral animals. Often their livestock and plant pathogens were slower to arrive, if at all, but epidemics of introduced human diseases had dramatic effects on indigenous peoples.

This led to one of the key elements of Crosby’s argument: that the members of the portmanteau biota “did not function alone, but as a team” (Crosby 1986, 287). He used as an example the co-evolution of pasture grasses and livestock in Europe, such that when native grasses in the neo-Europes, often unaccustomed to heavy grazing, were slow to recover, Old World weeds and forage crops spread quickly. Newly “Europeanized” landscapes, being constantly disturbed and remade, provided environments in which newcomers could thrive. Hence the profusion of Old World cardoon in the heavily stocked grasslands of South America that Darwin saw.

Critique

Crosby’s thesis was a stimulating addition to understanding the nature of European expansionism but said little about other forms of imperialism, or how the ecological might intersect with cultural, political, or, indeed, economic imperialisms. His discussion of the dynamics of imperialism was limited and questions of motivation were glossed over. Expansionism to him was the product of five factors, the first of which, left undeveloped, “was simply the emergence of a strong desire to undertake imperialistic adventures overseas” (Crosby 1986, 105). The other four were technical: suitable vessels, way-finding methods, weaponry, and energy. Analytically this is close to technological and ecological determinism, and does not explain a lot, as Crosby himself implied when he wrote of “the puzzle of the rise of the Neo-Europes” (1986, 270).

The book did, however, conclude with the observation that the Americas and Australasia “have provided windfall advantages to humanity twice, once in the Paleolithic and again in the last half millennium” (Crosby 1986, 307). Here there was a hint of a political economy of imperialism, the second set of “windfall advantages” representing the expropriation of surplus from the colonial periphery as recognized by Marx. This was the product of “accumulation by dispossession,” driven by enclosure of lands removed from their indigenous owners. A system of individualized land titles and tenure provided the spatial and social building blocks of new colonial
ECONOMIC IMPERIALISM

ecologies in the neo-Europes. Enclosure was enforced using technologies of surveying and fencing, allowing the effective management and containment of flows of people and animals alike. These technologies delineated private property rights in territory at the same time as excluding those dispossessed (Pawson and Christensen 2014). Fences also enabled the parceling of landscape for removal of indigenous land cover and its replacement by familiar crops to generate export of food and raw materials for metropolitan centers of capital. Rather than “ecological imperialism,” it would be more convincing to assess Crosby’s contribution as highlighting some ecological components of imperialism, which in turn might situate environmental history more strongly in the mainstream of critical scholarship.

If explanation of European imperialism was a weakness in Crosby’s argument, so too was the portrayal of the other. With qualification, this applies to both his representation of people and biota. Crosby mused that maybe “European humans have triumphed because of their superiority in arms, organization, and fanaticism” (1986, 7). While the discussion of the effects of Old World diseases on the indigenous peoples is persuasive, although hardly novel, he came close to portraying those peoples as passive victims, rather than active contestants of processes of colonization. His use of the term “Stone Age” marginalized the cultural attributes of Native Americans, Australian Aboriginals, and Māori as shapers of landscape as hunters, fishers, and gardeners. Nor were their histories of resistance, now clear from several decades of subaltern scholarship, recognized. This was perhaps inevitable given the manner in which the narrative was framed through the metaphor of “invasion.”

In some places, Darwin’s theories were read as supporting the apparent success of introduced plants and animals. The naturalist W.T.L. Travers wrote from Wellington to J.D. Hooker at Kew about how New Zealand’s indigenous plants “appear to shrink from competition with these more vigorous intruders” (in Crosby 1986, 255). Crosby’s position effectively endorsed this view, and it lay at the heart of his argument. Despite stating that there “is little or nothing intrinsically superior about Old World organisms compared to those of the neo-Europes,” he then wrote that “Old World organisms are almost always “superior” when the competition takes place in their home environment,” as well as “wherever colonial environments have been Europeanized.” “Europeanized” in this context meant in “a condition of continual disruption: of plowed fields, razed forests, overgrazed pastures, and burned prairies” (Crosby 1986, 291–292).

In this one passage, Crosby repeated two venerable but frequently disputed ideas in biogeography: first, the inherent competitive superiority of organisms sourced from Europe over those of other continents, and, second, that these “invaders” are more effectively disturbance-adapted than those from elsewhere. It is this position that underlay the asymmetry at the root of his understanding of European ecological imperialism. He asserted that only a very small number of weeds, animals, and pathogens from the neo-Europes have naturalized in Europe, quoting Hooker about “this total want of reciprocity in migration” (in Crosby 1986, 167). But this is a product of how the argument is framed and the evidence assembled: reference to Elton (1958), for example, would have produced a different picture. As an ecologist, Elton made no such spatial assumptions and produced many examples that counter any “want of reciprocity.” These include the devastating effects of the American vine aphid, *Phylloxera vitifolii*, on European vines, the impact of the Colorado beetle on the cultivated potato in Europe, and *Elminius modestus*, a barnacle from...
Australasia that by the 1940s had established itself as an intensive fouler of ships’ hulls along the coasts of southern England, northern France, Belgium, and the Netherlands.

Crosby’s argument was therefore ideologically freighted, in ways that might have been tempered had he taken account of pre-existing work in ecology. Instead he could claim that in a “Europeanized” Australia, “dandelions have a more secure future than kangaroos” (Crosby 1986, 292). This was consistent with his position: it is also not correct, given that the larger species of kangaroo have considerably increased in numbers within and beyond their range since European colonization (Flannery 2004). Behind that simple oppositional binary, of dandelion and kangaroo, lay another assumption. This is that it is possible to denote “a portmanteau biota” that is identifiably “European,” rather than a hybrid assemblage sourced from all the places with which Europeans and their networks were in contact. Yet Clark (1949), for example, had illustrated the colonial reach of Californian and Australian species, including the Monterey pine and Monterey cypress (Pinus radiata and Cupressus macrocarpa), as well as many eucalypts. It is therefore necessary to reconsider Crosby’s implicit geographies a little more deeply.

Networks and agents

The sort of spatial imagination that Crosby exhibited, of a dichotomy between metropolitan “core” and colonial “periphery,” has come under increasing challenge from postcolonial scholars, actor-network theorists, geographers, and historians (Pawson 2008). In their formulation, space (including imperial space) can be understood as a sphere of multiple trajectories, some stronger and more formal than others, and described using metaphors of webs or networks (Lester 2004). It is through these webs that projects such as the attempted “Europeanization” of overseas territories were mobilized, and the biotic materials upon which this depended were assembled and dispersed. The webs themselves are seen as connecting metropolitan, colonial, and trading sites in complex meshes, fragile yet dynamic, and influencing the ways in which those sites, or places, were continually reconstituted. From this perspective, flows of material, things, ideas, and practices go in multiple directions. This, although he did not use an explicit spatial imaginary, is consistent with Elton’s (1958) account of species movements.

In a world of webs and networks, the predominantly asymmetrical dynamic of a metropole that shapes “other” places is replaced by the potential for transformation generated by sites throughout the network. In other words – depending on the relation being examined – any number of places can function as metropoles, or act as sources of generative change. They can be simultaneously nodal in some of their relations and peripheral in others. Mid-nineteenth century Melbourne was a colonial city yet at the same time played metropolitan roles within Australasia. More broadly still, its botanic gardens acted as a site of dispersal of Australian plant species, notably many eucalypts and acacias, around the Pacific and Indian Oceans. With plants being shared across networks between far-flung places, this again questions the concept of a European “portmanteau biota.” For example, hundreds of plants were introduced into England from the seventeenth century, sourced from progressively more distant places such as the Americas, China, and Japan. Many of these had significant effects on its landscape, such as species of conifers.

A network perspective on biotic change echoes calls from biogeographers and ecologists to pay more attention to historical and contemporary geographies of dispersal through an emphasis
on trade routes and travel patterns (Blumler 2011; Olden, Lockwood, and Parr 2011). It also requires an understanding of the role of a range of agents, human and nonhuman, in activating and mediating movements along such routes. In this respect the nodal points that controlled flows of information and exchange, or centers of calculation, exercised the power to assemble, order, and disperse knowledge and material. The functions of botanic gardens and zoos as collectors, sharers, and acclimatizers of species have been widely discussed. Kew Gardens in London was “the pivot of a colonial complex of gardens in Calcutta, Jamaica, Singapore, St Vincent, and Mauritius that it orchestrated from its metropolitan vantage point” (Livingstone 2003, 172). But so too for their own distinct array of exchanges were gardens like those in Cape Town. The activities of commercial agents have been less well recognized, for example, nurseries sending plant collectors on long distance gathering trips, such as into the Himalayas from Europe, and seed companies, like Suttons, which claimed to “seed the world” with its tins of grass seed dispatched from Reading, outside London (Pawson 2008).

The landscape impacts of such extensive exchanges of biotic material across the world have been extremely complex. Even if the agents of change since Europe began to discover the sea have often been European, to describe the effects as “Europeanized” – as did Crosby – risks removing both historical and ecological complexity from the understanding of agency. The impacts of “competitive” alien pathogens and species in Europe have already been observed. Two of the most invasive plants in parts of Europe (and elsewhere too) are *Rhododendron ponticum*, native to Spain and parts of Asia, and Japanese knotweed, *Fallopia japonica*. Both were introduced as ornamental species. Many plants recognized at the time as weeds were, however, carried to the neo-Europes unintentionally, as impurities within cheap consignments of seed (although companies like Suttons prided themselves on minimizing such risks). The New Zealand landowner and naturalist, Herbert Guthrie-Smith, observed the consequences of using poor quality grass seed on his own property, and surmised that a lot of other weeds arrived adventitiously in the hooves and hides of stock and horses (Wynn 1997).

Then there is the problem of the kangaroo, which Crosby thought faced an insecure future. Since the European colonization of Australia many smaller species of kangaroo have been in steady decline, and some have become extinct. But the larger species (notably Eastern Greys and also Reds) have flourished in many places, sometimes excessively. The reasons are not straightforward. The provision of introduced pasture and waterholes for stock have long been given as reasons, but others include the shooting of dingoes by shepherds. For millennia Aboriginal peoples also regulated kangaroo populations by hunting, a form of check that diminished as Aboriginal numbers declined from disease and displacement (Flannery 2004).

**Reflections**

There is much to prompt reflection in Crosby’s grand narrative, even if his analysis of “ecological imperialism” is rather too straightforward ecologically, spatially, and historically. It retains some purchase with respect to the impact of pathogens transferred by Europeans. But even here the portrayal of asymmetry was overplayed with networks of flows being far more complex than his model allowed. This has been even more so for insects, plants, and animals. One consequence is that hybridized landscapes are now the norm almost everywhere, the product
of both human intentionality and ecological process with increasing homogenization of biotas, although non-natives may boost overall species richness in some regions (Olden, Lockwood, and Parr 2011). Questions arise as to what is “native” and what is “alien” and the extent to which it is productive to attempt to retain or recover some sort of imagined edenic state of landscape that pre-dates what Elton described as the worldwide “bombardment” of every place by introduced biota (1958, 29–30).

What are left are paradoxes, not certainties. Species identifiably associated with particular places often turn out to be recent arrivals from quite different sources. The emblematic eucalypts of coastal California are from Australia, the Torbay palm of southwest England is New Zealand’s *Cordyline australis*, and the tumbleweed that blows across the sets of American western movies came into South Dakota as a contaminant of flax introduced by Mennonite farmers from Russia. And the confidence that accompanied the introduction of so many species not only in the neo-Europes but also in Europe and other parts of the world to gain “windfall advantages” from the appropriation of nature has been replaced today by biosecurity measures designed to manage the risk of further invasions. Blacklists enforced at state borders attempt to exclude known pests; whitelists allow introduction of species considered unlikely to become invasive (Blumler 2011). But wherever species are introduced, the potential for dislocation as well as for evolutionary adaptation, as the history of biotic exchanges shows, renders such attempts at control problematic.

Ecological modernization

David Gibbs
University of Hull, UK

A growing recognition that the result of human impacts on the environment is a key challenge for global society has led to a number of responses from academics and policymakers alike. However, although there is broad agreement that the world is experiencing major environmental changes as a consequence, notably enhanced global warming and climatic change, there is much less agreement on how these problems should be tackled. There is a spectrum of opinions here, from that of deep green ecologists, who advocate wholesale restructuring of the economy and society, through to some economists who see the market as being capable of restoring environmental equilibrium. An approach to addressing environmental problems that takes a position between these two is ecological modernization. Unlike the more radical green approaches, ecological modernization suggests that the ecological crisis can be reconciled with current forms of economic development and institutions to form a new mode of development for capitalist economies. However, in some versions it also sees a greater role for purposive intervention than just relying on market forces.

Ecological modernization privileges the role of technology, especially the role of innovation, and market dynamics as drivers for change. While they may have been the source of past environmental degradation, it is argued that, when directed toward solving environmental problems, innovation and markets can be combined with the modernization of political institutions and processes to steer a change toward environmental (and economic) improvement. Competitiveness and economic growth are seen as compatible with environmental protection, with solutions to the major global problems such as climate change found in more modernization rather than in reduced industrial production or economic growth. Ecological modernization frames environmental problems in such a way that they can be solved politically, economically, and technologically in the context of existing institutions and power structures and of continued economic growth. Ecological modernization, at least in some forms, appears to allow us to have it all—not only does it deliver environmental improvement, but it also does so without seriously challenging existing economic practices (see Figure 1). Indeed, ecological modernization suggests that addressing environmental problems can produce win–win outcomes that increase firms’ profits as well as improving the environment. It is this seeming compatibility with mainstream economic activity, if only we could be forward thinking and modern enough to make this ecological shift, that helps to explain the appearance of ecological modernization in policy.

In policy terms, ecological modernization aims to move beyond “environment versus economy” debates whereby environmental regulation is seen as a hindrance to business. Rather, environmental regulation can be seen as a necessary catalyst for innovation and the development of new markets. The tradeoff thus turns into a mutually beneficial outcome where no one
ECOLOGICAL MODERNIZATION

Figure 1  Ecological modernization in action: solar roof panels on conventional housing.

loses, or in economists’ terms a “positive sum game.” In this form ecological modernization appears in the guise of a pragmatic program for business and government. In the absence of regulation and incentives, it is argued, companies will have little incentive to develop ecologically desirable (and profitable) innovations. By introducing environmental regulation, governments can encourage innovations and products that lead to high environmental standards and ensure the future competitiveness of their industries in global markets. As an approach, therefore, ecological modernization represents not just an academic and theoretical analysis, but also a practical guide to appropriate responses. These two approaches have also been characterized as the “analytical and descriptive” versus the “normative and prescriptive.” While ecological modernization may appear to offer hope for those committed to stronger environmental protection measures, critics have argued that ecological modernization can equally serve as a cover for business-as-usual with a slight green tinge, or “greenwash.” In this sense, the term could serve to legitimize the continued destruction of the environment and to foreground the industrial and technocratic discourses of modernity over more critical ecological ones.

Ecological modernization as theory

Ecological modernization has a relatively optimistic and constructive view of the potential for society to find solutions to environmental problems. The approach gives a central role to science, technology, and the state and proposes not only that economic development, social welfare, and environmental protection can be reconciled, but also that positive synergies for future development can be generated in the process. It focuses on technological solutions and eco-efficiency gains that can be introduced, and managed, with a minimal amount of change in existing institutional arrangements. One of the central arguments of ecological modernization is that our current institutions can be progressively transformed and modernized in order to avoid an ecological crisis.

The concept was first developed in the 1980s by Joseph Huber (1982) and Martin Jänicke
(1985). In Huber’s (1982, 1985) view, industrial society needed to experience a transition away from the current basis of industrial society toward a new relationship between economy and ecology to create a more ecologically rational organization of production. Huber called this transition an “ecological switchover” and, using a biological metaphor, suggested that in the process “the dirty and ugly industrial caterpillar will transform into an ecological butterfly” (Huber 1985, 20). An ecological modernization approach would involve structural change at both the macroeconomic level, through broad sectoral shifts in the economy, and the microeconomic level, for example, through the use of new and clean technologies by individual firms. As these shifts develop over time there will be a growth in eco-efficiency as the amount of raw material incorporated into finished products diminishes and waste streams are reduced, in terms of both their quantity and their toxicity. This view has a strong faith in the ability of the capacity of markets to deliver environmental technologies to solve major environmental problems.

In theoretical terms, the concept has been developed to analyze the necessary changes to the central institutions in modern society in order to solve the growing ecological crisis. Ecological modernization involves the transformation of institutions and social practices in industrialized societies, where the motivation to make this transformation comes from the growing recognition of environmental problems. Ecological modernization indicates the possibility of overcoming environmental crises without leaving the path of modernization. This use of the concept exemplifies Huber's ecological switchover whereby ecological modernization represents a major transformation of current industrial and economic systems into a form whereby its environmental impact is reduced and the resource base for future development maintained. However, ecological modernization does not assume that this will involve radical changes to our ways of living. The assumption is that processes of production and consumption can be restructured on ecological terms through the institutionalization of ecological aims. However, it is of key importance that environmental factors are not just taken into account in this restructuring process, but are considered as central to the future development of both production and consumption. The rationale for this is not to assert that ecological issues have primacy over economic rationales, but to give both equal weight in order to achieve the desired outcomes. At the heart of the ecological switchover concept are three central points:

- Production and consumption can be restructured toward ecological goals. This involves the development and diffusion of clean production technologies and decoupling economic development from its resource inputs, resource use, and subsequent emissions – that is, expanding economic growth is not accompanied by increases in either inputs or emissions.
- The “economization of nature,” through placing an economic value on nature, including the introduction of structural tax reform and a shift away from taxing environmental “goods” such as employment toward environmental “bads” such as pollution and carbon emissions.
- The integration of environmental policy goals into all other policy areas.

The development of ecological modernization theory

Ecological modernization theory emerged in a European context from the 1980s onward, in part as a practical application of the discourse
ECOLOGICAL MODERNIZATION

of sustainable development and in part as a counterweight to calls from radical ecologists for wholesale social and institutional change. From these initial formulations in the 1980s, a number of approaches have developed in ecological modernization theory (for overviews, see Mol and Spaargaren 2000; Spaargaren, Mol, and Buttel 2000; Mol and Sonnenfeld 2000). Three broad phases can be identified in the development of the theory. In the first phase, developed by Huber (1982, 1985) and Jänicke (1985), there was a heavy emphasis on the role of technological innovation, a critical attitude toward the state, and a belief in the power of market forces and actors to deliver change. Huber’s perspective was that ecological modernization offers a way out of ecological crisis through more industrialization, albeit with changed production and consumption. However, this view has been criticized for overemphasizing the industrial and technological aspects and neglecting the social context within which they occur. In Huber’s initial work, the ecological switchover is a logical, necessary, and inevitable stage in the development of the industrial system. From this perspective, technological developments are largely autonomously determined and lead to change in industrial systems and their relations with the social and natural environment. The key role of technology as a propulsive force in Huber’s work means that the state has a limited role in redirecting the processes of production and consumption. More generally, while a central argument of ecological modernization at this stage was that modern institutions can be restructured on ecological lines and away from a purely economic rationale, as a theory it had little to say on the extent to which institutions can be reformed – this was open to empirical investigation.

The second phase of work, from the late 1980s onward, placed less emphasis on technological determinism as a driving force, had a more balanced perspective on the role of state and market forces in the process of ecological modernization, and emphasized institutional and cultural dynamics. Hajer (1993) proposed two interpretations of ecological modernization. The first of these is Huber’s “techno-corporatist” interpretation, which emphasizes the “economization of nature” and elitist decision-making structures. A second interpretation shifts the focus from being simply on the necessary production and consumption changes, and extends it to encompass the need to incorporate greater democratization, a redistribution agenda, and ideas of social justice. Christoff (1996) characterized these two interpretations as “weak” and “strong” versions of ecological modernization (see Table 1). Drawing on Ulrike Beck’s work on risk society, Hajer further developed the second interpretation of strong ecological modernization as reflexive ecological modernization. In this formulation, political and economic development proceed on the basis of critical self-awareness involving greater public scrutiny and democratic control. Conversely, weak ecological modernization is seen as a lifeline for capitalist economies threatened by ecological crisis and unlikely to lead to the kinds of substantive change needed to avoid this.

A third phase of work on ecological modernization theory devoted more attention to consumption processes and attempted to deal with criticism that ecological modernization is a Eurocentric approach, given that the theory was developed in Germany and subsequent work focused largely on Germany, the Netherlands, and Scandinavian countries. Thus research has examined developments in a diverse range of nation-states including Australia, Brazil, China, South Africa, Russia, New Zealand, and the United States in attempts to see how far the theory can be used to explain a range of environmental policy developments in these countries.

(see Scheinberg 2003; Jepson, Brannstrom, and de Souza 2005; Kotilainen et al. 2008; Milanez and Bührs 2008; Schlosberg and Rinfret 2008; Curran 2009; Howes et al. 2010; Lai et al. 2012; Long and Patel 2011; Memon, Kirk, and Selsky 2011). While this third phase still conceptualizes environmental problems as the key motivation for the introduction of reforms in social, technical, and economic spheres, there are some additional changes. In particular, nation-states shift toward more decentralized and consensual styles of governance and there is a greater incorporation of social movements which become more engaged with the state’s reform agenda and less involved in confrontation with the state. Such reforms should increase the involvement of nonstate actors via negotiations, market mechanisms, and dynamics. Thus recent approaches to ecological modernization reforms of environmental policy involve a shift away from a model of environmental change that is hierarchical and dictated by the state. In the same vein, the technological aspects of reforms to environmental policy are not limited to addressing individual products, emissions, or production process steps, but should also include higher levels of aggregation, production–consumption chains, and networks.

Ecological modernization and the role of the state

Most work on ecological modernization has focused on the potential for environmental reform at the scale of national governments, environmental movements, and business enterprises. While other approaches to environmental policy, such as sustainable development, envisage the “hollowing out” of environmental policy, with competencies moving up to the international scale and down to the local scale, ecological modernization does not necessarily require de-emphasizing the nation-state. In the initial formulation of ecological modernization by Huber, the state plays little or no role in the ecological switchover. Indeed state involvement was seen as hindering the development and diffusion of clean technologies. However, subsequent research has argued that this is an overly technical perspective and that it is difficult to imagine any moves toward ecological
ECOLOGICAL MODERNIZATION

modernization taking place without some state intervention at various levels.

This may not necessarily involve the need for a strong, bureaucratic state – the suggestion is that the role of the state should change from being reactive toward acting in a preventive manner, to move toward participatory policymaking methods, to become decentralized, and to steer developments contextually rather than direct them in a top-down fashion. Thus ecological modernization, it is argued, requires political commitment to a longer-term and more holistic approach to the integration of the environment with economic development rather than a dirigistic approach, where government has a strong directive role. Thus it is argued that those nation-states where we can see ecological modernization in operation (at least in its weak form) are those which have consensual forms of government and decision-making arrangements that encourage more collaborative relationships, such as the Netherlands, Germany, Sweden, and Japan. Despite this, Huber in his later work has argued that, despite significant progress in these countries, they remain in the early stages of ecological modernization and that further progress has been repeatedly delayed. There is thus a need to explain why progress has been delayed and to develop further conceptualizations of the state in ecological modernization theories.

A key area of work which has sought to explain the potential for nation-states to undergo ecological modernization has been undertaken by Martin Jänicke. Overall, Jänicke argues that Huber’s emphasis on corporate ecological modernization is necessary but not sufficient to lead to environmental improvement. He suggests that the ability of nation-states to undertake holistic and longer-term environmental policy approaches is important and that this results from the interplay of their economic performance with their capacities for innovation, strategic thinking, and consensual government. From this he develops the concept of “environmental capacity” in order to understand both the conditions that encourage nation-states to address environmental problems and those that can subsequently result in the implementation of successful policy forms. He then introduces a second concept of “strategic capacity” which refers to the ways environmental protection can become a function that goes across the whole administrative apparatus of government. This means that different government departments should work together, rather than in separate “silos,” so that potential disagreements and contradictions can be defused and dismantled.

Jänicke then builds on this theory of strategic capacity to produce a model of policy explanation. He argues that the capacity for action on environmental issues sets the structural conditions for successful environmental policy, as well as its limitations. Capacity in this case therefore refers to both the opportunities and the barriers that may arise. In this model, solutions to environmental problems are developed within structural framework conditions and within what Jänicke calls “situative contexts,” involving actors and their strategies, together with institutional, economic, and informational factors. Strategies are defined as the general approach taken toward a problem – for example, using environmental policies to address problems and achieve goals. Actors, who include individuals, pressure groups, and third parties as well as government, are the opponents and proponents of special issues. The latter have relatively stable general interests and core beliefs, and their capacity for action depends largely on their strengths and competencies. An important dimension to this model is that the ability of actors to develop strategies can be significantly influenced by the situative context, such as an economic recession or a
major environmental disaster or pollution event, which could hinder or encourage policy action. The other components of the model comprise the “structural framework conditions,” which provide the backdrop to the situative context, actors, and strategies. Together these form the broad conditions for environmental action and give rise to an opportunity structure for actors. This consists of:

- the cognitive-informational framework, that is, the conditions under which environmental knowledge is produced, distributed, interpreted, and applied;
- the political-institutional framework comprising the institutional and legal structures and institutionalized rule and norms in society;
- the economic-technological framework which includes economic performance, technology levels, and sectoral composition.

The resulting capacity of actors to act (and the success or otherwise of these actions) will be influenced by the interplay of these three frameworks in any given situation. Jänicke suggests that utilizing this model to understand the implementation of environmental policy helps us gain an understanding of how the potential for ecological modernization may vary across different nation-states and at other scales. The ability to successfully implement policies will depend on specific situative contexts and structural frameworks, as well as on the composition of local actors and forms of strategies. However, while in theory ecological modernization is thus useful in helping us to think through some of the changes that need to be made to economies through political programs, in practice most subsequent research has rarely addressed the social processes involved through notions of situative contexts and the constellation of actors at different spatial scales.

EcoLOGICAL MODERNIZATION

Ecological modernization as political program

Ecological modernization is also used to describe a more pragmatic political program to redirect environmental policymaking. As a political program, ecological modernization has three linked components which are related to the theoretical arguments:

- compensation for environmental damage and the use of environmental technologies to minimize the effects of expanding production and consumption on the environment;
- the introduction of policies to encourage a shift in production and consumption processes toward the use of clean technologies and greater use of economic valuation in environmental policies;
- the deindustrialization of economies and a shift toward small-scale units of production, as well as a closer link between production and consumption.

While perhaps few policymakers would recognize the term, approaches based on ecological modernization are increasingly being utilized within policy which seeks to integrate economic development and the environment. Proponents of ecological modernization have argued that the process of shifting from the first to the second of the points listed is already underway in countries like Japan, the Netherlands, Germany, Sweden, and Denmark as material flows have become delinked from economic flows, with a simultaneous decline in the use of natural resources and emissions. This has involved moves to close substance cycles and the chain from raw materials through to the production process and waste and recycling, conserving energy and improving the efficiency and utilization of renewable energy.
sources, and improving the quality of both production processes and products.

As a pragmatic political program, ecological modernization approaches suggest that these changes will engender support from private sector businesses, given that they can have beneficial financial outcomes—ecological modernization is a response to environmental issues that stresses win–win outcomes. It is claimed that business can gain advantages in a number of ways: first, through greater business efficiency as a consequence of reduced pollution and waste production; second, through the avoidance of future financial liabilities, such as the potential future cost of the cleaning up of contaminated land; third, the creation of a better work environment has positive impacts on recruitment and retention of the workforce; fourth, there is greater potential for business through increasing sales of “environmentally friendly” products and services; and, finally, there are opportunities for the sale of pollution prevention and pollution abatement technologies to other companies and utilities. In total, then, it could be argued that ecological modernization has a well-developed perspective on how to conceptualize economy–environment relationships and a set of policy prescriptions that, taken as a whole, can engender the development of a new economic trajectory. Concepts derived from work on ecological modernization have certainly become incorporated into the policy agenda, even if their actual implementation has been limited and they are drawn from the “weak” conceptions in Table 1.

**Ecological modernization: a critique**

In recent years environmentalism has become institutionalized—environmental agendas and objectives are part and parcel of most nation-states’ policies and major corporations devote space in their reports and on their websites to trumpet their contributions to sustainable development and corporate social responsibility. Although it is clear that institutional changes and environmental improvements have occurred and that the changes advocated by the proponents of ecological modernization are desirable, there are a number of problems with ecological modernization as a theory and as a policy program.

First, one criticism of ecological modernization as both theory and discourse is that, in its weak forms, it can help to legitimize an environmental policymaking culture that absolves private sector businesses and major corporations of their broader environmental responsibilities. This is perhaps not surprising given its emphasis on technological innovation, on creating markets for new goods and services, and on the role of large producers and retailers in developed economies as a force for change. Indeed, this may be one reason for its widespread popularity, and some sectors of business have seen substantial profits from improved environmental technologies and stricter global environmental regulation, for example in the emerging clean tech sectors. For the advanced capitalist nations, which are struggling to remain competitive against the rise of emerging economies in Asia, imposing strong environmental regulations which require high-tech solutions has provided not only a competitive advantage for their own domestic industries but also a strong export market for these same environmental technologies. As a counter to this, developing economies have been critical of such initiatives, seeing them as a new form of protectionism and as “environmental imperialism.”

Thus while ecological modernization may be predicated on the potential transformation of capitalist economies, it is also liable, as a discourse, to be co-opted by powerful economic
actors such that there is greater dominance of global resources by transnational industry, national governments, and “big science.” Certainly the ecological modernization discourse has been incorporated into both corporate reporting and the agendas of global economic institutions without much apparent change to everyday practices. The underlying conceptualizations of ecological modernization can therefore act to perpetuate the dominant forms of economic power. At the same time there is little recognition in ecological modernization approaches that some industries may find it impossible to innovate to reduce their impacts – it may be too expensive or technologically impossible to do so. In these cases, for example in the fossil fuel industries or the automotive industry, an alternative strategy may be to lobby for exemptions or to attempt to dilute environmental policies. There are thus limits to the extent to which changes can be made within the modernization framework – not all sectors may be able or willing to make the shift. Moreover, other developments may represent a shift away from ecological modernization processes. For example, the increasing use of fracking for gas, especially in the United States, appears to be creating a new model for energy production, albeit aligned to the existing carbon-based system. The environmental impacts of this, through both increased carbon emissions and more localized concerns over water table pollution, are considerable and controversial (see Figure 2).

Second, despite a focus on the institutional reorganization of society, ecological modernization approaches often contain little detailed analysis of the forms of institutional adaptation or change that are required. It can be argued that this is a product of the undertheorization of the state in ecological modernization and oversimplifying assumptions about the role of states in ecological transformations. As was pointed out earlier, in Huber’s work the role of the (central, regional, or local) state was seen as minimal. In later accounts, there has been a more sophisticated understanding that the state performs an enabling and contextually steering role. Often, though, the appearance of institutional changes is presented as evidence that “ecological rationality” has started to challenge “economic rationality.” Although Jänicke’s concept of the “environmental capacity” of states focused on their ability to make the shift to ecological modernization, and others have argued that the integration of social and environmental movements into the policymaking process is driving the process forward, there is still little detail of the form of institutional adaptation or change required at the nation-state level, let alone at subnational scales.

One argument is that ecological modernization involves the development of an “enabling state” as the institutional response that will secure the efficient functioning of the market economy, but within a clear framework of state regulation. In this view, the enabling state will deliver ecological modernization through corporatist relationships between government and industry, although co-opting environmental movements when necessary. Certainly, many accounts have recognized the continued importance of the nation-state, albeit one that is no longer solely responsible (if it ever was) for environmental governance. This failure to adequately conceptualize the state and the social processes at work means that the type of embedded cultural transformations that will sustain factors, such as environmental improvements, reduced consumption, and greater equity, are unlikely to be realized.

Third, ecological modernization lacks a theory of power relations. In some accounts, the assumption often appears to be that the logic of ecological modernization is so obvious (and
profitable for business) that its widespread adoption is simply a matter of time so long as a mix of international civil society and environmental nongovernmental organizations keep up the pressure. In a situation where nobody seems to oppose it and where the theory lacks any scope to encompass power relations, there is little perceived room for opposition, and ecological modernization is assumed to occur almost automatically. In other accounts, ecological modernization will occur only if there is sufficient societal, political, administrative, and organizational capacity. Even then, this needs to be accompanied by the presence of a range of variables, such as strong corporatist institutions, innovative legal and informational systems, and a proficient regulatory system.

However, the reasons why such changes should occur, let alone when and where, are rarely addressed. The implementation of ecological modernization, as with any policy, however, is about the exercise of political and economic power, and, although this is rarely made explicit, ecological modernization is a fundamentally political concept. Whether it can be successfully introduced depends on questions such as who is in control, who sets agendas, who allocates resources, who mediates disputes, and ultimately who sets the rules of the game. Ecological modernization is thus as much an ideological and political issue as it is an ecological and economic one.

While the proponents of ecological modernization are not necessarily unaware of these issues, the driving force behind the development of “environmental capacity” and institutional reorganization is rarely made explicit, although there is a strong emphasis on market-based measures and pressures from civil society. Similarly, while some commentators have argued that ecological modernization is not a seamless progression toward a better future and that “ecological subversion” may reverse the semipermanent character of the ecological

Figure 2  Anti-fracking protest in France.
Some critics have identified ecological modernization as being part of the wider move toward the neoliberalization of society and economic policy, such that real transformative change is impossible. Indeed, ecological modernization has been criticized by both neo-Marxist and deep green critics who argue that the current capitalist system is inherently unable to reform itself along ecological lines beyond a weak “light green” reform program of “greenwashing” and that more fundamental structural changes are needed in the economy and society. In the process, the logics of neoliberalism and ecological modernization are said to have depoliticized environmental policy through scientific and “econocentric” discourses to exclude the consideration of alternative strategies. Certainly advocates of ecological modernization have had little to say about the impact of neoliberal economic policies on the environment or about the ability of markets to resolve environmental crisis.

Such a critique would suggest that ecological modernization needs a more radical edge if it is to lead to any substantive changes. This would require addressing the key underlying processes at work, including the associated power structures, social relations, institutional configurations, discourses, and belief systems, that currently lead to environmental and social injustice. At the stronger end of ecological modernization, the incorporation of environmental justice would require considering alternative modes of production, consumption, and distribution to current forms if ecological modernization is to be a more radical program of political action. To some extent, this point is recognized in the work of Hajer (1995) and his “argumentative approach.” His approach includes politics in the analysis in the form of a struggle for discursive hegemony whereby the actors involved attempt to secure support for and to impose their particular definition of environmental policy. In this case, the discourse of ecological modernization, at least in its weak version, appears to be politically attractive as it provides a means to both accommodate radical environmental critics and to revive developed nation economies through a new round of capital accumulation based on environmental technologies and products. However, ecological modernization is not (yet, at least) a distinct social theory; to become so, it needs to adequately incorporate theories of politics and the state.

Ecological modernization in geographical uses

Some geographers have drawn implicitly on the concepts of ecological modernization. Soyez (2002), for example, used the term “eco-modernization” as a synonym for ecological modernization. More recently, Bailey and Wilson (2009) and Bailey, Gouldson, and Newell (2011) use ecological modernization as a way to frame debates around climate change. However, despite the growing importance of ecological modernization as both a theory and a pragmatic program, relatively few geographers have explicitly engaged in the ecological modernization debate to advance its theoretical development compared to those working in the field of environmental policy and politics (for an exception, see Murphy (2000)). However, strong parallels with ecological modernization can be seen in the work of Hayter and Le Heron (2002) and Hudson (2000, 2001). Hayter and Le Heron drew on research by Freeman (1992) on techno-economic paradigms (TEPs) to develop his suggestion that a “green paradigm” will form the basis of future economic development. This paradigm, they suggested, will involve both technological and institutional changes. It will revolve around the
ECOLOGICAL MODERNIZATION

dematerialization of the economy, the internalization of environmental values by industry, and the prioritization of the environment within research and development (R&D), as well as take-back strategies and a shift toward selling services rather than products. In Freeman’s original theorization, new TEPs arise when the economy is confronted by crises that cannot be solved by the existing TEPs. However, far from being a technological determinist argument, in a similar manner to ecological modernization, emphasis is placed on the development of a set of matching institutional forms, including business organization, labor relations, R&D structures, and international regulatory forms.

While Hayter and Le Heron (2002) did not use the term, there are strong parallels between their view of a green TEP and ecological modernization. They argue that in a green TEP environmental imperatives form the motivation for more widespread systemic change, and priorities for innovation are geared toward reducing energy and materials use of energy and materials in transportation, construction, and manufacturing systems. Similarly, Hudson (2000, 2001) developed the idea of “eco-Keynesianism” as a way of resolving the competing pressures of generating profits, providing work, and protecting the natural environment. He argued that this would be an attempt at radical reformism which combined environmental and social sustainability while respecting the profitability imperatives of a capitalist economy (Hudson 2001). Although his “sustainable eco-capitalism” has a much stronger emphasis on social justice, as with ecological modernization, it similarly involves the widespread use of clean technologies and environmentally friendly production.

Economic development zones

Jinn-Yuh Hsu
Ling-I Chu
National Taiwan University

An economic development zone (EDZ) is, by definition, a special zone designed and established for the purpose of economic development. The establishment of EDZs is the process whereby the state assigns to specific pieces of land regimes of governing and regulation that are distinct from the normalized rules prevailing in the national territory (Ong 2006). Within EDZs, exceptional packages of incentives and preferential privileges are granted to induce investments. Compared with more traditional sector-oriented policies, these spatially specific strategies represent different state forms and powers to promote economic development. Normally, special zones are designed with the aim of achieving specific policy goals, including attracting foreign direct investment, alleviating unemployment, supporting economic reform strategies and industrial upgrading, and serving as experimental laboratories for the application of new policies and approaches (Farole and Akinci 2011). But, in practice, the performance of the zones is ambiguous, and needs to be examined case by case.

The history of EDZs

As shown by Easterling (2014), the historical roots of EDZs can be traced back to ancient free ports, medieval free cities, or maritime colonies. The Roman port of Delos, which is frequently cited as the primordial free port, as well as other Mediterranean free ports for trade, flourished in antagonistic Italian, Phoenician, and Muslim civilizations in the first millennium. In the Middle Ages, a network of “free cities” such as Hamburg, Bremen, Lübeck, and Cologne collaborated as the Hanseatic League to evade the jurisdictional power of monarchies, and later on to confront the sovereign authorities of rising nation-states. The European powers, including Portugal, Spain, Holland, France, and Britain on the one hand, extended their trading networks by establishing a series of colonies from the Middle East, Africa, and America to Far East Asia; the Chinese and Japanese emperors, for their part, developed sanctioned trading systems in Canton and Nagasaki respectively to cope with their encounter with the West. Some of these legacies, like Hamburg and Hong Kong, endured and were transformed into global hubs in the twentieth century.

It has been only in recent decades that the EPZ (export processing zone), a major kind of EDZ, has emerged as a powerful global form, even though its roots are ancient. In 1934 the implementation of the Foreign-Trade Zones Act in the United States marked the start of the new age of EDZs in their modern forms: freedom of trade was represented as a freedom from taxes. In the authorized zone areas, custom-free goods were sorted, refined, and processed, and then re-exported. From Ireland (Shannon Customs-Free Airport) to Mexico (the maquiladoras on the United States–Mexican borderland), this spatial technique was widely adapted in the postwar era. At the same time,
ECONOMIC DEVELOPMENT ZONES

More tax-exempt measures were adopted to attract manufacturing and service industries. To fire up development, latecomer states in particular elbowed their way into the global economy with EPZs, in which foreign capital was welcomed to take advantage of cheap labor and land.

At present, EDZs can be found all over the world, and the number has grown rapidly. For example, in 1986 the International Labor Organization’s (ILO) database of SEZs (special economic zones) reported 176 zones in 47 countries; by 2006, this number had risen to 3500 zones in 130 countries (Boyenge 2007). Among these newly established zones, most are located in developmental states. Despite the historical and current link between zones of exception and the ideology of free trade, they can also serve the interests of the developmental state, particularly in East Asia and Latin America.

The first East Asian EDZ was established in Kaohsiung, Taiwan, in 1965. Following it, Masan EDZ was set up in South Korea in 1970. As an agent of economic territorial nationalism, the East Asian developmental state was, on the one hand, inclined to make a distinction between domestic industries and foreign capital and, on the other, could not but take measures to connect the former with the latter in order to promote the national economy. Instead of being a passive administration that views its responsibility as simply providing a sound regulatory environment, the developmental state is interventionist and plays an active role in targeting strategic industrial development. Given these circumstances, EDZs became a crucial part of the developmental strategies that utilized their cheap labor and land and their loose regulation to attract foreign investment and transfer technology and international expertise, while maintaining the integrity of the national economy to a considerable degree.

Among the zoning programs in East Asia, China’s Special Economic Zones (SEZs) Policy is spectacular in comparison to its forerunners. Since the early 1980s, when post-Mao China decided to adopt an open policy, the state has kept on creating new capitalist spaces on the socialist mainland by establishing waves of SEZs. Deng Xiaoping considered the establishment of special zones as replicating new Hong Kongs along the Chinese border, acting as both an economic bridge and a political window to the outside world. Therefore, all the first four SEZs were located in border regions: Shenzhen adjacent to Hong Kong; Zhuhai across from Macao; Xiamen across the strait from Taiwan; and Shantou, which had strong traditional connections with Chinese communities in Southeast Asia. Once market development in the coastal SEZs gained momentum, different kinds of free trade zones, custom-free warehouses, export-processing and high-tech industrial parks were established in coastal and interior cities to attract foreign investment and accelerate the development of hinterlands.

EDZs in China have evolved into a unique system not only for export-oriented industrialization but also for transformation of the state itself. Ong (2006) argues that China’s opening and market reform policies relied not on unbundling or denationalizing sovereignty but on the production of new spaces of exception and border-crossing powers. According to Ong, the Chinese state’s flexible zoning practices create not only political spaces and conditions of variegated sovereignty aligned with an axis of trade, industrialization, and knowledge exchange, but also the regional space informally called Greater China in order to integrate disarticulated political entities economically as part of a path to eventual political integration.

Another key player in “zone fever” is India. The government of India has made various
efforts in order to promote waves of EDZs since
the 1960s. The Kandla Export Processing Zone
in Gujarat was established in 1965. This was fol-
lowed in the 1970s by the creation of the Santa
Cruz Electronics Export Zone (SEEZ), which
was expanded in the 1980s to include gems and
jewelry. The 1980s also saw the creation of EPZs
in Noida, Chennai, Cochin, and Falta (West
Bengal), followed by the Visakhapatnam EPZ in
1994.

But India’s push toward a more comprehen-
sive SEZ policy began in earnest following a
visit by the then commerce minister Murasoli
Maran to China in 2000. Hugely impressed by
what he had seen in China’s SEZs – and by his
discussions with Chinese officials – Maran acted
quickly to initiate a change in India’s policy
regime (Das 2009). This change took the form
of new SEZ rules notified in the Commerce
The new rules were a precursor of what would
later become the 2005 SEZ Act, which allowed
the private sector to assemble land and develop
the zones, unlike China. The main difference
between EPZs and SEZs is in their compre-
hensiveness. Whereas EPZs can be thought of
as industrial estates, SEZs typically contain a
full array of social facilities – housing, hospitals,
schools, and retail developments – that make up
a small city.

A spectacular characteristic of the new gen-
eration of EDZs, like the SEZ, is the rise of
zone-cities, or urbanization through special
zoning, particularly in China and India. One of
the most famous cases is Shenzhen, an “instant
city” which became a boomtown because of
its designation as an SEZ and saw sustained
rapid growth due to the extended implementa-
tion of favorable policies and the rapid and
continued build-up of state-financed infra-
structure (Chen and de’Medici 2010). These
special zones mostly turn a practical space for
the production of exports into connected places
of service provision and, most importantly,
urban infrastructures (Bach 2011; Easterling
2014). Free zones such as the EPZ, prior to the
last few decades, were usually fenced enclaves
for warehousing and manufacturing which
offered exemptions from customs or taxes. Yet
the zoning form that was largely relegated to
the backstage has recently taken a center-stage
position to become a primary feature of global
urbanism and a world city paradigm. Usually
located around harbors or airports, an SEZ
involves massive land development, and even
claims to be a city itself. The initiation and
operation of many SEZs are no longer solely
funded by government, as with EPZs, but are
jointly developed and managed with the private
sector in public–private partnerships. In practice,
the government provides the necessary planning
and construction, such as the infrastructure in
the harbor or airport areas, leaving the facilities
and particularly the urban infrastructure in the
SEZs and neighboring areas to the private sector.
Zone-cities are a key location for understanding
the social and cultural impact of globalization
on overlapping territories and urban space (Bach
2011), assuming the form of a contemporary
capitalist utopia and heterotopia, and of an
interface between geographies of management
and of imagination.

The main reasons for the wide adoption of
EDZ as a developmental strategy are that it pro-
vides a gateway to the international community,
lower operational costs, demonstration effects,
and, more importantly, a compromise between
liberal and protective regimes (Amirahmadi and
Wu 1995). EDZ creation may be driven by
political reasons. In countries with privileged
corporate groups which monopolize industry,
a separate economic zone rather than complete
liberalization may be more politically acceptable
to the elite, while also promising economic
mobility to the local masses (Amirahmadi and Wu 1995). Even though foreign investments and aid are welcome on condition that they create employment opportunities and stabilize the trade balance, the host states also have to find ways of ameliorating the negative impacts of liberalizing capital flows. Hence EDZ can be seen as a political-economic compromise involving the implementation of partial liberalization policies to protect the domestic economy so that it can avoid facing direct foreign competition in the early industrialization era. In order to find the right balance, the state experiments with zoning technologies, on the one hand, to exploit its cheap labor and land in attracting capital investment and, on the other hand, to avoid fully exposing the national economy to a relatively unstable internationalization process. As a result, the EDZ typically provides cocktails of exemptions from broader national rules that may include tax breaks, foreign ownership of property, streamlined customs arrangements, and deregulation of labor or environmental laws.

EDZs and liberalization

Heated debate about the role of the EDZs as free-market islands or bridges to structural transformation driven by economic liberalization always haunts developing countries. Globalizing processes intensify the spreading of EDZs. While a number of analysts believe that EDZs will provide their impoverished host country governments with a gradual, two-track alternative to neoliberal “shock therapy,” and therefore welcome their growing popularity (Rodrik 1999), others believe that they are second-best options to promote exports, in particular regions of developing countries, without having to undertake the challenge of broader structural adjustment. The real liberalization impacts of EDZs will depend on the particular national contexts, so there is no consensus between advocates of these perspectives (Schrank 2001).

The rapid growth of EDZ programs around the world since the 1990s, and their success in contributing to export-led growth in regions like East Asia, are due in part to the unprecedented globalization of trade and investment that has taken place since the 1970s and that accelerated during the 1990s and 2000s. Moreover, establishing linkages between local clusters of firms and global value chains (GVCs) has become a key development strategy for countries embarking on latecomer industrialization and seeking to engage in industrial upgrading (Humphrey and Schmitz 2002). In most cases, EDZs, and particularly EPZs, serve as the designated local industrial districts to host segments of global value chains. One of the major governance mechanisms is the statecraft of the developing countries. Meeting the challenge of global connection, the developmental states bring forth the modes of interscalar connection as a key dimension in exploring how economic and extra-economic regularities are materially, spatially, and temporally related. The state spatiality of EPZs can therefore be seen as special regulation spaces that cushion the tensions associated with global–local connections.

But participating in global value chains both enables and restricts the capability of the state to manage external connections, and produces different state spatialities that reshape the spatial forms and functions of EDZs. At first, the developmental states of developing countries strive to focuses on manufacturing roles, while product design and final markets are located in advanced countries. Since demand is often out of their control, it is even more imperative for latecomers to be “competitive” in factor supply. In this stage, the EPZs are the one of typical
spatial forms adopted by the state. However, in engaging more deeply in the global integration of economic activities, the state can no longer focus on the reduction of the cost of production factors, but has to provide a liberal and friendly business climate to attract high value-added investments. To fulfill the demands of liberalization, a special zone of a liberalized economy, such as South Korea’s Incheon Free Trade Zone, Taiwan’s Free Economic Pilot Zone, and China’s Shanghai Free Trade Zone, assumes the role of a bridgehead, connecting with and redirecting international economic flows. Since there are different types of global–local connections, the forms of zoning vary. EDZs, as a mobile technology, spread and evolve internationally in ways that correspond with distinctive geographical features of the industrialization process. The state can, albeit reluctantly, liberalize capital flows and legalize risky industries, such as those associated with financial derivatives, via EDZs, to create a friendly business climate and enhance competitiveness. With the establishment of EDZs, states are better positioned to act as agents of liberalization with a view to enhancing global competitiveness.

Given the state’s intention to mobilize zoning technology to cope with the pressures of globalization, the performance of the East Asian EDZs is ambivalent. It is widely recognized that the EDZs in South Korea and Taiwan, as well as in Malaysia to some extent, have performed relatively well in meeting the needs of industrialization, creating employment opportunities, and engendering technology transfer. Some EDZs have evolved into high value-added industrial estates. It is argued that domestic linkages between firms operating in EDZs and the local economy are crucial. These positive externalities could, but do not necessarily, spread locally. If the EDZs’ level of integration into the local economy is low, the spillover effects and externalities are likely to be limited, and the EDZ would be directly exposed to the potential volatility of global capital flows. For “footloose” transnational corporations (TNCs), substantial linkages may not develop because TNCs may prefer, for strategic reasons, not to become deeply embedded in the host country’s economy. Particularly for assembly-type work using inputs sent directly from the parent company, assembling in the zone and then shipping out, backward linkages with the domestic economy may not be generated. In some countries such as Madagascar, spillover effects and externalities are probably limited by the EDZs’ low level of integration into the local economy (duty-free imports act as import subsidies and prompt minimal local integration), the low skills of the labor employed, and the potential volatility of foreign investment (Cling, Razafindrakoto, and Roubaud 2005). Successful cases of national integration with the EDZs, such as South Korea, Taiwan, and now China, are cases where EDZ policy is accompanied by strategic state policy designed to encourage domestic firms to articulate with the GVCs, generating spinoffs from the TNCs in the EDZs. For instance, in the case of China, the state has a strong card in the shape of access to the huge domestic market to influence the TNCs in the zones to engage in technology transfer to local firms. Thus EDZs may be regarded as growth centers which are expected to generate economic multiplier effects, with employment and subcontracting work trickling down to surrounding regions.

Governing territory, borders, and sovereignty in EDZs

In contrast to the idea that EDZs are part of liberalizing processes and escape the control of the nation-state, regulation theorists such as Bob
ECONOMIC DEVELOPMENT ZONES

Jessop, Martin Jones, and Neil Brenner argue that EDZs actually reflect state accumulation strategies designed to strengthen the national economy. This line of research sees EDZs as a component of state strategies which represent initiatives to mobilize state institutions toward particular forms of socioeconomic intervention with a tendency to privilege particular social forces, interests, and actors over others. Jones (1997) showed that state institutions are endowed with distinctive spatial selectivities, which refer to processes of “spatial privileging and articulation” in which state policies are differentiated across territorial space in order to target particular geographical zones and scales. In this vein, they regard the partial insertion of the national economy into truncated GVCs as the main driver behind the formation of EDZs.

From a subtly different angle, Cameron and Palan (2004) argued that a bounded political economy is in fact a prerequisite for the regulation of all forms of international trade, and that international trade is a concept that would have no meaning if the world economy were not divided by national borders. In spite of being assembled to allow the diffusion of liberalization, the EDZ contrarily creates the “domestic” and the “international” economies as discrete spaces by visualizing the state border as if it were an economic boundary. The liberalization measures incorporated in EDZs reflect the state’s use of deregulation as a new means of reregulating economic flows, particularly finance and services. It is noteworthy that deregulation and reregulation processes are embedded in a series of social-political relationships of bordering, networking, and interscalar connections. Therefore the EDZ, one of the particular state forms, can also be seen as an arena where actors, including the state and firms, struggle over the construction of political-economic relationships, governance structures, and institutional rules and norms.

Another line of research, through a Foucauldian lens, considers the EDZ as a governmental technology in which market-driven strategies of spatial fragmentation respond to the demands of global capital for diverse categories of human capital, thus engendering a pattern of noncontiguous, differently administered spaces of “variegated sovereignty” or “graduated citizenship” (Ong 2006, 7). These scholars think of the differently administered spaces as the praxes of liberalization or neoliberalism that are put into effect as exceptions to the normal governmental rule that is supposed to prevail in the national territory. It should be noted that EDZs are used to reinforce rather than weaken national sovereignty, because the centralized state can define the general national interest by liberalizing part of its territory and people to articulate with international flows.

Since EDZs are further conceived as gateways to international economic flows, the discourse of inside/outside can be clearly defined. A wide-open door symbolizes a friendly business environment welcoming transnational corporations to establish a foreign–domestic nexus. The metaphor that the state can decide how wide the door should be opened also works well in symbolizing the capacity of filtering and selecting what is desirable and nondesirable. In manipulating zoning technologies, geo-economic hope arises in the discourse of (imagined) economic separation or interconnection. EDZs can be seen as a compromise between national security and economic development.

Zoning strategies always involve a balancing of geopolitical fears and geo-economic hopes (Sparke 2006). On the one hand, the zones can attract and retain liberal flows of capital, technology, and people to develop the national economy; on the other hand, these kinds of internally established borders bring about new security issues. Consequently, border control becomes
one of the key concerns with the setup of EDZs. An ideal pattern of border control will expedite the global economic flows to realize time economies, and at the same time filter out the “dirt” associated with unexpected or unwanted flows of goods and people and pre-emptively keep them outside the national territory (Sparke 2006). Advanced biometric technologies are utilized to monitor and govern the mobilities of people and goods; in so doing, states patrol and police the dividing lines between inside and outside to tackle the threats posed by external forces. Given that EDZs are regarded as the interface along the inside/outside line, they involve spatial practices of debordering and rebordering.

The contradictions of EDZ policies

Because zoning policy implies differentiating the treatment of land and people, it always generates social and spatial tensions. Some EDZs restructure the local economy in a way that is adverse for the poor, especially those in the agriculture sector. There is social outcry over land expropriation for the construction of EDZs and the resultant displacement of existing settlers in developing countries such as India and China, among others, as the displaced people consider the land that is essential for their livelihood or the compensation for land appropriation to be inadequate. In investigating India’s controversies over “land grabs,” Levien (2013) argued that, while the earlier models of company towns and industrial estates reflected a regime of land for production with pretensions of inclusive social transformation, the EDZ model nowadays represents a neoliberal regime of land for the market in which “land broker states” have emerged who indiscriminately transfer land from peasants to capitalist firms for real estate projects. The special zone policies in countries such as India often become the basis of a regime of “accumulation by dispossession” closely associated with the multiple forces seeking to turn land and other resources into capital. Levien (2013) argues that this type of real estate-driven agrarian transformation which the EDZ policy generates in the surrounding countryside will lead to land speculation that amplifies social inequalities in novel ways, marginalizes women, and creates an involuntary dynamic of agrarian change that is ultimately impoverishing for the rural poor.

As for the labor condition in EDZs, low wages are critical in attracting foreign capital, and employment is usually precarious or informal as a result of the EDZs’ setting aside of national labor regulations. People working inside EDZs are governed solely in relation to their potential for growth and productivity. Ong (2006) argues that these governance arrangements effectively suspend workers’ political rights, that individual workers themselves have an unclear political status, and that workers can be exposed to the worst abuses, including murder, with virtual impunity. However, Cross (2010) disagrees with the language of exceptionality by arguing that the EDZs should not be regarded as closed or bounded systems but should be structurally embedded in the wider economy. In other words, the labor condition in the zones is nothing more than the formalization of the informality that has existed outside the zones for a long time in industrializing countries, particularly in the Global South. Accordingly, the presumption of a Western system of political rights is not appropriate in explaining EDZs in the context of emerging economies where the political status of working subjects is never that of inalienable rights and entitlements. In this sense, the most significant achievement of the zones is that the new employment opportunities they provide render visible the insecure working condition in the wider economy.
The controversies about land appropriation, labor abuse, and environmental degradation never fade away in the construction of EDZs. In most cases, that the zones discriminate against certain groups of citizens, exempt capital from taxes and regulations, and force farmers to move out of their inherited land may in the end see the rise of various social movements. Consequently, states that are eager to carry out a liberalizing policy by spreading EDZs are very likely to be authoritarian regimes that are able to control social unrest. Certainly, in recent years, SEZ policy has been hotly debated. Those who stand to lose their land are organizing huge protests, and there have been scathing critiques of SEZs by politicians, scholars, media, and civil society (Aggarwal 2006).

### Conclusions

By and large, the EDZ started out as a state’s special and experimental strategy to explore the emerging opportunities of internationalization, and was gradually transformed into a major channel of global connections for the state. Situated in changing political and economic climates, two major trends in the institutionalization of EDZs can be noted. One is the “universalization” of EDZ exceptionalism across developing countries; the other is the utilization of special zones as a liberalization toolkit by developmental states. Rather than integrating EDZs into the general economy within national boundaries, states use them to offer special treatment as a way of exploring new windows of business and technology opportunities. Zoning technologies proliferate and extend to create a network of subcontracted parts covering much of the country. Ultimately, zoning became a part of the assemblage of globalization and has spread across the world (Easterling 2014; Ong 2006).

Economic geography: spatial interaction

Jiaoe Wang
Chinese Academy of Sciences

Spatial interactions consider the dynamics of flows of people, freight, services, energy, or information between locations generated by economic activities. They are demand–supply relationships expressed over a geographical space, and usually refer to a variety of movements such as tourism, commuting, migration, international trade, and the transmission of information or capital.

The consideration of spatial interactions has played a significant role in understanding regional development, particularly as the global mobility of people and goods has increased substantially since the 1990s. For instance, the total number of international tourist arrivals worldwide reached 940 million people in 2010, 2.2 times the 1990 level. Meanwhile, the volume of world merchandise exports reached 15,274 billion dollars in 2010, 4.4 times the 1990 level. The case of China is particularly illustrative as the mobility of people and freight sharply increased between 1990 and 2010. Passenger traffic volumes in 2010 (32.695 million persons) were 4.2 times the 1990 level, and freight traffic volumes (32.418 million tons) were 3.2 times the 1990 level.

The theoretical origins of spatial interactions are attributed to the American geographer E.L. Ullman (1957, 1980), who first formally defined the concept and proposed complementarity, transferability, and the lack of intervening opportunities as three interdependent conditions for a spatial interaction to occur.

Complementarity

Complementarity refers to a demand for or a deficit in a product in a place and a supply or surplus of the same product in another place. For instance, a city has a demand for vegetables and milk while the surrounding rural areas may provide them. Spatial differentiation does not necessarily correspond to complementarity as the former is only a necessary, but not a sufficient, condition for a spatial interaction to occur. For example, some European Union (EU) countries may have a shortage of coal, while China has a large surplus, but coal trade between the EU and China is limited. This is because the energy consumption of EU countries mainly relies on other sources, namely oil, natural gas, and alternative energy. Therefore, the surplus–deficit complementarity is commodity-specific and related to economic development.

A supply–demand pair is necessary for a spatial interaction to occur, which implies that a location generating a supply provides surplus products while a location generating a demand has shortage of them. The direction, distance, and route of an interaction depend on the respective locations of supply and demand. Due to complementary relationships, spatial interactions may occur over long distances, such as the flow of petroleum between the Middle East and the United States, or over much shorter distances, such as the flow of commuters from their places of residence to their workplaces.
Complementarity is a function of physical, cultural, and technical differences between regions, which are also closely related to the level of economic development. For example, China, Australia, Brazil, and India are the top four iron ore producers. China, however, is an iron ore importer while the three other countries are exporters. In 2010, China imported 619 million tons of iron ore from the other three countries due to high demand from the steel industry, an outcome of the growing demand from its construction, infrastructure, and manufacturing industries. Therefore, the top four iron ore producers are well endowed in iron ore reserves, but they remain complementary because of differences in their respective demand driven by economic development.

Cultural differences can also be a factor for complementarity. The United States imports soy sauce from China and curry powder from India, two products consumed in large part by Chinese and Indian Americans. Meanwhile, some international trades are generated because of technical differences. For instance, the United States, Japan, and EU countries export core computer components, mobiles phones, and cars to the whole world because of their technical advantages in related fields. Finally, David Ricardo’s classical economic concept of comparative advantage provides a relative measure of the degree of economic complementarity between two countries based on their opportunity costs. More recently, global garment manufacturing companies have been bypassing China and electing for lower-cost locations in Southeast Asia, such as Vietnam and Thailand, because of rising input costs in China, such as the cost of labor.

Intervening opportunity

The second interaction factor explains the absence or insufficiency of intervening opportunities between two complementary locations (Stouffer 1940). Complementarity will only generate a flow if there is no intervening or closer location (Rodrigue, Comtois, and Slack 2013). The flows that would otherwise occur between two complementary locations may be diverted to a third location if it represents an intervening opportunity, such as a closer complementary alternative with a cheaper overall transport cost. For instance, in order to have an interaction between a customer and a store, there should not be a closer store that offers a similar array of goods at the same price.

Figure 1 depicts how intervening opportunities change the spatial interactions between two locations. In Figure 1a, locations X and Y are complementary in terms of supply and demand of a good and there is no intervening opportunity between them. Therefore, an interaction of 3 units takes place between them. In Figure 1b, location Z, which acts as an intervening opportunity, joins as a demand market located closer to location X. As a result, the demand–supply relationship between X and Y is replaced by X–Y and X–Z.

![Figure 1](https://via.placeholder.com/150)

**Figure 1** How intervening opportunity influences spatial interactions.
Some interactions are also diverted from X–Y to X–Z. Location Z captures 2 units from location Y due to its shorter distance from X. Figure 1c shows another scenario where location Z has a similar supply to location X. In this extreme case, location Z substitutes for X and becomes the only supplier for location Y.

Under some circumstances, intervening opportunity may help to create interactions between distant supply and demand pairs. As Ullman (1980) noted, the trade-diverting effect of an intervening opportunity could eventually facilitate interaction between more distant complementary locations. He used the example of a mill (point a in Figure 2) where the nearest source of wood would justify the construction of a railway segment from the mill to the forest.

Interactions between point a and the more distant complementary locations such as point c and point d might never have been established had the transportation infrastructure not been constructed in a series of incremental extensions servicing intervening opportunities.

Transferability

Transferability refers to the possibility of interactions occurring between locations by overcoming distance, time, and cost. Even though a complementary supply–demand relationship exists between locations, no interaction will take place if the transfer cost is higher than the benefits derived (Rodrigue, Comtois, and Slack 2013). The cost of overcoming distance is known as the friction of distance, which is subject to factors such as existing transportation technology and the cost of energy. The shorter the distance between supply and demand, the higher the interaction.

The rule of distance decay describes the decrease of interaction as distance increases, often as a nonlinear function. For instance, although the Middle East ranks first in the world for oil production and exports, the United States imports more crude oil from Canada due to the shorter transport distance. Also, different goods have their own suitable transport distance. For example, high-value low-weight goods such as high-tech products are transferable at a global scale while heavy, low-value goods such as construction materials are usually consumed very close to where they were produced. In other words, high-technology products have a flatter distance-decay function than that of construction materials.

Transferability can be accomplished by different transport modes depending on the weight and value of goods as well as the distance involved. Steel factories and petroleum refineries are more inclined to locate in port cities where iron ore and petroleum are commonly imported. Undoubtedly, maritime transportation is the cheapest mode for carrying heavy cargoes in large quantities over long distances. Moreover,
transferable distance could be extended by improving the capacity and efficiency of the transport system.

Distance, expressed as time or cost, has played an important role in shaping spatial interactions. However, regulations and policy also have an impact. For instance, Canada and the United States are similar countries in terms of culture, language, and institutions. The national border between them is relatively innocuous but still exerts a decisive impact on continental trade patterns. Distance matters, but political barriers do too.

Further reading

The subfield of economic geography refers to research that examines how economic processes intersect with the geographical organization of society. It is now a large international field of study that can be traced back to the early years of the discipline in Europe, and is found in most countries. Over the last 60 years, at least in Anglo-American geography, some of the most important disciplinary debates about theory and method were played out within economic geography. The first attempts to construct a logical empiricist, quantitative human geography were undertaken by economic geographers beginning in the mid-1950s. Political economy as an approach, along with the emergence of radical/critical geography, was principally worked out in economic geography from the late 1960s. More recently, economic geographers have played key roles in debates about realism, feminism, post-prefixed approaches, and the relative merits of qualitative and quantitative methodologies. Given the authors’ limited expertise, this entry is confined to anglophone economic geographical research. Future entries are anticipated that move beyond the anglophone discipline alone, allowing a global understanding and appreciation of the field. For example, the 60-year-old Japanese Association of Economic Geographers has several hundred (mostly male) members and a rich tradition of indigenous theoretical concepts. Or again, a large cluster of economic geographers in the Chinese Academy of Sciences has played a key role in shaping the geographical development of post-Mao China.

In recent years, the term “economic geography” has become widely used also outside geography as a discipline (e.g., World Bank 2009). In particular, stimulated by the work of the Nobel prize-winning economist Paul Krugman, economists have developed a rich body of research dubbed the “new economic geography.” This work has close affinities with the location theory tradition within economic geography, particularly influential in the 1960s. The economists’ “new” economic geography (new for them), or more accurately labeled geographical economics (Overman 2004), is closely aligned with contemporary mainstream economic theory; that is, it is grounded in the rational choice of individual self-interested economic agents, whose actions are coordinated by the market, and produce equilibrium outcomes.

While engagement between economic geography and geographical economics is important, in this entry the former is described as it has evolved within geography (cf. Barnes, Peck, and Sheppard 2012). Economic geography’s considerable vitality is matched only by its variegation. Nevertheless, there are four features that hold it together as a distinctive subdiscipline. First, economic geographers conceptualize the spatialities of economic activities as coevolving with those activities: economic processes produce emergent spatialities that themselves shape the evolution of those processes. Economic geographers study how space, place, scale, connectivities, and networks are produced, but also how these
affect the evolving geographical organization of the economy. Second, economic geographers examine how economic processes coevolve with political, cultural, and biophysical processes. Commodity production and market exchange do not operate in a vacuum, nor are they foundational to other processes; they are shaped by (even as they shape) political processes, discourses, and identities, as well as by the material world (which economic activities seek to transform into forms that humans can use). Third, economic geographers argue that the seeming contemporary predominance of capitalist economic activities should not be mistaken for their ubiquity, inevitability, or desirability. More-than-capitalist economic processes coexist with capitalism, and may be necessary, as well as preferable. Questions of morals and ethics are therefore placed front and center within economic geography. Finally, economic geography is a pluralist field, with space for all manner of philosophical assumptions, scales of inquiry (from the globe to the body), theoretical languages, and methods of investigation (from qualitative to quantitative and everything in between).

In the words of Sheppard, Barnes, and Peck, “Economic geography has become a peculiarly open-ended subdiscipline, one that has tended to privilege the analysis of rapidly changing phenomena, studied in real time. It is an anti-canonical project; it is open-ended and will remain so, repeatedly breaking out of the boundaries created for itself” (2012, 18). The remainder of this entry seeks to summarize how such a discipline has come into being by providing, first, a genealogy of its anglophone intellectual development (see the section “A genealogy of anglophone economic geography”), and second, selected examples of research themes to illustrate the breadth of the field and its current predilections (see the section “Current research foci”).

A genealogy of anglophone economic geography

In tracing the shifting mix of approaches that have been gathered into the big tent of anglophone economic geography over more than a century, two points need to be borne in mind. First, changes over time are not simply a succession of approaches, with new replacing old along a trajectory of progress toward the best possible approach. Instead, the disciplinary landscape is like a palimpsest, with past versions of the discipline still partially visible, not completely erased, continuing to contribute to the subject’s vitality and present form. It’s messy, with different approaches jostling and rubbing against one another, with no external criteria to determine which one is “best practice,” but it makes for a lively subdiscipline (economic geography is always living in “interesting times”). Second, as geographers it is important to attend to the geography of this knowledge production: within our self-imposed geographical restriction to the anglophone world, different approaches have gained traction in different spatiotemporal contexts. An approach that makes sense in one context may not translate well to others, further undermining the possibility of any singular best practice.

From commercial to regional geography

Like the broader discipline, economic geography was historically tethered to nineteenth-century European imperialism. Initially called commercial geography, the subdiscipline’s charge was to provide practical geographical knowledge to the agents of empire: the military, the colonial bureaucracy, and the business classes. Focused on the commodity, economic geography delivered meticulously detailed information about where different goods were produced, and could
be produced, the necessary conditions of their production, types of regional specialization, trade patterns, and circuits of available transportation. While early economic geography might not have been intellectually exciting — one of its early exponents, George Chisholm, said, “if … there is some drudgery [to it], I see no harm” (quoted in MacLean 1988, 25) — it provided the commercial scaffolding of empire. The first-ever English language textbook in economic geography was Chisholm’s (1889) *A Handbook of Commercial Geography* (earlier ones had been published in German). Jammed with maps, tables, and economic geographical facts and figures, the *Handbook* was designed both to give Britain’s business classes an applied education and a competitive edge, and to provide its imperial civil servants with knowledge of the globe that they administered.

Chisholm’s book was also a volume of scientific knowledge. In 1882 the German geographer Wilhelm Götz distinguished between commercial geography, which “chiefly served practical ends,” and economic geography defined by “the scientific task of dealing with the nature of world areas in their direct influence upon the production of commodities and the movement of goods” (Götz quoted in Sapper 1931, 627). Chisholm took that scientific charge to mean positing “nature” as a central causative agent, arguing that the environment made each place in the world uniquely fitted to undertaking a particular type of economic geographical activity. This view became extreme, however, colored by racism, through the work of a number of environmental determinists working in economic geography at the beginning of the twentieth century. The Yale geographer Ellsworth Huntington (1915) was the most notorious, arguing that labor’s “mental” and “physical efficiency” peaked in temperate climatic regimes found in western Europe, parts of North America, and white settler colonies. In contrast, mental and physical efficiency fell to disastrously low levels in tropical regions, condemning them to “backwardness,” making them “The White Man’s Burden.”

By the end of World War I, economic geography had become well entrenched in both UK and American universities. It was human geography. During the interwar period, with a less rampant form of imperialism, and growing criticism of environmental determinism for its blatant racism and shoddy scholarship, economic geographers moved away from emphasizing global commodity production to stressing local economic interconnections, taking the form of unique regions.

The turn to the region was readily seen in economic geographical textbooks published in North America from the mid-1920s onwards. It involved characterizing regions using a common typological scheme made up of such categories as “leading industries,” “natural resources,” “modes of transportation,” and so on. Once all regions were classified, their differences, and thus their individual uniqueness, were immediately evident by reading along any given row of the typology. For example, Vernor Finch and Ray Whitbeck’s (1924) *Economic Geography* used a fourfold classification scheme for each of the regions the book covered: agriculture; minerals; manufacture; and commercial trade, transportation, and communications. Another example was Clarence Jones’s (1935) textbook *Economic Geography* that deployed an eightfold typology. In both cases, the typology functioned as a grid into which regional facts, variously mapped, drawn, photographed, and exhaustively described, were slotted. By typologically comparing the facts of different regions, economic geographical difference became transparent, and regional uniqueness shone by its own light.

The intellectual justification for this regional approach wasn’t articulated until just before World War II. The American geographer
Richard Hartshorne argued that by its very nature each region was a collection of exceptional features, describable only in their own terms. Consequently, no generalizing theories, no scientific laws, were possible. As Hartshorne (1939, 44) wrote, “Regional geography, we conclude, is literally what its title expresses. ... [I]t is essentially a descriptive science concerned with the description and interpretation of unique cases.”

Spatial science and the turn to theory

Hartshorne’s book was published at exactly the wrong time. The regional descriptivism it proposed for geography, and economic geography in particular, was quickly out of step with a set of larger changes pointing in exactly the opposite direction. From the beginning of World War II, a number of social sciences, and even some humanities, were transformed from the type of descriptive approach championed by Hartshorne to one that instead emphasized scientific generalization and explanation, and was designed to accomplish practical ends. In part because of Hartshorne’s influence, economic geography initially resisted that impulse, but by the mid-1950s it began to join in. The resulting shift to spatial science, represented by geography’s “quantitative revolution,” profoundly altered economic geography (Burton 1963). It swept away talk of ideographic regional uniqueness, replacing it with scientific forms of general theorizing and rigorous statistical techniques of description and analysis.

Spatial science was defined by five main features. First, and foremost, was its use of formal theories and explanatory models. Necessarily, these were imported from elsewhere: from economics (rational choice theory, general and partial equilibrium, and German location theory), and perhaps less likely, from physics (gravity and potential models, and later the entropy model). Second, was utilization of an increasingly sophisticated arsenal of quantitative methods. At first they were off-the-peg inferential statistical techniques. Later, specialized statistical measures and methods were designed in-house to meet the peculiar features of geographical data (e.g., techniques of spatial autocorrelation). Third was the deployment of computers. At first they were very crude and limited, but within a decade they performed hitherto unimaginable calculations, for example, the inversion of large urban and regional economic input-output matrices that would have taken a lifetime to calculate by hand. Fourth, a philosophical justification was made for spatial science based on positivism, the idea that only scientific knowledge is authentic knowledge. Fred K. Schaefer (1953) provided an early influential justification that was later broadened and deepened by David Harvey (1969). Finally, there was a focus on abstract spatialities. Regions remained part of the economic geographical lexicon, but conceived utterly differently. Regions were now explanatory, theoretical, and instrumental, spatial units to achieve policy and planning objectives (brilliantly realized in the parallel movement of regional science). Finch, Whitbeck, and Fielden Jones (and their respective textbooks) were simply no longer recognizable as part of economic geography.

Like most intellectual revolutions, spatial science began at only a few sites, from which it diffused. In Europe it was associated with Cambridge University, Bristol University, and Lund University; within North America, it started at the Universities of Iowa, Washington, Chicago, and Toronto, as well as Ohio State and Northwestern. In each of these places, groups of young, bright, ambitious, competitive, and almost exclusively white male students gathered to participate.

More than anything else the revolutionary act was the introduction of theory, making
economic geography for the first time a social science. It was, as Kevin Cox (2014, 145) calls it, “the great hinge of 20th-century geography.” While economic geography subsequently radically changed, the tie binding all subsequent versions was the generation of theory. While contemporary economic geographers might now reject the substance of spatial science, through their continuing theoretical sensibility they are heirs to that earlier tradition.

Letting many flowers bloom – post-spatial science

The first signs of trouble for spatial science came in the early 1970s when David Harvey (1973) disavowed his earlier support, declaring that the quantitative revolution had run its course, telling us less and less of any import. Harvey was the first of a series of high-profile defections. In retrospect, the problem was the mathematically abstract and narrow conception of economic geography that spatial science proffered. It was not true to economic geography’s own variegated disciplinary history; not true to the historical moment of the early 1970s that was increasingly politicized and drawn to issues of social relevance; and not true even to its own scientific logic, as assorted logical contradictions, inconsistencies, and gaps revealed.

The subsequent 40 years has seen the ceaseless proliferation of theoretical alternatives to spatial science. For the most part these alternative theories are not couched in the scientific hypothetico-deductive form. Nonetheless, they are used to explain, and in some cases to intervene within, a robustly drawn and variegated empirical world. They are not new Kuhnian paradigms that replace the old, constructed to cope with emerging anomalies. Indeed, there is no agreement in economic geography about what constitutes an anomaly.

In the early 1970s Harvey introduced classical Marxism as his theoretical alternative to spatial science, from which he continues to draw and find creative inspiration. Yet Marxist theory is only one component of a larger political economy tradition that has more or less dominated economic geography since that time. By political economy we mean the tradition that harks back to classical economics (Adam Smith, David Ricardo, and Karl Marx), emphasizing that economic processes cannot be understood without attention to politics and the state, that capitalist commodity production and exchange are not simply the result of self-regulating efficient markets. To reference economic geography’s common ground of political economy is not saying a lot, though. Political economy’s strands are multifarious, and heterodox. In rough chronological order, after Harvey’s classical Marxism, political economy has been taken up in economic geography as Doreen Massey’s Althusserian-inspired spatial divisions of labor thesis; as the locality approach; as regulation theory, taken primarily from French economists and influential in understanding both the decline of Fordist industry in the United Kingdom and the northeastern United States, and the rise of post-Fordist growth dynamics, especially in California; and an institutional approach concerned with identifying formative mechanisms of industrial districts, applied particularly to high-tech agglomerations.

Yet this list takes us up only to the mid-1990s. Since then it has become only more complicated and variegated. Uneasily bolted on to political economy was a cultural approach (“the cultural turn”), influenced by poststructuralism, and focused on how both discourse and gendered, raced, and sexualized identities shape economic processes. Examining gender became a disciplinary theme from the 1970s even within spatial science. Massey brought it to the fore in her
work on spatial divisions of labor, but it became even more central in a series of works published in the second half of the 1990s emphasizing culture, and drawing on poststructural feminist theory (McDowell 1999). Gibson-Graham’s (1996) *The End of Capitalism (As We Knew It)* was perhaps the most influential of those works, eclectically piecing together post-Marxism, feminism, and poststructuralism into a critique of political economy that proposed a new substantive disciplinary agenda of research on alternative or “diverse” economies.

Even more recently, Asian and German geographers have advocated for a “relational turn,” stressing the increasingly networked nature of economic activities. German geographers originating in Frankfurt, drawing on science studies, have explored the performativity of markets. Dutch and other European geographers based at Utrecht have catalyzed evolutionary economic geography, drawing on evolutionary economics to model how diverse populations of firms change, and the implications for the regions in which they are located. European and American geographers interested in questions of development and the Global South have advocated for a postcolonial approach to economic geography – one that seeks to understand distinctive economic practices emerging from beyond the North Atlantic realm, such as Islamic finance (Yeung 2005; Boschma and Martin 2010; Pollard, McEwan, and Hughes 2011; Berndt and Boeckler 2012).

Last but not least, European and North American scholars based (albeit sometimes intermittently) at the London School of Economics (LSE) have reconstructed a version of spatial science that is formal, resting on neoclassical micro-economic principles, deploying rigorous econometric testing, and aspiring to influence government policy. Its intellectual basis was the 1990s work of Paul Krugman that turned on his innovative theorization of the relation between spatial growth, trade, and agglomeration economies. That work catalyzed a “new economic geography” or geographical economics (Brakman, Garretsen, and Von Marrewijk 2009) leading to attempts to strike up a disciplinary conversation between geographers and economists, including a new journal, *the Journal of Economic Geography* (launched in 2001). The reconfigured LSE Department of Geography and Environment was another such outcome. In terms of impact and unity of purpose, it is now likely the most successful grouping of economic geographers in the United Kingdom.

In short, in less than 150 years, anglophone economic geography has moved from a handmaiden to empire to “physics envy” to an intellectually open, eclectic, pluralist, and possibly chaotic discipline straddling the humanities and social sciences. Anything goes, and sometimes does. Its seeming lack of a theoretical core can be disconcerting. Critics complain that the result is anarchy, eclecticism in which nothing fits, producing flighty, sloppy, and sometimes incomprehensible works. One result perhaps is Balkanization, a discipline of solipsism and solitudes. The counter response is that fragmented theorizing is necessary to understand the increasingly fragmented geographical economy in which we live and study. It is exciting, however, with no chance of contemporary economic geography “boring its audience to death” (Nigel Thrift’s fear at the end of the 1990s; Thrift 2000, 692). The unusual challenge for this subdiscipline will have less to do with breaking new ground, which it seems to do on a daily basis without breaking sweat, and more with holding its existing ground. This diversity and flexibility can be a weakness as well as a strength. Economic geographers must be willing to make space for diverse perspectives, promoting a culture of constructive and rigorous engagement and mutual learning (Barnes and Sheppard 2010).
From theoretical to methodological diversity

Underlying this efflorescence of variegated theoretical traditions are questions of method – of how to apply these perspectives to, and assess their validity against, “really existing” economic geographies. The term “underlying” is used here because questions of method have not received the attention they deserve (Tickell et al. 2007). Issues of methodology have been subject to a “don’t ask, don’t tell” policy. Economic geographers of all stripes insist on the importance of empirical methods, concerned with representing an empirical object. But what counts as empirical information, the methods used to collect, assemble, and interpret data, and rules for determining the validity and power of explanatory frameworks all have significantly shifted and multiplied.

Under commercial geography, the concern was the assiduous collection of information that was as precise as possible: ideally, numbers and statistics. Under spatial science the bar was raised to aspire to logical empiricism: the rigorous statistical testing of theory-driven hypotheses against the “facts.” The turn away from spatial science ushered in a “qualitative revolution,” however: a move to methods concerned with gathering and analyzing non-numerical data. This was motivated by trenchant criticisms of the so-called positivist philosophy underlying spatial science – criticisms that stressed the theory-laden nature of observation. It is not simply “just the facts.” Data are not out there, like apples, waiting to be picked; what is available depends on the theories and agendas of those (including economic geographers) collecting, ordering, and distributing data, and what economic geographers see depends on the interpretive and theoretical framework they bring to empirical work.

The “qualitative revolution” began with “intensive case study research,” pioneered by proponents of critical realism in the early 1980s (Sayer 1984). Qualitative methods have multiplied since, now including in-depth interviews, focus groups, oral histories, ethnographies, participant observation, discourse and textual analysis, following networks, action research, and more besides. In this new methodological environment, nothing is proscribed; everything is permitted, if not equally valued. Critics complain that the turn to qualitative methods in economic geography has induced slapdash and superficial research. In response, qualitative researchers stress the difficulty of, and care necessary to undertake, rigorous case study and qualitative research – that rigor means different things in different contexts. Methods must be appropriate to the necessary data, and if that is qualitative, reflecting what is important for understanding the object of inquiry.

The upside is diversity and rapid change. Most of the qualitative techniques listed above would have been viewed as beyond the pale, or at best, suspiciously avant garde, when first introduced. The downside has been the derogation of quantitative analysis and loss of associated skills. Lacking the training, economic geographers are increasingly unable to undertake, or knowledgeably critique, statistical and numerical analysis. There is emergent interest in mixed methods approaches, combining different (qualitative but also quantitative) methodologies in the spirit of engaged pluralism. Doing this effectively is even more challenging than rigorous quantitative or qualitative methods, however. First, research teams are increasingly necessary because researchers too often specialize in qualitative or quantitative methods, however. Second, developing mixed methods research designs that rigorously tackle the questions at hand, rather than mixing approaches together haphazardly, is still very much in the experimental stage in the social sciences.
ECONOMIC GEOGRAPHY

Current research foci

To illustrate the kinds of research currently receiving significant attention from economic geographers, and how this reflects the subdiscipline as it is described here, summaries of eight areas of focus are provided, organized around aspects of the spatial economy. It is not a definitive list, however (no definitive list is possible). Rather, these are simply current major areas of research in contemporary anglophone economic geography.

Worlds of commodity production: industry and services

From its early days, economic geographers have been interested in what is produced where, and how. While industries and services have different kinds of locational requirements (e.g., access to resources versus access to consumers), contemporary research focuses on theories that apply, in different ways, to both metasectors (some question whether the distinction remains meaningful in today’s globalized world). Within its current heterodox political economy phase, three major areas of work stand out, at the scales of the firm, the region, and the globe.

At the scale of the firm, the emphasis has moved away from explaining the rationality of location decisions to understanding how firms make decisions about what to produce and how, and the role that space plays in these processes. A particularly rich area of contemporary research is known as evolutionary economic geography. Drawing analogies between competition and the survival of firms and Charles Darwin’s theory of evolution, the paradigm of generalized Darwinism developed in evolutionary economics has been applied to explain why firms are founded, closed, and grow or decline in success relative to their competitors. Unlike economics’ focus on an idealized representative agent making rational decisions, and equilibrium outcomes, it is recognized that any regional population of firms, also those producing the same commodity, will vary in terms of size, technology, strategy, and labor relations. Hypothesizing that each firm has a production routine, analogous to genes in organisms, it is argued that the dynamics of a population of firms will depend on three processes: variation (between firms), selection (of firms, through competition), and retention (the propagation of routines within and between firms). A key question has been how firm dynamics relate to regional economic dynamics: How do some regions experience lock-in, whereby their economic structures stagnate and decline, whereas others remain dynamic, or attract emergent growth sectors? This is argued to be related to a region’s related variety: the more similar firms are, the greater are localization economies and innovation, within a particular sector. When they are less similar (unrelated variety) there are fewer such advantages, but the region is more open to qualitative change rather than path dependence (Boschma and Iammarino 2009; Boschma and Martin 2010).

At the regional scale of metropolitan areas, catalyzed by research on industrial districts, scholars have identified what they believe are keys to the success or failure of territorial economies, particularly in a world where globalization is always a threat to regional economic cohesion. The key is agglomeration economies: the relational assets in a region that facilitate both economic growth and resilience to change. One potential asset is related variety; others include reduced transactions costs, tacit knowledge or local “buzz,” the sociocultural milieu, and the presence of a “creative class.” Each of these has been identified as enhancing local economic dynamism and flexibility under the right conditions, and leading to regional decline under the wrong ones, fostering...
place-based explanations of regional economic growth. Key kinds of territorial economies identified include industrial districts, learning regions, and city-regions (Scott 2006; Storper 2013).

At the global scale, it has been recognized that many economic activities are increasingly spatially decentralized, with different locations around the world playing different roles in the production or assembly of a commodity. Multinational corporations, surrounded by an ecosystem of subcontractors and licensees, thus spread production around the world in what Richard Baldwin (2006) has dubbed “the great unbundling” of production. If the regional-scale research stresses the importance of local networking, geographers studying this unbundling seek to understand it in terms of global production networks (GPNs). They not only examine the economics and power relations constituting these networks, with some firms in a position to shape outcomes and others just bit players, but also trace how the territorial strategies of states, labor unions, and multilateral governance organizations each affect the structure and evolution of GPNs (Coe et al. 2004).

**Worlds of consumption**

Consumer markets traditionally were studied in terms of the location of retailers, consumers’ behavior, and spatial price gradients. Beginning with central place theory, this led to a more general theorization of the monopolistic nature of spatial markets. It was determined that geography challenges conventional economic wisdom. For example, spatial competition need not result in spatial price equilibrium and may not be socially beneficial (Sheppard and Curry 1982). In the past two decades, geographers studying retailing have turned their attention to the spatial strategies of corporate retailers, including their roles within global production networks. This recent research aligns with how economic geographers characteristically begin with geographies of production, unlike mainstream economics’ focus on markets and consumption, extending this to the production of services. Retail geographers now study: the impact of corporations on retailing, and their capacity to drive small retailers out of business and dramatically reshape geographies of consumption (Coe and Wrigley 2009); the role of geodemographic marketing in shaping consumption patterns and norms, segmenting markets, and customizing marketing to wherever consumers find themselves (location-based services); and the emergence of e-commerce and its material as well as virtual geographies.

With the poststructural and feminist turns to issues of identity, however, considerable research has examined the relationship between retailers, consumption, and identity, with particular attention to issues of social difference: the intersectionality of gender, class, race, sexuality, and geographical location (Jackson and Holbrook 1995; Cook and Woodyear 2012; Mansvelt 2012). This examines how consumers’ desires emerge from and intersect with their sociospatial positionality, and how these issues relate to marketing strategies (branding, store location, and spatial organization). The role of citizens as consumers also has received attention, examining how households are expected and induced to consume to foster economic growth, particularly in postindustrial territorial economies.

Most recently, geographers have taken up the question of marketization: how spatial markets emerge and the implications thereof. Geographers have found approaches in economic sociology more compatible with their sense of how capitalism works than economists’ categorizations of ideal typical market structures. They examine how information networks unequally shape participants’ ability to take advantage
of markets (“the strength of weak ties”), how trading technologies shape market structure and performance, and how markets themselves are produced. Market formations are regarded as emergent features, shaped by theoretical predispositions, ideology (e.g., neoliberalism), interests, technologies, and geographies. If perfect markets emerge, this is because the participants believe in their desirability and/or actively create them. Turning to the uneven geographies of marketization, geographers have examined the construction and elimination of boundaries, both those separating markets and those separating what is sold as a commodity and what is not – such as markets in waste, genes, and human organs (Grabher 2006; Mackenzie 2009; Berndt and Boeckler 2012; Gidwani 2012; Parry 2012).

Labor, work, and bodies

From the beginnings of the discipline, labor was considered an important economic geographical factor influencing the location of firms and industry. But there was no analysis of labor markets as such, and nothing on either the conditions defining work, or especially the kinds of bodies doing the work. That changed in the 1970s when radical economic geographers began emphasizing the centrality of labor within production and the role of a distinct social and political class, the working class (Lier 2007). The 1970s, though, was exactly the decade when old verities about labor, work, bodies, and the working class changed. Hitherto labor in the Global North was conceived as expending brawn working in a factory (engaged in “execution” rather than “conception,” to use Frederick Taylor’s famous pair of terms). The bodies were conceived predominantly as male bodies, and the social class to which they belonged, the working class, was taken by the Left as the vanguard of progressive politics. This became less and less true as the larger processes of deindustrialization, neoliberalism, and globalization gained purchase in the 1980s. Consequently, it became necessary to retheorize labor geography. While elements of radical geography’s approach were retained in that retheorization, many new elements were added, drawn from poststructuralism, especially feminist and postcolonial theory, and emphasized identity, embodiment, and transnationalism.

From the 1970s, deindustrialization in the Global North decimated traditional male Fordist industrial jobs along with their privileges (e.g., the “family wage”). It was the end of “Old Father Ford,” provoking a crisis in masculine identity, especially for young males (McDowell 1991). Furthermore, with the rollout of neoliberalism from 1980 onwards, traditional unions were also undermined, along with their associated left-wing politics. Traditional manufacturing jobs in the Global North were moved offshore, often into the Global South, to sites now linked by unfolding GPNs. Operating from free trade zones, large multinational corporations drew on abundant, very cheap labor, including pools of young women, who labored excessive hours and were subjected both to work injuries and to extreme disciplinary measures both inside the factory and outside. They became the world’s disposable workforce (Wright 2006).

Some in economic geography argued that labor should now be conceived as possessing agency, as having an ability to determine their geographical fate (a “labor geography” rather than a “geography of labor,” Herod 2001). But much recent empirical work examining low-paid service workers in the Global North, especially women, international migrants, and workers of color, shows the reverse. Employment is increasingly precarious, creating a “precariat,” with almost no opportunity to assert agency. This form of employment is defined by part-timeism, short-term contracts, and the absence of benefits...
(Peck and Theodore 2001). That’s less true at the opposite end of the labor market, where highly paid knowledge workers make up Richard Florida’s (2002) creative class. While they also may be on contract, carrying out project work, they are often well paid, enabling them to assert some agency by choosing the country, city, or neighborhood in which they live. In both cases, though, the larger point is that labor and work are not neutral. Workers always are more than a technical input into production. The social, cultural, and geographical contexts in which work is practiced leaves its mark (sometimes literally), shaping social identity, bodily comportment, and the life led, including where it is led geographically.

**Governance**

Within the political economy tradition dominating anglophone economic geography, there is consensus that markets cannot function effectively in isolation: issues of state regulation and governance also must be addressed (bringing formal politics into economic geography). Regulation refers to actions taken by state and quasi-state agencies, at various scales, constraining the actions of both producers and consumers. Governance embraces the broader sense of how commodity production and consumption are (increasingly) governed also by and through all kinds of nonstate institutions.

Much attention has been paid to how different forms of capitalism emerge in different territorial contexts, and how these change. Economic geographers have drawn extensively on French regulation theory, which argues that a functioning territorial capitalist economy must combine a regime of accumulation (how commodity production is undertaken) with a mode of regulation (how the state regulates the market to manage the national balance between supply and demand) (Dunford 1990).

Originally developed to explain the emergence and problems of Fordism as a national territorial economic system in the Atlantic realm after 1945, geographers have extended it to consider geographical scale and spatial variegation. They examine how regulatory regimes vary across space at the national scale, reflecting the persistence of national cultural and political traditions – variegated capitalisms (Peck and Theodore 2007). They also argue that local governments within a national territory may develop regulatory norms that differ from those at the national level, depending also on the central–local state relations in a given national context (Tickell and Peck 1992).

Particularly at the subnational scale, much attention has been paid to how local states act to foster investment in their territory. Urban entrepreneurial strategies include both inward investment strategies – subsidies and improvements to the local “business climate,” designed to persuade firms (and knowledge workers) to move in (or stay) – and incubator strategies – seeking to create conditions that foster local innovation, dynamism, and agglomeration economies (Hall and Hubbard 1998).

The rise and geographical differentiation of neoliberalism has received particularly close attention. Neoliberalism has become something of a leitmotif of anglophone economic (indeed, human) geography since 2000. This research includes analyses of the nature and diffusion of neoliberal governance, debates about how neoliberalism came to replace seemingly impregnable state-led modes of regulation, and explanations of why neoliberalism “in the wild” is persistently variegated and never converges on a pure, ideal–typical neoliberal model, notwithstanding the relatively ubiquitous presence of processes of neoliberalization (Larner 2000; Harvey 2006; England and Ward 2007; Peck 2010).
Turning to the question of how neoliberalization diffuses across space and time, economic geographers also study policy mobilities: how neoliberal principles become “best practice” policies that take flight, mutating as they do so, rapidly moving between localities (Peck and Theodore 2010). Important debates remain, particularly about whether neoliberalism has become ubiquitous, whether political economic accounts suffice, and whether and how it can be contested (Leitner, Peck, and Sheppard 2007; Barnett et al. 2008; Wray et al. 2013), but the uneven geographies of this shift from state regulation (e.g., Fordism) to market-centric governance are now quite well understood. There also have been many case studies documenting its impact – enhancing inequality within cities, regions, and nation-states, and between world regions.

In terms of governance more broadly, economic geographers have examined the role, influence, and evolution of institutions on territorial economies. They have unraveled the conditions under which institutions may facilitate or block regional and urban economic dynamism, examining how they can channel regional economic development along certain paths (path dependence), some of which may be highly beneficial (with institutions helping put in place “relational assets” that foster innovation and economic growth), and others of which may result in stagnation, when institutional lock-in prevents a region from rebounding from a negative shock. These are important issues to understanding the resilience of territorial economies (Martin 2000).

Finance

Economic geographers have paid some attention to money and credit over the years, but recently particularly to financialization. Research into forms of money and credit explored how the geographical extension of trade and capitalist economic relations required the development of forms of money and credit that enable exchange to occur across space as well as time. When non-geographers claimed that the globalization of finance markets, facilitated by cyberspace, is creating a world where geography no longer matters, geographers responded by studying why financial activities increasingly concentrate in a handful of centers of global finance (New York, London, Frankfurt, and Tokyo, now supplemented by Hong Kong, Singapore, and Shanghai). Face-to-face communication remains essential to take advantage of the tacit knowledge (e.g., insider information) essential to gaming the market; digital networks have resulted in an extreme spatial concentration of high-frequency trading servers, to gain a millisecond advantage over competitors. They also examined the different spatial scope of different kinds of lending, uneven geographies of how finance is governed, and the role of such institutional actors as pension funds and real estate investment trusts (Leyshon and Thrift 1997; Clark and Wojcik 2007).

Turning to the relationship between financialization and globalization, geographers have examined the role of uneven national regulatory and governance structures, such as Asian and offshore banking systems; connections across scales, as supranational finance institutions shape lending possibilities, and conditionalities attached to lending, in nation-states and localities; the emergence of novel financial practices in certain regions (e.g., Islamic finance, sovereign wealth funds) and at particular scales (e.g., micro-finance, Ithaca dollars); and uneven geographies of credit, lending, and indebtedness at every scale (from financial exclusion in neighborhoods to the lack of lending in sub-Saharan Africa). They study the financialization of nature, and the geography of finance crises – notably the
patterns of uneven geographical development underlying the 2007 global financial crisis, and its spatially differentiated consequences. Echoing related scholarship in the humanities and anthropology, arguing that financialization is as much a cultural as an economic phenomenon, economic geographers also examine how financialization and its emergent pro-market norms have become increasingly central to everyday cultural practices. They examine the increasingly pervasive nature of discourses and daily practices that reflect as they also disperse these norms, and the multiple ways in which investment and credit underwrite all kinds of activities (Pike and Pollard 2010; French, Leyshon and Wainwright 2011; Christophers 2013; Clark, Dixon, and Monk 2013).

Material worlds

The material worlds of nature and resources have been the focus of animated disciplinary discussions from the beginning, and for good reason. Currently around 50 trillion tonnes of the Earth’s material resources are annually appropriated for one human use or another, transformed into primary commodities by the “metabolic engine” of the economy (Bridge 2009, 1222).

When economic geography was first institutionalized in the late nineteenth century the discipline was primarily about material worlds, codifying meticulous lists of natural resources, their geographical distribution, and corollary environmental conditions. Interest waned in the 1920s and 1930s, and under postwar spatial science the topic of “natural resources” became an intellectual backwater. Drawing upon Marx, David Harvey (1974) reinvigorated the subject. His was not nature “red-in-claw” but social-nature, “the production of nature.” One of capitalism’s imperatives, Harvey argued, is to transform original “first” nature to produce “second nature” (Smith 1984). In the process, nature is commodified, subject to the market, becoming hybrid: nature and society join, forming “socio-nature” (Castree and Braun 2001). But to become a commodity, conditions have to be just right. As Erich Zimmerman (1951, 814–815) famously put it: “resources are not: they become.” Coal is merely a rock that makes your hands dirty until capitalism invents the steam engine. But once capitalism emerges, pre-existing nature is transformed. Nature still exists, but how it is exploited, used, thought about, and represented is irredeemably and sometimes cataclysmically altered.

With Harvey linking nature to political economy, economic geography overlapped with political ecology, which similarly brought a political economic understanding to resource use and production within, initially, the Global South. The exemplar is Michael Watts’s work in Nigeria, showing how social relationships, first under imperialism then under independence, made the country’s natural resources neither natural nor even a resource, creating instead maldevelopment, inequality, and social mayhem (Watts 2004).

Another political economic approach, Immanuel Wallerstein’s world systems theory, provided a different, macro-framework connecting economic geography and material worlds: the global commodity chain. By following the “thing” – a papaya, a cut flower, a barrel of oil – as it moves and is transformed from first producer in one place to final consumer in another reveals: (i) the differential forms and effects of materiality; (ii) the diverse geographies inherent in all commodities; (iii) the asymmetrical sociogeographical relationships within the production process; and (iv) the uneven effects of state regulatory regimes (Cook 2004).
ECONOMIC GEOGRAPHY

The most recent body of work about resources elaborates precisely on this last point, focusing on how one regulatory regime in particular, the regime of the last 30 years, neoliberalism, has stamped nature in its likeness. For examples as different as water, fish, trees, ores, and CO₂, under neoliberalism nature becomes privatized, commodified, priced, and marketed. Geography, though, remains vital. Each place does neoliberalism differently, creating not one seamless landscape of indistinguishable process but a patchwork quilt of variegated resource regimes (Heynen et al. 2007). Neoliberalism has also been the context for understanding the development of new markets for either goods or services ostensibly meant to improve environmental conditions. There are markets for carbon reduction, body parts, biodiversity enhancement, and more generally for the provision of environmental services.

Globalization and development

For many years, self-styled economic geographers in the anglophone realm concentrated their effort on the parts of the world they inhabited, those of the “first world” – Europe, Japan, and the white settler colonies of North America, Australia, South Africa, and New Zealand. With the implosion of the Soviet sphere, attention turned to questions of “transition” toward capitalism in the post-Soviet world. Yet the “third world” – those countries whose inhabitants suffered from colonialism and still struggle to overcome the economic disadvantages and global peripheralization they inherited from colonialism – was largely left to what was styled “development geography.” During this past decade, recognizing that problems of underdevelopment in the postcolonial world differ in scale rather than kind from those of impoverished regions in the first world, economic geographers increasingly are turning to study the post-colony, integrating development with economic geography (Slater 2004; Lawson 2007).

In so doing, economic geographers have focused on development at scales ranging from the globe to the village, tracing out how these are interconnected. They also are taking up the question of what is meant by development and what is at stake in the development discourses that circulate alongside global policymaking, in such forms as sustainable development and Millennial Development Goals.

At the global scale, geographers examine uneven geographies of economic globalization, considering such questions as: Why is it that economic inequality remains so persistent notwithstanding the increasing interconnectedness of the global economy? Why has China prospered, India struggled, and sub-Saharan Africa stumbled? Does free trade, and the unrestricted movement of direct and portfolio investment, level the global playing field, or does it reinforce pre-existing inequalities? Challenging the tendency in development economics to attribute success or failure to local, place-based characteristics (culture, physical geography, governance institutions), economic geographers argue that the uneven relations connecting places – the flows and mobilities of commodities, finance, ideas, and people, not to mention water and climate – may be equally important in determining the wealth of territories (Sheppard 2011). They examine not only how local possibilities are shaped by broader-scale processes, processes that localities seemingly have limited influence over, but also how local events can trigger significant broader-scale consequences. At regional and neighborhood scales, they examine why some localities prosper whereas others do not, and how these dynamics are shaped by both the colonial past and contemporary processes.
At the local scale, in fields, villages, factories, and urban neighborhoods, economic and development geographers study the embodied practices of individuals working to improve their livelihood prospects, but also how these connect to the households and other collectivities to which they belong. They show that what others dismiss as “traditional” practices, represented as being in need of development to modernize, are often better adjusted to the circumstances in which they emerged than are the practices of development that were introduced to replace them. Such analysis centers on the diversity of economic practices, their relation to the biophysical environment, and the role of power and constructed identities (race, age, class, caste, gender, etc.) in shaping these practices and livelihood chances. Substantive topics range from peasant farming and subsistence, to informal housing and economic practices, to formal employment in export processing zones, and connections between these places and practices (Rankin 2004; Porter 2006).

In terms of what is meant by development, research by economic geographers, documenting ways in which policy interventions informed by European notions of development undermine livelihood possibilities in postcolonial societies, raises questions about the ubiquity and universality of such notions of development. If the development trajectory that has brought prosperity to the Global North also brought impoverishment and environmental destruction to the Global South, then the problem may lie in this very notion of development, rather than in the failings of southern places and populations. Thus economic and development geographers have turned to interrogating northern definitions of development – as the product of globalizing capitalism – distinguishing between “development,” as the set of practices developed in a particular geographical context that have enabled its residents to live well in their own terms, and “Development” as a universal definition, to be foisted on all people and places, and against which their progress should be judged (Hart 2002). Geographers raising these questions draw on postcolonial theory, questioning whether northern theory (also in economic geography) and development principles are applicable across the Global South (defined as those, everywhere, who find themselves living precariously).

More-than-capitalist economies

Dating back to commercial geography, economic geographers have long taken an interest in the different economic practices to be found in different parts of the world. As ideas of development spread from the North Atlantic realm to be applied everywhere, noncapitalist practices came to be looked on as traditional and backward, as in need of replacement by integration into globalizing capitalism. Even economic geographers critical of capitalism and its consequences, documenting how it creates accumulation by dispossession or increased sociospatial inequality, have tended to accept capitalist practices (in some form or other), by now globally hegemonic, as the only kinds of economic activity worthy of their attention.

This default position has been influentially questioned over the past two decades, with economic geographers turning their attention to community and diverse economies. In their book, The End of Capitalism (As We Knew It), Julie Graham and Katherine Gibson, writing as J.K. Gibson-Graham (Gibson-Graham 1996), forcefully argued that many noncapitalist economic practices continue to coexist with capitalism, and in its very geographical heart (e.g., New England). Connecting Marxism with feminist and poststructural theory, they argued that such “community economies” practices,
going on under our noses, deserve far more attention from economic geographers than they receive, as a locus for potential alternatives to globalizing capitalism.

While such practices may have seemed obvious to development geographers, working in societies where the informal economy and subsistence practices predominate, their presence in the Global North proved something of a revelation. The result is a branch of anglophone economic geography now called the “diverse economies” school, focusing on variegated noncapitalist practices, and ways that they are tangential to or simply separated from capitalism. These include: local economic and trading systems, barter systems, labor sharing, workers’ democracies, and so on. Beyond the study of such practices, economic geographers have worked with communities. They have both brought an awareness about such practices, and fostered and expanded them using novel forms of academic research. This work has been criticized for focusing on seemingly insignificant and marginal practices, and for presuming that they can exist outside capitalism (they are more-than-capitalist rather than noncapitalist). Nevertheless, these ideas have brought attention to the different forms both that the economy can take, and through which neoliberalism, and capitalism more generally, can be contested (Gibson-Graham, Cameron, and Healy 2013).

Conclusion

The ongoing vitality and diversity of anglophone economic geography that circulates around geographical political economy promises a bright future. But its practitioners must be willing to engage constructively with one another and with scholars in cognate disciplines examining related questions. Geographers examine how economic processes shape, and are shaped by, geographical space (place, scale, connectivity, mobility); they examine how economic processes coevolve with political, cultural, and biophysical processes; they study how subject formation and identity at one end, and global political economic structures at the other, are interrelated; they take an interest in noncapitalist economic processes, critical of the proposition that regulated capitalist markets optimize societal wellbeing and ecological sustainability. Real-world-oriented, economic geographers study some of the major challenges facing contemporary human society and its relation to political economic processes: global production networks, the politics and culture of consumption, work and labor, the role of state regulation and governance institutions, nature–economy relations, financialization, globalization and development, and diverse economic systems.

Nevertheless, looking forward, it is possible to identify priority areas for new research. Economic geographers have paid too little attention to the geography of logistics – the transportation and communications networks – which has coevolved with globalizing capitalism, shaping its emergent geography at all scales. Notwithstanding the scholarship on material worlds, economic geographers have paid far too little attention to arguably the most urgent emergent aspect of the geographical economy: global environmental change, carbon economies, and ecosystem services. The wealth of economic geographical research about firms, consumers, and territories has yet to be complemented by systematic empirical analysis at the global scale (taking advantage of large historical databases).

It is hoped that these and other issues will be taken up in the spirit of engaged pluralism across different approaches within economic geography, and across different national communities of economic geographers. It is also our hope
that, through such engagement, economic geographers will continue to interrogate the moral foundations and implications of their analysis for the more-than-human world that we all inhabit.

Ecoregions

Tyra A. Olstad
State University of New York at Oneonta, USA

Ecoregions are geographic units distinguished by their place-specific ecological characteristics, including local climate regimes, physiographic features, soil types, ecological history, and, especially, communities of life. They differ from biomes in size as well as specificity: unlike large, general vegetation categories, ecoregions are classified into progressively smaller yet relatively homogenous units in which ecosystems may function similarly to those in neighboring ecoregions or ecosystem types in other biotic provinces, but are unique to their location. For example, the “Adirondack High Peaks” feature a unique mix of mountainous terrain, anorthosite bedrock, foggy, windy, and icy weather patterns and distinct assemblage of boreal and alpine species found only in one particular area in upstate New York; nearby “Highlands” and “Mixed Forests” enjoy milder conditions, while other alpine zones in New England have different geologic histories and compositions.

Delineation and purpose

Government officials – Robert Bailey of the United States Department of Agriculture’s Forest Service (USFS) and James Omernik of the US Environmental Protection Agency (EPA) – began delineating nationwide ecoregions in the late 1970s and 1980s, with the intent to “assist managers of aquatic and terrestrial resources in understanding the regional patterns of the realistically attainable quality of these resources” (Omernik 1987, 118) and provide a new spatial framework for managing the country’s natural resources and protecting environmental quality. Rather than being forced to rely on political borders, agency districts, or single factors such as a watershed or a species distribution, which do not follow or fully reflect the extent and complexity of ecosystems and thus provide poor ecological and spatial context for management decisions, Bailey and Omernik each sought a more holistic, integrative, scalable perspective that would help officials to make decisions based on knowledge of key localized characteristics, driving local forces, and connections between single places and much larger areas. In mapping “ecoregions,” they aimed to identify and account for relationships between biological, geological, hydrological, and climatological phenomena and processes in individual places, in adjacent and/or similar places, and at several different scales. Resulting maps help land managers more efficiently collect samples, estimate ecosystem service productivity, and make decisions based on informed predictions of how key species, physical features, and/or ecological processes will respond to local and/or landscape-scale natural and/or anthropogenic changes.

In the late 1990s and 2000s, nongovernmental organizations such as the World Wildlife Fund (WWF) and The Nature Conservancy (TNC) also took an “ecoregional” approach to mapping global biogeographic units, with the intent to inform conservation efforts and prioritize terrestrial and aquatic “hotspots” (areas that boast high species richness and endemism and face severe threats). Although the WWF and TNC’s maps of
“Terrestrial Ecoregions of the World” (TEOW), Freshwater Ecoregions of the World (FEOW), and, most recently, Marine Ecoregions of the World (MEOW) are, by virtue of objectives and expertise, more focused on issues of biogeography than with general ecosystem services or environmental conditions, they do account for place-by-place variation in and connections between abiotic and biotic (including human) forces – key ecoregional characteristics.

Government officials, conservation organizations, and independent scientists worldwide now use ecoregion maps and GIS shapefiles developed by the USFS, EPA, WWF, TNC, and other agencies and organizations to situate, integrate, ecologically synthesize, and geographically bound their work. Recent work based on ecoregions has included studies of area-source pollution, general anthropogenic impact on specific places, regional comparisons of species assemblages and health, evaluations of the usefulness of ecoregion classification in Europe, Oceania, South America, and southern Africa, and attempts to integrate geographic information systems and remote sensing technology into the processes of ecoregion delineation and monitoring.

Variations

The inherent complexity and dynamism of ecosystems make them difficult to classify and regionalize. In particular, ecoregion mappers struggle to account for microhabitats, ecotones, and dominant processes or factors. Depending on the scale, microhabitats, or localized variations in abiotic conditions and vegetation types, may be acknowledged or separated out into more internally homogenous units, but are generally treated as part of the “patch dynamics” or “mosaic” of larger, more heterogeneous ecoregions. Similarly, ecotones – areas of transition between ecoregions – are occasionally treated as separate entities but are, more often, split between neighboring units. Depending on how and where individuals chose to draw lines, this has resulted in slightly different borders on different ecoregion maps. Most significantly, from both a philosophical and practical perspective, there is no single accepted method for eco-regionalization; methods and methodology vary according to the interests and needs of those who plan to use the resulting maps (Olson et al. 2001; Omernik 2004).

Both the USFS and the EPA use nested hierarchies to inform management decisions on several scales, but they use different techniques for eco-regionalization to fulfill different agency needs. Robert Bailey (with the USFS) took an objective, universally replicable factor-based approach, beginning by identifying areal differences between climate types, then through “evaluation and integration of physical and biological components including climate, physiography, lithology, soils, and potential natural communities” (McNab et al. 2005). The USFS now recognizes four large domains (polar, humid temperate, dry, and humid tropical) in the United States, which are classified into divisions (with more fine-tuned climatic patterns and separate mountain ranges), then provinces, and finally sections (and subsections). Descriptions of the 190 separate ecological subregions in the conterminous United State, which range in size from thousands down to hundreds of acres, also include reference to unique hydrological features, disturbance regimes, land-use patterns, and cultural ecology. Overall, this hierarchical, nested approach allows land managers the flexibility to analyze, manage, and monitor natural resources and ecosystem services within forest landscapes, forest-wide, regionally, and/or nationally.

James Omernik (with the EPA) also took a hierarchical, nested approach to delineating
ecoregions, but he developed and used a more subjective weight-of-evidence methodology that considers how features and processes such as geomorphology, geology, soils, hydrology, climate, dominant vegetation, wildlife, and/or land-use history may play different dominant roles in different places. Using this approach, the EPA, and subsequently the international Commission for Environmental Cooperation (CEC), a partnership between Canadian, American, and Mexican parties, now recognizes 15 Level I ecoregions in North America (based on a mix of broad major vegetation types, landforms, and climatic factors), 50 Level II regions, and 182 Level III regions. Officials with the EPA, other US federal agencies, and state land management agencies have collaborated to further distinguish 968 Level IV relatively small ecoregions in the conterminous United States according to fine-tuned knowledge of localized ecological characteristics and driving forces. Although this place-by-place variation reflects a more nuanced and detailed understanding of each ecosystem and enables environmental protection officials to formulate more place-specific management strategies, it required laborious, less-replicable, expert collection and interpretation of field data (Omernik 2004, S34).

Most recently, researchers with the World Wildlife Fund, The Nature Conservancy, and partnering organizations have undertaken the task of delineating ecoregions worldwide in order to inform the conservation and/or sustainable use of natural resources. They have identified 867 TEOWs within 14 different biomes and 7 biogeographic realms (Afrotropical, Australasia, Indo-Malayan, Nearctic, Neotropical, Oceania, and Palearctic), 426 FEOWs within 12 major habitat types, and, most recently, 232 MEOWs within a hierarchy of 12 realms and 62 provinces. Their approaches were intended to provide “enough detail to be useful in … regional conservation … planning efforts” (Olson et al. 2001) and, especially, to help researchers and conservationists analyze biogeographic patterns and prioritize biodiversity conservation efforts on a comprehensive, global scale. Since completing the foundational work of mapping global ecoregions, the WWF has focused attention on a “Global 200” (now 238, to include aquatic ecoregions) and 36 WWF “Priority Places,” selected according to overall species richness, number of endemic species, taxonomic uniqueness or “extraordinary” adaptations, and global representativeness and rarity, as well as ecological history, ownership, and current level of threat. As Olson et al. (2001, 936) insist, “[c]onservation strategies that consider biogeographic units at the scale of ecoregions are ideal for protecting a full range of representative areas, conserving special elements, and ensuring the persistence of populations and ecological processes.”

Now that the USFS, EPA, WWF, and other organizations have proven the usefulness of defining, mapping, and using ecoregions for management and conservation efforts, many scientists and governmental officials in different countries are beginning to delineate ecoregions in order to address domestic research and management needs on a more place-specific level (on the scale of Bailey’s subsections or even Omernik’s Level IV). In addition to choosing between regionalization methods (nested hierarchy or not, factor-based or weight-of-evidence, what degree of heterogeneity to accept), many are also integrating remotely sensed imagery and geographic information systems into the classification process. While use of these tools and technologies may prove to be more cost-effective and efficient, there are questions as to whether simple overlay procedures are nuanced enough to precisely identify and delineate ecoregion boundaries, especially when operators still have to decide what degree
of internal heterogeneity (“patches”) to accept and how to deal with ecotones.

Concerns and future research

As more scientists, environmental protection and management officials, and conservation organizations use an ecoregion-based perspective to help inform and prioritize decisions, there are lingering concerns to consider. First, the multiplicity of available ecoregion maps (and corresponding shapefiles) provides a great deal of information and affords users flexibility and choices in matters of ecoregion sizes, borders, and distinguishing characteristics, but these options are only beneficial if users are aware of the existence of, and trade-offs between, different versions. While ecoregion maps can help provide a spatial and ecological framework for planning or decision-making, drawing borders and defining characteristics can also give the impression that ecoregions are formal and fixed when they are, in fact, complex, fluid, and dynamic percepts.

Second, ecoregions, by and large, reflect potential natural conditions. Places that have been heavily impacted or modified by humans may no longer feature the original soil type, hydrology, or species assemblages. Even when ecoregion descriptions include references to ecological history and current land use, ownership, and/or threats (especially, agricultural practices and large-scale resource harvesting), classification schemes may not always identify human activities as a dominant or driving factor. “Major Land Resource Areas” designated by the USDA Natural Resources Conservation Service bear similarities to USDA and USFS ecoregions, but are, as yet, separate spatial entities.

Third, as climate patterns change, species invade or go extinct, humans modify and/or attempt to restore ecosystems on local and global scales, and people develop new understandings of ecology and new environmental management practices, ecoregion maps will need to be continually redrawn and their uses reconsidered. In particular, scientists and environmental managers will continue to ask and try to answer questions such as: what tools and techniques for eco-regionalization are most accurate and effective? Can geographic information systems and remotely sensed imagery be used to precisely identify and delineate ecoregion boundaries, and/or how can they help scientists and land managers monitor changes within and between ecoregions? Is it necessary to consolidate current maps into a single, universal classification scheme or is it more useful to have multiple versions with different emphases? Are ecoregion-based management plans proving practical and effective? And, most importantly, how can eco-regionalization help people better understand relationships between multiple complex and changing geographical and ecological processes and phenomena?

Ecosystem services

Jessica Dempsey  
University of British Columbia, Canada

Ecosystem services, commonly defined as the benefits provided by ecosystems to humans, are an increasingly dominant way of conceptualizing relationships between humans and ecosystems. Many advocating this approach argue that focusing on the benefits that ecosystems provide to people will enlist more individuals and institutions in the conservation of biodiversity and in the project of environmentalism. By focusing on changes in ecosystem services and, ideally, economically valuing them, the argument is that decision-makers (i.e., governments, consumers, businesses) will make more sustainable and economically efficient decisions. For example, by calculating ecosystem services provided by a forest – including water purification services and carbon sequestration – those responsible for decisions about that particular forest will be able to better weigh the tradeoffs between different courses of action, between, for example, approving or rejecting a new soya plantation. Such calculations also prepare the ground for policy options that can facilitate payments between humans that “provide” or “secure” ecosystem service delivery to those who “consume” them.

The ecosystem services revolution, then, aims to make visible and ideally quantifiable the often underappreciated and undervalued ecological structures and processes necessary for human life on Earth. While sometimes oriented toward the production of new markets and commodities, ecosystem services are always matters of calculation, of creating qualitative distinctions in ecosystems (i.e., categories and classifications), differences that can be evaluated quantitatively. The point of this calculability is to organize ecosystems in ways that can render what they do for humans (i.e., the services they produce) equivalent and comparable, with the hope that these quantitative abstractions will incite sustainable and efficient decisions. This is by no means easy, demonstrated by three decades of conceptual and calculative debate on economic valuation of ecosystems.

Ecosystem services are not simply a new name for what ecologists have always studied, but rather are an increasingly dominant approach to ordering and organizing human and nonhuman (or ecosystemic) relations, setting norms for the management and governance of socioecologies. Ecosystem services must be seen as political, an approach that increasingly defines what is of value, contributing to the production of present and future natures. As with many contemporary political, economic, and cultural formations that define how we ought to manage and live, ecosystem services – as a metaphor, scientific practice, model, and policy approach – are largely formulated by experts located in scientific and governmental institutions of the Global North.

Ecosystem services seem to be poised to become a key universal guiding how we ought to live with, manage, and produce nature in the twenty-first century, in the so-called Anthropocene. But as with other “universals,” ecosystem services are highly variegated in definition and in practice, and marked by debates and contradictions.
The rise of ecosystem services

Ecosystem services, as a concept, emerged out of the implosion of two disciplines: economics and ecology. Erik Gomez-Baggethun and colleagues (2010) traced the history of the general notion of ecosystem services to the era of classical economists in the nineteenth century, including Ricardo, Mill, and Malthus, all of whom were explicitly concerned with the services humans receive by “natural agents” (p. 1211). The marginalist revolution of the twentieth century re-oriented focus to the sphere of exchange values, turning away from the non-priced or nonmarketed contributions of ecosystems. This ushered in the heyday of economic arrogance regarding the substitution of goods in face of increasing scarcity (and correlated high prices). The rise of environmental and resource economics in the 1960s provided some correctives to these blind spots and created methods to value environmental costs and benefits, including those without a market price. Departing from this significantly in the 1970s, heterodox economists with systems ecology backgrounds began to actively challenge the substitutability of ecosystems, arguing that there are “limits to growth” (Georgescu-Roegen 1971; Daly 1977). Ecological economics, as the discipline came to be known, advanced the notion that nature is a stock of “natural capital” that provides ecosystem services – a stock that is limited and being depleted.

For ecologists, a focus on ecosystem services began in the early 1980s along with deepening concern about ecological change and biodiversity loss (although thinking in terms of ecosystem functioning has a longer history in ecology). Ecologists Paul and Anne Ehrlich (1981) use the concept of ecosystem services to explain why all of humanity ought to be concerned with biodiversity loss. Their 1981 book *Extinction* put forward the argument that species diversity is central to the Earth’s life support systems, as it provides a basis for healthy ecosystem functioning, which in turn delivers the ecosystem goods and services humanity needs. Their book approvingly cites ecological economist Herman Daly’s focus on the “limits” to growth and the need for a steady state economy and pits this against traditional economic thinking and a global political economy that puts economic growth above all else.

In the 1990s, the concept of ecosystem services became central to conversations between leading ecologists and economists as they attempted to bridge the divide between the concerns of ecologists and the approach of mainstream economics. Many conversations take place at the Beijer Institute on Ecological Economics in Sweden, which undertook a project on the economics of biodiversity in the early 1990s. Within this project, ecosystem services are a key concept facilitating dialogue between ecologists and economists about biological diversity, especially for translating the problem of biodiversity into mainstream economics. The consensus emerging from the Beijer Institute is less focused on limits to growth and more focused on how to optimize and economically manage life on Earth.

This concept reached its high point in 1997. Ecological economist Robert Costanza and his co-authors published an article valuing the world’s ecosystem services at US$33 trillion (Costanza et al. 1997), a paper now cited over 10,000 times. The article led to enormous debate, largely focused on the methodological approach. The same year, ecologist Gretchen Daily (1997), also a participant in the Beijer meetings, published the edited collection titled *Nature’s Services: Societal Dependence on Natural Ecosystems*, a book cited over 4000 times.

Despite this growing elaboration of the concept in the academy, ecosystem services remained largely on the outside of much environmental
ECOSYSTEM SERVICES

law, policy, and advocacy, especially conservation policies and politics. Decisions made under the Convention on Biological Diversity scarcely mention the term until 2006 (see Table 1). Large environmental nongovernmental organizations (NGOs) such as Conservation International and The Nature Conservancy maintained their focus on biodiversity conservation through hotspots and other biodiversity related criteria (although this may be changing). The practice of biodiversity conservation by NGOs, biologists, and ecologists in the 1990s focused on the establishment of parks and protected areas and, in the so-called developing world, on what are often termed “integrated conservation and development projects” – projects that emphasize joint objectives of environmental protection and economic development. While focused on conservation and poverty alleviation, these approaches were not guided by quantitative assessments of ecosystem services.

The broader context of environmental law and policy, however, does take an economistic, market-oriented – often termed neoliberal – turn at this time, when governments began to place increasing faith in markets for achieving wealth and environmental governance. This included the creation of the 1990 Clean Air Act in the United States, establishing a cap and trade system to deal with emissions leading to acid rain. One early, possibly the first, ecosystem service market emerged to enact the broad principles of the Clean Water Act. Wetland banking – a scheme that allows for those who impact wetlands to purchase credits from firms who produce functioning wetlands – emerged to meet the broad principles of this act, while not impeding development (see Robertson 2004). Perhaps most famously, the 1997 Kyoto Protocol, which established binding reductions for developed countries, followed in the footsteps of the Clean Air Act by allowing for “developed countries” to exceed their reductions by buying offsets produced in the Global South through the Clean Development Mechanism. The CDM, while mostly producing credits related to increased efficiencies and fuel switching, does include credits produced via the carbon sequestration services of living systems, defined technically as “land use, land-use change, and forestry” offsets.

In the late 1980s and early 1990s, the elaboration of tort law in the United States to include damages to natural resources is another institutional driver of economic valuation of ecosystem services, as polluters like BP are required to pay for the cost of environmental

ECOSYSTEM SERVICES

damages like the Deepwater Horizon accident in the Gulf of Mexico, or the earlier Exxon Valdez spill. For example, in order to capture the “passive use values” – meaning the existence value, or sometimes called “nonuse” value of ecosystems – damaged by the Exxon Valdez oil spill, the state of Alaska commissioned a large contingent valuation study that led to a national commission on the methodology a few years later, headed by Nobel prize winning economists Kenneth Arrow and Robert Solow (see Carson et al. 2003 on the Exxon, and Kornfeld 2011 on the Deepwater Horizon). The notion of fungability in ecosystems was also a part of the European Union habitats directive (92/43/EEC) in 1992, which requires protected areas that are degraded to be replaced elsewhere with their equivalent (for a recent review of this policy and its elaboration see McGillivray 2012).

Millennium ecosystem assessment

The Millennium Ecosystem Assessment (MA), released in 2005, is a key turning point in the life of ecosystem services. A monumental work involving more than 1300 scientists over five years, the MA shifted the approach to international environmental assessment by focusing on auditing changes in ecosystems and biodiversity in relation to human wellbeing. The summary findings from the MA are grim. The MA found that 60% (15 out of 24) of the ecosystem services examined are being degraded or used unsustainably, including fresh water, capture fisheries, air and water purification, and the regulation of regional and local climate, natural hazards, and pests. Many of these ecosystem services were found to be degraded as a result of increased supply of other services, like food (MA 2005, 1). Importantly, the MA found that the effects of ecosystem service degradation are felt most by those with the lowest incomes, results that would not surprise geographers studying processes of uneven development.

Besides this assessment, the MA concretized a framework for understanding ecosystems as a stock of natural capital that provide ecosystem services, producing the now ubiquitous categorizations of services: supporting, regulating, provisioning, and cultural (see Figure 1). These categorizations are now commonly used to delineate what nature does for humanity. However, these definitions of ecosystem services are not without debate even among proponents of the approach, as some economists argue that the definition is too broad, and not appropriate for facilitating appropriate economic accounting (see review in Dempsey and Robertson 2012).

For the scientists and policymakers involved in the MA, proper management of ecosystem services is not about tracking human encroachment into some “pristine nature.” More than anything, the central governance problem emerging from the MA centers on measuring and managing tradeoffs between different ecosystem services, for example, impounding streams for hydroelectric power may have negative consequences on fish populations and thus on provisioning services. Or outputs of provisioning services such as timber (e.g., as a result of increased rates of logging) can have a negative impact on the regulation of another service, like the flood prevention service or carbon sequestration service that is provided by forest cover. These tradeoffs are complex and must consider temporal and spatial scales as well as degrees of reversibility (see Figure 2). For example, a tradeoff between maximizing a service like food production now which will impact the service provision later, or maximizing a service in one particular place (upstream) such as hydroelectricity is a tradeoff with the provision of fish in a different place (downstream).
The project of ecosystem services as it is articulated through the MA is most centrally about producing the conditions – in this case, the knowledge conditions or framework – where the value of different courses of action can be quantitatively assessed. The hope is, of course, that such knowledge will lead to optimal decisions and policy options, ones that consider not just traditional commodities, but also previously excluded ecological services. In focusing on tradeoffs among many ecosystem services, together, the approach appears to undermine a focus on achieving “maximum sustained yield” for a single commodity (i.e., maximizing fisheries, agricultural output, or timber production), and rather to maximize yield for a broader array of services that ecosystems provide, beyond what is traditionally priced. Ideally such modeling would also consider the way that consumption of ecosystem services at one time has effects for future generations and to consider the way that the consumption of ecosystem services in one place has effects for people and communities in other places (see Figure 2).

While many governmental, NGO, and private sector institutions welcomed the MA, the reports also generated debates (i.e., McCauley 2006; Reid et al. 2006) and pointed to challenges (i.e., Carpenter et al. 2006). Environmentalists, indigenous communities, and organizations...
as well as governments raised concerns about the utilitarian and economistic framing. For example, writing during a negotiation of the Convention on Biological Diversity just after the release of the MA, a collective of NGOs and activists noted this shift in tone of the negotiations toward the language of the World Bank and World Trade Organization, arguing that the focus should be on the public benefits that ecosystems provide rather than services that might fall under the WTO General Agreement on Trade in Services (ECO 2005).

Critiques come from inside the academy, too, as ecologists and economists alike express concerns. Reflecting on the outcomes of the Millennium Ecosystem Assessment, ecologists, including Steve Carpenter (one of the lead scientists in the MA), note that a barrier to the ecosystem service approach sits with a paucity of ecological knowledge, especially related to how changing quantities of biodiversity, or changing ecosystem structure, relates to changes in ecosystem functioning and services (Carpenter *et al.* 2006). Richard Norgaard (2010) provides a more fundamental critique of the ecological-economic model of the MA, taking issue with the way the MA conceptualizes nature as a “stock” that “flows” ecosystem services to humans. Norgaard asserts that the social and ecological problems of our time require a diversity of ecological approaches, further arguing that the stock-flow model fits too well with status quo institutional and deeply uneven power relations, and fails to question the broader political-economic obsession with economic growth. Many others, including ecologists (i.e., Adams and Redford 2010) and political ecologists (i.e., Sullivan 2009), focus on the perils of economic metaphors and practices that they say will lead to further inequities.

**Economic valuation: toward “the economics of ecosystems and biodiversity”**

Dogging natural resource, environmental and ecological economists for three decades is the question of how to value nonmarketed aspects of ecosystem services. The debate following the release of Costanza *et al.*’s (1997) paper that valued all of the Earth’s ecosystems demonstrates this. Costanza and his colleagues’ impulse was aggregative and summative, which led to loud criticisms from marginalist economists who saw his 33 trillion as “breaking the rule”: who could buy the whole Earth? Rather, these critics argued that valuation must focus on establishing credible market prices based on supply and demand (see Dempsey and Robertson 2012). There remains debate within the ecosystem services literature about valuation, including, for example, debates over the ethical implications of discount rates and the role for nonmonetary valuations (i.e., Heal 2000; Ludwig, Brock, and Carpenter 2005; TEEB 2010; Luck, Chan, and Fay 2009).
In response to these debates and gaps in knowledge, and also following on the heels of the Stern report and the Millennium Ecosystem Assessment, in 2007 the G8 environmental ministers created The Economics of Ecosystems and Biodiversity (TEEB) project to study the economic impact of the global loss of biodiversity. The head of the initiative was Pavan Sukhdev, a former international banker, whose writing and talks sometimes sound revolutionary. For example, he states that “the root causes of biodiversity loss lie in the nature of the human relationship with nature, and in our dominant economic model,” going on to say that our current economy “promotes and rewards more versus better consumption, private versus public wealth creation, human-made capital versus natural capital” (TEEB 2010, xviii, emphasis in original). Yet, despite this widespread criticism of contemporary Western culture and economies, in the next breath Sukhdev states that the main problem is that of externalities and market failure: “there are no “markets” for the largely public goods and services that flow from ecosystems and biodiversity” (TEEB 2010, xxi).

The first report emerging from TEEB in 2008 valued the cost of inaction on biodiversity loss and ecosystem change – in terms of lost ecosystem services – at about 50 billion euros per year. If current rates of ecosystem change and biodiversity loss continue, the report estimates that by 2050 (from a base of the year 2000) the opportunity cost in terms of lost ecosystem services would weigh in at 14 trillion US dollars. TEEB ended in 2010 after producing a number of reports that drew attention to the global benefits of biodiversity and the costs of biodiversity loss. Reports targeted specific end users: international and national policymakers, subnational policymakers, business and enterprise, and individuals.

These TEEB reports recognize the challenges, uncertainties, and politics of economic valuation. Yet they unequivocally state that economic valuation “of Nature’s public goods and service flows is both necessary and ethical” (p. xxi) in order to communicate with decision-makers “using the language of the world’s dominant economic and political paradigm” (p. xix). In pursuit of better valuations, TEEB produced a book (TEEB 2010) that synthesized the foundations of ecological-economic valuation. While this text recognized the wide variety of approaches to valuation, overall it largely consolidated a neoclassical (preference-based) approach to valuation, which is amenable to assessing tradeoffs between different uses of land and ecosystems (recall the role of tradeoffs in the Millennium Ecosystem Assessment).

A crucial debate in valuation is how marginalist approaches can be used to value the resiliency of ecosystems in conditions that are increasingly nonlinear with changing climates (i.e., that have thresholds where the system changes dramatically) (see TEEB 2010, ch. 5). Gretchen Daily (1997) and her co-authors note the limitations of measuring the additional value (or the reduction in value) in ecological systems that are “highly interdependent” and how “seemingly small changes in one place cause large impact on the overall system” (p. 396). When ecological thresholds or boundaries are approached, then changes in ecosystem services cannot be measured using traditional marginalist approaches: how does one value even a small change that leads to the collapse of an ecological system? Given this, TEEB (2010) warns that traditional valuation is not appropriate when approaching “ecological thresholds” (p. 223), and Ring et al. (2010) argue that there are cases where the “the basic theorems of welfare economics are not valid” (p. 17). These contradictions are recognized by scholars and experts, but often...
ECOSYSTEM SERVICES

not discussed when economicist approaches are embraced in the mainstream.

And how do new environmental markets appear in the work of TEEB? The written books are careful to note that the project is not about market-making, for example, stating that “[p]lacing blind faith in in the ability of markets to optimize social welfare, by privatizing the ecological commons and letting markets discover prices for them, is not at all what TEEB is about” (TEEB 2010, xxiv). Yet geographers Ken MacDonald and Catherine Corson (2010) argue TEEB is indeed part of a project of environmental market-making. Based upon participant observation at international meetings, they find that TEEB is central to “legitimating and circulating the narratives, images and ideas of nature essential to these new speculative nature markets” (p. 181). With the current decline in international carbon markets, it is unclear what the next decade will bring in terms of market-making and growth, and it seems crucial to recognize that ecosystem services does not equal market-making.

Emerging practices of ecosystem service assessment and policy

While there are ongoing debates and challenges to the concept, ecosystem services are now firmly found within the discourse and increasingly in the practice of the world’s largest conservation organizations, known as BINGOs (big international non-governmental organizations): the World Wildlife Fund, The Nature Conservancy, and Conservation International (CI). But taking ecosystem services from a model and conceptual framework into practice, policy, and politics is an ongoing project and one with enormous variation.

Calculating ecosystem services

Even if it is becoming common to speak in the language of ecosystem services, calculating those services with any ecological credibility is a whole other matter. To convince decision-makers to invest in ecosystems (i.e., protect or restore them), ecosystem services need to be more than a heuristic; they need to be incorporated into the cost–benefit or due diligence models of decision-makers (governmental, corporate). Ecosystem services must be turned into quantified flows that can be represented in numbers, ideally dollars and cents. This problem is widely recognized in the ecosystem services literature by proponents of the concept and approach. In response, academics (including not least ecologists and economists), conservation organizations, and international institutions are creating spatially explicit models that assess the flows of services from particular land and marine assemblages, biophysically and economically. This includes the integrated valuation of environmental services and tradeoffs (InVEST) tool produced by the Natural Capital project (a collaboration between Stanford University, the University of Minnesota, and two conservation organizations: The Nature Conservancy and WWF-US). InVEST is an open source computer modeling software tool that quantifies, maps, and values ecosystem services. To refer back to the conceptualization of the Millennium Ecosystem Assessment (above), InVEST aims to make quantitative the tradeoffs associated with different courses of action; it seeks to organize and structure encounters between humans and the “calculative goods” of ecosystem services – in the present and future – to compare and contrast different courses of action in land and marine use.

With the (idealized) knowledge of how increasing one particular ecosystem service (e.g., soya production) impacts on other ecosystem services (e.g., carbon sequestration, water quality,
pollination services) in the short and long term and over various spatial scales, this integrative framework is meant to help decision-makers optimize allocations of resources. In rendering the costs and benefits of different land uses visible and quantifiable, InVEST aims to give the state, or decision-makers, the tools to govern environmentally and economically at the same time, to design policies that could maximize value. InVEST is now being used throughout the world, for example, for water security in Latin America, to design coastal protection in the Gulf of Mexico, and aiding China’s new systems of protected areas.

Given the difficulties of understanding ecosystem functioning and services, one significant question is how such models can provide accurate quantitative assessments (see Johnson et al. 2012) especially with the uncertainties of climatic changes. This is a tension in the turn to ecosystem services. While ecologists increasingly adhere to nonlinear and surprise-ridden models of ecosystems (especially with changing climates), the turn to ecosystem services requires them to nail down interactions and outcomes – ecological and economic – that can be rendered quantitative now and into the future.

Ecosystem service policies and markets

Given these internal debates on how to define, calculate, and value ecosystem services (economically and ecologically), it is not surprising that the practice of ecosystem services policy is difficult to characterize. Implementing the ecosystem service framework now includes national accounting strategies all the way to full markets in carbon sequestration ecosystem services. The most developed policy framework is known as PES – payments for ecosystem services – a term that refers to monetary incentives given to landowners (or tenure holder) to manage their land for a particular ecosystem service (e.g., carbon sequestration or water filtration). PES programs are sponsored by a wide range of institutions from international development agencies to ENGOs to governments and for-profit firms. Although often characterized as market-based, not all PES are market-oriented, and many operate more like state subsidies. For example, these exist in the form of agri-environmental subsidies schemes, where farmers get paid in Europe producing landscape “services” rather than only crops. Such schemes are quite different than markets in wetlands such as those in the United States (discussed above) or markets in forest or ecosystem carbon sequestration where there are buyers and sellers and stronger assumptions about ecological substitutability and fungibility. This has led some to categorize policies in terms of “payments” and “markets” for ecosystem services – PES and MES, respectively. For further discussion on the distinctions between incentives and markets see Pirard (2012), Muradian et al. (2013), Vatn (2014), all of whom argue that markets are a poor way to describe much of what is going on in ecosystem service policymaking.

Indeed, many policies seem to be a mix of state-funded incentives and market-like governance. For example, McAfee and Shapiro (2010) describe Mexico’s PES program as hybrid neoliberalism in that it combines market norms with state-sponsored rule making and institution building (p. 586). Rather than straightforward commodification or the operationalization of market efficiency, McAfee and Shapiro find that Mexican PES policies are complex and contradictory and morphed into a hybrid program due in large part to the efforts of activists and campesinos who wanted to see the program move in a pro-poor direction. In a detailed examination of Costa Rica’s PES program, Fletcher and Breitling (2012) argue that it
operates more like a subsidy, as a way to support forest conservation through government funds distributed to forest owners (see also Vatn 2014).

Ecosystem service policy design, particularly in the Global South, depends on the goals of the program: are practitioners trying to achieve “efficient allocations” of services, or trying to alleviate poverty? Or both? Are they a part of a global resource transfer, or a way to deal with national or regional issues? Within critical geography and other social sciences, much work focuses on empirically examining and theorizing the terrain of payments and markets for ecosystem services. There is enormous variation in approaches and sites of empirical studies, but many researchers are now focusing on examining new relations of property emerging within payments and markets for ecosystem services, drawing out new (and old) dispossessions and hierarchies in the wake of such policies (see review in Dempsey and Robertson 2012).

Conceptually, much critical social science examination of ecosystem services draws from Marxist analysis and on the production of new commodities. For example, Kosoy and Corbera (2010) argue that payments for ecosystem services should be understood through the lens of Marx’s commodity fetishism. They draw out how payments/markets for ecosystem service projects disregard ecosystem complexity in pursuit of market transactions, obliterating other social and ecological qualities, values, and relationships, producing (not ameliorating) new socioeconomic hierarchies. Robertson (2012) draws from Marxist conceptions of value, arguing that the turn to ecosystem services must be understood as a transformation akin to that of labor under the advent of capitalist relations.

Proponents of ecosystem services are also expressing doubts about the feasibility of market policies. The Millennium Ecosystem Assessment led Reid et al. (2006) to note the limits of environmental markets. With the small scale of many ecosystem service markets, and high transaction costs, some wonder if the market approach achieves any efficiency gains (i.e., Kroeger and Casey 2007; Muradian et al. 2010).

National accounting standards

For years environmentalists have bemoaned the narrowness of gross domestic product (GDP) for measuring the health of nations and citizens. Drawing on the work of economic valuation, there are moves afoot within the World Bank and many governments to account for a broader range of ecosystem service values in national balance sheets. In 2012, governments adopted an internationally agreed upon method to account for natural resources like minerals, timber, and fish (known as the UN Statistical Commission of the System for Environmental and Economic Accounts (SEEA)). Going beyond natural resources, the World Bank is now leading the “Wealth Accounting and the Valuation of Ecosystem Services” (WAVES) partnership that aims to bring a broader suite of ecosystem services into national economic accounts and to promote and support this within developing nations.

At Rio +20 in 2012, 68 countries signed the Natural Capital Accounting declaration along with many multinational corporations (such as Walmart and Nestlé). Over 44 financial institutions and firms have now signed the Natural Capital Declaration, a finance sector initiative to integrate natural capital considerations into loans, equity, fixed income, and insurance products as well as in accounting, disclosure, and reporting frameworks. However, incorporating ecosystem changes into the quantitative models of the financial and corporate worlds is incredibly challenging (Dempsey 2013).
Ecosystem services in the big picture

A new universal

For many, ecosystem services represent a kind of new universal, a unifying concept that can finally bring environmentalism and conservation into the financial calculations of the private sector and the deliberations of governments, operationalizing the ever-elusive “green economy.” Ecosystem services, as Tallis and Kareiva (2006) argue, are “one of the few ideas that resonate in corporate and governmental board rooms, on stock exchanges and in farmhouses, mud huts, eco-tourist lodges and palm palapas” (p. 748). Proponents of ecosystem services often promote the approach in relation to the failures of biodiversity conservation: an approach that they say does not resonate with anyone but the converted or that separates humans from ecosystems.

Yet there are crucial commonalities between ecosystem services and other material-semiotic orderings, like biodiversity and even wilderness. All are concepts still largely produced in the same institutions: academics based (or trained) in the Global North, conservation organizations whose modus operandi is still oriented in the Global North, and institutions like the World Bank. In other words, the production of a world of ecosystem services is, in many ways, a reiteration of the (colonizing) concept of Western science and experts to discern from a distance the laws of, in this case, socioecological natures. As Sullivan (2009) asks, “what knowledge and experiences are being othered and displaced through the parlance and practice of ecosystem services?” (p. 23). In other words, what new and old orientations of power and knowledge does the material-semiotic object of ecosystem services facilitate? The turn from biodiversity toward ecosystem services ushers in new hierarchies and rankings with implications for what kinds of socioecologies will be invested in, or not. Will these be less violent? And, if so, for whom?

In addition to the work of critical scholars, there continues to be social movement and activist opposition to the ecosystem services turn. At World Trade Organization negotiations in late 2012, a statement released by the Indigenous Peoples Movement for Self-Determination and Liberation called for “the halt of all policies controlling the reproductive capacity of Mother Earth through market-based mechanisms that allow for the quantification and commodification of the natural processes of Mother Earth being branded as ecosystem services” (IPMSDL 2013). And there are signs that proponents of ecosystem services recognize this conceit. Indeed, a recent set of articles in ecology draw out some of these questions, focusing on the ethics of ecosystem services, noting explicitly that ecosystem services are only one metaphor or approach, and it may not be “culturally appropriate” in all cases (Raymond et al. 2013). Yet, despite these challenges, ecosystem services are being embraced in international policy, national governments, multinational firms, and financial institutions. This suggests that the approach is increasingly in the hands of institutions that have benefited most from ecosystem service decline, raising serious questions about how this particular metaphor/model can avoid the colonizing, violent and reductionist tendencies that hampered other environmental metaphors and models.

Will it work?

Linked to the above, there is the question of whether the approach can contribute to lessening ecological impoverishment; in other words, if this new environmental formation of ecosystem services will change decisions toward sustainability and if it can make the green economy a
realism. Bringing the changes in ecosystem service into conversation with political-economic trends tells us that it is certainly no panacea. Indeed, this is what a broadly based geographical political economy brings to the question of environmental change. When one examines power relations globally, one has to wonder if the ecosystem services turn results in little more than “tinkering” as Norgaard suggests (2010). Decisions – for example, to build new energy infrastructure to extract fossil fuels (pipelines, refineries) or the continued destruction of mangroves for shrimp farms are not likely to be reversed due to new calculative figures about the costs (for example, the reduction of ecosystem services resulting from ocean acidification and mangrove destruction). While economically “stupid” or “irrational” decisions may haunt us in the future, those stupid economic decisions pay in the present. A recent study commissioned by The Economics of Ecosystems and Biodiversity (TEEB) is revealing: the study tallied up the globe’s total unpriced natural capital (ecological materials and services for which businesses currently do not pay), like clean water and a stable atmosphere. It found that none of the world’s biggest businesses would be profitable if they had to pay for those services (Trucost 2013). “Irrational” economic decisions continue not only because we lack prices and values of natural capital, but also because many large, powerful (and currently profitable) industries, institutions, and governments depend deeply on these externalizations. Changing these externalizations means coming up against these deeply embedded structures.

Put another way, a major problem facing ecosystem service tradeoffs remains the same as it was for biodiversity conservation: who will pay the price of shifting to better, more “rational” decisions? How can we convince the state, for example, to stop approving business-as-usual energy infrastructure? A big question for ecosystem service proponents – scientists, experts, conservationists – is whether, and if so, how, this particular concept and model can be mobilized to break these deep political-economic entrenchments, and/or help us deal with “humanity’s shriveled ecological options and gross social injustices” (Norgaard 2010, 1224).

ECOSYSTEM SERVICES

“Ecosystem” is used in three ways. Following Pickett and Cadenasso (2002) these are the dimensions of meaning, model, and metaphor (these follow the three identified by Golley 1993, 72, as the early, undifferentiated uses: a particular object, an emphasis on energy and material transfer, and another word for ecology). First, it is a term that can mean a type of environment with characteristic plants, animals, soil and climate, or a particular instance of this type in a particular area. In the general part of that usage it is similar to the definition of biome and is used interchangeably, as the tropical savanna biome/ecosystem. In a particular instance “biome” would not be used, but such individual usage is common for areas such as the ecosystem of a particular lake, valley, or other geographic area. This usage is part of a hierarchy of terms related to environmental biology. Second, the “system” is emphasized and the word would apply to the structure of interactions and flows of energy and matter among the biotic and abiotic components of a particular area. Models are necessary to apply ecosystem to a particular instance. As metaphor, ecosystem is a rhetorical device to emphasize connectivity of humans with the environment. All usages derive from the original coinage (as a historical footnote, Willis (1997) reported that a young colleague of Tansley, A.R. Clapham, claimed decades later to have coined “ecosystem” some time before 1935) of the term by Tansley (1935; italics in original).

I have already given my reasons for rejecting the terms “complex organism” and “biotic community.” Clements’s earlier term “biome” for the whole complex of organisms inhabiting a given region is unobjectionable and for some purposes convenient. But the more fundamental conception is, at it seems to me, the whole system (in the sense of physics), including not only the organism–complex, but also the whole complex of physical factors forming what we call the environment of the biome – the habitat factors in the widest sense. Though the organisms may claim our primary interest, when we are trying to think fundamentally we cannot separate them from their special environment, with which they form one physical system.

It is the systems so formed which, from the point of view of the ecologist, are the basic units of nature on the face of the earth. Our natural human prejudices force us to consider the organisms (in the sense of the biologist) as the most important parts of these systems, but certainly the inorganic “factors” are also parts – there could be no systems without them, and there is constant interchange of the most various kinds within each system, not only between the organisms but between the organic and inorganic. These ecosystems, as we may call them, are of the most various kinds and sizes. They form one category of the multitudinous physical systems of the universe, which range from the universe as a whole down to the atom.

The hierarchical use, although Tansley might have objected, is still close to “biome” but with the climate and soils of the biome included (perhaps as a modern usage of “biome”); “biome” and the major biomes of Earth have separate entries in this encyclopedia). The narrow systems use has a history of development and a determination of scientific research all its own. This usage is conceptually important because it is a constant reminder of the connections of the
ECOSYSTEM

biotic and abiotic components. With this connection ecosystem is convenient as a metaphor when the connections may not be obvious but need to be reiterated as in some instances of environmental impact communication.

A biological hierarchy

Tansley did not specify all elements of a hierarchy, but he placed “ecosystem” somewhere between atom and universe. Odum (1959, 6) place ecosystem more specifically in a ten step hierarchy from protoplasm to biosphere, near the top: … – Community – Ecosystem – Biosphere.

Here ecosystem fits where others might place “biome,” but unlike biome it is not restricted to a large spatial extent or similar spatial scale. Ecosystem becomes multiscale because it is at the transition point between a biological hierarchy and a geographical one, and as a result is used in either sense and scale is dropped. Populations and communities can be aspatial, but in the hierarchy an ecosystem cannot (but in systems terms, below, it can be) – but the space can vary. In this sense the ecosystem of a nearby lake has a clearly defined location and extent and, while the location of the tropical savanna ecosystem may not be clearly defined, it is conceived as occupying some location of great extent on the planet. The ecosystem of a droplet of water may have a specific location and clearly has a specific extent. Ecosystem becomes a useful summary of the organisms and their environment and whatever scale.

The number of such ecosystems (or biomes) is undecided. Biogeographers will count roughly 7 to 15 biomes depending on predilection for fine division. Whittaker (1975, 135–161), blurring a distinction, identified 36 “biome types” as “major kinds of communities,” but many of these seem more like ecosystems, and include:

27 Fresh-water lentic communities (lakes and ponds) …
28 Fresh-water lotic communities (streams) …

Because ecosystem can be used at many scales, perhaps counting is irrelevant (if any water droplet has its own ecosystem). Given current interest in microbes, and microbiomes, the smallest extents of ecosystems may be shrinking. Whether we will examine the ecosystems of larger planets can be left to science fiction, for now.

Systems ecology

The narrower usage developed through a focus on the “constant interchange” in a system in question. The ecosystem of a particular lake may be in question, or a generalized ecosystem concept for lakes, but in either case a model system is defined. The interchange became focused on the flows of energy and matter among components in which the biological populations and communities were made abstract – much more so than in the population ecology based view. The types of flows can be seen in abstractions of the models, as in Figure 1, historically among the most influential.

The systems being flows of energy and matter may in part have been shaped by the interests in the potential applications of ecosystem concepts to the development of nuclear weapons and energy: much of the early funding (and relatively high funding within ecological research at the time) was from the US Atomic Energy Commission and was related to bomb testing and the development of experimental nuclear facilities. Tracing radioactivity in the environment was a concern and a systems approach in which biotic populations and communities were abstracted (and thus to some degree became abiotic, although Golley pointed to the biological
orientation as reason for why other disciplines, most notably geography, did not adopt the approach; see Malanson 2011) addressed this concern with models. This direction in research was enabled by the development and accessibility of computers in the 1950s. The models could be quantified and used to project outcomes for different scenarios. By the early 1960s, systems ecology could be touted as the “new ecology” with notable disdain for the more biological population-based ecology and especially for natural history.

This early period of growth was sustained by the International Biological Program, which fostered a systems approach in ecosystems (as defined above) for explanation and comparison. Under this program new computer simulations developed that are the foundations for current systems ecology. Today, systems ecology is used to address more complicated ecosystems (e.g., urban ecosystems; see Pataki et al. 2013), but the focus is still on the flux of energy and nutrients. Ecosystems scientists keep track of energy, often using carbon (e.g., gC m$^{-2}$ year$^{-2}$) as the currency of measurement because it is easier than explicit measures of joules, and nutrients (e.g., nitrogen) in increasingly complicated forms and processes.

Core ideas in systems ecology include (i) energy flow – the flow of energy (flow, given the first and second laws of thermodynamics)}
leads to structure as organisms evolve to use it to reproduce. The ecosystem structure that develops is called a food web. Food webs, not so identified, were studied before the term ecosystem appeared (Summerhayes and Elton 1923; see Figure 1), and the complexity led to a simplification in which the multitude of species were grouped into a hierarchy or trophic structure with a simpler food chain. The trophic structure is based on net primary productivity, primarily through photosynthesis, by the group of autotrophs. Higher levels, of heterotrophs, in the structure are occupied by primary consumers (herbivores) and secondary, tertiary, and so on, consumers (carnivores and omnivores), but with a limit to the number of levels because the amount of energy that is available to a higher level drops by 90% (a rough estimate that will vary widely among ecosystems) due to entropy, with loss of energy as heat through the processes of living.

(ii) Material cycles – the flow of energy drives cycles of matter. Ecosystem scientists concentrated on the cycle carbon because it was a way to track energy (entering the biota through photosynthesis), but the carbon cycle has become important in its own right because of its connection to climate change. Nutrient cycles have been a core study of ecosystems with macronutrients such as nitrogen phosphorous receiving early attention, but micronutrients now being examined. The detailed transformation of the molecular characteristics of the elements in question and how these are produced by or affect organisms is quantified. The biotic part of the hydrological cycle has also been a major component of ecosystem science. This systems focus tied closely to developments in other environmental sciences, notably hydrology.

Systems ecology is closely linked to modeling, as the transfers of energy and material are tracked and then projected in computer simulations. Intensive modeling efforts were the core of the International Biological Program, but were taken up by other projects with different conceptual structures and core epistemologies (Golley 1993).

Metaphor

The popular use of ecosystems is important because it is popular in the sense of reaching out to all (a Google search returns >50 million hits, although many are used as analogy as with business ecosystems or the Android ecosystem). With an increasing awareness of environmental consequences of human activities (perhaps part spurred by the atomic research) that developed in the 1960s, inspired by Rachel Carson’s Silent Spring and leading in the United States to Earth Day in 1970 and several related pieces of legislation, ecosystem became a shorthand for the connectedness in the environment at many scales. Although a kind of imprecise hand waving, this usage has rhetorical weight because it reiterates Tansley’s view of connectedness. In this sense, even short of what is seen for analogies, ecosystem is metaphorical.

This use is important for nonscientists to understand the place of people, every individual’s place, in the environment. At one end of the scale used, people are important components of the Earth’s ecosystem. While people are tied to smaller scale ecosystems of their locales these can be difficult to see in an urbanizing world, but the connection to a global ecosystem, and the power and importance of the metaphor, are strengthened in a globalizing world.

**Edge city**

**Richard P. Greene**  
*Northern Illinois University, USA*

An *edge city* is an employment center on the edge of an urban area. The term was first coined by Joel Garreau, a *Washington Post* journalist who ran a series of articles focused on edge cities including Tysons Corner Virginia, which was the model for Washington DC. He then published the book *Edge City* (1991) in which he says that an edge city:

- has 460,000 m² (5 million ft²) or more of leasable office space;
- has 56,000 m² (600,000 ft²) or more of leasable retail space;
- has more jobs than bedrooms;
- is perceived by the population as one place; and
- is not considered part of a “city” as recently as 30 years ago.

To Garreau, who identified edge cities for many urban areas in the United States, an *edge city* looks and feels like a new city. It is often found in the suburbs near a highway interchange, having office and retail space, and perceived as one place. Edge cities take many shapes and sizes, sometimes forming linear series or corridors — for example, one outside Chicago, which encompasses O'Hare International Airport, Woodfield Mall, and many office parks (see Figure 1). Its status was elevated in 1991 when Sears moved its corporate headquarters and 5000 jobs to the Hoffman Estates community from the company’s former headquarters in the 110-story Sears Tower (Willis Tower today) in downtown Chicago. People are now accustomed to edge cities because besides being places where people work, they provide diverse shopping and entertainment opportunities. In an *edge city*, regional malls might be intermixed with commercial corridors and upscale hotels, often present for out-of-town visitors who are on business in the *edge city* or even for those who live in the region who are looking for a weekend escape. Many of these characteristics sound much like the ones ascribed to big downtowns because, in fact, edge cities are providing something of a downtown atmosphere.

Although Garreau coined the term *edge city*, the concept itself had been studied earlier. For instance, the multiple nuclei model of urban development by Harris and Ullman (1945) recognized the phenomenon. Their model depicted growth and development occurring around multiple centers of economic activity in a metropolitan area, rather than around a single central business district (CBD). Urban geographers in the 1970s, 1980s, and 1990s were also active in monitoring both the evolving forms and the impacts of these outlying employment centers. Baerwald (1978) provided precise delimitation of an evolving suburban employment center outside Minneapolis through the use of aerial photographs and other data. Muller (1981) conducted a broad and comprehensive analysis of the trends of suburban nucleation with a case study on Philadelphia’s King of Prussia. Erickson (1986) modeled the process of multinucleation and found that the spatial distribution of employment was becoming more random. Cervero (1989) examined a number of traffic congestion-related issues for the 50 largest suburban employment centers and thus situated the concern in the urban planning literature.
Figure 1  Top 12 employment centers in Chicago area ranked by jobs in 2010.
Contemporary studies have attempted to develop better empirical methods for defining and comparing edge city growth through time (Giuliano and Small 1991; Fujii and Hartshorn 1995; Greene 2008; Antipova and Ozdenerol 2013). Giuliano and Small (1991) delimited suburban employment centers in Los Angeles using a job-density criterion – their cutoff to identify an employment center was a zone with at least 10 jobs per acre, or 6400 jobs per km². Another useful measure to delimit edge cities is the ratio of employment to resident workers (E/R ratio), reflecting the balance of workers and jobs. The ratio is defined as follows:

\[
\frac{E}{R} = \frac{\text{Number of workers working in area}}{\text{Number of workers residing in area}}
\]

Edge cities have been identified in terms of places with high E/R ratios, a criterion that corresponds to the third and fourth parts of Garreau’s (1991) definition.

Edge cities play an important role in helping direct the future of sprawl as they represent independent and competing employment hubs to the long-established downtowns of metropolitan areas (Shearmur and Motte 2009). As edge cities continue to grow and expand, the urban–rural fringe has the potential for expanding much farther outward than it did in previous cycles of growth, when the downtown dominated. This expansion is occurring as an individual figures his or her acceptable commuting range not to the long-established CBD, but to an edge city where he or she holds a job.

Founded: 1875
Location of headquarters: Cairo
The first work of electoral geography is generally considered to be André Siegfried’s 1912 Tableau politique de la France de l’ouest sous la troisième république (A Portrait of Politics in Western France under the Third Republic), although the Anglo-American tradition often identifies Edward Krebheil’s 1916 analysis of British parliamentary elections as the earliest work. Both Siegfried and Krebheil ask similar questions and employ similar methods: What is the spatial pattern of a vote, and what explains such patterns? Both ultimately sought to make a causal argument about the source of political preference and voting behavior. In essence, they compared maps of election returns with physical or social factors with similar spatial variations, and interpreted similarities in spatial patterns as evidence of causality. Siegfried focused on social variation caused by different physical environments (geology), while Krebheil identified variations in occupation as the key factor.

Subsequently, in the United States during the 1930s, John K. Wright introduced the mapping of legislative (congressional) votes, in addition to the mapping of election returns. This was an important conceptual innovation because it focused concern on political relationships per se, rather than using election results as a proxy for public opinion.

Early electoral analyses were undertaken before the advent of modern survey methods and before the invention of computers and information technology powerful enough for systematic spatial analysis. This meant that election returns were the best – if not the only – source of information about public opinion and its variation. Without systematic data on individual responses, however, causality could only be inferred by spatial coincidence. Hence Krebheil interpreted his findings (that industrial and less wealthy agricultural regions tended to support the Liberal Party while wealthier agricultural areas were Conservative bastions) to mean that there was a causal relationship between occupation and political preference. This relationship could be affected, however, by party positions on specific political issues; for example, support for Home Rule in Ireland explained the higher than expected support for the Liberal Party in southern Ireland. Such analyses were not statistical, however, and relied primarily on the visual inspection of maps. They also suffer from the ecological fallacy, inferring individual characteristics (and causal mechanisms) from aggregate data.

While techniques of electoral analysis have grown more sophisticated, the basic approaches, questions, and limitations in contemporary electoral geography remain similar to these early works.

The geography of voting

Until the advent of sufficiently powerful and inexpensive computer technology (roughly until the early 1990s), the task of mapping election returns remained relatively difficult. This gave academic geographers something of a monopoly on electoral cartography. Work in the 1930s by Wright showed maps of US presidential
ELECTORAL GEOGRAPHIES

elections, with some inferences about the explanation of persistent patterns. The main thrust of such work, however, was the visualization of election results and the identification of spatial patterns. This approach enjoyed a revival in the early 1980s with the work of geographers such as J. Clark Archer and Peter Taylor which emphasized the persistence of regional cleavages in American presidential elections. Indeed, Archer and Fred Shelley coauthored a “Resource Publication” of the Association of American Geographers (Archer and Shelley 1986, 87) that declared: “the task of the political geographer is the identification and interpretation of the sectional manifestations of political issues.”

Even at that time, however, academic geographers were losing their monopoly on electoral mapping, and high-quality electoral maps became common in the popular print media. Although the scholarly works use sophisticated statistical analyses to identify spatial patterns, they remain primarily concerned with where votes are cast. As information and GIS technology improved through the 1990s, it became even easier for media organizations to create maps showing election returns, often in real time. The ubiquitous red–blue map of the 2000 US presidential election cemented this practice.

Moreover, gender – a major determinant of political preference – tends to be spatially uniform and thus invisible to this kind of electoral analysis. With polling and survey data, the influence of these various factors can be assessed directly, so drawing causal inference from spatial patterns becomes a poor alternative. Consequently, scholarly attention to individual causality has shifted largely to the analysis of survey data in political science. Although Ron Johnston and his collaborators use polling data extensively for electoral analyses, the practice is limited among other electoral geographers.

Moving beyond the compositional effects shown by the geography of voting has been one of the major challenges for electoral geography. As Agnew wrote, “‘Mapping politics’ can offer more than cartographic illustrations that decorate more compelling aspatial accounts of electoral geography, but only if we work harder at understanding the roles of context and showing in what ways it counts” (1996, 144).

Geographic influences on voting

A second major theme in electoral geography is geographic influences on voting. Interest in this issue appears in the earliest works in electoral geography: What causes people to vote differently in different areas? As geography embraced statistical and quantitative techniques in the 1960s, it became possible to answer that question in a more systematic fashion. Johnston (2005, 581) has repeatedly articulated a contemporary version of this question: Do “similar people vote in the same way wherever they live?” Indeed, the question of whether place matters is one of the major points of dispute between political science and political geography (Johnston and Pattie 2006, 40–43). Political scientists such as Gary King argue that political behavior and
preference can be explained by purely individual factors, and that unexplained spatial variation is merely the consequence of imperfect knowledge about individual voters, that is, compositional effects. John Agnew (1996), Charles Pattie and Ron Johnston (2000) – the latter two typically working together – have carried on a spirited debate with this position, arguing for the contextual approach and for the existence of the neighborhood effect.

The contextual perspective asserts that an individual’s political preferences and behavior cannot be understood or explained by looking simply at her or his individual characteristics (income, occupation, age, etc.) but depend to some degree on place and location. For example, early work – ironically by political scientist V.O. Key – found that support for candidates was relatively greater in areas close to the candidate’s homes, an approach and finding that is still replicated in contemporary geography.

Contextual effects go beyond mere distance, however. Johnston and Pattie (2006, 44) identify at least eight scales (from the household to neighborhood to country) that may constitute the place of an individual and that can influence his or her vote. One can imagine, for example, that a booming economy may encourage a favorable view of the incumbent party among voters in general, but may have little effect if one’s spouse is recently unemployed. Most commonly, however, contextual effects are investigated at the neighborhood scale, hence the so-called neighborhood effect. Such an effect can result in greater homogeneity through person-to-person interaction, the adoption of common role models, and the influence of institutions (common schools, churches, etc.) Work by other scholars shows, for example, that the turnout of minority groups increases as the proportion and absolute number of minorities in the neighborhood increases. Alternatively, residents of a neighborhood may compete with each other for resources, or may judge their interests and status relative to their immediate neighbors. These latter two may produce greater heterogeneity of preferences than otherwise expected. Pattie and Johnston (2000) use data from the 1992 British Election Study (BES) to show that voters who spoke together tended to change their party preferences to match each other. Such face-to-face conversations are a consequence of living in the same area, and cannot be reduced to individual-level characteristics. At the same time, the effect of such information sharing has not always been shown to be significant, so the relative importance of the neighborhood effect remains an active area of research.

Beyond face-to-face interactions, political geographers have generally focused on political party activities as a contextual force. In his study of Italian elections, for example, Agnew (1996, 139) identifies two contextual effects that are closely tied to party activity and presence. First, the slate of parties may not be the same in every constituency, so that voters in different areas “consider the political options and what they mean in different ways.” Second, parties may have a more or less effective presence in different areas, with some having “familiar faces to present, congenial stories to tell, and the means to communicate them both” where others do not.

In a slightly different fashion, spatial analyses of campaign spending also reflect the position that location makes a difference in political preference. The mechanism in this case is slightly different. Political parties may invest resources in particular areas, building the kind of long-term presence that may produce local exceptions to national patterns. In electoral systems that use territorial constituencies, such as Canada, the United Kingdom, and the United States, parties typically vary campaign spending between constituencies. As Pattie and Johnston have
ELECTORAL GEOGRAPHIES

shown in the United Kingdom, parties typically maximize expenditures in their most competitive constituencies, where their candidate has a relatively even chance of winning or losing. Parties can thus create spatial variation through both long- and short-term activities.

With only a few exceptions, electoral geography has focused on election and referenda analysis, and have not pursued Wright’s investigation of legislative (roll-call) votes. This is unfortunate because such analyses can reveal the dynamics of the relationship between representatives and their constituents in a geographically sensitive manner.

The geography of representation

The third major area of electoral geography concerns the analysis of electoral systems. The preponderance of this research concerns so-called first past the post (FPTP) or plurality systems using territorial constituencies. Typically in such systems, two or more candidates compete for a single seat, and the voting constituency is a contiguous geographic area (“districts” in the United States, “ridings” in Canada, and simply “constituencies” in the United Kingdom). The candidate who obtains a plurality or majority of votes wins the seat. Outside the Anglo-American core, however, proportional representation (PR) is far more common. In PR systems, an elector casts a vote for a party rather than a candidate, and parties obtain seats (more or less) in proportion to the number of votes they receive.

The reasons for the focus on plurality systems are, arguably, twofold. First, the constituency system provides data that easily demonstrate spatial variation. The more than 300 ridings of the Canadian Commons, the 435 Congressional districts of the US House, or the 650 seats of the British House of Commons, for example, all provide scholars with multiple simultaneous elections with thousands of candidates, multiple parties, and a wide variety of socioeconomic and geographic contexts. Modern computer and GIS (geographic information system) technology has increased the availability and detail of such data to an extraordinary degree; in Quebec, for example, election results are available for over 20,000 geographically defined precincts. These data not only lend themselves easily to spatial analysis, but election outcomes in FPTP systems are highly dependent on the geographic distribution of the vote.

Second, Anglo-American geographers tend to live in states that use plurality systems. To the extent that scholarly interest and research funding stay close to home, the focus on such systems is hardly surprising. Indeed, Ronald Johnston and his collaborators are so dominant that their analyses of the British system constitute a plurality of publications in the subfield. Nonetheless, the collection edited by Warf and Leib (2011) includes case studies from Europe and Asia in addition to those of the United Kingdom and the United States. There is also periodic attention to historical cases, and to elections in former communist states.

Unlike PR systems, FPTP elections rarely result in proportionality, and the relationship between the proportion of seats won and votes received is called the seat–vote ratio. Table 1, showing the results of the 2011 Canadian federal election and the distribution of the 308 Common seats between five parties, illustrates this phenomenon. In the 2011 election, for each 1% of the popular vote, the Conservative Party obtained 1.4% of seats in the Commons, whereas the Liberal Party obtained only 0.6% of the seats for each 1% of the popular vote. While such results may be counterintuitive, they are easily explained by the nature of plurality systems. Candidates compete in separate constituencies,

and in principle only need to win by a single vote. If a party’s candidates, for example, come in second place in all districts, the party will not win a single seat even if they obtain a significant fraction of the vote. More generally, FPTP systems can generate a large number of “wasted votes,” votes cast for losing candidates.

Seat–vote ratios are dependent on both the boundaries of constituencies and the geographic pattern of the vote in each election. For example, in the 2008 Canadian federal election, run with the same district boundaries, the Bloc Québécois enjoyed a seat–vote ratio of 1 : 6. In general terms, such plurality systems penalize parties whose support is spread relatively evenly, unless it is high enough to constitute a plurality in many districts (as was the case with the Conservatives in 2011). These systems can provide opportunities, however, for parties or minority groups that have significant geographic concentrations and that form local pluralities in one or more districts (as was the case with the Bloc Québécois in 2008).

From a party’s perspective, the ideal set of constituencies is one that produces the most efficient distribution of their supporters, one that results in the fewest wasted votes for their candidates. In theory, the most efficient distribution of votes is one where a party wins each victory by one vote, and thereby maximizes its seat–vote ratio. In practice, of course, parties do not attempt to cut their margins of victory so thinly.

Redistricting and gerrymandering

Jurisdictions using plurality systems typically redraw their constituencies periodically in the process of redistricting (Morrill 1981). Such exercises are often highly controversial because they provide opportunities for political parties to create gerrymanders. While there is no single measure of what constitutes gerrymandering, it is generally understood to mean the configuration of election districts that confers an unfair advantage (or disadvantage) to a political party or minority group. Although proportionality is an attractive baseline for measuring gerrymandering, the seat–vote ratios inherent in plurality systems mean that even districting plans created through a nonpartisan process will typically produce nonproportional election results. The determination of what constitutes an “unfair” advantage (or disadvantage) is ultimately a political decision rather than a scientific one.

There are three principal techniques of gerrymandering. The first is malapportionment, or the unequal distribution of electors between constituencies. While the “rotten borough” (a highly underpopulated constituency)
was a long-standing British tradition, most states now limit the degree of population deviation they permit between constituencies. The United States has among the strictest standards, which in practice require the equal distribution of population between congressional districts within a particular state. Canada, in contrast, permits up to ±25% population deviation between ridings within a province as a matter of routine. One consequence is heavily populated urban ridings in Canada that dilute the voting strength of visible minorities as well as of city dwellers more generally. Like most federal states, however, the distribution of seats between provinces and states means that some degree of malapportionment is unavoidable.

Second, if a group is relatively small compared to the size of constituencies, it can be split between two or more districts. Such “cracking” works by lowering the number of a political or ethnic minority in a district below plurality, ensuring that they can never elect a representative of their choice.

Finally, if a minority group is too large to be split effectively between districts, it may be “packed” into one district to create a supermajority and thereby waste as many votes as possible. Methodologically and legally, the evaluation of packing can be difficult. The difference between a packed district and one with a “safe” majority is blurred, and depends on many factors, including the volatility of the electorate, turnout, citizenship rates, and population movement. Ethnicity and party may also intersect. In the United States, a district with a bare majority of African Americans may have a large Democratic majority; it would be competitive in racial terms but packed from a partisan perspective.

Jurisdictions have grappled with the partisan nature of redistricting in various ways. Canada and the United Kingdom, for example, use arm’s length boundary commissions in redistricting. Even such commissions, however, may be susceptible to partisan influence. In contrast, the redistricting process in the United States is typically under the jurisdiction of legislatures and thus tends to be a highly partisan affair. The actions of legislatures are limited through the legal system, and litigation is a normal step in the US redistricting process. For example, 31 of the 50 states had their redistricting plans challenged in court by the end of 2011 during that round of redistricting. Consequently, the electoral geography of redistricting in the United States tends to engage closely with constitutional law. In such studies, the primary questions concern not whether a districting plan is biased, but how the court system judges the plan in constitutional terms.

The centrality of racial conflict to the politics of representation also makes the study of redistricting in the United States distinct from other jurisdictions. Elsewhere gerrymandering and bias are typically discussed only in terms of political parties, but in the United States the representation of racial minorities, particularly African Americans and Latinos, is of at least equal concern.

Elite labor

Sarah Hall
University of Nottingham, UK

Elite labor emerged as a central component of the global economy following the deindustrialization and resulting tertiarization of the economies of Western Europe and North America from the 1970s onwards. Following the decline in the relative contribution of the manufacturing sector to the gross domestic product of these economies, a range of business services became increasingly important including both knowledge-intensive advanced producer services (such as finance, legal services, accountancy, and management consultancy) and creative industries (such as design, architecture, and advertising). For all of these services the knowledge and expertise of their employees represent the central “raw material” of such activities; these individuals collectively make up elite labor. As such, elite labor is typified by a high skills base that combines holding highly valued academic credentials (often at graduate level including masters and PhD degrees) with an appreciation of the taken-for-granted norms and cultures associated with each sector.

Given the close relationship between elite labor and the rise of advanced producer service firms and activities within the creative industries, early work within economic geography and cognate social sciences focused on examining it as a factor of production within these firms. Scholars emphasized how the nature of the knowledge embodied within elite labor shaped the organizational and geographical operations of these firms, particularly as they expanded their operations internationally. More recent work has developed this approach by focusing more explicitly on elite labor itself. This work has examined the operation of elite labor markets including their gendered nature, the role of corporeal mobility within them, and their geographies in terms of the dynamic relationship between different global cities in which these labor markets are concentrated.

Within this increasingly broad literature, it is important to note that the definition of elite labor itself is not widely agreed upon. These definitional issues stem, at least in part, from the genealogy of studies of elites and elite labor themselves. Most notably, the development of work on elites is characterized by its episodic advancement. For example, central social theorists of the nineteenth century such as Karl Marx positioned the ruling classes at the center of their analyses of the development of economic life. However, this interest in the power of elites diminished in the twentieth century. Moreover, those theorists who continued to work on powerful elites, notably Pierre Bourdieu, moved away from a focus on economic elites and elite labor to foster an interest in cultural elites, including academics and civil servants. More recent work, such as that by the sociologists Manuel Castells and Leslie Sklair, has understood elites through the lens of globalization, but has said comparatively little about the microsociological practices of elite labor and its wider socioeconomic implications. The result is a disparate literature on elites and elite labor with some work emphasizing their control over (economic) resources at the expense of other groups from a predominately Marxist perspective, while
other work adopts a more cultural and socially inflected account to examine how elites seek to reproduce their powerful position in society. This diversity in understandings of what elites are is reflected in the development of geographical literature on elite labor. However, while the theoretical standpoints of work on elites remain varied, the field can be characterized by a concern with understanding the ways in which elite labor emerges as powerful through its control of resources (be that economic, cultural, or financial), based significantly on their knowledge and expertise in the contemporary global economy.

Elite labor and service firms

In contrast to the manufacturing sectors in which the raw materials of production include not only the skills of workers employed within them but also material elements involved in activities such as car assembly, advanced service sector firms and the creative industries are characterized by the fact that the knowledge and expertise of individuals working within them are their central raw materials. For example, in corporate legal services, solicitors in law firms are expected to tailor their knowledge of the law of the jurisdiction in which they are operating when offering advice, often drawing on their previous working experience and their knowledge of the corporate culture of the firm in which they work. Reflecting this understanding of the centrality of the knowledge of individuals to the operations of their employing firms, early work on elite labor conceptualized it as a central factor of production for these firms that had important implications for understanding the geography of these sectors.

This literature specifies the different types of knowledge provided by elite labor to these firms. A key distinction is made between tacit and explicit knowledge. Drawing on the work of Polanyi (1944), tacit knowledge refers to embodied knowledge acquired through experience, while explicit knowledge is the formal knowledge that is widely agreed upon within any given sector (such as particular approaches to corporate valuation within financial services that are learnt through standard university courses and widely described in key textbooks). While both forms of knowledge are central to elite labor within highly skilled service sectors, tacit knowledge is seen as being particularly important. The cultural sensitivities and expertise derived from previous working experience that are central to the formation of tacit knowledge are seen as being particularly valuable in differentiating between different firms that are competing within any given sector.

The significance of varying types of knowledge within highly skilled service sectors has given rise to considerable debate concerning the different geographies associated with these different types of knowledge and the implications of this for the locational decision-making of firms. Building on the seminal contribution of Gertler (2003), scholars initially emphasized the need for material geographical proximity in order to share the tacit knowledge that was vital for corporate success through face-to-face interaction between individuals within elite labor markets. In this work, it is argued that shared cultural norms are needed to develop the trust-based interpersonal networks through which tacit knowledge can circulate. The geography of tacit knowledge embodied within elite labor thus gives rise to the geographical colocation of similar knowledge in highly skilled services. Examples include the cluster of high-tech firms in Silicon Valley in California, financial services complexes in financial districts such as Wall Street in New York and the City of London, and the media cluster in Leipzig.
However, following work on communities of practice (Amin and Cohendet 2004), scholars have subsequently examined the ways in which different forms of relational proximity can exist in which individuals may be geographically distant but relationally proximate through shared experience of, for example, working on the same projects for short but intense periods of time or through being embedded in the same corporate culture while working in different geographical locations (Amin and Cohendet 2004). This work has suggested that, using these relational proximities, tacit knowledge may be shared between individuals who are geographically disparate. This approach has led to a greater emphasis on conceptualizing elite labor and the firms in which it operates as forms of relational networks that cross-cut geographical space but are grounded in particular places at particular times (see for example Faulconbridge 2006). It has also facilitated a greater emphasis on the nature of elite labor in and of itself and elite labor markets more generally rather than placing elite labor as a factor of production within wider work on the geographies of advanced producer service firms and creative economy.

Elite labor and elite labor markets

The growing interest in elite labor and elite labor markets reflects the ways in which elites have become the source of considerable political, popular, and media attention following their central role in choreographing the financialized boom of the 2000s and the ensuing global financial crisis and recession. The centrality of elites to these significant economic changes has been reflected in a resurgence of work on elites within the social sciences (Savage and Williams 2008) that has sought to move beyond an emphasis on the formation of elites based on their educational and social background to include analysis of their practices and the ways in which these have been used to shape the global economy in particular ways. In so doing, this work includes analyses of the operation of elite labor markets and the implications of these for individuals within them.

The most notable feature of elite labor markets has been their dramatic expansion in recent years in light of the expansion of advanced producer services and the creative economy. As a result, traditional recruitment methods based around educational background at a limited number of exclusive schools and universities (see Bourdieu 1996) are no longer able to meet the demand for elite work. While recruitment has expanded, research demonstrates that entry into these labor markets remains very competitive. In response, individuals seeking to work in elite labor markets adopt a number of strategies in order to secure themselves positional advantage in relation to other potential new recruits in an attempt to mark themselves out as distinctive, and hence potentially valuable to employing firms. Strategies adopted in this respect include not relying solely on a first or undergraduate degree but also developing an extensive portfolio of work experience in their chosen field or undertaking an international degree program that they feel will have a scarcity value in the labor market, as well as carefully selecting the university and degree program they undertake. Research into these activities demonstrates how individuals seek to strategically accumulate credentials and work experience in order to secure entry into competitive elite labor markets.

These positional competitions within elite labor markets continue once an individual has secured their first position. At this stage, elite labor markets are often, implicitly at least, framed as global labor markets in which there is a global “war for talent” within so-called knowledge-based economies. At one level, these
ELITE LABOR

discourses suggest that global labor markets offer considerable opportunities for upward mobility of elite labor. For example, work on education and learning within elite labor markets has demonstrated how discourses of knowledge-based economies are used to encourage elite labor to invest in their economic potential and human capital through the continuous acquisition of new skills and credentials. However, Thrift (2005) highlights that this form of what he terms “soft capitalism” has “hard edges” such that not all elites are equally able to benefit from the opportunities within elite labor markets.

In this respect, work in economic geography on segmented labor markets is instructive. Through research largely conducted into the labor market experiences of minority groups, this literature has demonstrated how an individual’s experience of labor markets is shaped by the local contexts in which they operate and an individual’s experiences of them. This work has been usefully developed in order to consider one of the “hard edges” associated with elite labor that focuses on its geography. In much of the popular and academic literature that surrounds elite labor markets, elite labor is positioned as being global in geographical scope, with individuals within this group having the potential to move relatively freely between leading centers of economic activity, particularly global cities. However, by using work on segmented labor markets, it has been shown that elite labor is more geographically nuanced than has often been assumed to be the case. In this work, elite labor is characterized by its trans-local qualities such that while individual elites have the potential to render themselves mobile through migration and expatriation, their working practices are often tailored to the cultural norms and regulatory practices of the specific geographical location in which they work. This can limit their ability to move geographically since such mobility requires an understanding of the different working cultures associated with different geographical locations.

Building on this appreciation of the geographically nuanced nature of elite labor markets, a considerable body of research has emerged that looks at the mobility of elite labor and the implications of this for the nature of elite economic practice in different economic clusters, particularly global cities. Much of this work has documented how migration and expatriation of elite labor from established global cities such as London and New York to emerging centers, particularly in Southeast Asia, are used by firms in knowledge-intensive business services such as finance and law to aid in their internationalization activities by circulating taken-for-granted ways of working as they seek to tailor these on entry to new markets. However, these mobility patterns are becoming more complicated. For example, migration from (rather than to) emerging global cities such as Beijing and Shanghai is becoming increasingly common. These types of mobility will be potentially very significant in the future since they are being used by domestic firms in rapidly growing economies such as China to develop expertise within their own domestic elite labor markets, with implications for elite labor in both advanced and emerging economies. Moreover, the variegated impacts of the 2007–2008 global financial crisis and ensuing recession have created several new important migratory flows of elite labor within Europe and North America, such as the large elite French population living and working in advanced business services in London, partly in response to political changes in France targeting elite labor.

Developing largely in parallel to this work on elite labor mobility, geographers have been at the forefront of work that has revealed the gendered nature of elite labor, in terms of both the composition of elite labor markets and the
embodied performances and workplace practices of elites themselves. This can be viewed as another “hard edge,” in Thrift’s terminology, of elite labor markets. Much of this work builds on McDowell’s (1997) seminal analysis of the nature of gendered elite financial labor in London’s financial district in the 1990s. Here, she revealed that despite claims from employers within elite labor markets that the Americanization of the City of London following the deregulatory changes of the 1980s and the associated increase in the number of overseas firms within London had led to a more meritocratic City, including the greater representation of women within highly skilled financial labor markets, women continued to be underrepresented within financial services work in London. Moreover, elite workers employed within finance undertook a number of gendered performances pointing to the existence of multiple masculinities as well as femininities within these labor markets, ranging from the aggressive, ambitious trader to the “gentlemanly capitalist” of the boardroom. The significance of this work has been underscored by the financial crisis of 2007–2008 about which policymakers and the media argued that the underrepresentation of women with elite labor had contributed to the crisis because of the inherently greater level of risk taking associated with masculine performances in the workplace, claims that have been strongly critiqued for their essentialized understandings of gender by feminist scholars.

Taken together, work on elite labor has advanced considerably in recent years, moving beyond an initial focus on elite labor as a factor of production within knowledge-intensive business services and the creative industries to develop understandings of elite labor markets that have distinctive entry requirements and operate in geographically nuanced and gendered ways. In so doing, this work has demonstrated that understanding elite labor is important in terms of wider discussions about the reproduction of a variegated global economy as the nature of elite labor market practice is shaped by the cultural norms and regulations associated with the local contexts in which it takes place. This work has also drawn on and developed important methodological debates within economic geography and the social sciences because one of the explanations for the comparative neglect of elites in the latter part of the twentieth century has been the argument that securing research access to these groups is difficult, particularly for early career researchers. Moreover, even if access is granted, the power relations involved in elite interviewing are asymmetric, thereby shaping the kinds of knowledge and understanding that are produced. Economic geographers have developed a number of strategies in attempts to overcome this, such as fostering close research collaborations with the economic elites that they are researching. Meanwhile, in the wider social sciences, research into the geographies of money and finance has increasingly relied upon former financiers writing up their own personal accounts of working in the international financial system as a form of research method. While both of these approaches have resulted in rich insights being gained into contemporary economic elites, they also raise important questions concerning the importance of the positionality of the researcher in accounts of elite labor.

The development of work on elite labor in geography and the wider social sciences also has important implications beyond theoretical debates and methodological concerns. In particular, in policy circles, much has been made of the emergence of more meritocratic labor markets that embody the theory of human capital in which individuals progress following investment in their own skills and knowledges, with the onus on individuals increasingly to do this. However,
geographical work has revealed the limitations of this position, with career progression within elite labor markets continuing to be shaped by the geography in which an individual operates and other socioeconomic characteristics, notably gender. In the future, these debates will need to be extended to provide greater understanding of the emergence and development of elite labor in rapidly growing economies, particularly in the Asia-Pacific region and the BRIC economies (Brazil, Russia, India, and China). Indeed, an important part of this work will be not only to understand the emergence of domestic elite labor in these regions but also to analyze the implications of their growth for the more established location of elite work in North America and Western Europe that have been the main geographical focus of attention thus far.

Transnational corporations (TNCs) or multinational enterprises (MNEs) are perhaps the defining institutions of globalized capitalism and have been characterized as “the most significant actors in today’s globalised world” (Rugman and Verbeke 2004, 3). While their emergence is often thought to be a relatively recent phenomenon they have been in existence for centuries. Early examples of these would include the British and Dutch East India companies, which received their charters in 1600 and 1602, respectively.

While Stephen Hymer’s (1976) theory of foreign direct investment (FDI) examined the ways in which these companies were implicated in northern imperialism, more recently there has been a substantial growth of corporations originating in and from the Global South, beginning in the 1970s with those from the newly industrializing countries of Asia, such as Hong Kong (Yeung 1998). Traditionally FDI flows were dominated by north-north and north-south directionality with considerably lower levels of south-south flows, generally involving investment in proximate markets. However, the new millennium, in particular, has been marked by a dramatic increase in both south-south and south-north flows of FDI. Flows from the developing world have been increasing faster than those from the developed world, accounting for an ever-greater proportion of total FDI flows and stocks. For example, in 2012, developing economies generated almost one-third of global FDI outflows, and recent data reveals China to be the third-largest source of outbound foreign direct investment (OFDI) in the world; moving from sixth to third in 2012, behind the United States and Japan. By way of further example, Tata, originally an Indian conglomerate, is now Britain’s largest manufacturing company. Recent decades have also seen the emergence of sovereign wealth funds from the Global South, some of which now also hold substantial investments in northern government bonds and other investment classes. The emergence and expansion of these companies has implications for global development and consequently theories of FDI. For the purposes of this entry, “emerging market” and “southern” are treated as synonymous, although countries in the former category are often held to be more developed than the least developed economies and countries.

The rise of the South?

The emergence of southern corporations is both a driver and reflective of “the Rise of the South” (United Nations Development Programme 2013). In the Forbes Global Fortune 500 index of the biggest companies in the world, 89, mostly state-owned, are now from China. In 2012, of the eight Indian companies that made the list, five were state-owned. The growth of these companies is reflective of both the spatial dialectics of globalization and the “success” of particular state-directed strategies of late-development and the interaction between
EMERGING MARKET: SOUTHERN CORPORATION

them. These dynamics have given rise to some of the largest companies in the world. For example, according to Forbes, the Industrial and Commercial Bank of China is now the world’s largest company.

The growth of emerging market corporations is also both reflective and constitutive of the ongoing rebalancing of the global economy and in particular the shift in its center of gravity from the Global North to the “Global East,” as China is now the world’s second-largest national economy. The Chinese government has a declared “go out” policy for its corporations to encourage them to invest overseas to tap new markets, gain experience of overseas operations, develop scale economies, and access new technologies and other forms of knowledge. As stated by then Premier Wen Jiabao in March 2012: “This year, China will further its strategy of going abroad. The nation is at an important stage of accelerating the steps it has taken to make outbound investments. China will guide all sorts of companies to make orderly investments in the energy, raw materials, agriculture, service and infrastructure industries, using mergers and acquisitions” (quoted in China Daily, March 6, 2012). The economic reform program of the new leadership, announced in 2013, further promoted Chinese outward FDI by again relaxing some of the controls on outbound investment. The “global” financial crisis (GFC) was also seen by some companies as a buying opportunity and, partly as a result, Europe is now the largest regional recipient of Chinese FDI.

The fastest-growing economies in the world have recently been in the developing world. For example, Africa hosted up to seven of the world’s fastest-growing economies in the early years of the new millennium, although given rapid population growth and growing inequality this has not resulted in commensurate increases in per capita income or poverty reduction. Nonetheless, certain companies and conglomerates have been able to take advantage of relatively rapid economic growth to expand their operations. The best known example is perhaps the Dangote Group, headquartered in Nigeria. This is a diversified conglomerate engaging in the production of a range of commodities from cement to food. Whereas Dangote’s operations are regional rather than “global” in scope, some (South) African corporations have established a substantial extra-regional presence, such as Nando’s (fast food) having operations in 30 countries on five continents.

The pattern of regional investment is mirrored in Latin America by the multilatinas, which are corporations which have invested in multiple countries in the region, with the more successful of these expanding globally over the past decade. For example, Vale from Brazil is now one of the world’s largest natural resource corporations, with substantial, and at times controversial, operations in Africa and Canada, where it has been fined for fatal safety breaches.

Manufacturing firms

There is a variety of major transnational manufacturing corporations headquartered in the Global South. Sometimes these are diversified conglomerates, involved in seemingly disparate economic activities. ZTE, for example, a Chinese company best known globally for its operations in mobile telephony, is now a foreign investor in African land.

Examples of southern multinationals acquiring established brands abound, including that of the well-known British breakfast cereal brand Weetabix, now owned by the Chinese company Bright Foods. The bias toward asset exploration (acquiring strategic assets available in a host country) in the developed world on the part
EMERGING MARKET: SOUTHERN CORPORATION

of these emerging MNEs is reflected in the distribution of their investments between acquisitions and greenfield-type investments. During 2000–2013, the value of acquisitions by Chinese firms in the United States to greenfields was over 7:1 (Rhodium Group 2013). Chinese investment into Europe is similarly skewed toward acquisitions, particularly in recent years with distressed European firms representing good buying opportunities. According to Rhodium Group estimates, annual Chinese OFDI flows to Europe grew from less than €1 billion per year from 2004 to 2008 to €1.9 billion in 2009 and €2.7 billion in 2010, almost tripling to €7.6 billion in 2011. In 2012, Chinese firms invested a further €7.8 billion in the European Union, including large-scale acquisitions in utilities (Energias de Portugal), consumer products (Weetabix), industrial machinery (Putzmeister), and infrastructure (Heathrow Airport) (Rhodium Group 2013).

Agro-conglomerates

Agro-conglomerates from developing countries have now also become major investors in parts of the Global South. For example Karuturi Global, an Indian company, is now the largest producer of cut roses in the world, exporting 1.5 million stems a day to Europe from Kenya alone. With the global food price spikes of 2007–2008 and 2011, Indian corporations and the government have also been active in sourcing land in Africa to grow food crops to export back to India and to sell on international markets.

Service providers

While many southern corporations are now transnational in scope, home country advantages may remain important for their operations. For example, Infosys in India is one of the world’s largest providers of “back office” functions to transnational corporations. This company is able to leverage its international connections and the low labor costs and relevant English speaking skills of the Indian workforce to grow domestically, while also expanding internationally.

Generally, growing domestic markets, fueled by global resource demand, particularly from China, have also enabled the development and expansion of other service providers in parts of the Global South. For example, Ecobank is a pan-African banking conglomerate with operations in 33 countries on the continent and in a further four countries overseas. This bank is of particular interest not only for the scale of its operations but because it was founded on the basis of a joint initiative between the Federation of West African Chambers of Commerce and Industry and the Economic Community of West African States.

Sovereign wealth funds

Kuwait was the first country to establish a sovereign wealth fund, in 1953. Sovereign wealth funds take assets, typically from natural resources, and then invest them in other asset classes in order to secure “permanent income” from other sources once natural resource reserves run out (Collier 2010). A number of oil-rich states in Africa, such as Ghana and Chad, and some oil-rich Gulf states have followed the Kuwaiti example and established sovereign wealth funds in recent years. China also has over 3 trillion dollars in foreign exchange reserves, some of which are invested overseas and domestically through the China Investment Corporation. In some instances sovereign wealth funds serve as
EMERGING MARKET: SOUTHERN CORPORATION

holding companies. For example, Emirates, the largest airline in the Middle East, is owned by the government of Dubai through its sovereign wealth fund.

State-owned enterprises and natural resource companies

As noted earlier, while it is often thought that globalization is a private sector-led phenomenon, some of the largest southern corporations, from China in particular, are wholly or partially state-owned. Despite a general tendency of neoliberalization in the Global South over the last number of decades, southern states often maintain a direct presence, interest, or ownership in and of their energy sectors given their strategic importance. Strategies to ensure energy security have ranged from investment in overseas resources to the development of new domestic resources. For example, as a result of production by companies such as Copersucar, Brazil is now the second-largest producer of ethanol globally, behind the United States.

In the third world, emerging market corporations are increasingly being used to source critical or strategic natural resources to fuel national economic growth and meet security concerns in the context of growing ecological scarcity. Thus, depending on the sector in which they are involved, and whether this is deemed important to national and economic security, and whether or not they are state-owned, emerging market corporations may receive different levels of encouragement and support from home country governments. The three biggest oil companies in the world in terms of reserves are not well known “supermajors,” such as Exxon Mobil, but state-owned companies from Saudi Arabia, Russia, and Iran.

Are southern multinationals different?

Whereas extant theories of FDI examined the reasons why developed country TNCs might establish operations in the Global South, such as labor cost differentials, flows of foreign investment from developing to developed countries follow a different logic in a number of respects. Traditional theories of the internationalization of the firm suggest a gradual, incremental process starting with geographically (and perhaps culturally) close host countries before advancing to more distant locations (Buckley and Ghauri 1999). Yet emerging market or southern multinationals have tended to expand geographically at a much faster rate than extant northern corporations, often entering into distant markets in the early stages of their internationalization. One of the most prominent motivations of southern corporations to invest in northern markets is often brand acquisition, although in some cases they also succeed in establishing their own brand identity in those countries, as in the case of Nando’s discussed above. Also, while northern investing firms tended to engage more in asset exploitation (the transfer of a firm’s proprietary assets to overseas operations), the newcomers have been observed to be engaging more in asset exploration. This helps to explain why these firms move to, or establish operations in, high (labor)-cost locations in the developed world. By seeking to take advantage of knowledge in the new recipient country locations, acquire advanced technologies, and buy established brands, they aim to leapfrog ahead in their development, thereby avoiding the normally lengthy process of generating knowledge, developing new technologies, and establishing brand names. The Chinese computer company Lenovo’s acquisition of IBM PC is one early notable example of such an acquisition.
The case of Chinese MNEs and their investment strategy deserves special attention for a number of reasons (Brennan 2011). First, there is the primacy attached to the goal of facilitating China’s next stage of domestic economic development in relation to Chinese OFDI. Second, there is the degree to which China’s MNEs remain deeply embedded in China’s cadre capitalism. The Chinese model of OFDI is different from that of other countries, with 93% of Chinese investment in Europe now coming from state-owned corporations, for example. This represents a new model of globalization in contradistinction to the private sector-led one of western corporations. As China liberalizes its economy domestically, the power of the Chinese state is growing overseas through this and a number of other channels, throwing into question the ontological distinction between “states” and “corporations” as separate social forces in this instance. Thus, rather than globalization reducing the power of the Chinese state, it is respatializing it (Carmody, Hampwaye, and Sakala 2012). The growing significance of this trend has been underlined: “In no dimension of China’s economic engagement internationally is the interaction between the economic and political systems more prominent and important than in respect of the surge in China’s overseas direct investment (ODI)” (East Asia Forum Weekly Digest, April 2, 2012).

Third, there is a contrast between OFDI on the part of Chinese MNEs and some of the established theories. State-owned corporations are run differently, respond to strategic state imperatives, and have longer-term time horizons than the quarterly stock market returns that drive publicly listed corporations. Particularly as they may be able to access substantial foreign exchange reserves, this means that they can sometimes deploy countercyclical strategies. For example, when the price of copper collapsed in the wake of the GFC, and many western and other companies consequently were divesting from copper production in Zambia, Africa’s second largest producer, some Chinese companies took advantage of falling asset prices to buy out previous incumbents.

Given the sensitivity of some sectors in host economies, these corporations sometimes become embroiled in geopolitics, as when the US Congress voted 398–15 against the Chinese National Overseas Oil Corporation’s acquisition of a US oil company in 2005. This resistance is sometimes cited as one of the reasons for the rapid expansion of Chinese oil companies in Africa. While Europe’s receptivity to nontraditional sources of investment has been varied and fragmented, the Eurozone crisis resulted in a greater receptivity to such investment on the part of those actors who were previously apprehensive about southern MNEs (Brennan and Kim 2013).

Sovereign wealth funds from the South have sometimes raised concerns among policymakers and market players in the developed world. These stem from the dominant role played by national governments in the management of these large funds and from a lack of transparency and accountability arising from this. These concerns have led to the promulgation of the Santiago Principles, voluntary “best practices” for sovereign wealth funds, from an International Working Group established by the International Monetary Fund, representing 26 countries.

The future of southern multinationals

It can be anticipated that southern multinationals will be an increasing presence on the global landscape. Their early and rapid expansion into developed markets poses challenges for both the new entrants themselves and for incumbents. Perhaps the greatest challenge for the new
EMERGING MARKET: SOUTHERN CORPORATION

entrants is learning to operate in environments that are culturally and institutionally distant from their home environments. This is critical for such firms if they are to overcome the “liability of origin” and gain greater legitimacy in the developed world (Brennan and Kim, 2013). For host countries the challenge will be to ensure that investment by southern multinationals brings benefits by contributing to growth and employment.

Emotional geographies

Deborah Thien
California State University, Long Beach, USA

The field of emotional geographies comprises interdisciplinary scholarship focused on theoretical and substantive considerations of emotion, space, and society. Major influences on this work include feminist scholarship, humanistic and phenomenological approaches, health and wellbeing literatures, and the spatial turn in cultural theory. The resulting scholarship on the spatialities and socialities of emotion, affect, and feeling has emerged from diverse disciplinary perspectives both within geography (from feminist, health, social, cultural, critical race, and other geographies) and without, including long-established work in sociology, psychology, philosophy, and psychotherapy, as well as examinations from economics, neuroscience, literature, and political ecology, among others. These collective and diverse considerations have contributed to an “emotional turn” in geography.

Thinking about feeling

Emotion encompasses mental and corporeal, social and cultural, and spatial and historical elements. Scholars have sought to define, delineate, understand, and contest the specifics of each of these elements as well as their intersections and interactions. Socially and culturally inclined definitions of emotion regard it as a dynamic process, subject to shifting relations of power and to dominant views of emotion in any particular time or space. Emotion, then, can be understood as the continual taking place of dynamic, felt relations between bodies, happenings, spaces, and things. Bondi, Davidson, and Smith (2005, 1) emphasize the importance of “a non-objectifying view of emotions as relational flows, fluxes or currents, in-between people and places rather than ‘things’ or ‘objects’ to be studied or measured.” Such understandings of how the world is mediated by feeling attempt to make sense of emotion as a way of being, knowing, and doing in the world. Relational models of emotion incorporate both embodied and psychological dimensions. Such definitions, which build on the relations of body and mind and their attendant, shifting, and power-laden spatialities, are indicative of contemporary thinking about emotion and stand in contrast to those shaped by Descartes’s seventeenth–century theorizing of a mind–body separation.

Within the Cartesian framework, emotion is defined predominantly by its otherness from reason. Examples abound which suggest the disordered nature of emotion: “boundless grief,” “wild with anger,” “uncontrollable fury,” and “overjoyed.” Scientific inquiry has distinguished itself epistemologically in the practices of rationality, intellectual rigor, and (self-)discipline; in this tradition, science as a set of laws dispenses with that which oversteps the bounds. This binary is further cemented through emotion’s association with the body, in opposition to the reasoning mind. To be emotional in these terms is to be thought-less. Discursively and in practical terms, the power of reason has been a wide-ranging masculine domain, while women have represented, and have been represented by, the intimate messiness of the body and its feeling states (Harding and Pribram 2002).
EMOTIONAL GEOGRAPHIES

A consequence is that knowledge itself has been positioned as a desired/desiring masculine property, while emotion has been categorically restricted to the spaces of the personal. Another consequence of these authoritative discourses has been to make the study of emotion oxymoronic: it is seen as unreasonable and at odds with scientific objectivity. Scholarship around emotion can be read, therefore, for reiterations of power inequalities in the production of knowledge. Feminist scholarship has issued an important challenge to these Enlightenment binaries and has asserted new perspectives on emotion.

Feminist perspectives and influences on studies of emotion

The increasing legitimacy of emotion as an area for scholarship is often attributed to feminist critiques of masculinist scientific paradigms; in particular, feminists have challenged the legitimacy of binary oppositions, claims of objectivity, and the disembodiment of knowledge. The feminist deconstruction of binary oppositions has allowed for understanding the reason–emotion opposition as both an influential construct and a false divide. Emotion yoked to reason is no longer simply a feminized negative to masculinist rationality; rationality itself is reread as infused with emotionality. For example, the amplified dialogue about emotion within academia serves to counter the cool spaces of the neoliberal university in which students are positioned as rational consumers and instructional staff as dispassionate suppliers of goods and services. Emotions have been both feminized and privatized within contemporary academies, serving to contain emotions (Harding and Pribram 2002). Safely contained, emotions can be set aside while the “real” academic labor goes on. Paradoxically, emotion is figured as out of control and yet is tightly controlled.

Feminist scholars have contested masculinist claims of objectivity by arguing for the tentative, partial, and situated nature of knowledge. In contrast to the expert account that claims value-free results, many feminist social scientists have championed the use of reflexivity, an explicit practice of situating knowledge by openly acknowledging the place of the researcher in a given research context. Many feminist and geographic scholars have been inspired by Donna Haraway, who argues for “the view from a body, always a complex, contradictory, structuring, and structured body, versus the view from above, from nowhere, from simplicity” (1988, 589). Many scholars have read this as an invitation to write in the first person, which serves to highlight the ways in which knowledge is always embodied, always situated, and, indeed, always emotional. This practice has both personalized and politicized scholarship in complicated ways and has engendered its own feminist critique (Rose 1993). While the term “emotional geographies” is not synonymous with feminist or geographic research, there is a distinct vein of emotional geographies work that is influenced by feminist theory and practice and that prioritizes the embodied, relational, and placed experiences of emotion.

Feminist versions of emotional geographies scholarship acknowledge and address the uneven terrain of embodied spatial experience, that is, they understand emotion as embodied, not in universal or even readily recognized ways, but rather as always intermeshed with bodies and places and not in neutral ways. Matters of difference are thus vital to consider. Looking closely at embodied, emplaced emotional experience encourages thinking through not just what binds or sticks people together in and through place, but also how emotional disarticulations and disconnections can tell us something about one’s place (or lack of place) in wider networks and
how dominant emotional geographies shape social, cultural, and economic practices.

These relational and politically charged understandings of emotional geographies have implications for further study. For example, nonhegemonic emotional geographies can be explored, including indigenous geographies, which incorporate the effects and affects of colonial contexts and the associated power dynamics, as well as making space for non-dominant emotional expression. In this sense, acknowledging the place of emotion can be a progressive and political act.

**Emotion and affect**

A key debate that characterized early discussions of emotional geographies revolved around the terms “emotion,” “affect,” and their respective positionings with the field (Anderson and Harrison 2006). In broad strokes, those claiming emotional geographies tended to focus on issues such as relationality, subjectivity, and embodiment from a distinctly feminist stance. This typically feminist scholarship has sought to consider how feeling mediates experiences, to challenge the perception that emotion is “out of place” in scholarship, and to argue for an understanding of emotion and place as mutually constitutive and differentially felt. Those exploring affect have drawn inspiration from nonrepresentational theory (Thrift 2004), a post-structuralist approach that encourages scholars to focus on the practice and embodiment of knowledge. Feminist critiques of this work have noted a masculinist foregrounding of the body, one that is apolitical and universal. In her critique of geography’s humanistic history, Gillian Rose (1993, 11) described claims such as “aesthetic masculinity,” which “establishes its power through claiming a heightened sensitivity to human experience.”

This debate continues to be referenced, but typically now in the service of advancing conversations that move beyond the past divide, whether staking space for “more-than-representational” (Lorimer 2008) geographies, or actively reflecting on the differences and the similarities of these approaches and exploring the political implications for the study of emotion. Pile (2010), for example, has drawn on psychoanalytic geography as a way to combine the examination of emotions in emotional geographies and the consideration of affect in affectual geographies.

**Empirical dimensions: the health and wellbeing example**

Studies of emotion, space, and society have produced not only theorizations of affect, emotion, and feeling but also numerous empirical (typically qualitative) investigations that focus on the embodied, relational, and placed experiences of emotion. One substantial area of this work investigates issues of health and wellbeing, from an ethics of care to therapeutic landscapes. For example, scholarship on homelessness as a felt experience has sought to render the emotional valences and “woundedness” of chronic homelessness. Geographers working at the intersections of gender, health, and emotion have offered empirical explorations of agoraphobia, delusion, post-traumatic stress disorder, and HIV-AIDS.

Emotional geographies scholarship offers major contributions toward research at the intersections of gendered realities, the specifics of place, and the diversities of health experiences. First, the emphasis on the placed and embodied nature of emotion works to interrupt a neoliberal representation of a health consumer who is in command of not only (his) health and wellbeing but also (his) wallet. Instead of depicting health
EMOTIONAL GEOGRAPHIES

and wellbeing as a series of self-evident decisions made by a rational, autonomous, and economically empowered actor, particular and diverse health circumstances can be analyzed as subjected to and by social, cultural, political, and economic conditions, such as occupational segregation by gender, made manifest in localized bodies, such as the lone woman in a boardroom. Second, emotional geographies research offers a critique of emotion as the simple and feminized opposite to masculinized reason, and this critique has led to a further challenging of the emotional and gendered character of the spaces and subjects associated with health and wellbeing. For example, a nurse is readily identified as a female because of women’s assumed nurturing and empathic qualities; however, the loving care expected of nurses is complicated by the biomedical training they receive, by the bodies nurses inhabit, and by the dominantly masculinist spaces of medical facilities where cure is prioritized over care. An emotional geographies perspective encourages attention to these complexities and leads to valuable insights into the geographies of gender and health (Thien 2014).

Current and future emphases: emotion matters

In examining the academic landscape over the past decade, a clear progression of interest in and legitimacy of all things emotional can be readily identified. From geography, two edited collections have been produced (Davidson, Smith, and Bondi 2005; Smith et al. 2009). Emotional geographies conferences have been staged in the United Kingdom, Canada, Australia, and the Netherlands, with international attendance. The journal Emotion, Space and Society has shaped a dedicated and interdisciplinary space for this scholarship. Emotion, Space and Society went to press in 2008, and as of early 2015 has published close to 400 research articles. Special issues in the journal have ranged widely and include some of the following topics and themes: transnational migration; affective ontologies; activism and emotional sustainability; intimacy and embodiment; researcher trauma; ecology and emotion; geographies of trauma; gendered spaces; researching intimate spaces; emotions and motivations; urbanity and fear; children; movement; sound; feeling differently; practicing emotional geographies; scales of belonging; emotional and affective methodologies; touch; and emotional geographies of education. As these themes and topics suggest, the journal has been distinctly interdisciplinary, reflecting the breadth of the field.

Evolving and ongoing work in the areas of racialization, migration studies, sexualities, participatory geographies, geographic information systems (GIS), and sensory dimensions suggests rich future studies, both empirically and theoretically. Considerations of the emotional health of the academy (professors, students, and so on) are also underway. Methodologically, there is increasing attention to innovative ways of answering questions of emotion and affect.

Emotional labor

Joanne Entwistle
King’s College London, UK

Emotional labor is a concept used to describe the requirement that workers manage their emotions in face-to-face interactions at work. It is a form of labor that is critical to many occupations and professions in the health and service sectors and has been a critical concept within geography. Indeed, feminist geographers have been key in developing the concept and extending its application. The significance of emotional labor was first detected in developed economies in the North and West with restructuring away from manufacturing toward service sector jobs. This service economy is now global, and thus emotional labor is no longer seen as the preserve of Western economies. Emotional labor is different from emotion work; it refers to the overt management of emotions under conditions of marketization. It is labor required of many workers in the labor market that employers seek to harness and control as part of the overall “impression management” of their service or brand, and may be scripted (as in a call center, for example) or highly regulated and monitored (as in many hospitality environments). Feminist geographers have for many years addressed the changing nature of paid employment, and noted the increasing forms of new service work provided in private homes (McDowell 2009). Much of this work in the private spaces of the home is performed for “love” by relatives, as McDowell (2009) notes, though it may also be commodified as low-paid “caring” work. Further, some of this less formally regulated work falls into the category of sex work performed by strippers, prostitutes, and masseurs, which similarly demands emotional labor. What all this work shares is a concern to manage the emotions, though it may entail forms of emotional labor that are less scripted than in the corporate office or hotel (Brewis and Linstead 2000; Wolkowitz et al. 2013).

Arlie Hochschild’s (1983) study of air stewards in *The Managed Heart* has been particularly influential in proposing the importance of emotional labor and defining its characteristics. The bodily countenance of workers – their emotional labor – is often an essential aspect of that service; it is utilized by companies to gain competitive advantage and frequently features as part of their marketing and advertising (“service with a smile”). Emotional labor can take two forms, with different microgeographies: it can be performed as a form of “surface acting,” when emotions are displayed on the surface of the body (e.g., through a smile, kindly expression, soft voice) without being felt by the worker. Alternatively, laborers may have to work on their inner emotions to produce the desired surface and make it look authentic, through the suppression of unwanted emotion or the manufacture of the desired emotion. There is a gendered dimension to this emotional labor, with the particular requirements of the performance dependent on whether the emotional labor is performed by a man or a woman. Since much service work (though not all) is female-dominated, the emotional labor required is based on normative gendered expectations as to appropriate feminine appearance (Mears and Finlay 2005; Tyler 2009). Complex geographies of racial identity come into play as well.
EMOTIONAL LABOR

While this emotional labor enables companies to do their business more successfully and to gain competitive advantage, it may take its toll on the individual. The labor of emotional labor comes from the effort required by workers to work on, and contain, their emotions. It colonizes the inner life of the worker, who may experience a dissonance between outward expression and inner emotional life that can cause them to feel alienated from their own labor. This alienation is not unlike that which Marx describes in relation to nineteenth-century laborers, except that it takes the form of alienation from emotions generated at work.

Relations of emotional labor are ever more spatially complex under conditions of contemporary capitalism, in which increasing globalization has led many service sector employers to move their services to developing countries. This introduces different demands on workers who are located far from their clients/customers, as in the case of call center workers in India, who have to be English or American at night and Indian by day to accommodate a North–South geo-timescale (Bryson 2007). Moreover, complex patterns of migration and displacement have occurred in the domestic labor markets which mean that many domestic workers have to do emotional labor while simultaneously distanced from loved ones at home (Yeoh and Huang 1998). These complex geographies of employment extend the reach of emotional labor beyond Western economies and require an understanding of emotional labor from within a geographic perspective.

For some, the term “emotional labor,” while useful, places too much emphasis on the cognitive aspects of labor – the thinking or thoughtful processes – to the detriment of a more embodied understanding of the analysis (Witz, Warhurst, and Nickson 2003). Recent attempts to reclaim the embodied aspects of work have come through discussions of “aesthetic labor,” which refers to particular “embodied capacities and attributes” that enable employees to “look good and sound right” for the job (Warhurst and Nickson 2001, 13, 2; see also Warhurst et al. 2000). There is a more expansive geography associated with aesthetic labor: while emotional labor refers to specific workplace temporally and spatially bounded interactions, aesthetic labor goes further to examine all the ways in which workers have to maintain themselves to perform effectively at work. Thus, to be an effective worker who has to look right might involve keeping slim through dieting and exercise that take place outside workplace interactions. Emotional and aesthetic labor are not separate moments for the worker but conjoined; all emotional labor involves the creation of a particular aesthetic appearance, yet the effort to maintain the body is, at times, emotional (Entwistle and Wissinger 2006).

Conclusion

Emotional labor remains an important concept within organizational studies and geographies of the workplace and home, as it attends to the particular ways in which the capacities of individuals are harnessed and marketized by companies and other employers. Many economies now rely on “soft” qualities, like emotions – as opposed to brute physical strength or dexterity required in manual work. Today emotional labor remains a salient feature of the modern workplace (in its various locations) and one that continues to have academic viability within human geography.

Empire

Daniel Clayton
University of St Andrews, UK

Empire denotes an extensive, hierarchically structured, and usually militaristic polity encompassing diverse peoples and territories that is ruled more or less directly and authoritatively by a supreme power or ruler (emperor, monarch, state, or centralized elite), and that revolves around a spatialized logic of “inside” and “outside.” It is a transhistorical concept, and has long framed debates in the social sciences and humanities about the nature of cultural change, development, society, sovereignty, and territoriality. The term is derived from the Latin imperium (sovereign authority, and extensive command and influence), and is entwined with other ancient concepts (democracy, freedom, power, the state). Since the nineteenth century it has been closely associated with the terms “imperialism” and “colonialism.” Empires are sprawling political entities (such as the Roman empire, British empire, and Soviet empire), which subsume and subordinate the fortunes of alien and distant peoples and domains to the drives and dictates of a dominant center, culture, or figurehead. But the term is also used more colloquially, to evoke transcendent power or oppressive influence (as in corporate empire, empires of vision, and mosquito empire).

Geography and empire

Empires have been greatly shaped by geographical understandings, traditions, practices, concepts, and institutions – of frontiers, the exotic, and the unknown; expeditionary traditions of discovery, observation, mapping, description, and classification; colonizing practices of appropriation and dispossession; cosmographic and secular systems of geographical knowledge, and doctrines of environmental determinism and geopolitics; and learned societies such as the Royal Geographical Society (founded in London, 1830) and the National Geographic Society (founded in Washington, DC, 1888) and its popular magazine National Geographic. Felix Driver (2001) coined the expression “Geography’s empire” to capture the recognition that from the late eighteenth century imperial expansion went hand in hand with the promulgation of geography as a professional discipline. From ancient times through to the present – from geographical luminaries such as Strabo and Herodotus, to Dee and Mercator, Cassini and Humboldt, and Mackinder and Bowman – projects of “earth-writing” (geography’s Latin root) have more often than not fired and been fired by imperial imaginations and ventures. What is more, imperial imagery of intrepid (usually cast as “manly”) explorers, and the allure of the exotic, still permeate public perception of the subject. Cartography has been a mainstay of “Geography’s empire” (and remains so today in the guise of new
geographical information systems), inviting and choreographing imperial expansion, fueling myths of empty space, charting fecund lands ripe for European penetration, targeting alien territories for military intervention, and framing the racialization and sexualization of empire.

Questions might be raised about why an avowedly critical literature on geography’s complicity in empire only arose within the discipline in the 1990s, years after decolonization. We might also ask about why this complicity has been prosecuted (by and large) through a selective focus either on the world of European empires (and the diverse colonial domains within them) from the mid-eighteenth to the mid-twentieth century, or on the political economy and geopolitics of imperialism today (Butlin 2009). With some notable exceptions, geographers have shown less interest in Eastern and ancient empires, or, until very recently, in post–World War II geography’s connections with the Cold War and decolonization. Did Western geographers, many of whom had served country and empire in World War II, lack the desire to launch what would be a soul-searching critique of their discipline’s makeup because the imperial past was still too (uncomfortably) close to the present? Or was it the case that the theoretical language with which to advance such a critique was not in the air until later? The stubborn presence of empires in world history undermines the fantasy that academic knowledge is impartial and operates in a political and historical vacuum, and attests instead to its partial, power-laden, and often compulsive qualities. This recognition impinged on the fields of anthropology, history, sociology, and literature from the mid-1970s (and, since the 1980s, on political philosophy), before it did geography and was instrumental in fashioning new multidisciplinary critical projects of cultural and postcolonial studies.

Awareness of geography’s past and ongoing complicity in empire has played a major role in promulgating a critical human geography which, among other things, embraces questions of cultural difference, otherness, and exclusion; probes connections between power, knowledge, and geography; is antiracist and antisexist; and alights on the Western (Eurocentric) blinkers that have crimped the discipline’s outlook and the way its history has been told. Given the general contextual significance of empire to geography, however, it is surprising how few geographers have engaged in general terms with how empires are spatially organized. Historians and sociologists have taken the lead in this regard, and have shown that geography’s imbroglio with empire is not just a disciplinary affair but needs to be projected onto a much larger screen.

History, meaning, and character of empire

Empire can involve diverse forms of power, subordination, and dependence, and important distinctions have been drawn between its economic, political, ideological, and technological dimensions (how empires work as markets, projects of rule, cultures of dominance, and modes of territorial organization and transformation). There have been over 70 empires in history, and they have been typologized in terms of their declared aims, expansionist ethos, sources of social power, modes of command and control (formal and informal), systems of rule (direct and indirect), geographical character and reach (maritime and land-based), economic and political organization (into colonies, protectorates, mandates, trusteeships, trade monopolies, and domains of foreign direct investment), socio-economic configuration (mercantile and settler, tributary and territorial), and benefits and costs
EMPIRE

(in perceived and demonstrable terms). From the time of the Roman empire (Western, ca. 27 BCE–476 CE; Eastern, 330–1453 CE) and the early Chinese empire (Qin 221–206 BCE; Han 202 BCE–220 CE), through the modern era of European colonial empires (ca. 1450–1945 CE), to current debate about nature or the existence of an American empire, empires have been regarded as forces of both good and evil. Some see them as fostering collaboration, toleration, order, belonging, and modernization. Others have derided them as the incarnation of economic exploitation and xenophobia, and as the harbingers of a world divided by civilization, class, nation, race, and religion.

The modern (post-1400) era of empire building, starting with the Portuguese and Spanish (in Central and South America and the Indian Ocean), and followed by the French, British, and Dutch (in North America, the Caribbean, and Asia), has been closely linked with the advent of modernity and a “world-system” of capitalist production and exchange. During the second half of the nineteenth century empire became virtually synonymous with the terms “imperialism” and “colonialism,” which were coined to denote a European ethos of territorial expansion, exemplified by the imperial partition of Africa between 1885 and 1914, and which involved both intense national rivalry and the flowering of a more broadly European sense of superiority and justification (or smoke screen) for empire as a “civilizing mission.” By 1914 over three-quarters of the world’s land surface was under the imperial aegis of a small number of European powers, plus Japan and the United States. Marxist revolutionaries such as Lenin and Luxemburg argued that this imperialism was precipitated by the contradictions of monopoly capitalism and was a necessary stage leading to capitalism’s eventual demise. Liberals such as Hobson and Schumpeter were less sanguine about the latter, arguing that imperialism was bound up with a more convoluted set of relations between capital, class, nationalism, and political factionalism, and was a cyclical element of “great power” politics.

During the mid-twentieth century, and particularly during the postwar era of anticolonial struggle and decolonization, “empire” became a term of abuse. In the 1980s the *bête noire* of a new critical project, dubbed postcolonialism, returned to the scene of Europe’s garbled and bloody retreat from empire and probed how the hopes and promises of freedom and autonomy accruing from the transfer of power faded and became corrupted, and, in some parts of the world, were overshadowed by territorial partitions and violence. Independence and liberation became what Fanon (1967, 183), in the early 1960s, identified as a “zone of occult instability” rather than a clean break with the past. In 1965 Nkrumah deployed the expression “neocolonialism” to describe lingering imperial and emerging postcolonial structures of dependency on the West. Historians have since shown that, after World War II, Western (and especially American) intellectuals and politicians were convinced that they could steer the development of the decolonizing world, avert revolution and instability, and fashion a new global order of liberal-democratic-capitalist states that would serve Western interests. Key to this project was a paradigm of modernization geared to developing agriculture, promoting trade and its liberalization, and harboring pro-Western (if in some places authoritarian) political regimes through the transfer of Western capital and technology, and the use of diplomacy. In short, the fortunes of postcolonial nations were still fettered by Western values and norms. Western interests were bolstered by the coterie of international institutions created at Bretton Woods in 1944 (and centering on the United Nations), which
were initially geared to defending empire but soon had to adapt (some argue quickly, others say uneasily) to the travails of national sovereignty and impress of Cold War antagonisms on the “Third World,” which was a term originally used (in 1952) to characterize those nations (including many in the decolonizing world) that were nominally nonaligned with the capitalist or communist blocs.

Since the mid-1990s, academic and political consensus about the deleterious character of empire has become fractured. Following the late 1980s collapse of East European and Soviet communism, and latterly since the attacks on New York and Washington of September 11, 2001, and the financial crash of 2008, empire has returned as a way of talking about and dealing with global crisis and conflict (as has modernization theory). Empire is back in vogue as a live analytical and political concern. The postcolonial desire to consign empire to the past now seems misplaced. And the urge in other – “neoliberal” – quarters to champion the global ascent of an international liberal–democratic–free market system as the final and mature stage in the evolution of economic and political community, seems deeply divisive. The number of state-based civil wars (both with and without foreign intervention) has increased sharply since the early 1970s, and there is now a much greater range of opinion about empire than there was 50 years ago. Burly reaffirmations of empire’s modernizing and stabilizing influences jostle with singeing critiques of the death, destruction, and double standards wrought by “international” (military and humanitarian) interventions in different parts of the world. Within and beyond geography, the latter critical concern hones in on the appearance of new spaces of violation, vulnerability, and “exception” to national sovereignty and international law (e.g., the American detention camp at Guantanamo Bay).

As this discussion suggests, and as Colás (2007, 3) and other theorists stress, “the notion of empire is mixed up with all sorts of conflicting political sentiments and social processes,” making the search for “a normative or analytical equivalence between arguments for and against empire” more complex and perhaps more ambivalent than ever. However, it is still possible to generalize about empire. Colás and a longer line of theorists have viewed expansion, hierarchy, and order – or, more precisely, the ways in which they have been sought and the extent to which they have been realized – as the core attributes of empire, and as explanatory keys with which to compare different imperial formations, and to gauge how the meaning of empire has varied over time and from place to place.

While other types of polities share one or two of these core attributes with empire, it is their combination in empire that distinguishes empire from other forms of political community and imagined community (such as nation-states, city-states, fiefdoms, tribal federations, and ethnic homelands). Yet, while empires and nation-states are different political entities, their fortunes have long converged and clashed. As Burbank and Cooper (2010, 8–9) observe, when “nation-states … based on the idea [however illusory and divisive in practice] of a single people in a single territory constituting itself as a unique political community … did become meaningful political units, they had to share space with empires” whose boundaries were porous, whose resources were more diverse, and whose extensive command of space was intimidating. Today, as in the past, the specter of empire raises important questions about whether nations can be self-sufficient, and whether they are any better than empires at respecting ethnic pluralism or democracy or human
rights. “As long as diversity of political ambition exists,” Burbank and Cooper (2010, 9) continue, “empire-building is always a temptation,” yet because empires, by definition, impose, subsume, and dispossess, “there is always the possibility of [their] coming apart” as a result of opposition and overexpansion.

There is currently considerable debate – including within geography – about the recent emergence of a “liberal empire” spearheaded by the United States, buttressed by the United Nations, and cloaked as a new collective and consensual internationalism that intervenes in the world’s trouble spots in the name of global order and universal human rights. This empire is geared to policing and enforcing legitimate state authority, civil liberties, democratic rights, and humanitarian standards, and to rooting out terror and threats to “homeland security.” It is putatively consensual rather than coercive – supported by an array of public and private actors and institutions that have a collective interest (as well as their own vested interests) in making the world a secure and peaceful place. Some see in this liberal empire an older imperialism of free trade, and regard the United States as a hegemonic (consensus-oriented) power, coordinating an international community that wields a “higher” moral authority. American hegemony has been dubbed “soft power” (an ability to attract and co-opt rather than coerce) and “empire lite” (bending world affairs to the will of the US and international community with diplomacy and quick-fix military interventions).

Hardt and Negri (2000, xii) take this problematic of internationalism to its conceptual conclusion, arguing that,

In contrast to imperialism, Empire [today] establishes no territorial center of power and does not rely on fixed boundaries and barriers. It is a decentered and deterritorializing apparatus of rule that progressively incorporates the entire global realm within its open, expanding frontiers.

They are as concerned with resistance to the territorial elusiveness of empire as they are with the discourses of might and right that course through it. In destabilizing modern imperialism’s territorial fixations, their synopsis leaves room for new forms of identity and resistance to Western hegemony. Yet, at the same time, their empire denotes a supranational expansionism that is geared to “enlarge the realm of the consensus that support[s] its power” (Hardt and Negri 2000, 15, 190–194). Critics suggest that Hardt and Negri underestimate both the continuing significance of nation-state territorial sovereignty in a globalized world, and the need for global markets and multilateral flows of people, information, business and finance, and cultural influences to be politically and militarily regulated from recognizable power bases. Indeed, it is the attempt by those on the receiving end of this purportedly decentered empire to name and locate (reterritorialize) it – as Anglo-American, revanchist, and militaristic – and to bear witness to the dagger behind the cloak of internationalism that is one of most salient aims of resistance in many parts of the world today.

Another criticism of Hardt and Negri’s thesis must surely be that they underestimate the ways in which this decentered empire is wrapped around an American military empire – one of bases rather than colonies. The US military is currently deployed in more locations around the world than at any time in its history, and since the mid-2000s its military spending has accounted, on average, for almost half of global military expenditure. The global ubiquity of the United States’ strike force is part and parcel of what Gregory (2011) terms an “everywhere war” – a war that the United States deems a “virtuous” war because of its use of smart bomb and drone technology, ostensibly to make enemy targeting more precise (minimizing civilian casualties and
wanton destruction) and to forestall the need for sizable and costly troop deployments.

Marxist critics see US military expansionism as a reaction, in part, to what Harvey (2004, 63, 68) describes as “a chronic and enduring problem of overaccumulation since the 1970s,” and as having resulted in capitalist devaluation (especially in Latin America, East Asia, and Russia). Recent US military escapades overseas have been bound up with geoeconomic concern over control of the world’s energy resources and have been read as attempts to stop recession and devaluation coming its way. Harvey has dubbed this articulation of economics and militarism a “new” imperialism that “attempts to accumulate by dispossession,” although he frames the phrase with scare quotes because this imperialism looks a lot like that analyzed by Luxemburg and Marx’s “primitive accumulation” (the modes of imperial plunder and appropriation needed, Marx argued, to kick-start capital accumulation). The 2008 financial crash, however, exposed the effectiveness of this imperialism by exposing how colossal military expenditure was tied up with the precarious securitization of US government debt. In other words, the United States has sought to combat one type of risk by ramping up another.

The spatiality and tensions of empire

Colás (2007, 31) notes that, from ancient Greece to Guantanamo Bay, “processes of imagining and managing space are crucial in identifying the distinctiveness of empires, both among themselves and vis-à-vis other forms of rule.” Empires revolve around a hierarchical (inside–outside, center–periphery) spatiality, and a series of tensions and oppositions that this geography brings into play: between imperial expansionism and the need to delimit empire for the purpose of jurisdiction; between ruler and subject, and colonist and native; and between more intricate and diffuse gradations of rank and status across the metropolitan–colonial reach of empire. All empires have faced the problem of how orders and influences are transmitted, and how material and worldly goods are circulated. They have sought means of speeding up imperial flows and making them more secure, and technological change has been pivotal in this regard. In the modern era, and with growing intensity since the end of the eighteenth century and the coming of the Industrial Revolution, empire building has been aided and abetted by a string of inventions and innovations in shipping, navigation, banking, accounting, engineering, weaponry (including, by World War I, air power), communications (print, steamship, railway, telegraph, and radio technologies), visualization (photography and film, and museums and world exhibitions), medical science, and urban design. Technological change was integral to expansionism, furnishing the means of stretching imperial systems over more far-flung areas without losing control. But it was equally important to an increasingly ambivalent imperial existentialism, with rapid growth in metropolitan knowledge about the world, perceived speedup in pace of life wrought chiefly by communications technologies, and the growing material and cultural proximity of people and things that were once deemed alien and faraway, provoking both awe and disorientation.

All empires have also been concerned with how their imperial agents (settlers, traders, administrators, military personnel) are transplanted overseas from the mother country (and remain loyal to it), and how to accommodate alien and diverse populations and territories within imperial structures of command and control. Concomitantly, all empires have faced the questions of where and when it is best to centralize or devolve power, how to adapt imperial ambitions and ideals to colonial contingencies
and pressures, and how to avert and manage resistance and colonial malfunctions. For example, the ancient Chinese empire, Roman empire, and early modern Ottoman empire had centralized fiscal systems yet decentralized administrative structures that incorporated elements of local custom and tradition. From early days, then, the creation of imperial hierarchies involved two-way (albeit still unequal) and diverse mediations between center and margin rather than a one-way imposition. The sixteenth-century Spanish developed a system of trusteeship (encomienda), whereby Spanish settlers in the New World were granted rights to the labor of indigenous people and to keep the fruits of some of that labor, in return for loyalty to the crown and a duty to convert their native charges to Christianity. By contrast, the late nineteenth-century British espoused an empire of free trade and developed a system of “indirect rule” in Africa (governing through local intermediaries and alliances), although neither protectionist inclinations nor military might were faraway, whereas the more assimilation-minded French in West Africa and Southeast Asia failed to implement the metropolitan republican principles (of free expression, mass education, social justice) that were enshrined in official imperial rhetoric. Finally, while military aggression and intervention have long been seen and used as key power brokers of empire in the last instance, the postwar promulgation of guerilla warfare as a viable strategy for small numbers of insurgents to resist and disperse considerably larger and better equipped conventional military forces. The Vietnam War was the apogee of such “asymmetric” warfare and raised a gamut of questions – persisting to this day – as to whether militarism is a self-defeating imperial strategy, and whether different kinds of militarisms are suited to different types of terrains and imperial situations.

These and other imperial questions and processes comprise a large, complex, and contradictory spatial repertoire of imperial dominance and colonial governance from which present-day analysts, policymakers, and opponents of empire (and capitalism and globalization) alike draw “lessons” and identify general patterns and trends. Two trends in the history of modern empire building have been elucidated. First, a triumphalist “follow my leader” ideology, with the West arrogating to itself the power to decide on what counts as right, normal, and true (and what does not), and to define itself as the most advanced and civilized part of the world. Modern empires marshaled a Eurocentric (diffusionist) imperial worldview – overriding national animosities – in which all “good things” (reason, civilization, progress, etc.) were deemed to flow from “the West” outward, to be imbibed and emulated by “the rest.” This ideology made empire building a project of epistemological violence (working at the level of language, knowledge, and culture) as well as a palpably material project of geographical violence. To reiterate, geographical practices of observation, mapping, classification, territorial appropriation, and settlement are central to empire on both counts. Sometimes brashly and sometimes surreptitiously, geographers and those working within what became characterized as its traditions (explorers, cartographers, administrators, and so forth) extolled the “superiority” of Western knowledge (as objective, universal, and comprehensive) and denigrated “other” (native, distant, local) ways of knowing.

Second, the seventeenth-century advent of modes of sociospatial reproduction based on the coalescence of territorial sovereignty and political authority (often dated to the 1648 Peace of Westphalia) have been seen as heralding a general shift in the spatiality of empire away from a focus in ancient empires on people (on
the extraction of tax and tribute, the control of labor, and a proselytizing concern with conversion) to a modern concern with the use and administration of territory, resources, markets, and trade (in short, a focus on land and the creation of wealth). This modern territorial ideology became enshrined in British and French Enlightenment thought and a political philosophy of “improvement” (from whence came theories of development and a Western fixation with progress), and the territoriality of nation and colony both facilitated the accumulation of capital (not least, through the export of capital to colonies rather than wealth simply being extracted and drawn back to the imperial center) and created what Marx regarded as constitutive “limits” and “barriers” to it. This imperial ideology also coded imperial and colonial subjects in territorial terms, with figures of class, nation, gender, sexuality, and race assigned to fixed domains in a distinct imperial pecking order. Empire both traverses these domains and constitutes them by so moving, creating a politics and aesthetics of fixity and motion that parallel the workings of capital.

Yet there are significant exceptions to, and irregularities within, these two trends. The early modern Spanish and Ottoman empires are often invoked as both ancient and modern. And the British used the very ancient institution of slavery to build their characteristically modern empire; and then, during the early nineteenth century, built a new scientific racism (“hierarchy of races”) with one hand, as it was abolishing slavery in its empire with the other. Postcolonial thought probes such inconsistencies and paradoxes in imperial formations. To gloss just one important critical position, Bhabha sees a fundamental ambivalence at the heart of both colonial power and postcolonial identity, which is marked by hybridity and belatedness. Decolonization, he argues, was unable to proceed by returning “the eye of power to some prior archaic [precolonial] image or identity,” because the cultural identity of the colonized was mixed up with that of the colonizer. Such a quest for postcolonial authenticity was also belated, because the imperial and colonial forms from which the colonized sought to extricate themselves only became authoritative after the “traumatic scenario of colonial difference, cultural or racial.” Such a quest – for a clear break with the past, and to find some precolonial cultural or national essence and read it into the origins and history of anticolonial struggle – could “neither be ‘original’ – by virtue of the act of repetition that constructs it – nor identical – by virtue of the difference that defines it” (Bhabha 1994, 153).

Empire also has an ambivalent relationship with capitalism, and the history of that relationship reverberates through contemporary debate about globalization and the current economic crisis. Are the interests of nation and capital symbiotic? The US government’s recent unwillingness to fully bail out its “toxic” financial sector has brought this question to a head. And it can be found in Harvey’s analysis of the “new” imperialism, a much older question about whether capitalist accumulation relies on state protection and regulation, and military violence. Both questions lay at the heart of the activities of the world’s two utmost commercial agents of empire, the English and Dutch East India companies (founded in 1600 and 1602 respectively). Both of these trading monopolies had complex and at times stormy relationships with their respective states, and posed the enduring question of whether, for capitalism to thrive and for private interest to serve some national public good, violence needs to be subordinated to the rational and orderly pursuit of profit.

Another enduring tension, this time bridging the spatial and the cultural, is between the ideas of empire as expansive and as delimited – with
an “inside” and an “outside,” and with the edges of the known world manifested in fuzzy imperial frontiers peopled with monstrous and threatening figures of otherness. The imperial contours of this tension can be traced back to ancient Greece and Herodotus's idea of oikoumene (the humanly made, known, and interconnected world), and since ancient times cartography has been a prime means both of substituting fact for uncertainty and of underscoring the elusiveness of empire’s edges. Imperial and colonial sites (such as Madrid and Mexico City, London and Lagos, Paris and Phnom Penh), and imperial frontiers (such as Central Asia, the American West, and Equatorial Africa) have been key sites at which this tension between the known and unknown, and its cultural cipher as an opposition between civilization and barbarism, have been exhibited, negotiated, and contested. Furthermore, the origins of modern diplomacy can be located in state concern with how to manipulate not just geographical knowledge about distant places and obscure events, but also geographical ignorance emanating from the frontiers of empire, and how to translate it into sovereignty.

A considerable critical literature on the “culture of empire” examines how fantasy, speculation, and egregious assumptions about what was “out there” sparked and shaped myriad imperial conflicts, and also how imperial desire is bent on putting hierarchies “in place” (i.e., overcoming uncertainty and fluidity). Said’s 1978 book Orientalism was seminal in showing how these two elements of the spatiality of European empires combined (and often clashed) to generate potent “imaginative geographies” of how the world was presumed to be. Said averred that images and the geographical imagination of cultural difference and European superiority were as important to empire as guns and armies. Empires have been built and sustained with diverse texts, representations, and spectacles of power – maps, travel narratives, world exhibitions, museums, and imperial parades. Meanings and images coming from scholarship, literature, religion, and the arts and sciences were directly implicated in the exercise of power, and Said’s concern with how empires thus operate as texts (in the broadest sense) made a deep and lasting impression on geographers (Said 1993/1978).

Said demonstrated that imaginative geographies have a predilection to harden distinctions between “us” and “them” into binary oppositions. Yet he also recognized that such binaries often struggled to work their Manichean magic, and that imperial and colonial categories could be fluid and were in constant need of reiteration (citation) if representations of otherness were to become accepted as reality. On the one hand, binaries of “us” and “them” (Bhabha’s trauma of colonial difference) were enunciated and performed in and through abject (and acutely raced and sexualized) material spaces and spaces of representation – plantations, missionary stations, native reservations, and the racially segregated districts of colonial cities; colonial schools, courtrooms, and censuses – and in artistic and scientific representations of the natures and cultures of the colonized and the edges of empire as seductive and supine and in need of domestication and control. Reworking ancient celestial conceptions of imperial order and harmony between heaven and Earth, a modern imperialist ideology, and practice of sequestration commanded that everything “had a place,” and as Fanon (1967, 35–38) proclaimed, the place the colonized occupied was set apart from and beneath that of the colonizers. But, on the other hand, by the nineteenth century, spatial boundaries between center and margin were being lowered by the commercial traffic of empire and rapid technological change. Colonial divides were being crossed too (and
in the most intimate, libidinal ways), yielding fear and apprehension about the physical and moral degeneration (especially in hot climates) of the imperial self and colonial populations. Expansionism and speed made for anxiety as well as indeterminacy.

Said (1993/1978), and now a much wider literature on “tensions of empire,” argue that the increasing accessibility and experience of empire to a growing number of Europeans through travel and work, combined with the growing (if limited) accessibility of European ideas and Europe itself to the colonized and mounting metropolitan awareness of colonial conditions and (importantly) of resistance to empire, conspired at once to “produce” European culture (spur its arts and sciences, and infuse its political and popular culture), and to foster an existential crisis within it. Postcolonial thought alights on this motility and breakdown to advocate what Said (1993/1978, 97) describes as a “contrapuntal” reading (a term borrowed from the Cuban thinker Ortiz) of empire that is “inherently spatial”: to ignore or otherwise discount the overlapping experience of Westerners and Orientals, the interdependence of cultural terrains in which colonizer and colonized co-existed and battled each other through projections as well as rival geographies, narratives, and histories, is to miss what is essential about the world in the past century [sic]. (1993/1978, xxiii)

A colonial world “out there” wound up “in here,” and made a vital and lasting contribution to the metropolitan world, albeit, Said points out with reference to the novel as a nineteenth-century literary form, in diminished, distorted, and sublimated ways.

A related, and final, point addresses the spatiality and tensions of empire. Critical emphasis on the reach and swagger of imperial power runs the risk of lengthening the shadow that empire casts over the present – empire can appear ineluctable; and there is thus another, equally compelling, side to postcolonial critique, which is about showing – pace Fanon, Said, and Bhabha, among many others – how imperialism and colonialism have been challenged and compromised, and have morphed into novel and unexpected (“creole”) forms. Since the beginnings of modern European imperial expansion, the “placing of empire” has worked through a twin psychospatial tension: first, between imperial might and right (the impulse to expand and the need to justify that expansion); and second, and as Bhabha stresses, between mastery/fantasy and anxiety/dislocation (fear over a loss of control and identity). Furthermore, these two tensions revolve around two (vexed) geographies of identity formation: first, between metropole and colony (how they related to and addressed one another); and, second, between colonizers and the alien lands and peoples they encountered (how colonizers adapted to new physical and cultural landscapes from European backgrounds that had already been shaped by imperial desire and ideas about wilderness and savagery). Such tensions and geographies animate Said’s “contrapuntal” envisioning of empire, and make the task of postcolonial criticism not just one of exposing and challenging imperial hierarchies and modes of othering, but also about recovering and extolling countergeographies, counterhistories, and spaces of cultural invention and mixing, and thus about building a world with fewer barriers and borders in it.

With reference to the first tension and geography, European nations went to great lengths to justify imperial expansion, both to one another and to the peoples they were colonizing. Moreover, their fraught recourse to natural and divine law remains a vital historical reference point in legal and political battles over indigenous rights and sovereignty, not least in former British
EMPIRE

settler colonies such as Australia, Canada, and New Zealand. A fast-growing literature now demonstrates that the boundaries and differences between European and indigenous laws and practices were not as tightly defined as colonists and colonial administrations presumed, and that to continue to insist otherwise is an imperialist act and fiction.

If, as this literature suggests, the political burden of sovereignty finds its main ramifications in settler-colonial domains, then a second tension and geography, and its legacy, is more keenly felt in India (which has been an important fount of postcolonial theorizing) and other colonial situations where colonists were vastly outnumbered by their colonial subjects. By the mid-nineteenth century, the West was justifying colonization on the grounds that the beneficent/enlightened colonizer was bringing “gifts” of civilization (reason, science, and progress) to “the native” (in some discourses it is the native who beseeches them). For colonialism to endure and remain legitimate, however, it could never admit that it had completed its task – admit that “the native” was now “civilized enough” to run her or his own affairs. There was a constant need for the colonized to be placed in a subordinate position, to be “worked on” by European culture and reason. A “rule of colonial difference” thus cemented itself and came to haunt the nationalist imaginaries of postcolonial nations such as India. Independence did not bring full decolonization, this postcolonial story goes, because formerly colonized peoples and nations were still enjoined to pursue and accept Western standards and expectations – to sign up to a constitutively colonial modernity. While it was desirable to accept the “good” bits of modernity (its veneration of liberty, justice, and equality) and to jettison the “bad” bits (naked individualism, for instance), the “decolonized” could only ever become modern in a secondary way – after Europe and on its terms.

Conclusion

Admired and vilified, empire is a key comparative framework for geographical, historical, social, and political analysis, and is now central to what some see as a contextual and historical turn in economic and political theory. The word conjures up a long-lived arsenal of ideas and practices that do not belong to a bygone era but are thoroughly mixed up with the predicaments of the present. The spatiality of empire is integral both to the hope and the despair of the postcolonial condition, and to contemporary conceptions of resistance and the political. Lastly, critical exposure of the complicity of geography in empire is very much a matter of the present and not just something that concerns the past and the discipline’s heritage. The whole idea of empire remains key to how geography operates as a situated knowledge and discipline that deals with the world, and geographers are as vigilant today as they have ever been about the need to combat actually existing imperialisms and colonialisms.

Endemism

Kenneth R. Young
University of Texas at Austin, USA

Endemism is a measure of the uniqueness of the biota of a particular place. It is one of the basic ways used by biogeographers to characterize biological diversity across the surface of the Earth. Early explorers documented species that were new to science and evaluated their ranges, ecological tolerances, and potential usefulness. As they did so, the proportion of species unique to an area became one way to assess how different that place was from others previously explored. These place-to-place differences in species composition became included in the recognition of biogeographic provinces and regions. In addition, high endemism was also understood to indicate the presence of biogeographical barriers, which isolate species and restrict the establishment of new populations. Endemism can be used to refer to other taxonomic levels, for example, in referring to families or genera found restricted to a particular part of the world. The degree of endemism nowadays is used for biodiversity conservation planning, and places with high values have special significance given their distinctive taxa. The kind and degree of endemism gives insights into the historical biogeography of particular places, and helps in understanding the origin and evolution of the biota. It may also help in carrying out nature conservation under future conditions.

All life on Earth is endemic, as it is found nowhere else; as a result, the endemism of the planet would be 100%. Smaller extents of the Earth’s surface would have less percentage endemism, with many continents having around 50% to 80% endemic species, with the remainder being widespread, for example cosmopolitan species found on multiple continents. Places within large uniform parts of the world, including the oceans, share many species, and so would have a small percentage of endemism, and relatively low beta diversity (a measure of place-to-place change). Oceanic islands, on the contrary, have many unique species, and so typically have high endemism. In an ecological sense, isolation serves to limit or even prevent dispersal. As can be seen in these examples, endemism is both scale-dependent and place-specific.

Charles Darwin found unique finch species on the Galapagos Islands (Grant and Grant 2008). From the distribution patterns revealed by his collections and by looking at morphological details of the birds’ beaks, he developed an important line of evidence for showing how natural selection acts over time to result in speciation and adaptation. Islands such as the Galapagos have high endemism for two reasons: they are isolated by distance from the mainland and their biota has evolved further under those isolated conditions. Species colonizing an island or island chain are subjected to new evolutionary pressures. As a result, they have sometimes speciated in an adaptive radiation manner wherein they diversify to use available resources, especially if competitors or predators found on the mainland are not present.

Besides islands, high endemism would also be expected in places with significant dispersal barriers and/or numerous different microenvironments. Highly fragmented environments often have restricted range species. For example,
mountains have many limitations to dispersal given the rough topography and abrupt slopes that act to create different biophysical conditions; collectively these work to restrict species to relatively small areas, especially for habitat or elevation specialists, and for species with low vagility (capacity to disperse) that are not able to fly, swim, walk, or otherwise disperse across those barriers. There is a set of plant species that are restricted to growing on certain soil types; the distribution of the soil types would then determine where those specialized species can survive, creating habitat islands. A consequence of these kinds of controls on species distributions is high endemism for mountain regions or for other places with much natural variation in soils or topography, in contrast, for example, to lowlands with relatively uniform biophysical conditions.

Countries with mountains would likely have more endemic species than similar-sized countries with no mountains. Thus, it can be said that endemism also has a political dimension, as unique species are a particular conservation responsibility for the country in which they are found. Island nations, for example, need to devote considerable resources to protecting their unique species, which are often also prone to displacement by aggressive species introduced by humans. As another kind of example, South Africa has such unique plant lineages associated with a Mediterranean climate that the Cape flora is considered globally distinct. There is a trend of global biotic homogenization in the last several centuries, whereby humans reduce place-to-place differences in species composition through land change and the introduction of exotic species.

Systematic planning for biodiversity conservation uses endemism, along with other variables such as species rarity and overall diversity, to choose the best portfolio of lands to protect, given costs and land tenure. This helps with the decision-making process because it weights the degree to which endemism, rarity, charisma, usefulness, or other species traits are used in determining nature conservation strategies as networks of protected areas are assembled.

Relatively new techniques from molecular biology can now reveal the timing of speciation events, allowing for reconstruction of past evolutionary processes. For example, differences between closely related species in their DNA can reveal the order in which the different species evolved from a common ancestor. Further analyses can suggest the timing of those speciation events, which can then be tied to independent sources of information on Earth history from sedimentary records and fossils. Additional information on species distributions can be used to elucidate the influences of past plate tectonics, climate change, and species dispersal events on the history of the biota. Places with high endemism, for example Australia, have a history of isolation from other land masses, and this can be assessed using historical biogeography. The kangaroos and echidnas found there today live nowhere else naturally, although their fossils occur in other places. Australia was once connected to other land masses in the supercontinent Gondwana. In other words, endemism is a crucial data source for reconstructing the history of life on Earth.

Endemics are among the most threatened species, as they are rare by definition in having a small range. Endemics with small populations would be of the highest concern for conservation interventions. An endemic species with an ancient evolutionary lineage is defined as a paleoendemic; this kind of species would be of great interest for conservation because its loss would represent loss of information of an entire lineage. Neo-endemic species are relatively recently evolved, and their presence points to places having high rates of speciation
in the Quaternary period. Documentation of range-restricted species in the past may reveal previously unknown dispersal barriers, while widespread species in the past point to the presence of dispersal corridors or shifts in the locations and connectivity of the land masses.

Biophysical parameters in the next 100 years will be quite different from today. In fact, Williams, Jackson, and Kutzbach (2007) have shown that much of the world in the future will have “no analog” conditions, unlike any found today. Specialized species, especially if they are found in small areas today and if they have limited dispersal and colonization abilities, will be the most threatened and least likely to prosper. Hence, the study of endemism is also important for carrying out research and management of the biogeography of the future. Biogeographic shifts can be predicted using ecological and species distribution modeling, while management will require planning for conservation corridors and other interventions that permit the movement of populations to new sites.

don: SAGE.
Historically, countries across the globe have exploited and consumed ever-increasing quantities of energy resources to satisfy the growing demand for goods and services and to promote jobs and economic development. The historic pattern of progress has involved an ever-increasing and diversifying portfolio of energy resources. Since the prosperity and security of countries has been intimately tied to their access to energy, this entry begins with an overview of the geography of energy resource endowments. With the growing reliance on electricity to power economies and the need to meet increasing levels of reliability, it next turns to a discussion of how electricity is generated globally, and in particular in a subset of regions—the European Union, the United States, China, and India. As concerns over the negative externalities of fossil energy consumption have grown, analysts are increasingly focused on the demand side of the equation, aiming to reduce the amount of energy consumed per capita and per dollar of GDP (National Research Council et al. 2010). Overlaid on these transitions is the need for governments to develop energy policies to effectively direct investments toward sustainable, affordable, and reliable energy choices. These are the four topics covered in this overview of the geography of energy resources and use.

Energy resources

Understanding how the actions of humans affect the Earth’s landscape has long driven the discipline of geography. The demand for ever-expanding sources of energy has been one of the most studied causes of landscape transformation. The ensuing economic, political, and societal consequences of this transformation have led to the sobering realization that humans have grown dependent on energy in general, and fossil fuels in particular. This dependence has created a growing concern about the security of energy supplies.

The International Energy Agency (IEA) defines energy security as the “adequate, affordable, and reliable supplies of energy.” Today, countries from Japan to the European Union and South Africa are grappling with the fact that they are highly dependent on foreign sources of petroleum and natural gas. The economic burden that this reliance imposes on these countries hinders their efforts to become players in the global economy.

Today, the 15 nations with the largest energy reserves are geographically dispersed, located on six of the world’s seven continents (Figure 1). The United States, Russia, China, and Australia have the largest coal reserves, spanning four continents. The greatest oil reserves are found in the Americas and the Middle East, with the largest reserves in Venezuela and Saudi Arabia. These cover politically volatile regions where nationalized oil companies operate: the 12 largest oil companies are all state-owned and they control roughly 80% of petroleum reserves. At the top of
**ENERGY RESOURCES AND USE**

![Diagram showing global distribution of energy resources](image)

**Figure 1** The global distribution of energy resources: the 15 nations with the largest fossil energy reserves (Reproduced from US Energy Information Administration (EIA)).

This list are the Saudi Arabian Oil Company and the National Iranian Oil Company. Russia, Iran, Qatar, and Saudi Arabia host the largest natural gas reserves.

Interestingly, countries that are well endowed with one or two energy resources still rely on imports of other energy sources. For example, Saudi Arabia is the largest exporter of crude oil but has to import refined gasoline. Russia exports natural gas but has to import uranium. The United States is a net exporter of coal but imports oil. This interdependence explains why the challenge of energy security must consider the interactions between countries as much as it considers the resources of individual nations.

At the same time, the global energy map is changing, with potentially far-reaching consequences for energy markets and trade. It is being redrawn by the global spread of unconventional gas production, and by the continued rapid growth of renewables – especially wind and solar technologies.

In the United States, significant energy reserves can be found from Alaska to Pennsylvania (Figure 2). Coal is the largest American energy asset and is widely available in multiple states, but the largest coal reserves reside in Montana. In fact, if Montana were a country, it would rank in the top 10 based on coal reserves. Texas is home to the largest reserves of both oil and natural gas.

While the geography of shale gas outside of the United States is not well reported by the energy statistical agencies, shale gas resources in the United States are increasingly well documented. Shale gas production is progressing at a dizzying rate across North America, expanding almost twentyfold from 2005 to 2013, making the United States a net exporter of natural gas in 2009 (Logan et al. 2012). The US supply of shale gas is anticipated to double again by 2015 and to treble by 2030, as new investment flows into the sector (Deutch 2011; Zou 2012). Globally, the International Energy Agency (IEA) expects production from unconventional gas resources to double from 2010 to 2035 (IEA 2012). British Petroleum expects global shale gas production to grow sixfold from 2011 to 2030 (Hughes 2013). The result may be “the greatest shift in energy-reserve estimates in the last half century” (Deutch 2011).

In the United States, Texas is endowed with significant unconventional gas reserves, as is Pennsylvania. Low-cost natural gas is reducing coal use in the United States, freeing up coal for export to Europe (where, in turn, it has displaced higher-priced gas). The development of unconventional gas resources may also transform energy markets worldwide, especially for the developing world. Trillions of dollars in resources lie buried in the backyards of many of the world’s poorest citizens; if these were to be effectively and accountably managed, the economic development of these countries could surge.

Still, the extraction of energy resources such as oil, gas, coal, and uranium will inevitably decline despite improvements in efficiency and
advancements in technology. As a result, resource depletion is a fundamental issue that societies must consider. Are there meaningful peaks? Will depletion occur soon enough to be of concern? And does it in fact matter?

Affordable energy is another energy security concern. Many countries deal with this issue by instating energy consumption subsidies. The IEA estimates that fossil fuel consumption subsidies worldwide totaled $548 billion in 2013, with Iran, Saudi Arabia, India, Russia, and Venezuela topping the list (IEA 2014). The International Monetary Fund (IMF) estimated that in 2013 energy subsidies across 176 countries amounted to $1.9 trillion. On a post-tax basis, this is equivalent to 8% of all global government revenue for that year (IMF 2013). In most non-OECD (Organisation for Economic Co-operation and Development) countries, at least one fuel or form of energy continues to be subsidized, most often through price controls that hold the retail or wholesale price below the true market level. According to the Economist (2015), such handouts have caused extra consumption, which has been responsible for 36% of global carbon emissions between 1980 and 2010. Widespread fuel poverty has been a key driver of energy cost subsidies. Most of these countries have announced their intention to phase out consumption subsidies eventually, though at varying rates (IEA 2012). In the meantime, energy consumption subsidies are strong deterrents to energy efficiency by making investments in energy efficiency unattractive.

Electricity generation

Coal, natural gas, nuclear energy, and renewables are the principal energy sources used to generate electricity worldwide. The relative reliance of each energy source varies geographically, as shown in Figure 3. Coal is overwhelmingly the main source of electricity in China, and also the largest source in the European Union and the United States. While natural gas is the second largest provider of electricity generation in the United States, it ranks only third in the European Union, and provides just a fraction of China’s energy budget. Today, nuclear energy is the second largest source of energy for electricity in the European Union and the third largest in the United States, but accounts for just a fraction of electricity generation in China. The nuclear accidents at Three Mile Island, Chernobyl, and Fukushima have drawn public attention to the human costs associated with nuclear power. Geographic discussions have centered on the siting of nuclear plants, the dispersal of downwind radioactivity, and the proliferation of weapons-grade nuclear fuels on a global scale (Blowers, Lowry, and Solomon 1991).

The use of renewable energy – such as wind, solar, geothermal, hydroelectric dams, and
bioenergy – is growing rapidly in the electricity sector. Still, as can be seen in Figure 3, it remains a small player in the electricity markets of many of the world’s largest economies. Renewable energy is the third, fourth, and fifth largest source of electricity generation in China, the European Union, and the United States, respectively. Across all three regions, wind is the largest nonhydro renewable source of electricity generation, and the fastest-growing renewable energy resource on the planet. Wind turbines are being deployed across many countries, and are multiplying particularly in China, Denmark, and the United States. Unlike most energy resources that are hidden from the eyes of the average person, wind turbines are visible and serve as a reminder that all energy originates from a source. Wind turbines emit no greenhouse gases, are easily installed and decommissioned, and have prices comparable with conventional energy sources. The visibility of wind power is also a double-edged sword since the presence of a wind turbine alters the appearance of the landscape.

The national electricity demand of the United States could be fulfilled through about 3% of the land in the contiguous 48 states being used for wind energy. Unlike a coal plant, the land can also have other uses since only about 5% of land is used for access roads, electrical equipment, and wind turbines with wind energy (Pasqualetti 2000; 2011; Warren et al. 2005).

One of the most prominent hurdles to the diffusion of renewable electricity that exists today is the required backup. In addition, renewables are impeded by social and environmental obstacles, as well as costs.

How energy is used

With the rapid growth of energy consumption over the past half century, it has become increasingly clear that both the problems and solutions of energy demand growth are intertwined with geography. In addition, consideration must be given to the transportation of fuel, the generation of electricity, and the resulting impacts on the environment. In China and India, people are suffering from the pollution created by their coal plants and increasing numbers of motor vehicles. Air quality regulations in these countries are less stringent than in the United States and the European Union. Further, greenhouse gas emissions are being capped in the European Union and the United States, but China and India have not yet signed up to defined CO₂ emission reduction targets. Access to electricity and commercial energy fuels is also an issue in many countries, particularly those with significant energy poverty: at least 1 billion people worldwide are off the grid.

China and the United States are the world’s two largest energy consumers, together accounting for 38% of the world’s energy consumption in 2010. Germany and the United Kingdom are
two of the largest energy consumers within the European Union and are responsible for 31% of the its total energy consumption.

The focus will be on these four countries as well as the European Union in discussing energy consumption patterns and energy policies. These countries have been selected because they are important players in the energy arena: the United States, United Kingdom, Germany, and China account for nearly 40% of the energy used worldwide in residential and commercial buildings. Additionally, there are significant distinctions between these four countries and the European Union in terms of their economic composition, energy consumption patterns, policies, and political systems.

Table 1 summarizes the per capita GDP and energy intensity of commercial buildings in these four countries and the European Union. Of these countries, the United States has the highest per capita GDP and the second-highest energy intensity in commercial buildings. Germany and the United Kingdom are also affluent, but Germany is more efficient in using energy for commercial buildings: they are both wealthier than the EU average. Although China is another leading world economic power, the average Chinese citizen is significantly less wealthy than the average American, reflecting China’s developing country status. The energy intensity in Chinese commercial buildings is the lowest among this selected group by a large margin. Other research suggests that China’s intensity is driven by a low penetration of space cooling technologies and, to a lesser extent, by unmetered district heat. Incidentally, commercial buildings in China provide less thermal comfort than comparable buildings in the West. A close examination of the building energy codes in these areas illustrates the path dependency of regulations and policy innovation in different economic contexts.

In all three regions, industry is a large end-use energy consuming sector. In China, the majority of energy is used in the industry sector. Energy use is more uniformly distributed across end-use sectors in the European Union, with the four sectors each receiving at least 20% (services), and no sector receiving more than 29% (industry) (see Figure 4). The United States experiences a similar distribution, with the sectors ranging from 19% (services) to 32% (industry).

The value of energy products tends to be a large share of domestic economies across the world. In the United States, for example, energy expenditures were about 9% of GDP in 2012, or about $4000 per capita in 2013 (EIA 2015f). Almost half of these expenditures are on transportation fuels, which are about 95% petroleum-based (Brown and Kim 2015).

Energy demand has increased across the planet since the late 1970s. Geography was the key to coping with the skyrocketing demand for energy. The location of energy sources had implications not only for the surrounding environment but also for transporting the energy around the world (Pasqualetti and Brown 2014). Looking to the future, the IEA forecasts a 40% increase in worldwide energy demand, driven largely by China, India, and countries in the Middle East. According to the International Energy Outlook 2014 (EIA 2014), Brazil, China, India, and Russia will be responsible for nearly 70% of the growth in non-OECD energy usage over the next several decades. These shifts in energy consumption will also result in an evolving trading pattern that will financially benefit energy exporters (Bradshaw 2010; Pasqualetti and Brown 2014).

As a social science, geography is instrumental in understanding interactions and their effects on economic and political stability. It is no coincidence that throughout history the most bustling centers for economic trade have been

...the cities with the greatest energy resources. This relationship can be seen from the Industrial Revolution in London, with its access to coal, to today’s modern cities such as Abu Dhabi and Baku, which are surrounded by oil fields.

The geography of energy policy over the years illustrates the race-to-the-bottom principle, whereby localities, states, and nations strive to avoid increasing environmental regulation because of the anticipated loss of potential economic gains. Locations with less stringent environmental regulations and policies become pollution havens, encouraging businesses to provide economic benefits to their region at the cost of the health of residents. Today, a race to the top is emerging in some affluent countries where a premium is being placed on environmental protection and the value of maintaining ecological services (Pasqualetti and Brown 2014).

A review of the building energy codes has identified many common features. For example, they all include an efficiency requirement for building envelopes, space heating, and ventilation. However, depending on the different climate situations, space cooling is regulated in countries like the United States and China, which have large areas with warm climates, while the United Kingdom and Germany do not. The political system also affects building energy regulations. Because the US Constitution prohibits the federal government from passing...
laws to regulate building energy efficiency, those responsibilities are shifted to state and local officials. The relationship between building energy codes and climate change also varies from country to country. In the United States and China, the adoption and implementation of building codes has been spurred by the concern for rising energy consumption. Although building codes offer CO2 reduction as a co-benefit, it has not been the primary driver. In contrast, European countries have used building codes to tackle both energy consumption and climate change mitigation issues, in part because of their obligations to reduce their greenhouse gas emissions under the Kyoto Protocol. As a result, the goals of building codes are more aggressive in Germany and the United Kingdom: the aim is to make all new buildings built by 2020 consume nearly zero energy. In order to achieve that goal, European building codes not only have efficiency requirements, but also explicitly encourage the use of renewable energy. The United Kingdom goes even further by moving from regulating energy use to regulating building CO2 emissions. Table 2 compares the key features of building energy codes across countries.

The most frequent and successful policies to promote renewable energy employed by governments across the globe are feed-in tariffs (FITs). By the end of 2013, 98 countries, states, or provinces had FITs, increased from 34 in 2004. The strengths of FITs include guaranteed grid access over a prolonged period (typically 15–20 years), with prices based on the cost of generation plus a reasonable rate of return. FIT payment is typically administered by the utility and derives from an additional charge for electricity imposed on national or regional customers. The German Electricity Feed-In Law, for instance, adopted in 1991, was instrumental to the advancement of renewable energy in Germany during the 1990s. It required public utilities to purchase renewably generated power from biomass, hydro, solar, wind, and landfill gas sources. Nine years later, the Renewable Energy Act was adopted, promoting renewable energy mainly through stipulating feed-in tariffs under which companies producing renewable energy are guaranteed that they can sell their “product” at fixed prices for 20 years. A surge in the production of clean energy has followed. This act also helped cover over 10% of Germany’s total energy consumption from sources like wind, solar, water, or biomass, and made it the world leader in photovoltaics. As a result, since 1990, the installed power capacity from renewable electricity in Germany has increased many times over (Frank 2014), reaching about 27% in 2014, nearly three times the share in the United States. Fixed prices are set for purchases of renewable

electricity at a rate above the retail market price for each unit of electricity fed into the grid in Germany’s FIT. Additionally, German FIT requires that power companies purchase all electricity from eligible producers in their service area at this premium rate over an extended time period. These tariffs are guaranteed for 15–20 years, and differentiated by type of renewable electricity, location, and size. Germany’s FIT has created jobs and built the country’s solar and wind industries.

Figure 5 compares the electricity consumption, prices, and bills of households in nine industrialized nations. The North American nations of the United States and Canada have the greatest household electricity consumption and the lowest electricity prices. However, household electricity bills in the United States are the second highest of the nine nations. Further inspection reveals the highest prices and smallest consumption rates are found in the European nations of Denmark, Germany,
and Italy. Despite these differences, the resulting electricity bills of the North American and European nations are comparable, since bills are a function of consumption and prices. The high levels of energy efficiency in Italy, Germany, and Denmark enable bills to remain affordable even with relatively high prices. Thus, while the policy-driven surge in renewables has escalated electricity prices in many European countries, their strong building codes and other energy-efficiency policies have curbed consumption, resulting in affordable electricity bills.

Energy transition at the national scale intertwines consumers, policymakers, and energy providers; to be successful, it requires a persistent and predictable policy commitment. The term “energy transition,” or *Energiewende*, originated in 1980 in Germany alongside calls to end the use of nuclear and petroleum energy. Germany’s energy transition toward cleaner renewable energy benefited from a decentralized energy market and focused primarily on transforming the supply side of the energy equation. In Germany the increasing focus is now turning to energy efficiency and the demand side. While energy transition has been a success in Germany, neighboring Netherlands has not experienced the same level of success. The Dutch transition to alternative energy sources has failed to attain widespread use in the Netherlands in large part because of frequent shifts in energy policy and delays in implementation (Geels 2014; Verbong and Geels 2007).

Understanding energy transitions through the lens of polycentrism has been gaining traction; it is an approach to energy and climate policy that taps into the strengths of geographic analysis. The existence of multiple authorities with overlapping jurisdictions operating at multiple scales of action – engaging multiple stakeholders – can provide a powerful policy environment for enabling clean energy transitions (Brown and Sovacool 2011). This multilevel perspective may explain why, despite evidence indicating the need to increase the use of clean renewable energy, coal’s contribution to electricity generation grew from 2000 to 2010. Following the 2015 Paris Climate Conference, countries across the world are beginning to decarbonize their energy systems by implementing an array of new policies. Explaining the diffusion of such policy systems across time and space (Matisoff and Edwards 2014) is a critical need which can capitalize on the geography profession’s strong analytic and conceptual tools.

References

EIA (US Energy Information Administration). 2015a. “Crude Oil Proved Reserves, Reserves Changes,

Access to modern energy services is essential to all aspects of human wellbeing; therefore, guaranteeing secure and affordable supplies of energy is a key concern of the state. Energy security is best conceived as a property of an energy system. Thus, a national energy system can be more or less secure and there are a multitude of factors that determine how resilient a particular energy system is to shocks that might threaten its integrity and thus the security of energy services to industries, households, and individuals. This “whole systems approach” highlights the complexity of energy security as a system property in an increasingly globalized and interconnected global energy system (Mitchell, Watson, and Whiting 2013).

The contemporary concern about energy security is not new. Daniel Yergin (2006, 69) identified Winston Churchill’s decision of more than a century ago to shift the British Navy from coal (which Britain had in abundance) to oil (which made Britain dependent on oil imports from what was then Persia) as marking the origins of energy security as a strategic concern for the state. For Churchill, “Safety and certainty in oil,” he said, “lie in variety and variety alone.” Today we still see physical security of supply as the core challenge to energy security and – in the absence of self-sufficiency – diversity or variety is still seen as the solution to import dependence. However, in the contemporary context energy security is a much more complex notion than just physical security of supply.

Since Churchill’s decision, access to oil has become a strategic and economic necessity and a major cause of conflict. This empowerment of petroleum has also bestowed geopolitical influence on the major oil-exporting states (LeBillion and Bridge 2013). The geopolitical use of the “oil weapon” in the mid-1970s by the Arab members of the Organization of Petroleum Exporting Countries (OPEC) resulted in the creation of the International Energy Agency (IEA) to coordinate the interests of the Western industrially developed economies (members of the Organization for Economic Development and Cooperation, or OECD). The initial purpose of the IEA was to coordinate Western energy policy and manage the Strategic Petroleum Reserve, with each member required to hold oil stocks equivalent to at least 90 days of net imports and to maintain emergency measures for responding collectively to disruptions in oil supply of a magnitude likely to cause economic harm to its members. The actions of OPEC proved counterproductive as high oil prices triggered economic recession and promoted energy conservation measures that reduced demand for oil. It also encouraged the OECD states to develop their own oil and gas reserves in Alaska, the Gulf of Mexico and the North Sea. After a second oil shock in 1979–1980 caused by a revolution in Iran, the 1980s and 1990s were a period of relative calm with more than enough oil to satisfy demand. In early 1999, the front cover of The Economist Magazine carried the headline that the world was “Drowning in Oil” and pointed out that in real terms oil was cheaper than in 1973. They speculated that the oil price
ENERGY SECURITY

might fall as low as $5 a barrel. They proved to be wrong, and less than a decade later the oil price hit a record level of $147 a barrel.

In the first decade of the new century, the geographical locus of growth in energy demand shifted eastward with the rise of China. The decade saw China become the world’s top oil-importing country. China’s rise was part of a wider wave of emerging economies that fueled sustained growth in demand for oil and gas. The consequence of the previous decades of plenty and the associated low price was a lack of investment in new production, and the global oil industry struggled to keep pace with demand. The situation was compounded by continuing instability in the Middle East: the loss of production in Iraq due to conflict, in Iran due to sanctions, and in Libya due to the Arab spring and civil war. The resultant period of high oil prices stimulated the development of unconventional oil and gas in North America, as well as substantial new investment in more expensive reserves, often described by the industry as “the end of easy oil.” The advocates of “peak oil” have argued that the global oil industry is close to its maximum rate of production and that there will soon be a significant reduction in production. However, the optimism surrounding unconventional oil and gas and the prospects of increased production from Iraq and Iran have quieted such concerns, for the moment at least. At the same time, the 2008 global financial crisis dampened energy demand and it has yet to recover. Thus, a combination of confidence about future production and the slowing rate of demand growth have relaxed concerns about peak oil, yet the oil price remains historically high, with analysts talking about a price of around $100 a barrel being the “new normal.” History shows that oil prices are volatile and in the summer of 2014 oil prices fell dramatically as supply outstripped demand and Saudi Arabia decided not to cut back on production, seeking to test the resilience of US tight oil production. For oil-exporting states, a prolonged period of low prices presents a huge political challenge as many of the world’s more autocratic regimes are supported by the rent derived from oil exports.

Discussion so far has focused on the traditional concerns related to the geopolitics of oil, but there is an additional challenge that complicates the contemporary definition of energy security, namely climate change. Benjamin Sovacool (2011, 3) has reviewed the policy and scholarly literature and identified 45 different definitions of energy security. He distilled those definitions into four dimensions: availability, reliability, affordability, and sustainability. Thus, energy security is about physical availability, reliability or continuity of supply, at prices that are affordable, and in forms that are environmentally sustainable. The latter links energy security to the need to reduce the carbon emissions associated with the global energy system, which is the single largest source of greenhouse gas emissions. The tensions between the different dimensions are also clear to see. Energy security comes at a cost and a tradeoff must be made between the level of security desired and the ability of the consumer to pay the price. Equally, low-carbon energy sources, at present at least, are more expensive than the incumbent high-carbon systems. Thus many in the energy industry talk of a “resource trilemma,” the tension between energy security, affordability, and decarbonization. But the “low-carbon” transition brings with it new energy security concerns; for example, in relation to the security of supply of the materials, rare Earth minerals and elements such as lithium that are essential to these new technologies. The intermittent nature of most renewables is also a new source of insecurity: backup is required when the sun is not shining, when the wind does not blow, and
when there is insufficient water to power the turbines or cool the reactors. Thus, the current “energy transition” retains all of the traditional energy security concerns associated with the hydrocarbon economy that will continue to account for the vast majority of energy production for the foreseeable future, and introduces a new set of energy security concerns that are related to the introduction of low-carbon energy sources. This demands a more integrated conception of energy security that recognizes the complex interrelationship between energy security and climate change. Some have called this the “new energy paradigm.”

The energy security literature has a clear supply-side bias reflecting the needs of the industrialized energy importing states, but the importance of “security of demand” for energy-exporting states is also an increasingly important consideration. If energy-exporting states are to invest in developing new fields and building new infrastructure they need to be confident that there will be demand for their production at a price that they consider to be fair. “Transit security,” or security of transportation, raises a third area of concern, with international trade in oil and gas being vulnerable to disruption at key “choke points,” such as the Straits of Hormuz and the Straits of Malacca, or to political disruption, as in the case of the Russia-Ukraine gas disputes in 2006 and 2009.

A final dimension that is now center stage on the policy and research agenda is that of energy access. The United Nations has declared 2014–2024 the decade of Sustainable Energy for All in recognition of the fact that there are still 1.4 billion people on the planet that do not have access to modern energy services. Although energy access was not a Millennium Development Goal, it is now included as Sustainable Development Goal 7 to: “Ensure access to affordable, reliable, sustainable energy for all.” This places the energy security concerns of low-energy societies in global context and poses a global energy dilemma: “Can we have secure, affordable and equitable supplies of energy that are also environmentally benign?” (Bradshaw 2014, 21). Addressing this challenge requires a much broader conception of energy security based on an understanding of the socioeconomic processes that drive demand for energy services.

Enlightenment geographies

Charles W.J. Withers
University of Edinburgh, UK

The Enlightenment, usually taken to be an intellectual phenomenon and a historical period, broadly equivalent to the “long” eighteenth century in Europe, should also be understood as a matter of geography with global reach and significance. The term “Enlightenment geographies” embraces three related concerns: the importance of where questions, and matters of scale, space, and place, in explaining what the Enlightenment was; the explanation of philosophical inquiries concerning human difference, cosmopolitanism, sociability, and comparative cultural development with reference to geographical factors, such as climate; and the content and purpose of geography as a subject and as a set of practices in the Enlightenment. Thinking geographically about the Enlightenment in these ways has challenged essentialist conceptions of the Enlightenment, and nation-based interpretations of the Enlightenment as only a European enterprise. Explanation of the Enlightenment’s spatial dimensions extends from the broader “spatial turn” in the humanities and social sciences since the 1990s, including evident recognition of the importance of geography in the history of science in particular, and in studies of colonialism and of imperial history in general.

For most contemporaries then and for modern scholars now, the Enlightenment was both a historical moment – by convention, the “long” eighteenth century in Europe (ca. 1680 to ca. 1815) – and an intellectual movement characterized by challenges to established authority, advances in natural philosophical (“scientific”) method, and new ways of thinking about the world that were distinguished by belief in the power of critical reason harnessed for human moral and economic improvement (Livingstone and Withers 1999). Considerable attention has been paid to the Enlightenment’s biographical, historical, and intellectual dimensions: to its who, its when, its what, and to its lasting legacy, the Enlightenment’s so what? Since the mid-1980s or so, a key distinguishing feature of Enlightenment studies has been recognition of the fact that the Enlightenment and its ideas, motivating personnel, and material artifacts did not “float free,” somehow “above and apart from” their spatial setting and social context. Locatable as well as datable, the Enlightenment importantly had a where (Withers 2007). This view has its parallels in work in Enlightenment studies that has sought to de-essentialize the Enlightenment as a single unitary intellectual phenomenon (Mayhew 2010; O’Brien 2010). It is also a reflection and consequence of that broader “spatial turn” in the humanities and the social sciences since the 1990s: as Brewer put it in 2004, “A glance out across fields of knowledge quickly reveals that ‘space’ became the master metaphor of late twentieth-century epistemology” (Brewer 2004, 171). Consideration of the Enlightenment’s spatial dimensions and of the content and purpose of geography in the Enlightenment has challenged established orthodoxies and proposed new ways of understanding the period and its intellectual concerns. Three main and connected themes may be distinguished.
Enlightenment geographies as matters of scale

The Enlightenment in national context

The nation has been the commonly used frame of reference in examining the Enlightenment’s geographies. The idea of the Enlightenment understood in national terms has two main variants. The first is signaled by “the Enlightenment in France,” “the Enlightenment in America,” and so on. The second is evident in “the Italian Enlightenment,” “the Scottish Enlightenment,” and the like. In the first, the Enlightenment is held to have both defining characteristics and variant national expression by virtue of the content and material form of philosophical or scientific ideas and their presumed unproblematic movement from one nation to another. In this view, the Enlightenment travels over time and across and between national space and, often, does so from an originating “core,” such as France or the Low Countries, to a “periphery” elsewhere. The second variant is suggestive of more distinctive Enlightenment characteristics resulting from given national circumstances. Yet, in this perspective, differences within the nation are obscured, and shared experiences above the nation may be neglected. For these and other reasons, these historiographical perspectives have been criticized and revised in recent years (Kors et al. 2004; Withers and Mayhew 2011).

What matters is not that there could have been a shared and single Enlightenment apparent at the national level: it is just that scholars should not take that interpretation, and the question of national scale, for granted. Persistent and uncritical use of the definite article has encouraged the presumption that there was such a thing as the Enlightenment, and that how we understand its geographical dimensions and implications is, simply, to trace its origins, expression, and dissemination in a national context. Omitting the definite article — and thinking of diverse enlightenments rather than any single essential Enlightenment — is to caution about the importance of differences within and above the nation. The Enlightenment understood as a single intellectual movement is undermined by differences between nations and the diversity within nations. The idea of the nation was anyway relatively new in the eighteenth century. In France from the 1680s, for example, map-makers and military surveyors were centrally involved in knowing the extent of their nation: in the Enlightenment, the nation of France was constantly being put to shape geographically. Further, to understand the Enlightenment’s geographies as only a national matter neglects vital social distinctions within the nation. In Portugal, for example, Enlightenment was characterized more by foreign intellectuals working within that nation than it was by nationals’ expertise.

Because Enlightenment ideas and ideals did not easily respect national boundaries, and rather than think of the Enlightenment as having only national expression, we should also approach its geographies in terms of transnational connections.

Cosmopolitan networks: the Enlightenment as a Republic of Letters

In eighteenth-century Europe and beyond, what sustained critical commentators in their inquiries over the power of reason and the improvement of the human condition was the spoken and the written word. Writing, reading, recording, and reporting bound people together in networks of communication and exchange. Ideas about natural diversity and human difference were shaped by the receipt of new data – plant species,
Cultural artifacts, and, on occasion, living human specimens.

Considered above and beyond the nation, the Enlightenment was a Republic of Letters (and of artifacts), defined by correspondence, a cosmopolitan intellectual outlook, practices of material and intellectual exchange, and networks of institutional communication. Such transnational geographies are apparent, for instance, in the makeup of the personnel involved in the expeditions that undertook to measure the transits of Venus in the 1760s. They are apparent in the difference between the publication of influential works – Adam Smith’s *Theory of Moral Sentiments* (1759), for example – and their reception and, often, later translation, and the mediated engagement with their cognitive content in different intellectual and institutional settings (Butterwick, Davies, and Sánchez Espinosa 2008). Thinking about the Enlightenment’s geographies in terms of cosmopolitan networks is well illustrated by the case of the Enlightenment in Latin America, or, more properly, in Portuguese South America and in Spanish South America. Enlightenment in Spanish South America centered not on European theories of reason or in the mobility of European texts but, rather, on the interpretations that could be placed on Aztec monumental epigraphy, on the dynamics of local Mexican scholarship, and on the efforts of the local intelligentsia in resisting attempts to transport the monuments and the scholarship back to Europe. This work has been supplemented by studies in the history and geography of Latin American Enlightenment science that point to the making of science as a form of local public good and to the importance of natural history expeditions and indigenous medical knowledge. The result is that the Latin American Enlightenment has been both “denationalized” and “creolized,” and Enlightenment in Spain and in Iberia has been rethought (Canizares-Esguerra 2001).

Yet, the Republic of Letters was not, as it were, a free country with open borders. Correspondence and material exchange took place principally between people deemed credible authorities by virtue of their social status. Those accumulative networks of correspondence and exchange that sustained the Republic of Letters centered on the intellectual interests of metropolitan Western Europe more often than they did on the peoples of the Pacific, or of America, or even of northern Europe. The facts of social and geographical variation do not weaken the idea of the Enlightenment as a dynamic and cosmopolitan phenomenon. They remind us of the need to pay attention to the global but unequal and asymmetric reach of Enlightenment ideas, and to the strength, direction, and cognitive content of the networks sustaining the Enlightenment at scales above and beyond the nation. This being so, the ways in which the Enlightenment’s cosmopolitan and national geographies were grounded in specific local settings can also be examined.

Local sites and active settings

The Enlightenment was always an actively local affair. Consideration of the Enlightenment’s geographies at a local scale is wholly consistent with its study at national and transnational levels and is in keeping with that more general de-essentialism that is a characteristic of recent Enlightenment historiography (Mayhew 2010; Withers and Mayhew 2011). Working with the Enlightenment at scales above and below the national reveals a series of situated local settings and practices – polite conversation in salons, instructive rhetoric in lecture halls, instrumental practice on board ships and in chemical laboratories, contemplative private
reading in domestic drawing rooms, taxonomic ordering in herbaria, and so on. Looking at the Enlightenment’s geographies in terms of one setting or as a series of local sites, most commonly in an urban context (see Elliott 2010 on Enlightenment England), discloses articulations of practice and performance, and often the presence of competing ideas that never attained widespread currency for one reason or another. Certain venues, such as learned academies and societies, and to an extent the universities, were key sites for the presentation and criticism of new knowledge. An overemphasis on local settings and the dynamics of individual places alone runs the risk of diminishing the shared dimensions of intellectual culture and popular practice and of failing to examine how Enlightenment ideas moved over space.

In sum, the Enlightenment operated, and may be studied, at different geographical and social scales. Understanding these scales as important, distinct, and yet related is not to accord a primacy of one over another. What matters is the relationships between scales: national pictures always had variant local expressions, cosmopolitan networks were always “earthed” in specific social settings and epistemological concerns; the practices of (say) Enlightenment botany in one place may not have been the same in another. Recognition of these different scales neither privileges one over another, nor sees any one topic as intrinsically more important than another. Rather, what is emphasized is that the Enlightenment should be understood as about processes of intellectual and material production and exchange in places and over space, not just as a period in time or as a philosophical movement. The result overall of such geographical thinking is to displace the idea of the Enlightenment as an essential thing by views of it as multiple and variegated, with, always, meaningful geographical qualifiers.

Enlightenment geographies as matters of practice

Exploring, mapping, and enlarging the globe

Geographical exploration in the Enlightenment aimed to bring the globe under the sovereignty of science, accumulating new knowledge through empirical inquiry and speculative theorization. In the Pacific, exploration revealed what was talked of as a new “Fifth division” to the world, Europe, Africa, and Asia having provided the first three and the Americas the fourth (Withers 2007, 89). Oceanic navigation gave the world a new and more certain shape, at least in terms of its continental margins. But Enlightenment voyages of discovery did not reveal or represent this geographically more diverse world easily, equally, or at once. Several explorers died undertaking such work. Others were imprisoned, yet others being either underfunded or overwhelmed by data. Continental interiors remained largely unknown. China was described in travelers’ accounts and depicted on the maps of Jesuit missionaries, but much was based more on hearsay rather than hard fact. The Arctic and Antarctic regions were not explored until much later.

Geographical discovery revealed a world of different peoples and diverse cultures, and an unimagined natural plenitude. The result was not always precision and certainty – although these were intentions commonly promised in the wording of explorers’ narratives – so much as a sense of wonder, even of astonishment. Contemporaries had to choose their words and actions with care: cultural contact commonly began with moments of linguistic and gestural incommensurability. Map-makers had to rethink their works. Guides to travel and to scientific procedure looked to establish methodological
rigor and descriptive standards in order to effect meaningful comparative analysis. The Enlighten-
ment even brought new types of map-makers into being. Most European nations had a mix of navigator-map-makers, geographers, commercial publishers, and land surveyors. The Enlightenment was distinguished by the rise to prominence of the professional military or state surveyor. France took the lead among the nations of Europe in being systematically surveyed in the Enlightenment under the direction of the Cassinis. In Bengal, military surveyors such as James Rennell produced atlases and maps that promoted and reflected the commercial expansion of Britain’s empire. Enlightenment map-making emphasized empirical observation and quantifiable measurement in the service of the state.

For many of the peoples encountered through geography and represented in mapping, such cartographic delineation often silenced or marginalized them. Symbols of geographical engagement, Enlightenment maps are often also works of cultural effacement. So, too, many Enlightenment painted depictions of “foreign” landscapes are framed by European conventions – of sublimity, of the primitivism of native otherness, or of the boundless luxuriance of a nature later subject to the remorseless logic of resource extraction. In the Enlightenment, moves toward realism in representation were associated with the development of standards in measurement, observational training, systematic collection, and comparative explanation in science. Yet, geographical encounter with the faraway and with the exotic nearer at home – of the Lapps, for example, or the Scottish Highlanders – was most often undertaken on Europe’s terms. What commonly followed in the wake of explorers’ ships were unequal commercial and cultural relationships (Carey and Festa 2009).

Knowing the world: the rise of authoritative science

The new facts obtained by Enlightenment exploration challenged established views of the age and origins of the Earth and the authority of religious interpretations, as well as providing the foundation for modern scientific disciplines extending from that more general pursuit, “natural philosophy.” Two examples, geodesy and botanical classification, illustrate these claims.

In the early Enlightenment, the shape of the Earth was hotly contested. To adherents of Newton’s gravitational theory, the Earth was elliptical in shape, flattened at the poles. To proponents of Descartes’s ideas about vortices, the Earth was a different shape entirely – extended at the poles, flattened at the equator. The solution to these contrasting views over the geography of the whole Earth demanded empirical testing in those parts of the world that would permit proof, namely on the equator, and if not at the North Pole itself, then as far north as possible. Two expeditions were undertaken to this end in the 1730s. The first, in 1733, under the guidance of the Newtonian and French mathematician Pierre-Louis Moreau de Maupertuis, went to Lapland. The other, in 1737, under the direction of Charles-Marie de la Condamine, was based in the Viceroyalty of Peru. The results of the expeditions proved Newton and Maupertuis right. In such ways, geographical fieldwork, often from local sites but with global consequences, could test, corroborate, and refute book-based reasoning. Mathematics, and not the scriptures, became the language through which nature’s secrets were revealed and explained.

From the mid-1730s, botanists increasingly put the world of plants to taxonomic order. In the schema proposed by the Swedish naturalist Carl Linnaeus, the botanical world was classified on the basis of plants’ sexual characteristics, and involved a standard nomenclature of generic and
of specific names. Linnaeus also identified five global climate zones by which to explain the distribution of plant types, and he experimented with the acclimatization of species from one zone to another as part of his interests in economic and colonial development. For Linnaeus and many others, botanical inquiry with a utilitarian end in view was central to enlightenment as a process of human improvement. It is important to note, however, that his taxonomic ideas, formulated in Uppsala and based on fieldwork in Dalecarlia, were not accepted everywhere. Even as the empirical natural sciences became established, the map of Enlightenment scientific activity looked different in different places: the Enlightenment natural sciences were formulated within and reached across particular geographical circumstances (Clark, Golinski, and Schaffer 1999).

Encountering human difference

Enlightenment geographical discovery was greatly concerned with the “shock of the human new”: reports about human cultural variety flooded in – of pygmies, “cannibals,” Pacific natives, North American tribes, Australian aborigines – and challenged long-standing explanations on the basis of first-hand observation. New evidence about human variety helped establish what Enlightenment contemporaries termed the “science of man,” that is, they brought questions of science as observational and deductive method and of utility as outcome to bear on the moral and the human world, not just on the physical and the natural world.

Conceptual models of human development commonly placed “European man” at the head of sequential and progressive stages of social development and positioned other peoples and cultures beneath them, at different developmental stages. The Enlightenment was thus characterized by geographies of human difference in time, wherein ideas about different social systems were used to advance theories about relative social development, and by geographies of human difference over space, in that these different social systems and stages of human development were present simultaneously across the world.

Climate was often invoked in explanation of these different human geographies. An important figure in this regard was Montesquieu, whose 1748 *L’esprit des lois* (*The Spirit of the Laws*) is a key work on the effects of climate as a physical determinant of the moral bases to human behavior. What geographers and naturalists such as Linnaeus took to be the “temperate zone” Montesquieu saw as a space of moral and cultural equability. But to the north and, especially, in the warmer south, climate determined different degrees of cultural capacity vis-à-vis the “norm” of temperate Europe. Montesquieu was in part advancing an environmental explanation based on others’ theories. But he was also providing, broadly, an attempt to explain the nature of the human condition and its geographical variability. Others thought his emphasis on physical causes misplaced: for Voltaire and Hume, for example, social agency and not temperature or latitude was the basis to human difference. In such debates, Enlightenment commentators were developing and employing new analytical and rhetorical instruments by which to explain human difference. Even the terms they employed – “race,” “nation,” “variety,” and “species” – changed over time and were differently used in different Enlightenment settings.

In his initial classification in 1735 of the genus *Homo* and its single species, *sapiens*, Linnaeus incorporated four *varietate* (varieties): “Europaeus albus” (white European man), “Americanus rubens” (American red man), “Asiaticus fus-cus” (Asian yellow man), and “Africanus niger” (African black man). His classifications changed as new data were acquired. Linnaeus took the
world to be made up of different fixed varieties. Others saw more dynamic relationships within la variété humaine. At the same time, ideas of the progressive, stage-by-stage, development of human society from hunting, pastoralism, and agrarianism to commercialism, helped position the “West” in relation to the “rest.”

What people then understood as the “science of man” was in several senses a “geography of man.” Human geography was a matter of location and distribution (who was where?). Inquiries into human distribution as a matter of geography (why were those peoples there?) sought explanation in climate and latitude. For others, geography was not a fixed natural base against which human cultures were determined, but rather something that could be molded by human agency. For that reason numerous works of economic commentary and of philosophical speculation in the Enlightenment were concerned with improvement as the geography of the future—not with what was and has been, but with what could be.

Enlightenment geographies and the subject of geography

Geography’s print cultures

As Enlightenment geographies revealed the world to be bigger and more diverse, geography’s print cultures incorporated and disseminated that new information. Alongside mapping, these print cultures took, broadly, two forms: books of geography and geographical periodicals, and texts in which geographical reasoning featured as part of the production, mobility, and reception of the Enlightenment’s ideas.

English-language books of geography produced in Britain tended to position Britain as the leading nation in advancing geographical understanding, the French doing likewise for their geography texts. Geographical authors were seldom geographers by background or training, being usually compilers of others’ facts. Some authors were abreast of Enlightenment theorizations about human difference. William Guthrie’s A New Geographical, Historical and Commercial Grammar (1770) explicitly linked geography to theories on the stage-by-stage development of human societies (Mayhew 2000). In North America, Jedidiah Morse’s Geography Made Easy (1784) and American Geography, or A Present Situation of the United States of America (1789) were the first books in Enlightenment America to shape its national consciousness through geography. Before and after independence from Britain, the new geography of the North American continent represented challenges to established knowledge and to political administrators alike. Mapping made the new republic visible as a geopolitical space, albeit slowly. For geographical authors, new information was needed if the emergent nation was to be understood and governed properly. Morse’s works are part of a distinctive geographical print culture in early America. Morse reversed established publishing practice, putting America before—and, by implication, above—Britain and Europe. The fact that he regarded Connecticut (his home state) as the most virtuous in the new nation, and saw the Southern states as being prone to indolence through drink and the effects of climate, illustrates geography’s moral dimensions as a basis to national identity (Mayhew 2000; Withers 2007).

The Encyclopédie, ou Dictionnaire Raisonné, edited by Denis Diderot and Jean d’Alembert and published in Paris between 1751 and 1765, has been seen by later commentators as the Enlightenment’s manifesto. Its editors considered it to provide a new map of the intellectual world in which the connections between categories of knowledge were presented. Geography had
close links with mathematics and with history and was divided into several parts, natural geography and political geography being the main divisions. If the Encyclopédie’s production and reception are considered, rather than its content, the Enlightenment may be seen to be a geographical phenomenon embodied in print. The Encyclopédie was published in Geneva, Lucca, Leghorn, Neuchâtel, Berne, and Lausanne, in addition to Paris. Many of the authors of the Paris edition were members of local academic institutions. Whereas its authorship was largely Parisian, the Encyclopédie’s sales reveal a different geography. Sales were generally higher in provincial France than in the nation’s capital, and in towns with an administrative and cultural focus. Patterns of readership and of authorship disclose different enlightenments.

Medical space

In France in the Enlightenment, significant geographical work was undertaken by the ingénieurs-géographes, military engineers trained in trigonometry and in survey techniques in order to realize the shape and content of their nation. In France and elsewhere in Europe, topographic mapping was paralleled by work designed to fix the position of the prime meridian, either at Paris or at Greenwich. In several countries, medical map work aimed to link topography and human wellbeing, often by association with local variations in climate and soil type. The Bolognese geographer and naturalist Luigi Marsigli prepared a plague map of the eastern Adriatic coast in 1700 in which, among other features, he calculated and represented the time geographies associated with distance from the center of the outbreak. Large numbers of map-based medical topographies were produced in France in the 1770s and 1780s, works that were, in effect, syntheses of meteorological, climatic, and demographic data geared toward more effective political administration. In Germany, the physician Leonhard Ludwig Finke outlined in 1772 what might be thought of as a “proto medical geography” by drawing on his experiences as a regional medical officer. In New York in the 1790s, physicians used dot maps to aid their treatment of the disease and speculate on its causes. For these and other philosophers and for officials at work on behalf of the state, their reasoning was geographical, the end in view political. Geographical thinking, and geographical techniques such as mapping, were tools for the practical improvement of the human condition.

Sociability and sites of geographical education

The Enlightenment was characterized by considerable civic engagement with geography in schools, learned academies, and universities, and in public lectures. There were seven géographes du Roi listed as members of the Parisian Académie des Sciences between 1699 and 1793, and a further 17 persons there recorded “geography” as their principal disciplinary interest. But, as noted earlier, many botanists, mathematicians, and physicians either employed geographical methods in their work or saw improvements in a nation’s geography as a worthwhile end in view. Geography was widely taught in Europe’s universities in the Enlightenment, in association with civil history, mathematics, and moral and natural philosophy. Because instructors in different institutions placed different emphases on different parts of geography, local geographies of geographical teaching can be sited. In Königsberg, Immanuel Kant concentrated on physical geography. In Göttingen, under Tobias Mayer and others, mathematical geography was to the fore.
There were over 20 different public geography classes in Edinburgh between 1708 and 1800, a story echoed in London and overseas in Europe and North America. In school, in public classes, and in the home, geography was spoken about as well as read and drawn or committed to memory and was learned through play involving geographical games and “dissected maps” (jigsaws in modern terms), as well as via formal instruction. For women and children especially, the home was commonly a site of geographical learning and of sociability.

The continued importance of the Enlightenment’s geographies

The Enlightenment’s where is as important as its when, what, who, and why. In the Enlightenment, the Earth was revealed as an object of geography through the geographical practices of exploring, mapping, and reporting. Geographical knowledge was a key component of Enlightenment theories about human culture. Geography the subject was a species of Enlightenment knowledge, evident in texts, instruments, polite conversation, and cultures of formal instruction (Livingstone and Withers 1999). The too often privileged geographies of metropolitan Europe were connected with and dependent on other parts of the world. Particular places – the Americas, Oceanic islands – were key sites for the making of world knowledge, not margins to an Enlightenment “core.” These facts of geographical difference require us now to dismiss the idea of the Enlightenment as an essential feature, explicable only at the scale of the nation. Uncritical (and too often repeated) notions such as “the Enlightenment project” should be dispensed with.

The Enlightenment – and its geographical differences – is with us still. That is, the Enlightenment continues as an object of modern study because of its political implications, its ideals, and its languages, and not least because it is unfinished (Schmidt 1996; Carey and Festa 2009). The Enlightenment continues as a scholarly object because its unequal legacy continues still. Progress is always shadowed by its “other,” exclusion and persecution: Enlightenment always had a dark side. Scholars continue to ask what’s left of the Enlightenment, and to inquire about its longer-reaching consequences, the Enlightenment’s so what? Because we live with the Enlightenment’s consequences, it is important that we continue to address the Enlightenment’s geographies.

ENLIGHTENMENT GEOGRAPHIES

Environment and celebrity

Dan Brockington
University of Sheffield, UK

There are many different varieties of environmentalism. Different environmental movements can be fundamentally opposed to each other and pit different social groups against each other. Perhaps the starkest examples occur when environments championed as wilderness, and suited best for luxury safaris for the international rich, are at the same time claimed as the dwelling places of much poorer rural residents of poor countries. Appreciating these varieties of environmentalism is essential to understanding the work of celebrity in environmental affairs, because we have to see not just how the support for environmental issues comes to be “celebrified,” but what sorts of environmental causes are espoused by celebrities, and what sorts are not.

As argued below, there are different kinds of celebrity at work in environmental causes, and that, for all of them, the nature of their involvement has changed recently as a more general professionalization of celebrity advocacy has taken place. The changes, for environmental causes, are bound up in the close relationship that mainstream environmentalism enjoys with contemporary capitalism. This also results in new forms of exclusion for other environmental causes. The entry ends with a conclusion on thoughts as to what further study of the work of celebrities and the environment can entail.

As described elsewhere (Brockington 2009), there are three types of celebrity at work in environmental affairs. First, there is the category of people who are already famous, and who lend their fame to conservation causes, with varying degrees of commitment. Some of the most prominent to do so might include Harrison Ford (an actor) who supports the work of Conservation International or Cate Blanchet (an actress) who supports a variety of environmental causes. In this category royalty have a particularly long tradition of supporting particular environmental and conservation causes. The Duke of Edinburgh (husband of the British queen) for example was involved in the establishment of the Worldwide Fund for Nature (WWF). His son, Prince Charles, and grandson, Prince William, have recently helped to set up United for Wildlife to campaign against poaching. The late Prince Bernard (of the Netherlands) was similarly active in his support of the WWF and conservation organizations in South Africa.

Second, there are the wildlife filmmakers and documentary makers who come into the public view because of the way that they speak for and represent nature. The most famous are Sir David Attenborough and the late Jacques Cousteau, others include the late Steve Irwin, Saba Douglas-Hamilton, or Charlotte Uhlenbroek. The films this group made were not necessarily focused on promoting conservation messages per se, at least not at the outset. Instead, this genre was used simply to capture the awe-inspiring beauty of nature and provided a source of entertainment in its own right. Conservation films, by contrast, were typically poorer in quality and had the unfortunate tendency to harangue tired viewers. More recently, the goals of nature filmmaking and conservation have drawn closer, however, as the filmmakers began to recognize the need to conserve scenic
ENVIRONMENT AND CELEBRITY

habitats and the charismatic species that formed the subjects of their documentaries. There is now more support for conservation within the sector as a whole.

The third group of celebrities working for environmental causes are those who have become famous because of their environmentalism. Some may only be famous within particular environmental movements, but others are now more widely known public figures. They include Henry Thoreau (a posthumously famous US environmentalist), John Muir (a champion of protected areas in the US), Gray Owl (a Briton who successfully masqueraded as an Ojibwa elder in Canada for decades), Sir Peter Scott (who co-founded the WWF), Dianne Fossey and Jane Goodall (both for their work with primates), and Jonathon Porritt and George Monbiot (both British environmentalists).

Note that fame is working in slightly different ways across these categories. This has been effectively brought out in the work of Olivier Driessens (2013). Drawing on Bourdieu’s work on different forms of capital and field theory, Driessens distinguishes between symbolic capital and celebrity capital. The former is recognized authority that is bound to specific social fields. The latter is recognizability and is not restricted to any particular field. This, Driessens observes, allows celebrities to migrate from one social field to the other, for example, from musical entertainment to rainforest protection (as has the musician Sting).

There are different sorts of such migration visible in the three categories of environmental celebrity offered above. The first group are using their celebrity capital in different domains – in environmental fields – from those where they first earned it. The second probably involve the least migration. From the public point of view these people make ideal spokesmen and women for nature. After all, the role of championing environments is precisely what their day job consists of; the authenticity appears to be natural. The third group have to try to allow their visibility within the environmental field to cross over into other domains. Particular individuals (such as Jane Goodall) have been especially successful in adopting this public intellectual role, particularly after taking on the role as a UN Ambassador for Peace in the 1990s.

It might be possible to approach this categorization of celebrity interest in the environment from the other way around and categorize not the celebrities involved, but the sorts of environmentalism for which they speak. There is a tendency for the rich and famous to support the landscapes and wildlife the rich and famous get to enjoy. One of the oldest conservation organizations, established in 1903 as the Society for the Preservation of the Wild Fauna of the Empire (now Flora and Fauna International), was popularly known as “the penitent butchers” because of their strong representation of the interests of wealthy big game hunters. Prince Bernhard’s support for, and secret funding of, violent antipoaching activity in southern Africa is very much in that tradition of aristocratic support for landscapes the wealthy love. Another tendency is that animal rights and welfare causes often tend to be popular among the glitterati; we could count Virginia McKenna’s Born Free Foundation as a prominent example. This introduces interesting tensions within the conservation movement as the animal rights movement is not necessarily the same thing as environmental conservation, which is more concerned with landscapes, species, and ecological systems than with individual animals. Thus, for example, Born Free activists have named and otherwise identified individual lions and will go to great lengths to protect each one, even in circumstances where the funds expended might arguably generate a
greater conservation benefit if the focus was the protection of whole ecosystems.

What is missing, perhaps unsurprisingly, from this list are the “environmentalisms of the poor.” These are the concerns for resources – firewood, thatching grass, grazing, and access to the same – which tend to characterize the lives of rural people in poorer parts of the world. There are relatively few nongovernmental organizations (NGOs) who champion these causes, at least few of the sort which work with celebrity, and fewer celebrities who can lend their name to this sort of environmentalism with integrity and authenticity. Vandana Shiva (an Indian environmentalist) or the late Wangari Mathai (a Kenyan Nobel peace prize winner) might count among that number, but they are a notable minority.

The history of fame and celebrity is a little unusual. As the list of famous environmentalists above demonstrates it has been a more or less continual feature of public life since the late 1890s. There has been a steady small stream of public spokespeople for natural causes for a long time. This is the not the case in other causes. International development, for example, was one of the main causes of fame in the Victorian era, but produced no famous figures in the first decades after World War II (Brockington 2014).

Recently, however, that has changed, and this is to do with the general rise of celebrity advocacy across all causes. It is undergirded by the rise of NGOs more generally from the late 1980s onwards. As neoliberalism took hold and faith and investment in states declined so NGOs stepped up, and forward, to become the vehicles of conservation, development, and environmental projects. They have mushroomed in number and size, and with it has their need for good publicity and celebrities to support their causes.

Mirroring that increase has been the rise of celebrity itself. This is not a recent phenomenon – historians of celebrity date its significance as a social phenomenon from at least early Victorian times (Boorstin 1992/1961). Contemporary forms emerged with the rise of cinema in the early years of the twentieth century. Celebrity flourishes in part where different media provide new ways of being seen and new potentially lucrative sources of income. Accordingly when the forms of media multiply – with cable and satellite TV, new glossy magazines, and the Internet – then the number of celebrities also multiplies. This is what happened in the 1990s (Marshall 1997). Thus the rise of celebrity advocacy is partly due to the rise of celebrity itself.

But we should not think that technology determines celebrity. Celebrity is also a means of organizing fame and appearance (Gamson 1994). And this is particularly visible in the last 15 years when there has been a reorganization of the relationship between the celebrity industries and the NGO sector. This is now coming to drive the relationship between environmental causes and celebrity.

In its simplest terms, the work of the famous for good causes, including environmental issues, is now much more systematic and organized than before (Brockington 2014). Celebrity liaison officers have full time posts in most of the major charities in the United Kingdom; these have generally been established since 2000. Three of the largest talent management companies in Hollywood have established foundations to manage the charitable interests, and appearances of their clients, also since 2000. There are now websites (Look to the Stars) which document the charitable activities of the famous and newspaper columns doing the same. Celebrity advocacy has become a specialist niche of the celebrity economy more generally. Companies (such as the Global Philanthropy Group) exist to advise celebrities on their philanthropy and help them to give wisely and build their brand while doing so.
ENVIRONMENT AND CELEBRITY

Environmental causes feature prominently in these developments. Ecorazzi was one of the first websites documenting the work of the famous for environmental causes and, as its name suggests, specializing in environmental causes. There are also specialist nonprofits which work to link environmental causes for the famous. Consider, for example, the Environmental Media Association (EMA) whose “generation E” campaign involves partnering with environmental groups with EMA’s role being to secure “talent,” that is, celebrities, as well as all of the other paraphernalia of successful media events and networking to support media rich campaigns.

Undergirding this professionalization of celebrity advocacy in environmental causes is an important fact: the work of celebrity for environmental causes is part of a more general trend – the integration of capitalism with environmentalism (see also Conservation and capitalism). There is a tradition of seeing environmentalism as opposed to commerce and business, of resisting the advances of development, use, and modification of the environment. But, as we have just seen, there are many varieties of environmentalism. These days the dominant form of environmentalism, mainstream environmentalism, enjoys a close working relationship with corporate capitalism.

Celebrity environmentalism is part of that trend in several ways. In the first instance it is a business in itself. Celebrity environmentalism makes commercially valuable films, books, and images. This has been true for a while. Gray Owl rose to prominence as a great publishing success and made wildlife films. The Adamsons’ work with lions was also a publishing success story (although that was not the reason driving their work). But it is central to the business model of some wildlife and nature film presenters that they use their fame and public prominence to promote other businesses and products. The Irwins, an Australian family, are probably the most successful at this – even after the death of the main presenter Steve Irwin (famous for his Crocodile Hunter series). Others will sell access to their expertise and knowledge of nature in the form of safaris and holidays for the privileged.

But, more generally, the rise of celebrity advocacy within the NGO movement as a whole has been fueled by corporate hunger for access to celebrity. Celebrity sponsorship for commercial purposes is expensive. Associating with celebrities via NGO intermediaries is free. Therefore many companies are seeking links to NGOs, as part of their corporate social responsibility agenda, but are doing so partly on the grounds of the celebrity support to which they could then get access. It is routine these days for NGOs to advertise the possibility of access to celebrity patrons on their corporate sponsorship web pages. Indeed, NGOs have to be careful that their celebrity patrons do not inadvertently endorse companies’ products. Free association is allowed, but free endorsement would threaten the celebrity business model.

Celebrity environmentalism is therefore both manifestation and lubrication of the close relationship that many environmental causes enjoy with capitalism. At the more powerful end of the spectrum, where the more influential groups are gathered, the displays resulting are, literally and deliberately, spectacular. Prince Charles can muster the world’s leading financiers in the heart of the City of London in support of his campaigns to make the carbon in rainforests valuable. The Conservation Caucus Foundation brings together the world’s largest NGOs, companies like ExxonMobil, International Paper, BP, DuPont, and Walmart, over one hundred of the top politicians in the United States, and leading celebrities like Harrison Ford in prominent displays of concern and networking opportunities for environmental causes.
“Spectacular” here does not just mean an extraordinary event that draws the eye. It has a more formal meaning which further deepens the intertwining of capitalism and environmental causes, and is best explained in Jim Igoe’s work, drawing on the writings of Guy Debord (1995/1967; Igoe 2010). Debord wrote critically of how commodified images – what he called “spectacle” – shape social relationships in late capitalism. He argued that such spectacular images, and the processes that bring them to our attention through popular media in the first place, effectively obscure as much as they reveal. Igoe (2010) argues that this plays a vital role in the promotion of conservation and environmental causes. Using the example of the African Wildlife Foundation (AWF), he shows that images of happy and successful conservation initiatives, and the wielding of powerful brands by conservation NGOs, conceal the patterns of inequality and local impoverishment that often beset human populations living in or near conservation areas as well as profound and unexpected transformations to ecosystems. As Igoe puts it: “The fetishization of connections and relationships through spectacle thus shields Western consumers from the more complex and problematic web of connections and relationships in which they are actually enmeshed” (Igoe 2010, 389).

How can we better understand the role of celebrity in environmental affairs? There are three possibilities. In the first instance a constant gap in celebrity studies is the relative lack of audience studies. Outside of business schools’ studies of marketing and advertising (which produces samples largely composed of US undergraduates) audiences are relatively neglected. It has been suggested that celebrity advocacy is marked by the lack of purchase from which it suffers in many audiences (Brockington 2014). Many people are just not that interested. But this study was of British audiences and celebrity cultures and responses to celebrity vary enormously from country to country. Exploring the contours of this and the ways in which celebrity can be important to identity work would be important contributions.

Second, as Igoe’s work shows, it is important to follow particular consumer goods through society and explore the social relations they embody. Ethnographic approaches can be used to examine the creation, production, and consumption of different celebrity-environment spectacles and show what is elided, omitted, or concealed by them as much as what is supported.

Finally, Holmes has suggested, following Sklair, that we can speak of a transnational conservationist class (Holmes 2010). He has also shown that we cannot assume that this is a united class, but that there will be important divisions and differences within it based on, for example, national identity. Celebrity support for environmental causes is part of this elite formation. Accounts of how these elite networks function and what power they wield would be a valuable addition to this growing field.

ENVIRONMENT AND CELEBRITY

Environment and consumption

Laura Pottinger

University of Manchester, UK

Awareness of the environmental consequences stemming from processes of production and consumption has grown in recent decades, as consumers become increasingly anxious about the negative effects of contemporary lifestyles. Persuading individuals to shift their consumption practices is a core strand of contemporary environmentalism, but the increasing popularity of politicized consumption is not without critique. Theorists in geography and beyond have paid close attention to the impacts of key spheres of consumption such as food, energy, transport, fashion, and tourism, and have sought to understand how environmentally damaging processes can be mitigated or reversed. Changing consumption behavior may be one solution that enables environmental resources to be better managed or protected.

The subset of consumption practices aiming (or claiming) to be more environmentally or socially responsible are variously referred to as “ethical,” “green,” “sustainable,” or “political” consumption. The diverse set of approaches encompassed by these labels are also sometimes referred to as “alternative” because of their oppositional or separate relationship to mainstream markets, though the degree to which individual approaches reject market relations varies. Fairtrade, for example, utilizes capitalist commodity markets and global supermarket chains to sell products in order to provide producers with a social benefit alongside profits. Other approaches entail a more fundamental rejection of consumerism, the attachment to materialistic values and possessions, and a growth-oriented economic model based on consuming in progressively greater amounts. “Voluntary simplicity” approaches, for example, instead advocate a reduction in overall consumption and simpler lifestyles. Broadly, green consumption as an environmental solution implies that disparate, individual purchases and everyday actions are significant when considered together, and can be connected to form a powerful political voice capable of reforming global actors such as corporations and governments. Critics, however, note its limitations for environmental protection, suggesting that consumer capitalism and environmentalism are fundamentally opposed.

Environmental implications of consumption

Historically, environmental resources were assumed to be inexhaustible inputs into capitalist systems of production and consumption. The ways these systems of commodity production functioned and evolved depended on treating the environment as an externality ripe for human exploitation. In the latter half of the twentieth century, this instrumentalist view shifted toward seeing the environment as fragile and in need of protection, and recognizing that finite natural resources could not be exploited indefinitely. Yet accelerated consumption patterns continue, particularly in Western economies and newly industrializing nations with burgeoning middle classes. This is having dramatic consequences...
ENVIRONMENT AND CONSUMPTION

for the climate, ecosystems, and biodiversity, as a result of raw material and energy input into production, distribution, use, and disposal of commodities.

Modern agriculture, industrial production, and personal transport, for example, are still largely dependent on oil and other finite, nonrenewable energy sources. This creates carbon emissions that contribute to anthropogenic climate change, and there are often controversial consequences of extraction, such as oil spills or violent disputes. Pollution of the biosphere, deforestation, and overfishing of marine resources can all be seen as stemming from the ways our food, clothing, houses, holidays, cars, computers, and so on are produced and consumed. These damaging impacts are exacerbated by how we consume and what we expect from our lifestyles, or are persuaded we deserve. Affluent consumers see buying fresh food and flowers out of season, disposable “fast” fashion, foreign holidays, and individual car travel as the norm, and global brands hotly compete to satisfy these desires. The rate and quantity at which consumers buy and throw away commodities has negative environmental consequences, particularly within the industrialized economies of the Global North. In the United Kingdom, for example, household purchase and disposal of uneaten produce accounts for millions of tons of wasted food each year, which has significant impacts not only for landfill (Figure 1) but also in terms of the energy and water used up in production.

History of consumption research

Consumption is defined as the using up of a good or service, and incorporates selection, purchase, use, upkeep, repair, and disposal as waste or recyclables. Processes of consumption closely overlap with those of production, and together these are fundamental elements of social life. Commodities, which are things produced for the purpose of exchange, can hold important social and symbolic value, and are utilized to display class, taste, gender, or group membership. In the consumptive act of eating food, the human body is sustained and biologically (re)produced, and consumption is also implicated in the production of meaning and identities.

However, the spheres of consumption and production were traditionally separated in academic research, with spaces of production historically receiving more attention than those of consumption, particularly in Marxist and economic theory. Early social theorists such as Theodor Adorno and Max Horkheimer in the 1940s took a moralistic stance, focusing on the negative sides of consumption, and conceived consumers as “passive dupes,” controlled and manipulated by consumer capitalism and advertising. In the second half of the twentieth century, Pierre Bourdieu drew attention to the role of gift-giving and “conspicuous consumption” of luxury goods in defining identities and maintaining class distinction. From a more optimistic perspective, later cultural theorists, like Stuart Hall in the 1970s, emphasized the creativity and resistance enabled by consumption practices, suggesting that consumers possessed the capacity to subvert and appropriate meanings associated with commodities.

The latter half of the twentieth century has been characterized by accelerated levels of human consumption and production accompanied by growing interest in the dynamics of consumption and its environmental impacts in popular writing and media coverage. Environmental concerns have moved up the agenda since the 1970s, with companies like the Body Shop among the first to recognize the potentials of green capitalism by aligning business with an environmental/social justice ethic. In one way,
the current fascination with green consumption marks the success of environmental campaigns and green agendas of the late twentieth century, which questioned the economic centricity of development paradigms. The Brundtland Report, published in 1987, redefined sustainable development as necessitating a balance between the economic, social, and environmental, implying that, rather than acting in opposition to environmentalism, economic growth can be compatible with preserving diverse ecosystems and protecting the planet (WCED 1987).

**Perspectives on green consumption in geography**

Until recently, consumption has been relatively ignored within geography. However, interest in the subject has grown in the last few decades, with research into consumption drawing on two major approaches. First, some work is driven by economic geography perspectives, including that on global value chains (GVC) and global production networks (GPNs). This research has furthered understandings of the
spatialized relations in networks of production and consumption and how they touch down and are embedded in communities, environments, and localities. Research on GVCs and GPNs has both informed and interrogated an array of social and environmental codes of conduct that seek to modify and adapt unsustainable production processes, such as the Ethical Trading Initiative, which is a multistakeholder alliance of companies, trade unions, and nongovernmental organizations (NGOs).

Second, other work reflects the “cultural turn” more strongly, and considers how consumption practices are made meaningful by consumers. This research draws economic relationships between production and consumption together with critical analyses of the cultural and material dimensions of consumer conduct. It addresses consumption as an emotional and affective practice, which can be motivated by desires for novel experiences or authenticity or by concern for others, for example.

A prevailing view across approaches within geography is that environmentally damaging processes persist because of a spatial and cognitive distance between spaces of consumption and production (Scales 2014). Powerful global firms like multinational supermarkets extend across the globe through vast networks of national suppliers, producers, and subcontractors. The effect of the increasing globalization of production practices, supply chains, and consumer brands is that consumers are dislocated from the impacts of their consumption on the environment. This means that they are less able to see the environmental effects of the products they buy, either because production is hidden behind the factory door or because waste products are exported to another country for disposal.

Some geographers have drawn on the theory of “commodity fetishism” proposed by Karl Marx, which suggests that a veil is drawn between commodities and the conditions of their production, concealing the social and environmental source of the value of commodities from the consumer. From this perspective, the disconnection between spheres of consumption and production allows “enchantment” with commodities to be created; their magical, alluring qualities are achieved by masking the true nature of their origins. For example, the glossy, multimillion dollar campaigns advertising the latest smartphone do not portray the long working hours factory employees endure or the conflict minerals used in their fabrication. The removal of consumers, both geographically and ecologically, from spaces of production makes them unaware of the environmental impacts of waste, resource depletion, pollution, and so on. This lack of understanding means that they may be less likely to change damaging environmental practices.

Informing consumers is a popular solution aimed at overcoming the dislocating effect of globalization and, in turn, combatting some of the negative environmental impacts of consumption. Underlying many campaigns that promote green consumption is the notion that consumers would act more ethically if only they were made aware of how the commodities they buy are produced. The thinking here is that consumers who lack knowledge can be educated, which will cause them to change their behavior, and that this in turn will persuade companies or governments to reform. Consequently, the way green consumption is mobilized often depends on increasing consumers’ understanding of environmental issues and the impact of their individual actions.

NGOs are among those trying to achieve this, including ethical consumption campaigning organizations and conservation charities, for example World Wide Fund for Nature (WWF), Greenpeace, and the Fairtrade Foundation. They
facilitate green consumption by providing consumers with information and advice, developing labeling and certification schemes, lobbying governments, and engaging with companies through multistakeholder groups. As a result, many corporations have also begun to recognize the value in “greening” their image, not only to mollify those customers dissatisfied with a poor environmental track record, but also to actively attract eco-friendly consumers and generate new markets. The rationale behind green consumption is that consumers wield the power to challenge global brands by voting with their cash, thereby persuading environmentally destructive corporations to change. Supermarket customers may be able to buy air-freighted asparagus all year round, but consumers can also choose to purchase less environmentally damaging products as a way of persuading companies to behave more ethically. However, while some argue that these increasingly complex and spatially diffuse supply chains are driven by consumer choice, others reject what they see as an oversimplified relationship between supply and demand, and highlight the ways that demand and desire are created and manipulated through advertising and branding.

There are two main ways in which NGOs and other campaigning organizations aim to reeducate dislocated consumers and to promote green consumption: first, by providing information; and, second, by reconnecting consumers with practices and spaces of production.

Providing information

Providing consumers with accurate, easy-to-interpret information is often seen as a panacea for encouraging behavior change and “better” consumption practices: buying eco-friendly products, boycotting environmentally damaging brands, or making lifestyle changes like recycling or using public transport. This may take the form of state- or NGO-led campaigns, or sensationalist exposés of unsustainable or undesirable practices. For example, the popular documentary film *Food Inc.* (2008) scrutinizes the corporate food industry, exposing the harmful outcomes for animal welfare, human health, and the environment resulting from the practices of major companies producing cheap food in the United States. Perhaps the most prominent method of information provision is via ethical product labeling (Figure 2), such the Soil Association’s Organic food certification and Forestry Stewardship Council (FSC) labeled timber.

While the assumption that educating discerning consumers will generate more environmentally friendly consumption behaviors has
permeated campaigns, media coverage, and academic literatures, it has also been criticized. The idea of the consumer who makes self-interested “rational choices” about the environmental impact of their purchases based on available information comes from classical economics. However, it has several flaws. First, consumers are not always rational in their purchasing decisions. Second, it assumes a straightforward transfer of information from the producer to the supposedly ignorant consumer, which overlooks the ways in which information is received, reworked, or even ignored by individuals. Third, it also fails to account for constraints such as time, money, or access that might prevent consumers acting on information provided.

As a consequence, people’s actions when consuming often do not match their stated pro-environmental intentions, producing what has been termed the “attitude–behavior gap.” The issues confronting “ethical” consumers are complex, often contradictory, and rarely are they easily encapsulated in product labels. For example, consumers may find it difficult to weigh up the negative carbon emission impacts from air-freighted fresh produce against the social justice imperatives of fairtrade that stimulate economies in the Global South. More recently, the idea of the “rational” consumer has been criticized for assuming that consumption practices take place in a vacuum rather than being embedded in social networks and contingent on complex, wide-ranging factors such as economic capacity and commitments to friends or family members. Research into ethical consumption has shown that much of what we may consider to be ordinary consumption actually has very little to do with choice. The justifications people give for not consuming ethically should perhaps be understood as expressions of genuine frustration at being burdened with too much responsibility (Barnett et al. 2011).

Reconnecting consumers with practices and spaces of production

A second approach that uses knowledge to promote green consumption is that of “reconnecting” consumers through localized or alternative consumption practices. This can be challenging, particularly for global issues such as climate change, where individuals are unlikely to directly register the impacts of their consumption on carbon emissions. Attention to moral geographies of consumption has raised the question of whether ethical actions are only possible in local places that we know or feel some connection toward. Since space or distance is often understood as a barrier to responsibility, one solution to the problems associated with consumers’ increasing separation from production has been the idea that we should “think globally, act locally.” This assumes that people are more likely to support their own communities, worry about the plight of local farmers, or defend nearby green spaces under threat of development, and so on, than to care for distant others.

Buying commodities produced locally or sold by small independent businesses is presented as one way consumers can overcome the alienating effects of globalized production. Many alternative food networks (AFNs), for example, are premised on reconnecting consumers with local agricultural producers. AFNs may include local vegetable box schemes (Figure 3), community gardens (Figure 4), or farmers’ markets, which provide food differently from mainstream market relations, often with a significant emphasis on community, trust, and place-based production. Sourcing locally grown food is appealing because, in addition to reducing the environmental impact of the transportation of food by cutting down “food miles,” it gives the impression that the network spanning production to consumption can be more easily known.
While buying local makes sense for consumers on many levels, uncritical championing of localization is problematic, especially where it works by identifying local and rural environments as bounded places under threat from outside influences such as global corporations. This presents the global/local as a binary opposition in which the local is the privileged location for trust and responsibility, while the global is seen as threatening. This can lead to defensiveness and intolerance of outsiders or new ideas. It also limits the scope of moral duty and action to immediate locations, suggesting that we can or should only care about those who are in close proximity. Furthermore, the ability of such reconnected consumption practices to expose the true nature of fetishized commodities is questionable. Eco-labeled commodities and ethical food are still marketed and made enchanting, just in a different way. The example of how food is offered within farmers’ markets (Figure 5) illustrates how ethical consumption itself can fetishize commodities. Physical proximity, interaction between producer and consumer, the aesthetics of the market, and promotional material that draws on geographical imaginaries of local places all help to repackage ethical food as “connected,” adding mystique and allure through ideas about authenticity.

**Politics and governmentality in green consumption**

Though we may have become more aware of the impacts of our consumption practices since the late twentieth century, researchers in geography are divided over the effectiveness of green consumption for protecting the environment. There are two main perspectives on political agency in green consumption. The more optimistic perspective highlights how consumption has become an important mode of political action that is democratic and accessible to a wider demographic than traditional party membership or political lobbying, and symbolizes a flourishing engagement in political and environmental issues by a wide range of people in their everyday lives. Theorists writing from this perspective (e.g., Barnett et al. 2011) stress the participative and collective dimensions of what they call “political consumption” (rather than “ethical consumption”). The implication is that naming consumption activity as “political” redefines it as action that makes collective claims.
on states or institutions, forcing them to act on environmental issues. Consumption is frequently understood in terms of voting, and this analogy seems to stitch together the seemingly individualistic nature of consumerism with the collective ideals of citizenship. Deirdre Shaw’s (2007) interviews with ethical consumers, for example, found that participants routinely expressed their purchases in terms of “votes,” and felt a reduction in their overall consumption would limit their power to effect change. The idea that we can register a vote for organic agriculture or rainforest protection with each purchase we make is compelling. Although some strands of ethical consumption seek to reduce overall levels of consumption, ethical consumption is attractive to individuals because on the whole it is not based on asceticism, constraint, and consuming less; rather, it is about consuming better.

This perspective argues that, as consumers, we want to feel empowered by this sense of agency rather than seeing ourselves as passive dupes, constrained by hegemonic marketing forces. By celebrating the citizenship dimensions and political dynamics of consumption, “political consumption” to a certain extent overcomes the moralizing tendencies displayed in previous academic and societal treatments of consumption. Importantly, individual acts of shopping
or purchasing can be joined together through ethical consumption to create a powerful collective voice. This perspective argues that the policies and marketing strategies reconnecting consumers spatially and cognitively, such as labeling, do mean that consumers are more aware, and in some cases environmentally irresponsible corporations have been persuaded to clean up. The logic that companies will respond if their action equates to more sales makes green consumption seem like a win–win solution.

The second perspective sees green consumption less positively as reformist, neoliberal, and symptomatic of citizens’ disengagement with traditional modes of politics. Critics suggest that the increasing turn to lifestyle politics demonstrates disillusionment and apathy with traditional forms of political lobbying and campaigning. Some have noted that this heralds the increasing commodification of nature and the social realm, as entities that were previously viewed as unsaleable are transformed into goods that can be traded. An example is emissions trading, an approach adopted by various countries and aimed at controlling pollution, which uses a market-based system of providing economic incentives for reducing pollutant emissions. Carbon credits can be bought and sold by governmental bodies, effectively enabling the purchaser to buy the right to pollute.

In contrast to prevailing paradigms of sustainable development, this more skeptical perspective argues that green consumption can only reinforce rather than challenge the logics of neoliberalization and relentless economic growth, which are fundamentally incompatible with environmentalism, limiting political activism to questions of what to buy (or not buy). This perspective sees the politicized representation of consumption—as voting as problematic in a number of ways. First, by aligning consumption with political clout, it seems to encourage increased levels of consumption, which both fails to address the corporate interests this serves and the material environmental impacts of overconsumption, such as resource depletion, landfilled waste, and energy usage. It also sidesteps the fact that, while democratic principles allocate each citizen with the same number of votes, not everyone can participate equally in a “market democracy,” because it privileges those with more money, resources, or human capital.

Second, the rhetoric of consumer choice is used to stimulate awareness and evidence support for green consumption, but emphasizing choice displaces responsibility into the hands of individual consumers. This prevents claims being made on the real culprits: more powerful actors, such as states, institutions, or corporations, who are better equipped to mitigate environmental ills. Third, focusing on consumer choice and “ethical” consumption invokes the “unethical,” “irresponsible” consumer who must be persuaded to act differently and make better decisions. This could be seen as a renewed moralism and judgmental stance that is both elitist and exclusionary. From this perspective, ethical consumption is too tied up with questions of taste, class, and status displays of eco-awareness, which perhaps reflect the expendable wealth of the consumer more than their environmental friendliness.

One way to analyze green consumption from this more pessimistic perspective is using theories of governmentality to address the role of identity and subjectivity in environmentally conscious consumption. Drawing on Michel Foucault’s work, this theorizes the intersection of the “consumer-citizen” and neoliberal forms of governance, in which responsibility is seen to be devolved to individuals whose preferences are expressed through the marketplace rather than by making claims against a social state. These approaches aim to understand how
consumers are governed and controlled, and have aided political economic theorizations of the connection between macro-level attempts to shift from state to market and the everyday processes at work at the individual level. These approaches often argue that “ethical” consumers may inadvertently be complicit in maintaining systems of inequality or environmentally damaging practices.

Drawing on governmentality theory with reference to alternative food networks and organic agriculture, Julie Guthman (2008) laments the way that what counts as political action today has been reduced to the individual purchases made by consumers. For Guthman, considerations of what to eat have taken precedence over collective boycotting. She argues this has been damaging to environmental movements seeking change in agricultural practices, and has “made agro-food politics so anemic” (Guthman 2008, 1181). Efforts to build what she deems marginal alternatives not only distract environmental activists from the big issues, but they foreclose collective options and are in fact very closely aligned with the neoliberal discourses of consumer choice, localism, entrepreneurialism, and self-improvement.

Under this perspective, even radical alternatives like organic food can be seen to change in character as they are mainstreamed into conventional consumption channels such as major supermarket chains. Both the scale and methods employed in organic agricultural production have been dramatically transformed to enable consumers to buy fresh organic produce year-round, bringing what began as a resolutely alternative food institution in line with conventional industrial agriculture and diluting the progressive environmental intentions of organic producers. In other sectors, radical alternatives have been co-opted superficially to “greenwash” the image of less sustainable companies, through corporate social responsibility initiatives or the creation of new “green” products. Paradoxically, promoting green consumption can be seen as creating new markets and industries rather than reducing consumption (Luke 1997).

New directions in theorizing environment and consumption

These critiques may imply that consumption-based approaches rarely accomplish more than assuaging an individual sense of inertia, making us feel better about our impact on the planet while substantively achieving relatively little. To overcome this, some geographers suggest that we move away from thinking about individual consumers and, instead, pay attention to the intermediary networks of campaigning groups and NGOs that mobilize ethical consumption (Barnett et al. 2011). What these organizations are very good at is connecting purchasing practices to wider themes of environmental stewardship or solidarity by providing people with resources to facilitate their engagement. This interpretation sees consumption not as an individualizing and depoliticizing practice, but as one of many activities linked together in a broad, collective effort that forms part of contemporary environmentalism.

What this more recent work shows is that individuals rarely identify themselves as “consumers,” but instead use purchasing practices to further their commitment to existing environmental concerns. Understanding individuals’ narratives about their prevailing commitments and routines, therefore, has become an important object of research. Contemporary studies of consumption have moved beyond conspicuous green identities and choices to address the everyday ethics at play in more mundane practices of “ordinary” consumption such as showering or
using electricity (e.g., Hall 2011). This atten-
tion to practices of consumption marks a move
from understanding agency in the purchases of
rational decision-makers, to recognizing how
consumers’ desires and behaviors emanate from
everyday practices and ordinary routines. This
area of research pays attention to the material
and social settings in which consumption prac-
tices are embedded and shows how attempts at
changing behavior are framed by infrastructural,
institutional, and cultural contexts.

In contrast to the moralizing tendencies
sometimes associated with ethical consump-
tion, researchers have found fertile ground in
exploring the embodied dimensions of green
consumption, looking at the role of bodily
sensations, feelings, and emotions in fostering
environmental commitments. Geographers and
anthropologists have addressed the pleasurable
and aesthetic dimensions of sustainable
consumption, particularly around alternative
models of food distribution and consumption
such as organic vegetable boxes, Slow Food,
and Community Supported Agriculture. These
studies have elucidated the tangible, tactile mate-
rialities of alternative food, and have revealed
how consumers experience these types of green
consumption. They highlight the importance of
looking at the roles played by moods, aesthetic
sensibilities, and pleasure in nurturing ethical
and political behavior, alongside individuals’
verbally articulated rationales for involvement.

While mobilizing the pleasurable dimensions
of alternative green consumption may be a wor-
thy pursuit for ethical consumption campaigner-
s and academics alike, critics note that this
emphasis on pleasure compromises the efficacy
of consumption as activism, as these practices
are inseparable from questions of taste, quality,
and distinction. Alternative food networks are
perhaps too entangled with making choices
about what is “good” to eat, and alternative
food itself is often valued by consumers as much
for its flavor, health benefits, and freshness as for
its contribution to challenging environmentally
damaging practices.

Alongside renewed interest in consumers’
routines and experiences, promising avenues
have opened for exploring moral geographies
of consumption and how ethical consump-
tion practices are distributed across space.
Studies of alternative consumption such as eco-
tourism and farmers’ markets, for example, have
demonstrated how geographical imaginaries of
destination/producer countries are commodi-
fied and marketed as environmentally conscious
(Coles and Crang 2011). These studies draw
attention to the way space is consumed and
culturally encoded, and to how the practices of
consumers both in space and of space itself are
tied up with values of quality, taste, and distinc-
tion. Importantly, researchers have highlighted
concerns that spaces of alternative consumption
such as farmers markets can be elitist enclaves
that dissuade nonwhite and lower-income
groups from participation, and that they may
be implicated in the potentially exclusionary
processes of urban gentrification.

Geographers are also moving beyond notions
of the environment as a valuable external
resource and essential input into processes of
production, to consider how consumption takes
place in space and how we consume space
and place. Emerging research into the tactile,
emplaced, and experiential facets of consump-
tion, such as studies exploring urban food grow-
ing, community gardening, or foraging where
the distinction between producer/consumer
becomes blurred, for example, is beginning
to overcome problems associated with view-
ing the environment as an externality that
individuals must be persuaded to care for at a
distance. With an increased sensitivity to the
interconnected nature of environment–society
relations, researchers are gaining a clearer picture
of how environmentally conscious behavior
ENVIRONMENT AND CONSUMPTION

is experienced and may be motivated in the everyday, ordinary consumption practices of individuals.

Recent decades have witnessed a surge of interest among scholars, policymakers, and activists in the linkages between environment and development. Growing recognition of the multiple environmental crises facing humanity as well as increased awareness of the connections between human welfare and environmental integrity have made clear the need to study issues of environment and development from integrated, holistic perspectives. At the same time, environmental concerns have been progressively incorporated into development policy and planning at local, regional, national, and international scales.

The “greening” of development thought and practice is most clearly evidenced in the rise of the sustainable development paradigm, which development agencies, lending institutions, non-governmental organizations, and governments around the world have embraced as an approach for uniting social, economic, and environmental aims in development agendas.

Human–environment geography has been uniquely positioned to probe the environment–development nexus given the field’s long tradition of research on the dynamic and recursive relationship between the nonhuman, biophysical world and processes of social and economic change. Nonetheless, delimiting an “environment and development” field of research in geography is a challenging assignment. The difficulty derives, in part, from the complex and shifting meanings of the two terms. As Cowen and Shenton (1996) explain, “development” tends to be conceived of in two broad ways. On the one hand, it is understood as an immanent process, one that unfolds historically without explicit direction (as in “the development of capitalism”). On the other hand, development is thought of as a positive transformation – typically economic or social in character – that is deliberately fostered. This latter notion of development as an intentionally pursued improvement has become increasingly predominant in the post–World War II “age of development.” Nevertheless, disagreement continues over how exactly development should be defined and measured. Sachs (1999, 7) has gone so far as to claim that as development agencies have diversified their emphases and strategies – moving away from a traditional focus on economic growth and incorporating themes such as injustice, gender, and the environment – the result has been “semantic chaos,” with development becoming “a shapeless amoeba-like word.”

Probing the term “environment” also reveals ambiguous and competing meanings. Eden (2007, 62) notes that while the environment once signified, in a relatively unproblematic manner, “the surroundings that we seek to manage or that influence us,” the term no longer enjoys such definitional modesty. In the academic literature, ambiguity regarding the meaning of environment is related to the fact that it tends to be used interchangeably with “nature” – a term laden with its own history of complex and disputed meanings. This word-switching occurs despite some generally, if implicitly, agreed-upon distinctions between the two terms: nature, for instance, is typically thought of as organic and
environment as inorganic (Eden 2007). Beyond these academic ambiguities, social constructivist research shows that understandings, valuations, and representations of the environment shift over time and space, and that the environment’s multiple constructions – for example, as a natural resource repository, as an assemblage of “goods” and “services,” as a web of interconnected living and nonliving things, and as a threatened landscape – are the products of contextual factors including media portrayals, economic imperatives, scientific understandings, and prevailing value systems.

How “environment and development” is bounded as a field of study, then, is a function of how the two terms are understood. As the content of this entry demonstrates, most research in geography that explicitly adopts an “environment and development” framing is concerned with the theories, policies, and practices of intentional development in its assorted forms. The entry also, however, engages relevant geographical scholarship on the relationship of environment (broadly conceived) to more general processes of capitalist development. The picture that emerges is of a robust, multifaceted area of study, one notable for maintaining a critical awareness of development’s complex and uneven socionatural implications.

**Development through resource mobilization**

One of the principal ways that the nonhuman, biophysical world intersects with – and enters into – development processes is in the form of natural resource inputs. Indeed, strategies to “mobilize” resource endowments have figured prominently in a wide variety of development policy frameworks. In the post-World War II years, as the emerging field of development economics came to focus on promoting economic growth and modernization in the “underdeveloped” regions of Asia, Africa, and Latin America, intensified resource exploitation was often seen as a critical means for achieving development ends. Rostow’s influential linear stages of growth model is illustrative (Rostow 1960). Contending that “it takes more than industry to industrialize,” Rostow posited that for a traditional society to develop economically it was necessary to boost productivity in agriculture and the extractive sectors via the application of modern science and technology, the rationale being that increased output from these resource industries was needed to provide the food, raw materials, and capital for industrial expansion (Rostow 1960, 22). Ideas like these animated the work of the World Bank, International Monetary Fund, and other international development organizations in the post-World War II decades, resulting in a stream of development funding into resource-intensive megaprojects. At the same time, intensified resource exploitation also played a central role in the state-led development and modernization programs of twentieth-century socialist governments (Khrushchev’s Virgin Lands Campaign being a notable example), as well as in the autarkic development schemes of postcolonial governments in the Global South. Meanwhile, the broad transition toward a neoliberal development paradigm in the last decades of the twentieth century frequently resulted in a “doubling down” on natural resource extraction, as free-market policies opened countries’ resource sectors to foreign investment, and international financial institutions encouraged the expansion of resource industries, including as a means of debt repayment.

Thematically, work in geography on the role of resource mobilization in development and
modernization programs has proceeded along various fronts. One line of investigation has focused on the large-scale water-infrastructure re-engineering schemes that have been planned and carried out by governments across the Global North and South. Such projects have often involved the construction of large dams, which have been extolled by proponents not only for their practical benefits (e.g., electricity generation, urban water provisioning, flood control, agricultural expansion), but also as symbols of modernity. Another body of research has centered on programs of agricultural development and modernization, including those associated with the “green revolution.” Coined in the 1960s, this term refers to an assemblage of agricultural technologies, inputs, and practices (including hybrid, high-yielding seeds; synthetic pesticides and fertilizers; and intensive irrigation) that came to be strongly promoted by international development agencies as a means of boosting agricultural production – and averting food crises – in “Third World” countries. A third line of research has focused on the efforts of political leaders to promote development and modernization by exploiting subsoil resources like oil and minerals. Programs designed to capitalize on these subterranean “riches” through extractive-industry expansion have commonly held the twin objectives of sparking regional and national economic growth, while also providing revenue for states to pursue other development initiatives – an approach on display in Venezuela’s long-standing attempts to “sow the oil” and in Bolivia’s recent efforts to use natural-gas revenues for social programs.

At a conceptual level, work on resource-based development strategies has benefited from engagement with Marx’s historical materialism, which has provided geographers a theoretical framework for understanding capitalist economic development as a continuing process of resource mobilization. Marx considered the rise of capitalism to have been predicated on a process he referred to as “primitive accumulation.” This involved the “freeing” of land and other natural resources from the fetters of noncapitalist social formations, thereby allowing for their incorporation into capitalist circuits of accumulation – through, for instance, enclosure and privatization. Marx’s treatment of primitive accumulation focused on its role in England’s historical transition from feudalism to capitalism. Recent scholarship in geography and cognate fields, however, has stressed that key aspects of primitive accumulation remain central to present-day, “advanced” capitalism, as witnessed in the recurrent efforts of capitalist firms to appropriate publically or communally held natural resource stocks.

Work on these ongoing efforts to make land and resources available for capitalist development dovetails with scholarship – in both Marxist geography and the field of industrial ecology – that engages the economy as a “metabolic engine” through which labor is continually applied to elements of nature in the production of commodities. Such conceptualizations of the economy as a process of material transformation are, in turn, helpful for appreciating why such a wide variety of development models, from across the political and ideological spectrum, have included strategies of intensified resource exploitation. These understandings also serve to underscore the basic fact that development is inherently an environmental – and, thus, geographical – process, one that involves the reshaping of landscapes, the reorganization of human–environment interactions, and the generation of new socionatures. Research on development’s material-geographical transformations further highlights the extent to which development is a highly contradictory process,
one that entails social and environmental costs and benefits, which tend to be distributed unevenly in both social and spatial terms.

Development’s contradictions

The idea that development gains inevitably flow from expanded natural resource production—an idea underpinning much post-World War II development thinking—has been increasingly called into question by scholars from a variety of fields. A multidisciplinary body of work on the “resource curse” has been especially notable for casting doubt on conventional assumptions regarding the role of resource mobilization in development. In particular, studies in this area have found that natural resource abundance is often, in fact, associated with poor economic performance, along with various other social and political maladies. While the resource curse literature has assorted strands, research tends to center on the consequences stemming from resource-rich countries’ overreliance on export-centered primary commodity industries, such as fishing, forestry, hydrocarbon extraction, and mining. This overreliance, resource curse theorists aver, leads to political and economic “distortions” that ultimately undermine the contribution of natural resource exploitation to development.

While the resource curse thesis has gained traction in development policy debates, human–environment geographers have pointed to several limitations of this body of literature (Bridge 2008). These include a bias toward national-scale analyses, which leaves research ill-equipped to account for the multiscalar and spatially discontinuous socionatural impacts of resource exploitation, as well as a tendency to privilege physical resource availability as the primary determinant of development outcomes—a tendency that may obscure important social, political, and economic factors. Thus, while research in geography has also called attention to many of the social and environmental costs associated with development through resource mobilization, geographical scholarship, by and large, has favored in-depth studies that capture the socially and spatially complex ramifications of these activities. This work has underscored that while some people and places may reap the rewards of new patterns and trajectories of natural resource exploitation, others bear the negative social and environmental implications of these activities—in the form of, for instance, displacement, environmental degradation, marginalization, and pollution.

A leading example of scholarship in this vein is Hecht and Cockburn (2010). This influential work within the field of political ecology offers a detailed, critical analysis of the efforts of Brazil’s political leaders and economic elites to develop the country’s Amazônia region. Training their sights on the large-scale development and modernization schemes of Brazil’s military dictators of the 1960s and 1970s, Hecht and Cockburn document the environmental destruction and social dislocation that these programs unleashed, while also showing how the negative socionatural implications of development policies have been experienced especially acutely by the poor and indigenous residents of the Amazônia.

Geographical research has also brought to light the sociospatially uneven impacts of large-scale water development. This research shows that while grand projects of waterscape re-engineering may benefit some actors by fostering certain activities (e.g., industrial expansion or urban growth), other groups typically bear the costs of these projects (e.g., displacement, livelihood destabilization)—a dynamic that has been on display in cases like the Sardar Sarovar Dam (Narmada River, India) and the Three Gorges Dam (Yangtze River, China). In
addition, scholarship on the political ecologies of agricultural development – including green revolution initiatives – has drawn attention to the environmental impacts of the transition to “modern,” resource-intensive agriculture (e.g., reduced genetic diversity, unsustainable water usage, agrochemical contamination), as well as its social ramifications, such as the marginalization and disempowerment of small-scale farmers. Meanwhile, work on oil-based development strategies has emphasized that such efforts are frequently predicated on the creation of “sacrifice zones” – areas such as the northern Ecuadorian Amazon, the Niger Delta, and northern Veracruz (Mexico), where the negative socionatural effects of intensive oil extraction are concentrated.

Through scholarship like this, geographers have contributed to a more general critique of the post-World War II development project that has been mounted in recent decades by scholars and activists, including those associated with the “postdevelopment” school of thought and political action (e.g., Sachs 1999). By recording and explaining the ground-level effects of resource-intensive development activities, geographical scholarship has called into question the extent to which the forms of development promoted by the postwar development apparatus actually constitute “improvement” and “progress,” thus contributing to a destabilization of the very meaning of development. Moreover, the uneven, contradictory, and often counter-productive character of resource-intensive development suggests, for many, a fundamental tension between environment and development. For Marxist scholars, the idea of such a tension is captured in the concept of the “metabolic rift,” which refers to the ecological disruptions and crises that result from capitalist expansion.

Work on development’s social and ecological contradictions also raises questions about how such programs have been – and continue to be – promoted across various social, political, and geographical contexts. In this respect, geographical scholarship on the discourses and ideologies of development is insightful. Influenced by post-structuralist approaches, especially Foucauldian discourse theory, geographical research has shown how development actors mobilize particular historical narratives, spatial imaginaries, and scientific “truths” in their efforts to advance their development agendas, in the process making some development trajectories appear preferred or predetermined, and others impossible. In their introduction to the influential edited volume Liberation Ecologies: Environment, Development, Social Movements, Peet and Watts (1996) deploy the concept “regional discursive formation” to refer to the constellation of ideas and imaginaries that run through a region’s discursive history and create the conditions for particular development interventions to be “thinkable” – often at the expense of alternative development visions. Such scholarship helps to elucidate the stakes involved in development-related sociopolitical conflicts. As well as being material struggles over productive resources (and the distribution of costs and benefits generated by their exploitation), these conflicts often have strong symbolic dimensions, with the actors involved contending for “control over the human imagination” (Peet and Watts 1996, 37).

Development environmentalized?

Within the broader arena of world politics, serious problems with orthodox, resource-intensive development had become progressively more apparent in the last decades of the twentieth century. One set of concerns centered on issues of natural resource availability. The notion that the Earth imposes “natural limits” on human
societies has deep roots in Western thought, with one especially influential origin being Malthus’s writings from the late-eighteenth and early nineteenth centuries on the relation between population growth and food supply. A number of studies in the 1960s and 1970s, meanwhile, rekindled alarm over the Earth’s capacity to supply resources for continued demographic growth and economic expansion. These included The Limits to Growth, a study that was commissioned in the early 1970s by the Club of Rome, a nonprofit research foundation. Based on the results of a computer simulation that modeled the interaction of natural and human systems, the study’s authors suggested that population growth and economic expansion would, in the not-too-distant future, lead human societies to “overshoot” the world’s carrying capacity, resulting in the collapse of the global system.

At the same time, concern also revolved around the impacts of modern industrial development on environmental conditions and human health. Rachel Carson’s Silent Spring, which dealt with the detrimental effects of pesticide use on the environment, raised awareness after its publication in 1962 regarding the ecological implications of industrial production, especially in the United States. Public awareness regarding the negative side effects of modern industry was further heightened by a number of high-profile cases of industrial pollution in countries of the Global North and South, including the Love Canal disaster (United States), the Bhopal gas tragedy (India), and the nuclear catastrophe at Chernobyl (Soviet Ukraine).

In the context of these mounting concerns, a new paradigm, sustainable development, took hold in global policy circles. As Adams (2009) details, the concept of sustainable development has a complex provenance, with roots in various scientific, intellectual, and political-institutional currents – colonial nature conservation and scientific resource management among them. Meanwhile, the core ideas of sustainable development – including the notion that environment and development are reconcilable – emerged from the 1972 United Nations (UN) Conference on the Human Environment, held in Stockholm, and the term itself was codified in 1980 by the International Union for the Conservation of Nature in its The World Conservation Strategy. Then, the World Commission on Environment and Development’s (WCED) 1987 report titled Our Common Future – also known as The Brundtland Report, after the WCED’s chair, Gro Harlem Brundtland of Norway – propelled the concept into prominence on the global stage. The UN had established the WCED in 1983 and charged it with assessing and proposing potential solutions to the environment and development problems facing world society. WCED findings were published in Our Common Future, which underscored the need to move toward sustainable development, for which it gave the following, now well-recognized definition: “development that meets the needs of the present without compromising the ability of future generations to meet their own needs.” The term swiftly migrated into a wide variety of policy circles, and the UN has subsequently organized several major conferences aimed at implementing sustainable development, including the 1992 Conference on Environment and Development in Rio de Janeiro, which produced Agenda 21, an action agenda for sustainable development in the twenty-first century; the 2002 World Summit on Sustainable Development in Johannesburg; and the 2012 UN Conference on Sustainable Development in Rio de Janeiro.

Geographers have engaged the discourse and practice of sustainable development in a number of ways. Like numerous other observers, geographers have drawn attention to the amorphousness and malleability of the concept,
which helps to account for the extraordinarily broad range of political and economic actors that have “gotten on board” with sustainable development. Critics contend that while the idea of sustainable development holds radical potential as an alternative to traditional development models, this potential has been diluted as powerful actors have laid hold to the concept and defined it in ways that buttress current power relations and political-economic trajectories. This tendency was on display at the 2002 World Summit on Sustainable Development, which produced agreements that entrenched the idea that neoliberal, market-based strategies should be prioritized in efforts to achieve environmental protection and social development (Mansfield 2009). It is also seen in the efforts of private firms – including mining, oil, and gas companies – to co-opt and deploy discourses of sustainability as a means of justifying the continuation of their activities.

Given the manifold uses to which ideas of sustainable development have been put, understanding the implications of the “sustainability turn” in development thought and policy requires that researchers investigate: what exactly is being sustained; why it is being sustained; to whose benefit; and to whose disadvantage. Geographical research that has addressed these issues in the context of concrete sustainability initiatives has revealed sustainable development to be a highly political – and often strongly contested – endeavor (for valuable examples of such research, see chapters in Krueger and Gibbs 2007). Such accounts of the politicized nature of sustainability run counter to the overwhelmingly technocratic and managerial framings that characterize mainstream discussions of sustainable development (Mansfield 2009). In this sense, work by human–environment geographers on the late-twentieth-century “greening” of development intersects with the field’s now significant body of literature on the histories, practices, and discourses of nature conservation, including work on protected-area formation in various historical-geographical contexts. While nature conservation initiatives, like sustainable development programs, are frequently framed in apolitical terms (e.g., as noble efforts to preserve “at risk” landscapes), work by political ecologists and others has exposed the uneven power relations and complex political-economic agendas shaping the rollout of these initiatives – laying bare, for instance, the ways in which the creation of protected areas in diverse world regions has been entangled with capitalist expansion, the consolidation of political authority (including that of colonial powers over colonized lands and peoples), and state-based projects to order and rationalize rural landscapes and their inhabitants. Further, research has revealed the often-harmful implications of conservation-area expansion for local populations, who have commonly found their resource and territorial rights restricted by interventions aimed at “saving” the nature on which they depend for their livelihoods.

Significantly, the late twentieth-century rise of the sustainable development paradigm took place in conjunction with a reorientation of conservation strategy within global environmental policy circles. With the negative socionatural consequences of conventional “fortress conservation” models increasingly apparent, international conservation organizations came to champion “participatory” approaches that could meet the social and economic development needs of people living in areas targeted for conservation – the result being a bevy of what have often been referred to as “conservation-with-development” initiatives (Perreault 2009). Thus, the “greening” of development has been associated with a concomitant “socialization” of nature conservation. While these trends have intersected in several
important ways, a shared emphasis on livelihoods has constituted a key point of convergence.

The livelihoods approach and the question of scale

Increasing understanding within the development community of the limitations of traditional, large-scale development programs for improving the welfare of the poor (who are often, in fact, further marginalized by these programs) has contributed in recent decades to a growth of interest in “bottom-up,” or “grassroots,” development approaches. In general, these approaches are strongly actor-oriented, often placing the household or the community at the center of development strategy; seek to foster the participation and empowerment of the poor, while also raising their standard of living; and place emphasis on incorporating local or indigenous knowledge into development policies. These “neopopulist” approaches, as De Hann (2000) explains, place faith in people’s adaptive capacities and, in particular, their capacity to create enhanced and sustainable livelihood systems even in the face of changing environmental, social, political, and economic circumstances. The result is that such approaches embody a relatively optimistic view of the environment–development nexus. By emphasizing human agency, neopopulist developmentalism has countered the determinism of orthodox Marxist development theory (e.g., dependency theory). It has also challenged the tendency of mainstream development to blame the rural poor for environmental degradation.

This shift toward “people-first” development policies has coincided in the academic literature with the rise of the “livelihoods perspective.” As Perreault (2009) discusses, though the concept of livelihood has become a mainstay of environment and development geography, there exists little agreement regarding the exact meaning of the term. Broadly, however, “livelihood” is used to refer to the ways that people make their lives – in social, economic, and cultural terms – as well as the capabilities, relationships, and assets (including natural resource endowments) that allow them to do so. The appeal of the livelihood perspective, according to Scoones (2009, 172), lies in its rather straightforward call to “look at the real world, and try to understand things from local perspectives.” Much of the work on livelihoods that has been undertaken in human–environment geography has sought to understand the complex and diverse ways in which individuals, households, and communities are able to adapt to and make the most out of their situations in the context of structural constraints and different forms of political-economic and environmental change.

One of the great benefits of the livelihoods perspective is that it counters a bias toward national-scale analysis that is present in much environment and development research. In addition to the resource curse literature cited above, many sustainability metrics take the nation-state to be the preferred scale of analysis, as do several other theories and models that have been developed to explain the relationship between socioeconomic development and environmental change, such as the environmental Kuznets curve and the forest transition theory. Studies adopting livelihoods approaches, in contrast, provide significantly more fine-grained accounts of environment and development dynamics given both the explicit focus of these studies on local-scale processes as well as a tendency for researchers to adopt qualitative methodologies. The result is that such studies typically allow for greater attention to social and spatial variation in environment and development dynamics at subnational scales.
There is a risk, however, that research adopting a livelihoods approach becomes overly localized and fails to account for the diverse ways in which people’s practices of production and social reproduction are shaped by – and depend upon – extra-local processes and systems. The rural development literature is indeed now replete with evidence of the various ways in which livelihoods, even in the more remote parts of the world, have become diversified in ways that make the inhabitants of rural spaces increasingly reliant on nonfarm, nonlocal forms of income, such as wage labor and migration remittances. In this context, it is important to resist the assumption that livelihood systems are spatially bound – that is, simply “local.”

Human–environment geographers have been, on the whole, cognizant of this risk and have guarded against it. This is especially the case among political ecologists, who have long insisted on the need to undertake multiscalar analyses that contextualize the decision-making of resource users and environmental managers within wider-level processes and power relations, from the household-scale to the global-scale. McSweeney (2004), through a case study of the dugout canoe trade in Central America’s Mosquitia, provides a valuable analysis of the complex and multiscalar spatialities of rural livelihoods. With the objective of understanding the lived experience of the Mosquitia’s rural poor, McSweeney’s analysis of the historical influence of extra-local forces, namely international capital, on the dugout canoe trade draws attention to the ways that supposedly isolated livelihoods in the region have long been shaped by interactions with broader-scale networks and economies.

Another potential peril associated with the “localization” of environment and development policy and research relates to a tendency to conflate “local” with just, democratic, and sustainable. In an important intervention, Purcell and Brown (2005) refer to this assumption as the “local trap” and contend that it implicitly or explicitly runs through academic and policy discussions. As noted above, the turn toward “bottom-up” development strategies can be understood as a response to the “top-down” character of traditional development. Purcell and Brown recognize that many calls for more localized decision-making in development stem from the real problems associated with neoliberal globalization and mega-development projects (which tend to be managed by national- and international-scale actors). They argue, however, that there is nothing inherently more socially just or environmentally sustainable about the local. Moreover, the evidence suggests that, in practice, efforts to localize environment and development decision-making have had mixed results. Drawing on work from critical geography on the social construction of scale, the authors note that scales of decision-making should not be understood as having any inherent qualities in themselves, but rather “as strategies that are pursued by and benefit social groups with particular social and environmental agendas” (Purcell and Brown 2005, 280). The task for researchers, then, is to pay close attention to the specific agendas of those actors who are empowered by efforts to “re-scale” environment and development decision-making toward the local level – for it is these agendas that will determine the socionatural outcomes of localization strategies.

Differentiated communities, heterogeneous environments

In-depth, place-based studies by human–environment geographers have also helped
to make clear the importance of taking into account both social and environmental difference in analyses of the environment–development nexus. Regarding social difference, research has “opened up” the household and the community in order to better understand the role of gender, class, ethnicity, race, and other forms of social differentiation in shaping systems of resource access and environmental decision-making, including in the context of development interventions. A valuable example of scholarship in this vein is Carney (2004) on the gendered impacts and dimensions of wetland development – namely, irrigated rice schemes and horticulture projects – in Gambia. Carney documents how these development programs have led to repeated gender conflicts due to the fact that they have increased women’s labor burdens, while at the same time weakening women’s customary rights to rural lands and resources. Meanwhile, scholarship has also broadened the analytical focus to examine not only how social difference shapes environment and development trajectories, but also how sociocultural identities are themselves constructed through initiatives of resource development and environmental management. This work has provided valuable and nuanced insights into the lively interrelations between environment, development, and identity.

Just as the category of “society” has been unpacked within the environment and development literature, so too has that of “environment.” In particular, geographical scholarship has worked to elucidate the complex ways in which the biophysical qualities of particular resources or environments shape development processes. Efforts to grasp how nature’s heterogeneity influences socioeconomic change have a long history. The Marxist theoretician Kautsky, for instance, in his turn-of-the-twentieth-century writings on agrarian change in Germany, identified a number of ways in which the variability of the natural environment shaped the form and trajectory of capitalist development in agriculture. In human–environment geography, the long shadow cast by early twentieth-century environmental determinism led many researchers to abstain from affording nature an active role in development, instead focusing on the often-dramatic ways in which human action – including via development interventions – transforms the environment, in the process “producing” new natures. Meanwhile, theories giving analytical priority to physical geography features in shaping development outcomes have often been roundly critiqued. Recent years, however, have seen an expansion of efforts to understand and theorize the recursive relationship between environmental conditions (understood as heterogeneous and dynamic) and socioeconomic change. The result has been a greater appreciation of both nature and the technologies through which nature enters into social life as actors – or “actants” in the language of actor-network theory – in development.

Useful examples of research in this vein come from recent scholarship on “development waterscapes.” Sultana (2013), for instance, explores the water-technology-development nexus in her examination of efforts to develop safe drinking water in the Bengal Delta. Sultana’s analysis highlights the active role of specific forms of nature and technology in development processes. In particular, she highlights the ways in which the qualities of the region’s groundwater resources (including the widespread presence of arsenic in these waters), as well as the characteristics of the technologies that have been promoted to extract groundwater for human consumption (namely, tubewells) have actively contributed to the creation of a new set of “technonatural assemblages” that both enable and challenge development.
Conclusion

Development has long been a central concern for human–environment geographers. This is especially the case for political ecologists for whom issues of resource use and environmental management in rural areas of the Global South have been a traditional focus. In recent years, however, the field of political ecology has undergone a process of change, as researchers deploy novel theoretical frameworks, expand into previously unexplored thematic areas, and broaden the geographical scope of their investigations, for instance, into cities of the Global North. Nevertheless, despite this process of scholarly variegation, a strong interest in the environment–development nexus remains. Looking forward, it is possible to identify topics that are likely to garner increasing attention from geographers interested in the dynamic relationship between socioeconomic change and the nonhuman, biophysical world.

One is the expanding role of private-sector actors in the development enterprise. As the social and environmental practices of transnational firms, particularly those operating in poorer areas of the Global South, have come under increasing scrutiny and criticism, one response has been for these corporations to become more directly involved in social and economic development efforts, typically as part of their so-called corporate social responsibility agendas. This is especially the case for resource companies, such as mining and hydrocarbon firms, many of which now carry out development programs in their areas of operation, at times in partnership with state agencies and nongovernmental organizations. While this trend toward corporate-led development has been discussed in the academic and policy literatures, its ramifications for environment and development trajectories remain underexplored.

Another topic likely to attract increasing attention in upcoming years is “degrowth.” As economic growth is increasingly recognized to be environmentally unsustainable (given the close and difficult-to-sunder linkages between economic production and energy and raw materials usage), there has been a burgeoning of interest in sustainable degrowth, a concept that typically is used to refer to the intentional scaling-down of production and consumption in ways that enhance human wellbeing and environmental conditions. Meanwhile, numerous areas of the world have experienced imposed degrowth in the context of urban and regional economic decline— the city of Detroit being a leading example. While a variety of nongrowth-oriented economic paradigms have been developed in recent decades (e.g., the steady-state economy model of Herman Daly and others), the crisis of climate change, coupled with the ongoing economic crisis, has, for many, made the need to transition to such a paradigm all the more urgent. Human–environment geographers, with their extensive tradition of research on the environment–development nexus, are well placed to contribute to studies of degrowth— immanent and intentional— and its, no doubt, complex socionatural ramifications.

Environment and disease

James D. Tamerius
University of Iowa, USA

Throughout human history, humans have attempted to mitigate the detrimental effects of environment on health. We have constructed shelters, developed farming practices, domesticated animals, and relocated to more amenable sites. These developments have – in part – led to decreasing mortality rates and have enabled global populations to surpass 7 billion. However, increases in population size, animal husbandry and farming practices, land-use change, and industrialization have generated new environmental sources of disease. Indeed, environment remains a large factor in human health, particularly among low-income populations in developing countries.

“Environment” is a term used to describe the objects, soil, air, and water that surround humans and their physical domain. Environmental factors can cause disease either directly or indirectly. An example of a direct effect occurs when a human is exposed to extreme temperatures and cannot maintain normal body temperature (hyperthermia or hypothermia). The environment can also modulate disease indirectly through interactions with a transmissible disease system. For instance, surface water and suitable climatological factors can enable the maintenance of biological vectors, such as mosquitoes, that transmit pathogens to humans.

Disease risk varies strongly across space and time, partly due to the variability of natural environmental factors. Local hydrological, biological, climatological, and geological characteristics modulate exposures to various physical, chemical, and biological elements that cause disease. The vulnerability of a population to disease is also a critical factor determining the presence of a disease in a population and its burden on a population. The vulnerability of a population is closely tied to social, economic, and political power. Indeed, the social movement and the field of study called “environmental justice” emerged as research demonstrated that poor and minority communities in the United States were disproportionately affected by environmental disease. This trend is observed worldwide where low-income communities in developing countries are particularly vulnerable to diseases mediated by the environment as a result of inadequate infrastructure, increased susceptibility to disease, and limited access to proper health care.

Here we discuss the environmentally mediated systems and processes that disproportionately contribute to the global burden of disease: air pollution, diarrheal disease, and vector-borne disease. We also discuss other topics such as heat waves and emerging diseases because of their strong associations with environment and environmental change. Finally, we describe the expected effects of global climate change on disease.

Air pollution

Air pollution refers to the presence of any physical, biological, or chemical agent that contaminates either the outdoor or the indoor atmosphere. Air pollution can be generated from anthropogenic or natural processes. Major air
pollutants include microscopic particulate matter (PM), ozone ($O_3$), nitrogen dioxide ($NO_2$), sulfur dioxide ($SO_2$), and volatile organic compounds (VOCs). Currently, tropospheric $O_3$ and PM are considered to be the most important pollutants in terms of health impacts worldwide (Haerens 2011). Exposure to air pollution has been tied to the development of chronic obstructive pulmonary disorder (COPD), asthma, lung cancer, cardiovascular disease, and severe lower respiratory infections. Indeed, air pollution is related to more than 3 million deaths worldwide every year and accounts for 3.2% of the total global burden of disease (WHO 2013).

Historically, the primary anthropogenic source of air pollution has been smoke from fires used for cooking and heating. This trend has continued in modern times where approximately 3 billion people use solid biomass fuels (wood, animal dung, and crop waste) for heating and cooking. The concentration of PM$_{10}$ (PM up to 10 $\mu m$ in size) in homes using biomass fuels can be 10–50 times greater than concentrations considered safe. The inhalation of these soot particles makes individuals, particularly children under the age of 5 years, more susceptible to severe lower respiratory infections caused by bacteria and viruses such as influenza, respiratory syncytial virus, pertussis, mycoplasma pneumoniae and human metapneumovirus. Exposure to indoor PM from stoves can also increase the odds of developing COPD. The health burden of indoor PM is greatest among women and children due to the large amount of time they spend inside near the stoves. Indoor air pollution is not as problematic in developed countries where cleaner fuels and improved ventilation limit exposure.

Outdoor pollution accounts for about one-third of the disease burden of air pollution. Industrialization and the burning of fossil fuels dramatically increased the scale and geographic scope of air pollution beginning in the eighteenth century. As the negative effects of air pollution have become more apparent and new technologies have emerged, the most prosperous societies have developed and implemented air pollution mitigation strategies. As a result, emissions of major air pollutants have been declining in most countries in North America and western Europe since the 1970s via controls on emission sources, the use of cleaner fuels, and closures of outdated factories. However, outdoor air pollution remains particularly problematic in rapidly developing countries where energy consumption and the number of motor vehicles (especially unregulated two-wheelers) are increasing. Indeed, outdoor PM concentration in many urban areas of the developing world often exceeds three times the concentration considered safe. In many of these countries, measures aimed at reducing air pollution are not instituted because of their costs.

Local environmental factors can exacerbate the effects of air pollution. For instance, photochemical smog can become especially severe in areas that are prone to temperature inversions (atmospheric phenomenon where cool air is trapped at the surface below warmer air), which limit vertical mixing in the atmosphere and concentrate pollutions near the surface. Valley regions are particularly susceptible to this phenomenon because surrounding mountains can also limit horizontal movement of polluted air. Indeed, photochemical smog is particularly problematic in Los Angeles, Beijing, and Mexico City due to high emissions and favorable atmospheric and terrain factors. Further, SO$_2$ can interact with water droplets in humid environments and generate “classical” smog which caused the “Great Smog” event during the 1950s in London. This event was particularly severe because of a temperature inversion that trapped pollutants near the surface, and because it was
associated with cold weather that prompted people to heat their homes (wood fires), which intensified emissions (Fenger 2009).

**Water pollution**

Water pollution is the contamination of natural water systems by chemical, physical, or biological agents. Water quality is affected by both natural and anthropogenic sources. The most important sources of water pollutants include agricultural and mining activities, landfills, and industrial and urban wastewater, as well as natural geologic emissions. In addition to pathogenic microorganisms that cause disease (see diarrheal diseases, below), contaminants such as heavy metals (e.g., lead, mercury, arsenic) can cause cancer and brain damage and affect child development.

In developed countries, water supplied to the public is treated by means of filtration and disinfection processes. These treatment processes eliminate a vast majority of contaminants, but some pollutants, such as arsenic, lead, and microorganisms, may remain in the water. In developing countries, untreated waste water is often discharged directly into surface waters. Furthermore, natural sources of arsenic in some regions, such as Bangladesh and West Bengal, have contaminated drinking wells and caused arsenic poisoning in a significant proportion of these populations. Ironically, the drinking wells in these regions were created to mitigate the effects of contaminated surface water.

Heavy metals from industrial processes can also accumulate in surface waters and become concentrated in fish and shellfish. Humans can become exposed to the metals if they rely on these fish and shellfish for their diet, and be afflicted by cancer and birth defects. Further, fertilizers can contaminate freshwater and marine ecosystems, and lead to algal blooms. Algal blooms can produce toxins that are harmful to humans, thereby making water unsuitable for drinking. Algal blooms can also harm fresh and saltwater fisheries and result in malnutrition for people that depend on local fish for their diet.

**Diarrheal diseases**

Diarrheal diseases are primarily caused by bacteria, virus, protozoa, and parasitic worms. The most common agents of diarrheal disease are rotavirus and *Escherichia coli*. Diarrheal diseases are the second leading cause of death in children under 5 worldwide, and account for 1.5 million deaths annually (WHO 2012). Like most environmental diseases, the burden of diarrheal diseases exists almost entirely in developing countries due to poor infrastructure and increased susceptibility resulting from malnutrition, and existing and prior infections. Although diarrheal disease is common in developed countries, deaths from such diseases are rare.

People typically become exposed to diarrheal pathogens from contaminated water, although transmission pathways are multifaceted and complex. Following the excretion of human and animal waste, diarrheal pathogens can be transmitted to a new host through several environmentally mediated pathways. Diarrheal pathogens frequently contaminate surface and groundwater via open defecation and faulty or inadequate sewage systems. People in low-income areas that do not have access to treated water can become exposed to the pathogens by drinking contaminated water from rivers, streams, lakes, and wells. Diarrheal pathogens can also be transmitted when food becomes contaminated while it is being grown (contaminated irrigation water), shipped, handled, or prepared. Although boiling water is an effective measure for sterilizing water, the costs for fuel can be prohibitive.
in low-income populations. Washing hands with soap is also an effective measure to prevent the spread of diarrheal diseases, but access to handwashing facilities can be limited. Bathing in contaminated waters such as rivers and lakes is common practice in many developing countries and contributes to pathogen exposure.

Environmental factors are involved in the transportation of diarrheal pathogens, their survival in the environment, and human behaviors. For example, incidence of cholera in coastal areas is strongly associated with sea surface temperature, sea surface height, water nutrient levels, and solar radiation, which act to amplify the concentration of the reservoir (e.g., zooplankton) and the pathogen in coastal waters, and transport them into human environments. People may also respond to their environment by modifying their sources of drinking water, which can cause incidence of disease to vary by time. For example, fresh rainwater may be used for drinking water during the rainy season, whereas people may resort to drinking stagnant and contaminated surface waters during dry seasons. Temperature and humidity are also known to modulate the survival of diarrheal pathogens on surfaces and in water, which potentially modulate their transmission between hosts.

Vector-borne diseases

Vector-borne diseases are infections that are transmitted to humans by infected arthropod species. The most common vectors include mosquitoes, flies, ticks, mites, fleas, and lice. Major vector-borne diseases worldwide include malaria, dengue, yellow fever, and Japanese encephalitis. Malaria is by far the most significant cause of disease and mortality in humans worldwide and contributes to 1 million deaths per year (Murray et al. 2012). Vector-borne diseases primarily burden developing countries in tropical environments, although some vector-borne diseases such as West Nile virus and Lyme disease are prevalent in developed temperate countries.

Environmental factors can modify vector-borne disease systems by affecting the vector, the host (e.g., humans), or the pathogen. For example, reproduction in arthropods is temperature dependent and, despite favorable summertime conditions in temperate regions of the world, cold winter temperatures can interrupt disease cycles by terminating the reproductive cycle of vectors, such as mosquitoes. For this reason, most vector-borne diseases spread by mosquitoes are most prevalent in tropical regions that remain warm and humid year-round. On the other hand, diseases transmitted by ticks can remain prevalent in temperate regions despite harsh winter conditions because they can transmit pathogens, such as viruses, into their eggs. The eggs can remain viable over winter and then hatch when temperatures increase, thereby continuing the disease cycle. Further, some pathogens have disease reservoirs such as birds that can winter in warm locations where the disease cycle can continue uninterrupted. During the spring, the birds harboring the pathogen (e.g., West Nile virus) can return and initiate the disease cycle in a temperate region.

Environmental control is one of the primary methods to control and eradicate vector-borne diseases, in particular, permanently modifying environmental characteristics that favor the propagation of vector populations. Vector control strategies will vary depending on characteristics of the vector and the local environment, and include improved drainage, leveling of land, filling depressions, lining canals, adding gutters and roof drains onto structures, implementing wet-dry irrigation strategies, and use of pesticides.
Emerging diseases

An emerging disease is a disease that has recently appeared in a human population, or a disease that is rapidly increasing in incidence or geographic range. Recent emerging diseases include HIV (human immunodeficiency virus), Ebola, the Nipah virus, West Nile virus, SARS (severe acute respiratory syndrome), and influenza A/H1N1pdm. Most emerging diseases are zoonotic agents that are transmitted to humans through close contact with another species.

Increased disturbance of natural environments by humans has been accelerating the rate of emergence of new infectious diseases (McMichael et al. 2004). There are several human-induced environmental changes that facilitate the emergence of novel infectious agents, such as tropical deforestation, building of roads, irrigation, dam building, crop and animal production, urban sprawl, poor sanitation, and polluted coastal areas. For example, deforestation can result in habitat fragmentation and increase “edge effects,” which promote greater interaction between hosts, reservoirs of novel pathogens, and disease vectors. Natural variability of the environment can also facilitate the emergence of novel agents. For instance, in the early 1990s increased winter precipitation in the south-western United States associated with an El Niño event generated an abundance of food and led to a 10–15-fold increase in deer mouse populations, which carried a unusually virulent strain of hantavirus. As a result of the deer mouse population increase, contact between humans and deer mice intensified, leading to an outbreak of hantavirus in humans.

The emergence of novel pathogens is often complex, with both natural and anthropogenic environmental changes interacting to generate disease. For instance, in the late 1990s in Malaysia, slash-and-burn deforestation caused a thick haze to form over the region. The fires and the haze were intensified by drought conditions related to El Niño. The haze limited photosynthesis in fruiting and flowering trees (food sources) and caused fruit bats to seek out sources of food in human environments. Ultimately, this sequence of events enabled the transmission of the Nipah virus into domestic pigs and, subsequently, into the human populations (Bing et al. 2002).

Heat waves

Although many environmental disease systems are highly complex and include interactions between numerous biological and environmental agents, the environment can also act directly on humans and generate disease. Heat waves are characterized by prolonged periods of elevated temperature and humidity and are often associated with increases in morbidity and mortality. Exposure to high levels of heat and humidity limit the body’s ability to dissipate heat and can result in elevated body temperature and heat stroke. In addition, heat waves are associated with increases in respiratory and cardiovascular events. Indeed, in the summer of 2003 a heat wave in western Europe caused as many as 70,000 deaths (Robine et al. 2008).

The severity of a heat wave is dependent on many environmental and social factors. The increasing proportion of elderly populations in developed countries has increased the vulnerability of these countries to heat waves given the susceptibility of the elderly to heat (Sheridan et al. 2012). Increased temperatures due to the “urban heat island” effect place urban communities at greater risk for the effects of extreme heat. The rapid urbanization that is occurring in developing countries will likely increase vulnerability to heat waves in the coming decades.
Further, global climate change is expected to increase the severity and frequency of heat waves and overall temperatures. However, there are several behavioral, technological, and societal strategies to mitigate the effects of extreme heat. For example, regions characterized by hotter and more humid environments typically have higher tolerances for extreme heat conditions than do cooler areas. This suggests that humans can adapt to increasing temperatures. However, it is unclear whether human adaptation can keep pace with rising temperatures associated with global climate change.

Climate change

Increases in the concentration of greenhouse gases caused by anthropogenic emission has altered the radiative balance of the Earth. In response, global temperatures have been increasing since the early twentieth century and are expected to continue to increase. In addition to increasing temperatures, climate change is associated with changes in atmospheric moisture content, precipitation, and the frequency and intensity of storms, droughts, floods, and heat waves. Accordingly, climate change will have significant impacts on environmental factors and processes that mediate disease.

Direct effects of climate change will include an increase in the frequency and intensity of heat waves, which can cause a significant number of deaths and create health emergencies in both developing and developed countries (see heat waves, above). Increasing temperatures and humidity levels will encourage a geographic shift in the distribution of vector species, such as ticks and mosquitoes, to higher latitudes and elevations. Further, existing drainage and storm water systems in some regions may not be sufficient to manage the influx of water from extreme rainfall events. These surface waters may promote the growth of vector species and lead to increased incidence of vector-borne disease. Likewise, these events could increase exposure to diarrheal pathogens if wastewater treatment plants become overrun and increase opportunities for exposure in undrained environments. On the other hand, some areas will become more prone to droughts, which will increase the scarcity of fresh water and force people to utilize contaminated water sources. Agricultural production will also be negatively affected in some regions and could cause malnutrition and increase susceptibility to disease.

There is significant confidence that climate change will modify the incidence and geographic distribution of diseases. Our ability to predict the effects of climate change on disease is limited by our inadequate understanding of disease systems, and the variability of social, economic, and political factors which modulate population vulnerability to disease. Indeed, the effects of climate change on disease will not be uniformly distributed across space, and will likely disproportionately impact low-income communities in developing countries.

Conclusions

Environmental factors and processes significantly contribute to human disease. These diseases are typically generated through a combination of local environmental factors and social vulnerability. Thus, we observe significant variability over space and time with regards to the type and intensity of diseases mediated by the environment. As human populations have increased in size and density, and new technologies and lifestyles have emerged, we have changed the way we interact with the environment. Most of these changes have been beneficial to health, although others have created new sources of disease.
The disparity in social, political, and economic development contributes significantly to the variability of disease burden that is observed worldwide. Environmental change and new demographic profiles will continue to generate new sources of disease.

Environment and everyday life

Alex Loftus
King's College London, UK

Intellectual and social context

The relationship between the environment and everyday life has not received the attention it deserves within either environmental scholarship or activism. In recent years, nevertheless, a critique of everyday life, a theorization of its conditions of possibility, and a growing recognition of the empirical complexity to researching everyday life has begun to emerge. In part, these three concerns reflect the influence of the environmental justice movement on dominant environmentalisms as well on geographical perspectives on the environment. In part, they also encompass a view that mainstream environmental movements have made catastrophic mistakes: in contrast rich possibilities might be found within a critique of everyday life.

Major dimensions

Environmental justice

As indicated above, the recognition that everyday life is crucial to the practice of an environmental politics comes through most clearly within the environmental justice (EJ) movement. For Whitehead (2009, 664) the EJ movement “reflects the apotheosis of second-wave environmentalism, combining as it does a concern with questions of nonhuman environmental justice alongside a strict focus on the everyday spaces of city life.” Here the environment has been understood as that which is lived and practiced, that which is breathed, cycled over, and played upon. Rather than focusing their energies on the preservation of green spaces for the benefit of a narrow elite, activists have demonstrated the ways in which environmental injustices are produced and reproduced at an intimate, everyday, and bodily level through the perpetuation of structural inequalities. Thus, for Pulido (2000) the ongoing reproduction of hegemonic white privilege within the United States ensures the continued exposure of raced communities to toxic waste. Pulido explores the everyday aspects of such environmental racism through a focus on the geographies of Los Angeles.

The roots to the environmental justice movement are often traced back to antiracist and working class struggles within North America. Perhaps the two sets of events most readily cited in relation to the genesis of the movement are the struggle against toxic waste in Warren County (Bullard 1990) and the struggle for relocation among homeowners sited on the toxic dump known as Love Canal in New York state. When told solely from these two North American narratives, accounts tend to overlook the importance of environmental justice as a force within locations across the Global South. In post-apartheid South Africa, however, the environmental justice movement has been one of the most important sources for alternative political imaginaries over the last twenty or so years. For McDonald (1998, 2004) EJ activists...
were able to effectively position the delivery of basic services as the central post-apartheid environmental question. In one of the most profound reinterpretations of environmentalism, many South Africans began to view the environment less as the National Parks from which so many were excluded or displaced under apartheid but rather as the sewage being handled by the municipal worker, the garbage being reclaimed by men, women, and children from the municipal dump, and the contaminated air being breathed by the asthma sufferer in a landscape liberated from, but now reinscribed by, the injustices of apartheid. Myers has noted that an overemphasis on the successes of the South African EJ movement can lead to a neglect of the unevenness of a movement which is still notable for its absence in many sub-Saharan African countries, nevertheless EJ has had an active presence within many Latin American and Asian struggles over the last three decades.

**Against the abstractions of the global**

Environmental justice activists are not the only ones to challenge the more abstract, global concerns of mainstream environmentalism. Illich (1973), Schumacher (1973), and Mander and Goldsmith (1996) have all in very different ways made a case for the importance of the local, very often positioning this against a universalizing and abstract environmental politics. Small is Beautiful, Schumacher’s paean to “enoughness” in the face of claims that “bigger is better” has been seen as the basis for an understanding of “intermediate” or appropriate technologies. The development interventions of NGOs such as Practical Action have sought to build on such a philosophy and construct a model of sustainable development informed by existing practices of everyday life in historically and geographically specific contexts. Local Agenda 21, one of the key policy innovations to emerge from Our Common Future and the subsequent Rio Earth Summit provided a more formal recognition that achieving global environmental sustainability would require shifts at a local scale, and that many of the key actors in environmental sustainability had not been adequately recognized. Through Local Agenda 21 the abstractions of the global became something experienced at a far more humble level. Environmental interventions needed to ensure improvements in the spaces that people cycled or walked. The resurrection of a canal towpath thus came to represent the movement for sustainable development at a far more mundane, everyday level. Nevertheless, even if such interventions are experienced most directly at the level of the everyday and are informed by a more nuanced scalar politics than prior manifestations of environmentalism, the everyday is rarely discussed explicitly within such work. Instead, local institutions, civil society, communities, and small-scale entrepreneurs become the key actors within what can sometimes become an atavistic and romanticized counter to the modern abstractions of the global.

**Between the marvelous and the mundane**

Elsewhere, geographers have borrowed from both actor network theory and science studies to better understand the more mundane – but no less important – politics of urban wildlife. Seeking to attend more closely to the intermingling of human and nonhuman within urban environments, Hinchliffe et al. (2005) have emphasized what Stengers refers to as cosmopolitical experiments. Practices that are “unnoticed by urban politics and disregarded by science” become central to an analysis that
is more sensitive to the myriad ways in which urban ecological assemblages come to be produced within everyday encounters. Others, such as Michael (2006) have stressed the relationship between technoscience and everyday life and sought to think through an environmental politics that is more explicitly concerned with such interrelationships.

Less theorized accounts of environmentalism and the everyday are abundant – one needs to make only the briefest of searches on YouTube – but these are often premised on a simplistic reading of the idea that change needs to come from the individual, an unproblematic reading of the subject and a complete divorce from the broader contextual factors that provide opportunities and obstacles to an environmental politics in differing historical and geographical contexts. In the effort to shift attention from spectacular manifestations of environmentalism, the result is often a bland appeal to the micro and an individualistic claim that the acts of many single actors will add up to the change necessary for an environmental revolution.

These more naive claims to the everyday, or to a politics of the grassroots, have, not surprisingly, attracted criticism from a range of different quarters. While deeply sympathetic to many aspects of environmental justice activism, and seeking to learn from the organizational success of movements to organize across raced, classed, and gendered constructions, David Harvey (1996) has questioned the ability of the environmental justice movement to move beyond a militant particularism in order to achieve the “global ambitions” that it often seems to set itself. Elsewhere, Harvey (2008, 29) writes that “Paul Hawken … in ‘Blessed Unrest’ makes it seem as if social change in our times can only emanate from the practical engagements of millions of people seeking to transform their daily lives in creative ways (a position that is sometimes taken in the works of Gibson-Graham and Escobar).” Instead, Harvey calls for a dialectical approach that is attendant to how social change works across and through several different moments simultaneously: everyday life is one of these moments alongside relations to technology, relations to nature, social relations, and relations of production and ideas.

Whitehead (2009) considers these questions in more explicit reference to the manifestations of environmentalism in the contemporary moment. Although heavily influenced by the environmental justice movement, Whitehead notes his disappointment at the inability of the environmental justice movement to live up to its own claims to be shifting the practice of environmentalism to a more intimate sphere. Instead, as he notes, the focus has often been on the spectacular manifestations of environmental injustice, the most extreme cases of poisoning from toxic waste and the most devastating health consequences of environmental racism. In becoming increasingly preoccupied with such catastrophic events EJ becomes increasingly divorced from the very intimacies from which it claims to emerge. Paradoxically, it speaks less to those affected on a day-to-day basis by ongoing environmental injustice and environmental racism. Whitehead’s response is to develop a far more rigorous “critique of everyday life.” In an early take on such everyday environmentalisms, he explores the meaning of such a politics in the post-communist city of Katowice (Whitehead 2005). Claiming that environmentalism often finds itself caught “between the marvelous and the mundane” or rather between spectacular claims around a looming apocalypse – often used as the basis for large scale environmental summits (Death 2008) – and a more banal claim that everyday acts, such as turning off the light switch will make all the difference, Whitehead seeks to develop an alternative basis for an everyday environmentalism. Such a critique requires a
thoroughgoing analysis of the conditions of everyday life and a critique that emerges immanently from the processes, relationships, and paradoxes through which that everyday life is practiced. Thus, Whitehead (2005, 2009) turns to a more thorough reading of Henri Lefebvre, whose three-volume *Critique of Everyday Life* provides one of the most far-reaching theorizations of the conditions of possibility immanent to a practice of everyday life. In a more recent paper, he sees such an immanent critique of everyday life emerging in disadvantaged groups’ engagements with the Black Country Urban Forest in the West Midlands of the United Kingdom.

The resources to be put to work from Lefebvre’s three-volume *Critique of Everyday Life* are numerous. Outside of these three volumes, Lefebvre made an effort to distinguish between some of the elements of his critique: “daily life” (*la vie quotidienne*), everydayness (*la quotidienneté*), and the everyday (*le quotidien*). Whereas daily life has always existed as the rhythm that structures humans’ existence (permeated with historically and geographically specific cultures, myths, and values and deeply rooted in connections with nature), the everyday marks the movement of daily life into the era of modernity (Lefebvre 1988, 89). Everydayness becomes the bland homogenizing effect of this entry and the disciplining of a variety of patterns into a more mundane repetition. The everyday, however, remains open as a space from which critique might be possible. Thus, for John Roberts (2006, 67) “if everydayness designates the homogeneity and repetitiveness of daily life, the ‘everyday’ represents the space and agency of its transformation and critique.” One might think of the disciplining effects of the alarm clock or the daily commute and yet one might also think of the situated knowledges emerging as an emancipatory critique within a worker’s understanding of her labor process. This crucial category of mediation permits a way out of the trap that Whitehead identifies in which environmentalism is trapped between the marvelous and the mundane. A radical critique becomes possible within the homogenizing of everyday practices.

**Everyday environmentalism**

Lefebvre is one of several theorists who figure prominently in Loftus’s (2012) *Everyday Environmentalism: Creating an Urban Political Ecology*. Loftus begins with a recent perspective on the nature of the environment. Eschewing the kind of dualistic understandings that have been propagated within mainstream environmentalism, Loftus seeks to develop an environmental politics as it emerges from the practices of everyday life. Criticizing mainstream environmentalism for the disempowering way in which apocalyptic visions are so frequently precursors to the ceding of power to technocratic elites, Loftus seeks to grasp the fragmented and incoherent environmental knowledges that emerge from historically and geographically specific practices. Although it is now commonplace within academic writings to reject dualisms, the implications for a critique of everyday life have not been explored. However, if the practical activity of everyday life is seen to be woven out of and weaving together particular socio-natural constellations, conditions of possibility begin to emerge not only for a fundamentally different environmentalism, but also for a broader transformative project.

Loftus’s empirical examples are drawn from very different contexts. First, he draws on the everyday practices of provisioning a household with water in post-apartheid informal settlements and formal townships. These acts make and remake what many have referred to as the “waterscape” and within them the conditions of possibility are forged for a critique of both the
practices and the produced environment – or waterscape – itself. Thus, a rapprochement becomes possible between the kinds of scholarly critique developed within urban political ecology and the wellsprings of anger that have been tapped when waters run dry, when environmental injustices are reproduced in the post-apartheid period and when everyday access to the means of existence are frustrated by the mediation of the exchange abstraction. Second, Loftus draws from the practices of artists in London as the socio-natural fabric of the city becomes the material out of which alternative urban futures come to be forged. In both London and South Africa, everyday environmental praxis comes together to provide conditions in which new worldviews are incubated and also the materials and practices out of which new environments might be forged.

The theoretical resources that might be drawn upon within such a praxis-based understanding are many, ranging from geographical thinkers such as Harvey and Smith to feminist writers on situated knowledges. What unites these thinkers is a recognition that the quotidian acts of producing and reproducing the world contain with them conditions of possibility for thinking about that world differently. Ontology and epistemology are thus seen to be related, just as theory and practice come to be identified in a mutually symbiotic manner.

Future directions

If there has been an increasingly explicit discussion of the ways in which everyday life matters for an environmental politics – building on what had been an implicit recognition previously – there is still much work to be done on how this might be put to work in generating new understandings of the possibility for more just and democratic socio-ecological relationships. First, more empirical work is needed to analyze the relationship between historically and geographically specific acts of making distinctive environments and the forms of environmental knowledge implicit within these acts. Second, the relationship of such research with actually existing environmental movements needs to be considered in far more depth. Distinguishing everyday environmentalisms from more mainstream environmentalisms, Cooper (forthcoming) suggests further research on nonenvironmental environmentalism. Others have pointed to the need for a more explicit recognition of the identities that emerge within such everyday environmentalisms. For those seeking a more explicitly normative agenda, there is the possibility of considering how such environmentalisms might be shared among different communities and the ways in which they might provide a basis for future possibilities. Overall, a new field is being defined and the potentials for a new environmental politics to emerge on the basis of such discussions are great.

ENVIRONMENT AND EVERYDAY LIFE

Environment and gender

Andrea J. Nightingale  
*Swedish University for Agricultural Sciences, Sweden*  
*Norwegian University of Life Sciences, Norway*

For some readers the topic “environment and gender” invokes women’s roles in and knowledge of environmental issues. Yet scholars have long argued that the importance of gender in relation to environment extends far beyond women or even gender relations. Like the social sciences more widely, over the past four decades there have been significant shifts in how environment and gender are conceptualized, both as separate analytical constructs and in relation to each other. Gender is only one dimension of power, but has served as a critical entry point for rethinking environment–society dynamics, or what is perhaps best thought of as “socio-natures.” Therefore, “gender” requires one to not only analyze relations based on biological sex within society, but also to analyze how such relations are constructed, contested, and internalized, and how these processes of power are co-emergent with ecologies and environments. Similarly, “environment” is not a taken-for-granted entity; rather, like gender, it is a socially constructed domain that is dynamic biophysically and also in terms of what we imagine it to be. When these insights are taken seriously, they transform how all scholars approach environment–society questions and provide potent analytical tools for understanding the operation of power in relation to environment.

In this entry, the evolution of thought on environment and gender is traced and this history is placed within debates about gender and environment as separate intellectual agendas in the social sciences. It is shown on the one hand that theoretical advances concerning environment and gender in geography have served to transform the wider debate, and on the other hand, at times, that geographers have been slow to incorporate analytical advances from other debates. Many of these conversations have taken place within feminist geography and feminist theory, but by no means are all contributions to the environment and gender debate self-styled as “feminist.” The entry tries to distinguish between feminist thinking and other work that attends to gender, acknowledging how important all of them have been to the overall understanding of environment and gender. The following key concepts are brought forward as being particularly important contributions to social science understandings of environment–society dynamics more generally: politics, intersectionality, and co-emergence.

Politics refers to contestations and collaboration between people and between institutions that serve to order and govern everyday affairs. In this sense, politics encompasses government, but also signals relations beyond governments that are instrumental in framing society–environment dynamics. Intersectionality is a term used to capture the operation of power and how it frames social difference (gender, race, ethnicity, caste, class, and disability, among other markers of difference). Intersectionality highlights the ways that different dimensions of identity come together to shape how social difference operates and forms everyday experience for both
individuals and groups. Co-emergence captures the way that societies and environments are intertwined and internally related. The boundaries between them are a product of how we think rather than the way the world is. Separating what is society and what is environment becomes nearly impossible once one focuses on how they are interrelated. The idea of relationality is core here. When phenomena or objects are relationally produced, it means that one does not exist without the other. Any change in one will result in a simultaneous change in the other. Further elaboration on all of these concepts follows below.

The entry begins with the history of environment and gender in the 1970s, with feminist critiques of Enlightenment thinking. In this work, feminists argue that the oppression of women is linked to the overexploitation of environment and as such is inherently a political question. The marginal position of women within patriarchal societies must be addressed in order to shift environmentally damaging practices. This analysis swiftly diverged into two related, but somewhat separate, strands of thought, both of which are alive and well today. First, ecofeminists argued that women have innate, privileged knowledge of environments, which inspires in them a desire to protect nature. Second, other scholars explored politics more explicitly and probed how the social construction of women and nature facilitates certain kinds of oppression of women and overexploitation of environments. In other words, the link between environment and gender is not fixed, but rather a constructed and contested relation. They criticized ecofeminists for assuming an essential link between women and nature, and instead focused on how, and with what consequences, women become associated with nature. The idea that links these two debates, however, is the notion that gender politics and environmental issues are not separate questions, but rather are inextricably linked. And, as the entry explores more fully below, taking this critique of the Enlightenment seriously requires a reformulation of the environment–society nexus itself.

In keeping with the focus on politics, and closely related to the critique of ecofeminism, a number of scholars in the 1980s and 1990s drew from historical materialist thinking to argue that women’s productive relations bring them into culturally, historically, and geographically specific relations with environments. These relations can give women important knowledge of environmental questions, but that knowledge arises from experience rather than innate inclinations. This work insists on a more nuanced understanding of social relations and how they link societies to environments through productive (and extractive) relations. It is closely related to debates in political economy that seek to show how class relations play out within environmental issues, a field now known as political ecology. Therefore, rather than overexploitation of environment being a necessary outcome of patriarchy, the critique here shows how the organization of society is linked (dialectically related in historical materialist terms) to the political economies of environmental use. Historical materialist work on gender was thus crucial in pointing to the multiscalar social relations that mediate the society–environment nexus and cautioning against assuming that class alone was adequate to explain how social inequalities arise in environmental management. The idea that gender, class, race, and ethnicity combine to shape productive relations was an important precursor to later work on intersectionality in relation to environment.

The debate was far from finished, however, and in the 1990s and 2000s a number of scholars drew from insights in feminist theory and the emerging intellectual agenda in geography
around social construction of environment to explore how gender and other social relations (intersectionality) are constituted in relation to environments. There are two contributions from this debate. First, gender needs to be understood as an outcome of the operation of power and thus a dynamic concept that serves to mark differences between men and women. Taking account of gender therefore requires scholars to look within and beyond household- and community-level relations, as well as probing how forms of social difference intersect to shape the ideas and practices that generate inequality. And perhaps most importantly in terms of a political ecology perspective, there are political economic consequences of gender in terms of accumulation, property, dispossession, and control over surplus labor, all of which are driven by, as well as being manifest upon, environmental conditions. Intersectional social differences, in other words, are not merely unfortunate by-products that need to be managed by special attention to disadvantaged people. Rather, power operates to create inequalities based upon gender and other social differences. These in turn result in unequal access to land and property, differences in wealth, and a greater ability by some people to “get ahead” (control their surplus labor). These kinds of inequality are often manifest on the landscape as degraded land (marginalized people forced to overexploit their resources), fertile land (wealthy people being able to invest in land improvements), protected areas (local people kept off the land to preserve it), and so forth. Below these ideas are taken up more fully.

Second, environment is similarly a dynamic and contested analytical construct. Within most of physical geography and some parts of human geography, “environment” refers to the natural or material world, assumed to be unproblematically distinguishable from “society,” and, perhaps most importantly, to be a real entity that pre-dates its social construction. Many human geographers, however, have argued that such a taken-for-granted understanding of “environment” masks two important processes. One, what counts as environment and how it is distinguished from society are political and, as such, historically and culturally contingent. Second, by assuming environment is a nonhuman domain, it closes down an analysis of processes and objects that are not clearly social or natural. Rather, this work argues that environments and gender (society) are relationally produced, or co-emergent.

Thus the environment and gender debate has come a long way from insisting on women’s role in environmental management. Now it captures a range of scholarship that seeks to hold both gender and environment as contested, political and unstable analytical constructs that are perhaps only partially useful as starting points for a socio-natural analysis of power, social inequality, and environmental change. The remainder of the entry elaborates on this history of “environment and gender,” and shows the key contributions to wider understandings of environment–society (socio–nature) that have emerged from a concern with gender, namely politics, intersectionality, and co-emergence.

Ecofeminism: linking social systems with human use of environments

Ecofeminists are in some sense the originators of the environment and gender debate, and while parts of their analysis have been largely discredited, they made important contributions that continue to be influential today. First, they placed a concern with how social relations extend to environmental domains firmly on the intellectual agenda. They argued that the logic which serves to oppress women is the same logic that leads to overexploitation of the environment, and this
logic is closely connected to science and capitalism. Second, they argued that women have different knowledge of environment from men, and we need to harness such knowledge to find less damaging society–environment interactions.

The basis for these two contributions is grounded in what has become an important feminist critique of Enlightenment and Cartesian thinking. The Enlightenment is associated with the rise of science and the analytical separation of environment from society. Cartesian thinking refers to work inspired by Descartes who reframed the environment as a machine, departing from his contemporary metaphysical counterparts who conceptualized the world as a living being. This mechanistic model paved the way for the scientific method, which prioritizes examining components of natural systems in isolation from other components in order to understand them. Feminists in the 1970s critiqued this dominant “scientific” paradigm on two grounds. First, Enlightenment thinking analytically separates environment from society, producing a host of other binary associations that seem to logically follow: rational–emotional, mind–body, men–women, heterosexual–homosexual, white–people of color, and culture–nature, to name some of the more persistent formulations. Second, feminists argued that Enlightenment thinking associated women with one half of these binaries: emotion, body, and nature. This second argument in many respects led to a core split within feminist thinking on environment: those who embraced such associations and sought to politically mobilize them and those who argued that binary thought needs to be rejected entirely. Ecofeminists, who embraced the idea that women are closer to nature, explored how women are more likely to protect the environment than men due to their role as mothers – a position popularized by Vandana Shiva (1988). They also advocated for a more connected or spiritual approach to environment–society dynamics in order to overcome the mechanistic model perpetuated through science (Diamond and Orenstein 1990).

Before moving on to critiques of ecofeminism, it is important to note the crucial contributions it has made, not only to environment and gender debates, but also to social science and geographical scholarship more widely. First, feminist thought continues to be strongly informed by a critique of Enlightenment and Cartesian thought. Many feminist geographers begin their analyses across a range of topics with the need to unpack binary distinctions, the most relevant here being the opposition of environment with society. A more elaborate discussion on the implications of this move follows below. Furthermore, feminists have been at the forefront in critiques of reductionism and the scientific method, highlighting the limitations of these approaches for understanding some of the most pressing environmental problems of our time. Following Merchant (1982), they have argued that “nature” cannot be reduced to a set of interlocking parts, but rather needs to be analyzed as a relationally constituted whole. This has fed into recent debates in science studies and nature–society geographies on how to theorize “environment–society” and how to develop new methodologies to capture their nexus. In this sense, contributions from environment and gender scholarship have been foundational in helping to steer the current direction of nature–society geographies.

Second, while most feminists are wary of essentialism, there continues to be a tradition of ecofeminist thinking that begins with an understanding that the oppression of humans and overexploitation of nonhumans are linked. Most recently, queer theorists have entered the debate and insisted on nature as more than a stage for the playing out of social relations. This
body of scholarship argues for a fundamental transformation in how we understand our relationship to the rest of the world socially and environmentally. Some in this tradition (re)turn to spirituality to find other, nonreductive and nonmechanistic paradigms for framing the place of humans in nature (Anderson et al. 2012). This strand of scholarship has perhaps fewer adherents within geography, but is closely related to deep ecology and also to the growing field of ecocriticism within the humanities.

**Historical materialism and the critique of essentialism**

Despite these important contributions from ecofeminism, the idea that women are closer to nature was criticized almost as soon as it was put forward. In particular, the reduction of all women to one inherent nature was deemed to be problematically essentialist. Essentialism refers to the idea that particular groups of people possess fundamental or essential characteristics. Attributing essential characteristics to a group or category of people ignores important differences between members of the same category, and as such can mask some of the dynamics that serve to keep some people “closer to nature” than others.

Feminists of color were at the forefront here, criticizing the white, middle-class bias in much of feminist thinking at the time, and demonstrating the importance of foregrounding differences between women (Mohanty, Russo, and Torres 1991). In addition to race and class, other forms of difference also serve to shape who has what experiences and what knowledges of environment, including sexuality, disability, and geographical location (i.e., north–south). Therefore the question is not whether women are closer to nature than men, but rather how some women (or men) come to be materially and symbolically associated with nature, and the implications of those associations socially, politically, economically, historically, and materially.

Speaking explicitly to the environment and gender debate, the Indian feminist Bina Agarwal (1992) drew from her background in political economy to argue that the focus needs to be on relations of production and reproduction that serve to bring (some) women closer to nature than others. Women who engage in agricultural labor, or are responsible for gathering essential natural resources (wood, water, etc.) to support household reproduction, do indeed gain crucial knowledge of environmental processes. They are more likely to be invested in long-term ecosystem health, but the crucial insight here is that a propensity to protect the environment arises from the material conditions of everyday life, rather than from innate tendencies. These insights have been taken up within development practice, which now targets women for various conservation schemes. So while, on the one hand, feminists celebrate how development practice has recognized the need to understand intra-household dynamics when designing development interventions, on the other hand, they are wary of how development targets women as a source of competent and willing labor for environmental management schemes.

Within academia, Agarwal’s work fed into what is now known as feminist political ecology, although at the time Agarwal named it “environmental feminism.” Feminist political ecology has perhaps been most productively developed within geography, as elaborated upon below. The historical materialist lens, Agarwal suggested, provided an important set of tools for unpacking the category “women” and recognizing how people with different class and associated productive relations necessarily come into different relations with environment.
ENVIRONMENT AND GENDER

This laid a foundation for thinking about intersectional social relations in feminist political ecology: although now, the structuralist framing of gender, class, and race in environmental feminisms has been replaced by a performative understanding of gender and social difference within “new” feminist political ecologies. And while Agarwal herself never took the analysis this far, her work begins to show how social difference is in part generated from production and thus is co-emergent with environment. This last point is elaborated on below in “the production of socio-natures” section.

Cyborgs and socio-nature: retheorizing society–nature

While the debates between ecofeminists and their critics were in full flow, Donna Haraway (1991) argued for a reconceptualization of both environment and gender. She drew from early feminist critiques of science to imagine a post-Enlightenment understanding of environment–gender. Her account tackled many dimensions of science and our conceptualizations of environment–gender at once. She has been profoundly important in changing the entire character of environment–society debates, most recently with her work on human–animal relations. The entry will attempt to summarize and make sense of her rich argument by framing it around two core contributions: (i) reimagining the entry points for probing environment–society dynamics, and (ii) reimagining how we can know and make claims from our scholarship.

Enlightenment thinking opened up methodological space for research techniques wherein detached observation and attempts to isolate parts of the whole were valued. This is recognizable to most readers as the “scientific method” wherein variables are isolated and tested one by one against hypotheses. Haraway rejected this kind of detached scholarship and reconceptualized environment–society by insisting on its social construction and relational emergence. She turned to metaphor and figuration to reimagine, in an “ironic and blasphemous manner,” the interconnections between conceptualizations, discursive constructions, political economies, and the materialities of different bodies and species. She used the figuration of the “cyborg” to review the boundaries of human/nonhuman and to playfully show the (re)production of those boundaries and what it means to be human. She argued that humans are relationally produced from the encounters we have on an everyday basis, and thus the very meaning of human (or the social) emerges from how we define ourselves against the nonhuman (or nature).

In subsequent work, Haraway developed this critique further to probe the boundaries of kinship, bringing back and also going beyond questions of gender. She explored how difference is constructed, not only between men and women (although this was a crucial starting point for her), but also between humans and other species. She argued that our scholarship – and the political economies of science and technologies that result – goes astray when we forget that our analytical constructs are not “life itself.” She used the example of genetics to show how “genes” are an abstraction of very complex biochemical reactions that are not fixed in time and space. They are “real” in the sense that we can create them through genetic technologies, we can even move them around across species, but “genes” are not life itself. They are one lens through which we try to understand life, and a lens that has very specific biological, political, economic, and societal consequences. Thus one of the core contributions to come from the environment and gender debate has been to show the interconnection
between how we understand “life,” and the lives that become possible as a result. Perhaps most importantly, these lives are necessarily already bound up in social-political as well as ecological dynamics that cannot be separated from our analytical constructs of “life itself.”

Furthermore, if we embrace such a relational emergence of environment and society, then we have to develop new methodologies to study these dynamics. Haraway made a profound methodological intervention by adding her voice to other feminist critiques of neutral observation. She demonstrated through the example of primate behavior research that the background of the researchers – particularly their gender – was instrumental in shaping how they interpreted the behavior they observed (Haraway 1991). Therefore, she argued that detached observation was not possible. The expectations, assumptions, and background, or “positionality,” of researchers shape how they design, analyze, and interpret their research. She rejected “the god trick,” her name for detached observation, as being impossible to achieve, and rather argued for a commitment to “situated knowledges.” Situated knowledges is an epistemological and political stance that demands one be accountable for “how one learns how to see,” arguing that the way one sees is at least in part derived from one’s positionality. She joined others in the social sciences at the time, including Foucault, in arguing that knowledge is contingent on the people and the conditions under which it is generated. Therefore, science needed to shift from attempting to reduce observer “bias” to creating objectivity by acknowledging the position from which we are able to see.

Haraway’s work, which began in the environment and gender debate (in her words, a socialist, materialist feminism), has provided a foundation for an entire generation of scholars to research the implications of environment and society conceptualizations. These contributions have emerged in conversation with parallel work in science and technology studies and geography to encompass a wide variety of perspectives trying to make sense of “socio-natures.” An elaboration on how this debate has been taken up by “new feminist political ecologists” follows.

**Feminist political ecology**

While Haraway’s ideas were almost immediately influential within feminist theory, some of the core dimensions of her argument were slow to be taken up by geographers working on environment and gender. Rather, most scholarship on environment and gender continued to (ontologically) treat the two as separate, interacting phenomena. The goal was to refine an understanding of how gender relations shape environmental issues. Within this work there were two parallel strands: the first was a merging of the ecofeminist debate with historical materialism to show how environmental questions are “gendered.” The second was to take the historical materialist debate further and think more carefully about the way that social relations have political economic effects which are both driven by, and manifest within, environmental governance contexts. There are not clear lines between these two strands, but the first has a more explicitly feminist agenda than the second. Linking them is a concern with how usufructuary rights and forms of property are mapped onto access to and control over resources.

Diane Rocheleau, Barbara Thomas-Sluyter, and Esther Wangari’s 1996 book, *Feminist Political Ecology* (1996), best exemplifies the first strand. They sought to push forward the environment and gender debate by arguing that environment is “gendered” in three key ways:
ENVIRONMENT AND GENDER

1 gendered knowledge, or how access to scientific and ecological knowledge is structured by gender;
2 gendered environmental rights and responsibilities, including differential access by men and women to various legal and de facto claims to land and resources; and
3 gendered politics and grassroots activism, including an examination of women’s roles within environmental movements.

The concern with gendered knowledge builds directly from historical materialist accounts to probe how men and women have differential knowledge of natural resources. Examples from development practice abound here. In development, men generally have access to agro-forestry extension workers, new training opportunities, and other knowledge associated with “science,” whereas women have knowledge gained from their activities as subsistence providers in households. By focusing on how people gain knowledge, this framing helps to avoid lumping all women together as having innate understandings of environment. It also brings into view the processes and contexts—here development interventions and training opportunities—through which such differentiation is perpetuated and reinforced.

The second theme, gendered rights and responsibilities, points to unequal access to land and resources by men versus women. While Rocheleau, Thomas-Slayter, and Wangari’s (1996) book emphasizes examples from developing countries, other feminist political ecologists reviewed how similar processes are at work in so-called developed countries as well (Seager 1993). The regularization of land tenure through the distribution of land titles most often assumes that male heads of households are the “rightful” owners of land, undermining women’s de facto claims to use-rights and control over land. In some contexts, development projects seeking to change land use intersect with these conflicts over land and resources, to the detriment of women. Researchers therefore need to probe how land use and rights intersect with gender relations to disadvantage some and privilege others.

The third theme, gendered politics and grassroots movements, examines social movements, highlighting how women have taken leadership roles and gained self-confidence within community struggles for control over natural resources. This interest in social movements resonates with the hope in the wider political ecology debate that environment could become a rallying point for transformational politics. Although certainly not without their contradictions, environmental social movements seem to have potential for the emancipation of women and impoverished communities, in addition to environmental protection (Peet and Watts 1996; for an alternative argument, see Reed 2000). On a conceptual level, environmental movements help to show how social difference is related to environmental knowledge and desires to protect nature. Social movements can help to provide people with new knowledge of nature, in addition to environmental issues acting as a focal point for collective action across forms of social difference including gender, race, and class.

The themes in Rocheleau, Thomas-Slayter, and Wangari’s (1996) book developed in conversation with a growing political ecology literature in geography that does not necessarily have an explicitly feminist agenda (Peet and Watts 1996). Here, concern with gender relations is an empirical question: rather than beginning with gender as a focus, this work looks into which social relations are most important in any given context. Many environmental conflicts that most intrigue political ecologists are strongly shaped by gender relations as well as class. Several studies explore the way that gender, as historically, culturally, and
geographically specific male–female sex roles, combines with class and race to structure access to particular types of knowledge, space, resources and social–political processes. Conceptually, this work contributes to debates on property rights and their relationships to social inequality and environmental outcomes. In particular, it probes how gender and class shape property relations and usufructuary rights to land and resources. Well-intentioned development projects that seek to mobilize women’s labor, or to make particular lands more productive through new agricultural technologies, often lead to dispossession of resources for women and marginalized community members. In other words, social relations of power cannot be undone by development interventions, but rather social relations powerfully influence control over, access to, and distribution of resources and the environmental consequences of these relations and development interventions.

Political ecology has been particularly important in showing that attention to gender should not be confined to the household and community level only, but rather also needs to be researched at the level of policy. For example, Schroeder’s (1999) work in the Gambia traces shifts in how development projects imagine the roles women should play and the ways these assumptions intersect with gender relations within households and communities. An inadequate understanding of local gender relations and how they structure control over land and resources and shape production often results in reversing gains made in earlier development interventions. An analysis of environment and gender therefore needs to account for not only how men and women are differentially engaged in environmental conflicts and development programs, but also how conceptions of gender frame the design of interventions. In other words, social relations are not separate from environmental governance, but are foundational to which schemes are put forward as important, how successful they may be, and how they may fuel existing conflicts.

It is important to note here that, within both feminist and wider political ecology, an analytical separation between environment and gender (or society) is retained, and this separation helps demonstrate how environment is a potent terrain within which struggles over access to, control over, distribution of, and knowledge of resources are played out. Today, many scholars continue to investigate these four core aspects of environmental conflict: access, control, distribution, and knowledge. A crucial contribution from the environment and gender debate has been to insist that each of these processes is structured by social relations within households, communities, and across scales to the global.

Intersectionality and new feminist political ecologies

The environment and gender debate was far from finished, however. A number of scholars were uncomfortable with the emphasis on women in feminist political ecology. This conflation of women and gender was not consistent with other developments in feminist theory. Rocheleau, Thomas-Slayter, and Wangari (1996) insisted that their interest was in gender as socially defined roles for men and women, but in many places the book slips back into an uncritical focus on women. In part this occurs because of their desire to spotlight the contributions of women who are often invisible within development projects and the global spheres wherein a book of that type circulates. They therefore attend to the knowledge, struggles, and activities of locally based, often illiterate, women. The danger with such slippage, however, is in reverting to an essentialized understanding of women as having
a privileged understanding of nature simply by virtue of their biological sex. In addition, the slippage closes down a careful analysis of how political, economic, cultural, and symbolic processes serve to *define* gender. But perhaps most significantly, conflating gender with women masks how gender is implicated in the construction of “environment” itself. In short, what is not sufficiently probed is how gender comes to be relevant in the first place.

Such an uncritical focus on women as a unified category was not consistent with concurrent advances in feminist theory. Chandra Mohanty, Judith Butler, and others argued that biological sex was an inadequate basis for understanding social difference (Butler 1990; Mohanty, Russo, and Torres 1991). Rather, social relations, first, “add up” to structure how individuals (in this case) have access to, control over, and knowledge of environments. Second, the production of social difference is performed in the everyday and as such is constantly up for negotiation and transformation. This formulation is often referred to as “intersectionality” to capture how class, race, ethnicity, gender, and other forms of social difference are not separable, but rather emerge together from the operation of power to shape which social relations are relevant and contested. Feminist geographers apply this understanding to space to show how space and social relations are mutually constituted within everyday activities (performances) (Massey 2005).

A new generation of feminist political ecologists took up these ideas to retheorize gender within the environment and gender debate. These “new feminist political ecologists” place more emphasis on intersectionality and processes of subjectivity in relation to environment than they do on women per se. Subjectivity comes from Foucault’s (1995) and Butler’s (1990) conceptualization of the operation of power. Subjectivity emerges from the exercise of power and the internalization of power by the subject, and as such is dynamic and continually (re)constituted. For example, people who are biologically female are often subjected as “women,” but what being a “woman” means and the extent to which it reflects different dimensions of biological sex is contextually contingent. At the same time, those subjected as women internalize as well as resist these notions of “women,” serving to transform (or cement) what it means to be “women” (Butler 1990). While these ideas are highly abstract, they have also been very important in moving beyond a focus on women within environment and gender debates. Attention to subjectivity demands an exploration of the processes, contexts, and moments wherein social difference such as gender, race, and class are invoked and (re)produced, and the consequences they have for both social relations and environments.

New feminist political ecologists thus argue that research needs to pay more attention to how the performance of intersectional social relations is crucial in defining “men,” “women,” “villagers,” and so on. For example, Harris (2009) explores how gender is crucial in the design of large-scale dam projects in Turkey. Project designers worked from particular assumptions about how gender structures household labor, water needs, and the ability to retain new “knowledge” of irrigation and other technologies. These assumptions shape how the dams function and for whose benefit. In addition, masculinities and femininities are transformed by shifting relations to water as a result of the dams. Environmental issues, therefore, are not simply about environment, with perhaps some unfortunate social justice implications. They are foundational to how inequality is conceptualized and maintained within societies and across scales. What makes this kind of analysis “new” is the attention to how gender itself is transformed through environmental issues, as well as gender
relations shaping the struggles that emerge around environment.

Conceptually, this opens up space to understand how changing environments and changing social relations are co-emergent. Any attempts at environmental transformation will lead to transformations in how social difference is defined and performed. This last point distinguishes the new scholarship from earlier historical materialist accounts. Historical materialists are similarly concerned with how environmental projects serve to reshape social relations around those environments. New feminist political ecologists attend to these dynamics, but do so through a more fundamentally relational perspective that seeks to illuminate how the very meanings of “women,” “men,” “race,” or “ethnicity” are transformed by environmental projects (Sundberg 2004).

It is in this sense that this entry argues that gender and intersectional subjectivities produce environments and ecologies (Nightingale 2006). Social relations are not simply played out in environmental projects; they are mapped onto the landscape in ways that have tangible nonhuman effects, and which in turn serve to reshape or cement social relations. For example, land use is framed by intersectional social relations and land use itself serves to transform which species are present, how soils develop, and other dimensions of ecologies, all of which then have implications for what kind of work is performed by whom as ecologies change or remain the same. This kind of argument needs to be distinguished from environmental determinism that suggests environments form societies. The difference lies in how both “environment” and “gender” are conceptualized. A determinist perspective assumes environments have the same influence on all people, with the same outcomes. A new feminist political ecology perspective recognizes both as dynamic assemblages of humans and nonhumans that relationally emerge. So it is not a case of environment shaping society, or society impacting upon environments: rather, the “new” environment and gender debate takes both as contingent, dynamic, and linked material-symbolically: in short, co-emergent.

The production of socio-natures

Through the idea of co-emergence, new feminist political ecologists have thus taken up the challenge originally posed by Haraway to retheorize environment itself. Inspiration for this move was also fueled by debates within geography on social constructions of nature, materiality, actor networks, and posthumanism (Castree and Braun 2001). These debates share a common concern with how society and environments are relationally produced, and a desire to find new theorizations and vocabularies to avoid making analytical separations between them.

When environment and society are kept as separate analytical categories, this leads to a Cartesian separation of humans from their environment, as if somehow we could ever exist outside of it or have no influence within it. This kind of Cartesian thinking has spawned innumerable studies of “human impacts” on environments that fail to account for how what is considered important and worthy as “environment” is relationally constituted with society. In other words, what we value and do not value in nonhumans reflects what we value in society. Again, these debates can seem very abstract, but they have important empirical implications. For example, environmental conservation continues to be justified in the name of protecting a variety of charismatic species, such as tigers, rhinoceroses, or pandas. By focusing on these species, people do not value, and in fact most often do not see, other species and habitats that are equally
important to overall ecosystem integrity, such as micro-organisms, noncharismatic species such as rats, or even humans themselves. This lack of a wider focus sometimes has disastrous consequences for conservation goals, but, most importantly, it also justifies an uneven valuing of different people and their different levels of engagement with environments. The idea of co-emergence draws attention to places, spaces, and species that often fall outside of our consideration as “environment.” Environmental justice activists – many of whom are women – argue precisely that. When “nature” is assumed to exist outside of places where most humans live, it is difficult to bring urban pollution concerns forward as, for example, “environmental issues.”

New feminist political ecologists seek to capture these relational dynamics by keeping in view the networks, relations, and assemblages of humans and nonhumans that serve to constitute “environment” as well as the social-political consequences of how socio-natural difference is conceptualized and becomes important. As such, the environment and gender debate continues to add cutting-edge conceptual contributions to wider debates around environment and society. Taking account of women remains important, but by no means the only, or even necessarily core, agenda of the environment and gender debate. Rather, the debate now retains an emphasis on the politics of environment, adding new tools and new insights from an intersectional and co-emergent conceptualization of “environment and gender.”

Environment and health

Susan J. Elliott
University of Waterloo, Canada

How is health shaped by the environment? How does the environment shape health? Contrary to what is portrayed by media reports, these are not contemporary concerns. Today’s media are full of references to climate change, chemicals in the water we drink, pollution in the air we breathe, contaminants in the food we eat, inexplicable increases in (re-)emerging environmentally related illnesses (e.g., asthma, food allergies, and infectious diseases such as the West Nile virus, dengue, and chikungunya), but documented interest in the study of how the environment shapes health – and vice versa – began as early as 400 BC with Hippocrates’s famous treatise On Airs, Waters, Places, in which he wrote:

Whoever wishes to investigate medicine properly, should … in the first place consider the seasons of the year … Then the winds, the hot and the cold … the qualities of the waters … and the ground, whether it be naked and deficient in water, or wooded and well watered, and whether it lies in a hollow, confined situation, or is elevated and cold; and the mode in which the inhabitants live, and what are their pursuits, whether they are fond of drinking and eating to excess, and given to indolence, or are fond of exercise and labor, and not given to excess in eating and drinking … For if one knows all these things well, he [sic] cannot miss knowing … the diseases peculiar to [a] place. (Hippocrates 1923, 71)

Essentially, Hippocrates was saying that where we live, and how we live in those places, shape our health. Historical evidence has borne out this assertion. Thomas McKeown (1975) clearly illustrates through historical data that major advances in health in the nineteenth and twentieth centuries had much more to do with lived environments than advances in medicine and/or clinical care, as is often thought. A classic example is tuberculosis, a well-recognized disease of poverty. McKeown shows that the decline in mortality from this infectious disease began long before the disease mechanism was identified (1882), the development of an antibiotic to use in treatment (1947), and the introduction of a vaccine (1953). So what was the cause of the decline? McKeown (1988) explains that the introduction of basic population-level public health measures (e.g., better nutrition, access to safe water and sanitation) led to better health conditions in general, particularly for the urban poor. Indeed, in 2007 over 11,000 readers of the esteemed British Medical Journal voted for advances in water and sanitation as the greatest medical advance of the previous 150 years.

Clear articulation of what is meant by the complex concept of health is a useful point of departure for understanding how it is shaped by the environment; defining environment is just as complex. The definition of health has undergone several iterations in the postwar era. The evolution of health from more than simply the absence of disease to complete physical, social, and emotional wellbeing set the stage for a revisiting of the biomedical paradigm and for the development of models of health and
wellbeing that emphasize not only multiple determinants of health but also the role of the social, cultural, political, physical, and economic environments within which health and well-being are shaped. Alternative health frameworks began to emphasize the role of socioenvironmental factors, in addition to lifestyle and biology, in the production of health and illness, while at the same time diminishing the role of the formal health-care system. Health is now considered a resource for everyday living that allows individuals to manage, cope with, and even change their environments. What is environment? One plausible response is Einstein’s view: the environment is everything that is not me.

In the context of environment and human health, we often think of the physical environment (e.g., air quality) and its impacts on human health (e.g., asthma). But what of the social environment (e.g., social capital), the economic environment (e.g., unemployment rates), the cultural environment (e.g., the role of women), or the political environment (e.g., access to opportunities and institutions)? These environments, too, have been shown to influence human health, which is why the World Health Organization, in a meeting in Sofia, Bulgaria, in 1993, crafted a very broad definition of environmental health that includes quality of life in the concept of health and refers to the influences of the physical, biological, chemical, social, and psychosocial environments. This definition has a further, prescriptive component addressing the correction, control, and prevention of those factors in the environment that can (potentially) adversely affect the health of present and future generations. Regardless of how long these issues have been under consideration or how they are defined, they remain at the forefront of concern for researchers, policymakers and the general public alike, despite the fact that skeptics still exist (see, e.g., Harrison 2000).

Measuring environment and health

The classic example of an environment and health relationship found in virtually every health geography textbook involved the ingenuity of Dr John Snow of London, England. Snow solved the mystery of the cholera outbreak of 1858 by mapping the location of deaths due to this infectious, water-borne disease. At the time, of course, most households did not have piped running water. Rather, standing water pumps, from which local residents drew their daily requirements, were scattered throughout the neighborhoods of inner-city London. When cholera started claiming many lives in the mid-1850s, there was no apparent explanation. At this time, there was little knowledge of the links between cholera and contaminated water. There were, rather, ill-defined notions that cholera – and other infectious diseases – were spread by “miasma,” or bad airs. Snow was suspicious of these notions and decided to map the deaths from cholera occurring across the city. What he found was that there had been a cluster of deaths in the vicinity of one particular pump located on Broad Street. The local water supply was drawn from the River Thames, which was essentially an open sewer for both industrial and human waste. Several water companies drew their water from the Thames, and “treated” the water before distribution to local households; clearly, some companies did a better job than others. Snow ceremoniously cut the handle off the Broad Street pump in order to seal his discovery.

Snow’s action was, however, based on pure speculation: the data that existed were descriptive (a mapping of the deaths), and there was no science (i.e., an understanding of the biological mechanism causing the disease) to substantiate his claim. Some were skeptical (Johnson 2006), and this illustrates the pervasive “rub” in environment
and health: we suspect these relationships, but measurement – of exposures and of outcomes – is elusive. Concomitantly, however, in the absence of strong science, decisions must still be made by politicians and policymakers. Should Bisphenol A (BPA), used in the modern day production of plastics, continue to be used in baby bottles? Or the millions of water bottles that adults use? What type of mass-produced energy source is really “safest” – coal, nuclear, or gas? What about fracking? (Jackson et al. 2014). We also have to make these decisions at the individual and/or family levels. Should I use pesticide on plants in the back garden? Should I or we eat organically grown food even though it’s much more expensive? Where is the evidence and how can we go about getting it?

Design

There are several different study designs to choose from in any health research endeavor. The strongest of these is the randomized controlled trial (RCT). In such a study, the researcher has control over both the exposure of interest as well as the sample exposed. Typically, RCTs are undertaken to test a new treatment for a known illness, often a newly developed pharmaceutical. The researcher would select a control group (which did not get the newly developed pharmaceutical or would receive a placebo) and an intervention group (which would receive the newly developed pharmaceutical), and assess the impacts (ideally in a double blind manner; that is, neither the researcher nor the subject would know if they were receiving the newly developed pharmaceutical or the placebo). Widely heralded as the strongest study design and yielding the most credible results, RCT is impossible to implement in an environment and health study. For many reasons, including ethical ones, it would be impossible to expose, say, a group of children to lead for a period of time and then assess the impacts compared to a control group not similarly exposed. As an aside, we often have access to “natural laboratories” in environment and health research. For example, the 1976 explosion at a chemical factory in Seveso, Italy, allowed researchers to follow the workers and residents of the surrounding community for the next 30 years to assess the long-term health impacts; however, because this was not an RCT, the researchers could not control for all of the potential confounding factors that may also have influenced the health outcomes of interest (e.g., whether residents smoked, and whether they were exposed to other sorts of toxins in the residential environment).

Since we cannot run RCTs in environment and health research, we are limited to observational studies – essentially, observing what has already happened. One form of observational study is the case control design. In this type of study, a number of cases are identified – for example, a cluster of leukemia cases – and these individuals are studied for their exposure histories. This was the study design used in the famous case of Woburn, Massachusetts. In this case, a seemingly inexplicable cluster of childhood leukemia cases occurred in a residential neighborhood. Area residents suspected the local water supply to be the culprit. For some time, the water had smelled of chemicals and led to rashes and burning on human skin. Residents worked to convince local authorities and physicians that there was indeed a link between the leukemia cases and the water supply. A local industry was subsequently convicted of contaminating a city well. (The story was later made into a Hollywood movie entitled A Civil Action, starring John Travolta.)
A second type of observational study is the cohort study. In this approach, sampling is on the basis of exposure, as opposed to outcome (as in the case control study). Cohort studies can be one of two types: retrospective or prospective. In the former, a cohort of individuals is identified who are thought to have experienced an exposure. The cohort is then studied to determine what, if any, adverse health effects they might have experienced in the past. This is the typical type of study done in environment and health research, often because a community realizes it may have been exposed to something (e.g., an air pollutant, a leaking landfill, or a contaminated water supply) as a result of some ill-defined symptomatology or an inexplicably large number of cancer cases in a neighborhood. This self-identified cohort may then be studied to assess potential ill-health effects experienced in the past during the exposure. An example here is the Sydney Tar Ponds in Nova Scotia, Canada. This site, known as the most heavily contaminated industrial site in Canada, saw approximately 100 years of coal smelting and steel production, characterized by inappropriate waste disposal practices. The site is now contaminated with 700,000 tons of known carcinogens. Residents living within two miles of the site have been very concerned about the impacts of the exposure on their daily lives as well as anxieties around reproductive health and decision-making. In most instances, a mixed methods approach will provide the most comprehensive picture (Gatrell and Elliott, 2014).

Measurement

Complicating matters further are issues of measurement: it is no easy task to measure exposures and outcomes, and to ascertain the pathways through which individuals are exposed. Each of these aspects of measurement is elaborated on in what follows, drawing on the environment and health literature for illustrative examples.

Exposure

What are we exposed to and how do we measure it? With respect to the former question, toxins in our environment that have long-term, irreversible effects are of most concern. For example, neurotoxins (e.g., pesticides and heavy
metals like lead, mercury, and chromium) attack the nerve cells. Radiation can cause genetic damage to the self and to one’s offspring. Teratogens (some solvents and heavy metals) can cause birth defects and carcinogens (e.g., PCBs) cause cancer. Another environmental health concern plaguing us now is endocrine disrupters. The first compelling evidence for this concern comes from animal populations that have shown changes in fertility and other reproductive problems, including the feminization of the male of the species (Bergman et al. 2013); however, when individuals report to their friends, family, physician, or local public health official that they feel they have been exposed to some environmental hazard, it is very difficult to measure that exposure. First, the exposure happened in the past, and recall bias will impact on how accurately we are able to measure the exposure (do you remember, for instance, how often you spent time in your basement in the last five years? How much time you spent in the shower or bath? How much tap water you consumed? How much time you spent in the garden or yard of your house?)

Second, often the exposure comes from an illicit, undocumented source, for example, chemical contamination by an industry to the public water supply in Woburn, Massachusetts. Third, we rarely know what the exposure contains. For example, when Lois Gibbs first discovered yellow ooze seeping into her basement in her Love Canal neighborhood home, all she knew was that it was yellow ooze. Toxicologists then had to discern the composition of the ooze, which is very difficult to do. When toxicologists investigate a toxin, they need to know what they are looking for so that it can be identified. Are we looking for polyaromatic hydrocarbons? Dioxin? Dieldrin? Trichloroethylene? Each of these toxins has a unique identifying character. We cannot simply run yellow ooze through a chemical scanner and identify its contents.

Fourth, we know very little about the synergies between chemical contaminants. That is, we may know with some certainty the relationship between trichloroethylene (a chemical primarily used in the process of dry cleaning) and bladder cancer, but what if the trichloroethylene is mixed with polyaromatic hydrocarbons? Is there a synergistic effect that can actually cause more harm to human health than if one were exposed to these chemicals in isolation? Finally, all of this science is very new. Until as recently as the 1960s, chemical companies invested in television advertisements promoting the wonders of chemicals and how they were going to change our lives. A current challenge is that technology can outpace knowledge. For instance, we can now measure contaminants in exceedingly small amounts, yet we have very little if any knowledge of the impact of exposures at that level on human health.

Outcome

If we can ascertain what an individual or a community has been exposed to, we must then determine what health outcomes we should be documenting. This is a very difficult task, for a number of reasons. First, we simply do not know how community-based (as opposed to occupational) exposures to these chemicals will affect human health. Therefore, we do not know what to look for. In the highly regarded Upper Ottawa Street Landfill study undertaken in Hamilton, Ontario, Canada, researchers documented the entire health histories of residents who had unknowingly been exposed to (illegally dumped) liquid industrial waste for over five years. Every organ system was examined. This process was extremely time-consuming and resource-intensive. But, not knowing what to look for, these researchers looked for everything. Ultimately they discovered very little: some...
red, itchy eyes; and some psychosocial stress. Why might this have been the case? It could be that the dose that residents were exposed to was insufficient to have an impact on their health (as the sixteenth-century Swiss German physician Paracelsus remarked, it is the dose that makes the poison). It could also be that, as in many cases, the health impacts experienced are ill-defined symptoms that are difficult to trace to any specific exposure. For example, we often hear reports of headaches, rashes, stomach problems, sleeplessness, fatigue, and psychosocial distress. These symptoms could be due to any number of factors; again, how do we control for all the confounding factors that exist in a community “laboratory”? The third reason why these researchers, despite their very thorough examination of the population, may have found very little in the way of health effects, relates to the issue of latency. That is, if we are concerned about cancers or some other type of chronic illness, it takes time (perhaps 15–20 years) for such illnesses to develop. Following an exposed cohort for 20 years is very expensive research and is fraught with difficulties (e.g., control for confounders, sample attrition).

The abovementioned concerns are not to belittle feelings of anxiety and concern around exposure — that is, the psychosocial impacts of exposure. Psychosocial impacts can be defined as the combination of distress, dysfunction, and disability resulting in social, behavioral, and psychological impacts on individuals, groups, and communities as a consequence of actual or perceived environmental contamination. These are real impacts, worth studying primarily for two reasons. First, they are health impacts in and of themselves (recall the earlier definition of health). It is difficult to have full health when one is anxious, worried, or distressed. Indeed, despite whether the exposure is actual or perceived, these are real effects that have real consequences. As the sociologist W.I. Thomas expounded in the 1960s, if a situation is defined as real, it will be real in its consequences. For example, the study of the Sydney Tar Ponds found no excess levels of adverse reproductive outcomes (i.e., stillbirths, miscarriages, low birth weight); however, the perceptions held by local residents of the impacts of the tar ponds on reproductive health was so strong that they were making decisions about fertility based on this perception. For example, some families were putting off having children until the site was cleaned up. Others were deciding not to have children at all. Still others were choosing to adopt from outside the community.

The second reason why it is important to study the psychosocial impacts of exposure is their relationship with physiological health. For example, when the chemical factory in Seveso, Italy, blew up in 1976, and workers and local residents received high doses of dioxin exposure, researchers who followed this cohort for over 30 years expected to find elevated rates of cancers, particularly liver cancer. They did not, but they found a fivefold increase in cardiovascular disease. The researchers speculated that the exposed cohort worried so much about developing cancer that they developed cardiovascular disease as a consequence.

Pathways

There have been many situations in which an actual documented environmental hazard exists, and individuals and communities are worried about their health. But before we can claim a relationship, there has to be a clear pathway for the exposure. For example, the contamination from the Sydney Tar Ponds site was to a tidal estuary. A moratorium on fishing was established, and area residents did not obtain their water from this source, so, if there had been an
exposure, what was the pathway? Such pathways are clearer in the case of Bhopal, where a train derailment led to the release of 40 tons of methyl isocyante into the air. Individuals could then have breathed it in. This could have been a pathway for exposure. Another clear example is the radiation exposure at Chernobyl. It was relatively straightforward to assess immediate exposure through documentation of radiation sickness, and later through the consumption of contaminated crops and livestock.

Evaluation

Once exposure and outcome have been measured, the existence and strength of the relationship between them need to be evaluated. This evaluation can be undertaken by calculating odds ratios, that is, the likelihood of an individual experiencing the health outcome of interest given the exposure of interest. For example, at Seveso, the researchers documented an odds ratio of 5 for cardiovascular disease, indicating that those who had been exposed were 5 times more likely to develop cardiovascular disease than those who had not been exposed. An odds ratio of 5 in environmental health research is quite high; typically, we see odds ratios between 1.5 and 2. While these odds ratios may be statistically significant, they may or may not be clinically significant. For example, studies of the relationship between air pollution and premature mortality in Montreal, Canada, indicate an odds ratio of about 1.03 of dying prematurely on a “bad air” day. While this relationship is only marginally significant in statistical terms, it might be regarded as clinically significant because the odds ratio is being applied to a large urban population (i.e., approximately 2 million people). This environmental exposure may not be a high risk but affects a large number of people, potentially legitimating public health response.

Even if a relatively robust odds ratio is apparent, there is still a need to ascertain whether there is a causative relationship between variables. In the 1970s Sir Austin Bradford Hill gave an after dinner speech wherein he outlined what are now euphemistically known as the Bradford Hill criteria or the “9 diagnostic tests of causation.” Briefly, Bradford Hill asserted that one could not claim causation unless most, if not all, of these criteria were met. They include strength, consistency, and specificity of association; temporality (i.e., that the cause comes before the effect in time); existence of a biological gradient or dose–response curve; biological plausibility of the association; coherence of the relationship with what we already know; experimental data; and, analogous evidence in the literature (for further information, see Bradford Hill 1965).

What does the future hold?

Two fundamental aspects of environment and health will guide geographical and related public health research for at least the next couple of decades. The first is how we view issues of human health and the environment. In this context there is movement toward the “One world, one health” movement, which brings all actors in the ecosystem (animals, humans, natural environment) together into an integrated whole. This development is implied in John Last’s definition of sustainable health:

If human affairs are conducted in such a way as to sustain life-supporting ecosystems in a stable state of equilibrium, then humans will survive and flourish. If, however, a local, regional or global ecosystem is degraded beyond the point where it is sustainable [think Aral Sea], then the health and survival of humans in that ecosystem cannot be sustained. (Last 2014, 1175)
ENVIRONMENT AND HEALTH

There is no question that the greatest environment and health question currently facing human kind is global environmental change, including climate change. Again, the health effects of global change are often indirect and difficult to assess, and the availability and quality of evidence vary widely. Malaria is increasing – is that due to climate change? The West Nile virus is found in places where it has never been found before (North America) – is that due to climate change? And will the climate warm by 2°C or 4°C and what havoc will the latter wreak? (New et al. 2011). Faced with this prediction, most scientists have been literally stunned into silence and have been paralyzed by their incapacity to envision this climatically changed world. In the meantime, others continue to ponder the capacity for adaptation and resilience. In this regard, Brown (2014) and O’Brien (2012a; 2012b) lament the lack of focus on true transformation that would benefit those who are most vulnerable. With respect to this last point, as is the case with all health outcomes, it is invariably the most vulnerable (the poor, the marginalized) who continue to be most impacted by the environmental determinants of health. Much work therefore remains to be done to link the domains of environmental health and social justice (Walker 2012).

Environment and law

David Correia
University of New Mexico, USA

Environment and law have multiple meanings. Environment, in all uses, refers to the surrounding arrangements, relations, and factors required for a given system, organism, or object. Its common usage refers to the biophysical foundation for human and nonhuman life, but its use extends to nonbiophysical domains such as the built environment, the social environment, the digital environment, and so on. Environment as the biophysical serves as a synonym for one definition of the word “nature.” For Raymond Williams (1985) “nature” is among the most difficult words in the English language. Often it describes an essential or inherent quality of something, as in the phrase “human nature,” which is used as a way to describe the condition of being human. Law too has no singular meaning. Legal scholars generally understand law as a way of ordering and making sense of the world. Law is a collection of negotiated rules that govern behavior and are enforced by a state or through social institutions. Law is spatial. It draws literal and figurative boundaries in the world. It is a set of historically produced, unevenly mediated, social and spatial practices driven by logics of boundary-making and categorization that produce the effect of law as a form of social domination claimed as legitimate.

According to legal geographers like Nicholas Blomley and David Delaney, the law reflects and produces sociospatial relations (see Blomley 2008; Delaney 2003). As a mode of inquiry, legal geography maps the social relations and spatiality of law.

For legal scholars influenced by liberalism, the domination that law requires serves as a means to a just end. Law defines and enforces a particular and just social order (Dworkin 1986). For critical legal scholars, however, the force found at the heart of legal authority can also serve as “an apparatus of violence that disorders, disrupts and repositions preexisting relations and practices all in the name of an allegedly superior order” (Sarat 2001, 3). To law, nature is the material, nonhuman, primordial stuff of the world; and law makes sense of this world, translating the nonhuman into legible forms and stable categories. So it is through the categorical logics of law that the irreducible complexity of “nature” becomes the legible and orderly category of “environment” placed in managed relation to the human. Making nature legible as “environment” reflects a central epistemological effect of law, a shift from the radical otherness of nature to the ordered legibility of environment is perhaps law’s most important accomplishment. Law works to reduce the irreducible complexity of nature into discrete juridical categories or objects of interest. Environment in this sense is made legible to and by the state, courts, and legal authorities.

While this diversity in use and meaning complicates any straightforward definition, two broad domains of environment and law emerge. The phrase “environment and law” can be examined as, first, a reference to natural law or the perceived intrinsic or innate laws of systems understood or depicted as natural (whether biophysical or social) and which serve as one origin of sociolegal relations; and, second, as the manner in
which legal reasoning influences environmental management and nature–society relations more broadly.

Natural law

As a reference to fundamental properties, natural law refers to universal claims to legitimate law whose legitimacy exists as a function of its basis in nature or in the divine. This is the idea, in other words, that law emerges from nature and, as such, exists as an objective, universal, and neutral source of legitimate authority. Various forms of natural law can be found throughout history, including in Greek and Stoic philosophy among others, and in all cases it serves as a means to understand the complex, shifting, and porous boundary between the natural and the social. Carolyn Merchant (1980) in her influential book The Death of Nature examined the relationship between Renaissance views of nature and social organization. For example, one common view of nature, both in the Renaissance and in contemporary environmental thought, is that nature is best understood as a designed order arranged in hierarchical relationships. This view, according to Merchant, serves as a powerful and conservative rationale for resisting change to a particular social order. In other words, if nature is orderly and hierarchical, society should be too, and thus society must not depart from a natural order. This depoliticizing logic is recast when nature is depicted as an active unity of opposites in dialectical tension. Where such a view is influential, so too is the idea that change serves a progressive function in society. In other words, political change is natural and thus imperative. This has made its way into modern legal and political theory though a number of avenues. Thomas Hobbes (1994) elaborated laws of nature that described the rights and obligations of humans that emerge through submission to a sovereign authority and serve as the means to overcome a state of nature he depicted as “nasty, brutish and short.” Hobbes’s “state of nature” is a condition of constant and universal jeopardy that exists without the possibility of human cooperation and, therefore, security. We can escape the anarchy of nature by submitting to a voluntary social contract based on law and order that is by definition not natural. Hobbes offers a paradox in which nature’s laws cannot operate in a state of nature and thus require law and order as much as we do.

According to Jean-Jacques Rousseau, the governed social world of legal standards and codes does not save us from nature but rather serves as the origin of social inequality. In contrast to Hobbes, Rousseau found in nature not a world of violence and misery, but a state of human equality corrupted only with the emergence of a social contract that imposes social inequality. He famously wrote in Discourse on Inequality:

The first man who, having fenced in a piece of land, said “This is mine,” and found people naïve enough to believe him, that man was the true founder of civil society. From how many crimes, wars, and murders, from how many horrors and misfortunes might not any one have saved mankind, by pulling up the stakes, or filling up the ditch, and crying to his fellows: Beware of listening to this impostor; you are undone if you once forget that the fruits of the earth belong to us all, and the earth itself to nobody. (Rousseau 1984/1754, 109)

In both cases, and despite their differences, Hobbes and Rousseau turn to natural law as both the measure and the means of legitimate sociolegal relations.

Both understand the origins of legitimate social liberty and political freedom as expressions of natural law – nature and its intrinsic properties as society’s wellspring. This is particularly explicit
in the writing of John Locke, who located in nature the very laws from which he described the terms of an emerging, and unequal, social order. According to Locke (1976/1690), by natural right, nature, once transformed through human labor, becomes the private property of whoever transforms it. Thus natural law emerges in order to impose a social order that legitimizes the very social inequality Rousseau, for example, condemned. It may be unequal, in other words, but it is found in nature and thus is natural and therefore legitimate. For Locke nature’s law serves as the means through which common rights become private rights. This right to the private accumulation of wealth becomes the basis for social inequality and serves as the key element in liberal formulations of law depicted by Locke as “life, liberty and property.”

Where natural law theorists posit law as emerging from nature or the divine, positive law theorists argue that law must be imposed by a sovereign politico-legal authority. Positive law makes normative claims regarding law’s legitimacy without recourse to morality. Likewise common law is understood as imposed, although, unlike positive law, common law refers to a legal system organized by principles established by the precedent of previous decisions by judges.

Where environment and law collide

Law is a key means through which human uses of nature are understood and regulated. This takes a number of forms. Environmental legislation and statutes such as the Clean Air Act (1970) and the Clean Water Act (1972) in the United States regulate how natural resources are managed for commercial and industrial uses. A series of industrial accidents and influential books on environmental issues shifted public perception of nature in the 1970s, gave momentum to a series of laws that marked a shift in how natural resources were managed for commercial and industrial uses, and paved the way for such legislation. The publication of Silent Spring by Rachel Carson in 1962 drew in sharp relief the human and nonhuman cost of the widespread release of chemical pesticides into the environment. These concerns were heightened in the late 1960s as a series of industrial accidents gave further momentum to environmental concerns over resource management. In January 1969 a Union Oil platform off the California coast exploded, sending an estimated 100,000 barrels of crude oil into the Santa Barbara channel. Months later, the heavily industrialized Cuyahoga River near Cleveland caught fire (and not for the first time). In 1971 Barry Commoner, a professor of biology at Washington University in St Louis, Missouri, published The Closing Circle. In it he argued that US society should be restructured to conform to what he called the four laws of ecology: (i) everything is connected to everything else; (ii) everything must go somewhere; (iii) nature knows best; and (iv) there is no such thing as a free lunch.

The US Environmental Protection Agency (EPA), created in 1970, enforces laws such as the Clean Water Act through the promulgation of administrative law, which governs the ways in which the EPA enforces environmental regulation. The Endangered Species Act (1973), for example, established a legal framework controlling economic activity in habitats deemed critical to the survival of threatened species. The Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) of 1980, commonly known as Superfund, created a legal mechanism and fund to clean up major contaminated sites. These environmental laws defined the purpose of the EPA and transformed government agencies; for example, the United States Forest Service, which during the first half of the twentieth century managed forest resources
entirely in service to an industrial timber industry, was turned into an agency that was required to mitigate the negative effects of those uses.

Following the rise of environmental regulation by federal and state agencies via administrative law, *civil law* tort actions by environmental organizations became a frequent tactic used by a variety of environmentally minded plaintiffs to force state agencies to limit industrial uses of nature.

The arena of *international law* has also become a key site of struggles over the environment. Signatories to the 1989 Montreal Protocol agreed to prohibit the use of ozone-depleting substances. A multilateral fund was created to finance conversion efforts. To date it is the only treaty universally ratified by member countries of the United Nations. The 1992 Framework Convention on Climate Change, or the Kyoto Protocol, sought to resolve the problem of anthropogenic climate change by stabilizing and eventually reducing global greenhouse gas emissions. In contrast to the Montreal Protocol, which relies on mandatory reductions to accomplish its goal, Kyoto is based on a cap-and-trade scheme. Limits on greenhouse gas emissions were established for each signatory and these countries then establish limits for different industries. Individual firms are given a legal right to emit an amount of greenhouse gas no greater than an industry average, thus providing the firm with a legal claim to a portion of the atmospheric commons. If a firm is able to lower its emissions, often through the application of clean technologies, it can sell its unused claim to the atmosphere on a carbon market or to other firms. To date, 192 countries have ratified the agreement; the United States and Canada are not among them.

International law has also been a key site for struggles around the rights of nonhuman nature in legal questions. In US case law, nonhuman nature has no standing and therefore cannot claim legal rights. Acknowledgment by US courts of the possible standing of nonhuman nature has been rare. In the landmark case *Sierra Club v. Morton* 405 U.S. 727 (1972), the Sierra Club, a membership-based US environmental organization, sued the US Forest Service to stop the development of land near Sequoia National Park. The US Supreme Court determined that the Sierra Club lacked standing (the ability to demonstrate a connection to harm as a result of the activity in question), but the ruling included a dissenting opinion by Justice William O. Douglas regarding the question of legal claims to nature, including standing for nature itself. In an expansive opinion, he wrote:

> The river as plaintiff speaks for the ecological unit of life that is part of it … The voice of the inanimate object, therefore, should not be stilled … before these priceless bits of Americana (such as a valley, an alpine meadow, a river, or a lake) are forever lost or are so transformed as to be reduced to the eventual rubble of our urban environment, the voice of the existing beneficiaries of these environmental wonders should be heard.

While nonhuman nature has no legal standing in US common law, the formal extension of legal rights to nature are found in legal documents worldwide. The Swiss Constitution requires that consideration be given to the animals, plants, and other organisms. Chapter 7 of Ecuador's 2008 Constitution is titled “Rights of Nature” and begins with Article 71 “Nature, or Pacha Mama, where life is reproduced and occurs, has the right to integral respect for its existence and for the maintenance and regeneration of its life cycles, structure, functions and evolutionary processes.” In 2012 the Waitangi Tribunal, a special jurisdiction unit of New Zealand’s Ministry of Justice charged with investigating and making recommendations on claims brought by Māori, heard a claim by the indigenous Whanganui River Iwi,
which asked the tribunal to grant legal personhood to the Whanganui River. The subsequent agreement established a legal framework that extended legal standing to the river.

Since the mid-1980s the relationship between human migration and the environment has become a widely debated topic among policy experts, political actors, and activists, and in the media. This attention has fueled a renewed interest in the issue by geographers, as well as by other social and natural scientists. It is in the context of global environmental change, but essentially in the context of anthropogenic climate change, that the relationship between the environment and human migration has been politicized, debated, and examined. As a result of these debates, environment and migration has become as much a topic of scholarly interest as a discourse used by a wide variety of actors which sometimes bears little relation to actual natural and social processes.

Earlier interventions have offered forecasts of hundreds of millions of “environmental refugees” or “climate refugees” (people forced to relocate because of environmental and climate change) as a way to draw attention to the consequences of environmental change such as sea level rise, droughts and desertification, or cyclones, heavy rains, and floods. The claims that environmental change would induce such a massive displacement of people were criticized from a variety of disciplinary and political positions which underlined the impossibility of singling out the environment as a sole driver of migration, and castigated the crude environmental determinism informing the environmental refugees thesis. Subsequently, in the late 2000s, in response to a knowledge imperative, to funding opportunities, and to policy demands from international organizations (such as the International Organization for Migration and the World Bank), Northern governments, and nongovernmental organizations, major research projects have been undertaken in order to offer a more refined picture of the relations between human migration and the environment. These have led to a much more nuanced, dynamic, and complex understanding of these processes, and have emphasized methodological issues. Although most participants in the debate share the assumption that environmental change can somehow cause human migration, they reject the existence of a linear causal relation between these two phenomena. The projects have also offered new normative visions and policy proposals.

The definition of what constitutes “environmental migration,” “environmentally induced migration,” “environmentally induced population movements,” “climate migration,” “climigration,” and so on is strongly contested, and disagreements over definitions are constitutive of the history of the field (Gemenne 2012; Piguet 2013; Morrissey 2012). Generally speaking, the “environment” has been understood in a rather narrow and naturalistic sense in these debates. It relates to the nonhuman biophysical world and includes some elements of socially modified nature, most notably climate change. The whole debate is still largely informed by neo-Malthusian conceptions of the Global South (Morrissey 2012). Its focus has been essentially on Southern countries, rural areas, agricultural livelihoods, and poor vulnerable
ENVIRONMENT AND MIGRATION

people. It has also often been characterized by an understanding of environmental migration (especially that caused by climate change) as something happening in the future. At the same time, population movements caused by industrial hazards, urbanization, or deindustrialization in Northern countries have generally not been considered as falling within the realm of environment and migration. Similarly, research on migration and the environment has tended to discuss temporary or permanent displacement from degraded environments, but has rarely considered the environmental amenities that may motivate people to settle into new environments. For instance, suburbanization is generally not considered as an issue of environment and migration, although, arguably, many people choose to relocate in suburbs away from a noisy and polluted inner-city environment in order to enjoy environmental benefits such as a garden.

Nor are European colonial settlements understood as earlier examples of environment and migration in spite of the fact that these processes had environmental causes and (often deleterious) environmental consequences. Wealthy North American citizens who move to Florida after retirement are generally not considered to be environmental migrants.

Indeed, environment and migration is still essentially considered in policy and scientific debates as an issue, a problem, or even a looming crisis. In these assumptions, it is a problem that happens in poor Southern countries and that needs to be solved, or at least managed, if possible, at an international level. Thus, so far, managerialist and policy-driven perspectives have dominated this scientific field, with many contributors to the academic debate also working as experts and consultants for a variety of governmental or international institutions. Indeed, it has been argued that scientists working in this field should be seen as “policy entrepreneurs” rather than as neutral observers (Gemenne 2012). Most contributors to these debates tend to agree that the environmental changes are real enough and that, although they may not directly produce migration, they tend to reinforce factors affecting human vulnerabilities.

Some radical geographers and political ecologists have questioned the framing of the whole environment and migration debate, unearthing some implications of the environment–migration nexus, especially in terms of racialized, gendered, and political-economic processes. These have notably argued that putting too much emphasis on environmental change obscures the real social processes leading to situations of poverty, exploitation, and dispossession. Rather than being the effect of unintended environmental change, human displacement may actually reinforce existing structures of power such as capital accumulation, patriarchy, and state domination.

Earlier conceptualizations of environment and migration relations

The institutionalization of the social sciences, including geography, as academic disciplines at the end of the nineteenth century in Europe and North America was closely linked to the development of nation-states as territorially bounded and competing entities. Knowledge of population and the control of population movements are important features in the constitution of a territorialized sovereignty. Early social science contributions to the study of migration shared some of the territorial assumptions of this emerging paradigm of sovereignty: mobility and migrations, rather than fixity, were in need of explaining.

In an insightful article Etienne Piguet (2013) has shown that the link between migration and environment was an important concern for the
founders of migration studies at the turn of the nineteenth and twentieth century. The influence of environmental factors in explaining patterns of migration was quite widespread then. It was used, for instance, to explain the great “barbarian” invasions and the fall of the Roman empire. Policy-oriented knowledge was also important, for instance, in order to select places appropriate for European colonists to settle in. This is hardly surprising considering the origins of academic geography as a naturalist and determinist form of knowledge and its institutional contribution to the consolidation of the power of emerging national states.

However, studies on the influence of the environment on migration almost totally disappeared from the literature between the beginning of the twentieth century and the mid-1980s. According to Piguet (2013), there were different reasons for this. The growing domination of natural landscapes by industrialized societies led to the idea that natural factors had less of an influence on human actions. Crude physical or environmental determinism was increasingly rejected in the social sciences. Human and physical geography became dichotomous disciplines with different sets of explanations, and human migration was regarded as a social phenomenon to be explained by social, rather than by environmental, factors. The growth of an economic paradigm in migration studies further entrenched the separation between the natural environment and migration. Finally, so-called refugee studies or forced migration studies developed from the 1980s, predicated on the political definition of refugees in international law, which revolves around the notion of persecution and is thus hardly compatible with environmental factors.

Accordingly, the reappearance of the relation between human migration and the environment was not triggered by migration scholars or geographers. Rather, it was the work of environmentalists and policymakers which sought to politicize the consequences of global environmental change. It was thus strongly impregnated with determinist assumptions about the causal influence of the environment on human societies: in spite of strong criticisms, these assumptions have proved quite resilient in subsequent debates.

The environmental refugees thesis

The renewal of studies on the environment–migration nexus was predicated on what has come to be known as the environmental refugees controversy. Although this controversy was always more complex and fine-grained than later accounts of it, it is generally considered to have set up two opposing theses, variously described as the maximalists versus the minimalists, the alarmists versus the skeptics, or the proponents of the environmental refugee thesis versus its critics (for detailed accounts see Gemenne 2012; Morrissey 2012).

The notion that environmental degradation could lead to population displacement was entertained from the 1970s by prominent environmentalists such as Lester Brown, founder of the Worldwatch Institute. Yet, it is commonly agreed that the foundational document for the revival of the environment–migration linkage is a policy document entitled Environmental Refugees, written by Essam El-Hinnawi and published under the auspices of the United Nations Environment Programme (UNEP) in 1985. It offers the first definition of environmental refugees and a rudimentary typology of the environmental causes of displacement: it distinguishes between those “temporarily displaced because of an environmental stress,” such as earthquake, drought, or flood, those “permanently displaced
and re-settled in a new area” because of development projects, and those who are victims of slow-onset environmental degradation such as deforestation and desertification. As the choice of the word “refugee” suggests, El-Hinnawi insists that those whom he thus categorizes are victims and are forced to move. But he also hints that those refugees from the third category are partly to blame because of their supposed “mis-use” of the environment through, for instance, slash-and-burn agricultural practices. This first intervention was thus instrumental in framing the debate and construing environmental refugees as both victims and perpetrators of environmental degradation.

The work of biologist and environmentalist Norman Myers has proved to have the greatest influence on the revival of the migration and environment debate. From the early 1990s and into the early years of the twenty-first century, both alone and in collaboration, Myers has repeatedly offered the most gripping account of the potential migratory consequences of environmental change (e.g., Myers and Kent 1995). He is also responsible for offering quantified projections of future environmental refugees. His prediction that there would be 200 million environmental refugees by the year 2050 has been very widely repeated and even amplified, generally quite uncritically. It was, for instance, cited in the authoritative Stern Review on the Economics of Climate Change, published by the UK government in 2007.

This strand of studies was infused with a strong positivist perspective and a globalist bias. It framed climate or environmental change as a “global” problem that would therefore have global migratory consequences, which could be quantified. Often carried out by environmentalists and natural scientists with little training in migration studies, such research assumed that migration would be the quasi-automatic response to a degraded environment. It forecast future migration patterns by combining maps of populations and estimates of environmental impacts, especially the impacts of climate change. For instance, densely populated coastal areas (notably in Asia) or low-lying island states (such as the Maldives and Tuvalu) were flagged as potential victims of climate change–induced sea level rise. These projections were underpinned by a form of neo-Malthusianism, whereby environmental degradation and poverty were explained with reference to population rather than to social, political, and economic relations. In this sense, environmental refugees appeared as the logical result of global processes of environmental degradation.

The limited literature in geography, migration, and development studies which dealt with migration as a result of environmental variations, especially in the context of drought and desertification, offered little support for these estimates. Rather, local and regional empirical studies tended to show that migration was only one possible coping strategy in the face of environmental change, that such migrations tend to be short-range rather than international, and that it is extremely difficult to disentangle environmental causes from other drivers of migration. Furthermore, empirical studies highlighted the importance of the differential vulnerabilities created by social relations along gender, class, ethnic, and age lines. Whereas the impact perspective projects environmental hotspots onto whole territories which are thus classified as at risk, more concrete analysis avoids such sweeping generalizations and displays a much more nuanced context- and place-specific analysis.

The environmental refugees thesis thus came under sustained attack from the late 1990s and early 2000s, especially from geographers and migration scholars (for an influential example, see Black 2001). These authors, although
they shared the concern of the maximalist/catastrophist school about the linkages between environmental change and migration, nevertheless expounded the idea that this relation was direct, monocausal, and linear. Rather, they insisted that migration decisions are essentially multicausal and that the environment cannot be abstracted as their primary cause; that migration (especially temporary and circular migration) has long been a response to environmental uncertainties (a form of livelihoods diversification) and thus should not be seen as something radically new and catastrophic; and that most vulnerabilities which may lead to forced migration are the result of sociopolitical (mal)development projects rather than of an apolitical or ahistorical environmental change. Some of these “skeptics” thus reproached the “proponents” for their purported depoliticizing agenda, for ignoring the political economic contexts of migration, and also for describing as “migrants” people who should simply be regarded as “refugees” and in need of protection.

Because of the widely shared dissatisfaction with the environmental refugees literature, and as a result of the constant calls for more empirical research and greater theoretical clarification, a number of important works have recently been published on the topic. They have also benefited from public funding made available by national governments and international organizations in order to produce policy-oriented research. This has been the case, for instance, with the research program EACH-FOR funded by the Commission of the European Union from 2007 to 2009, and with a major report commissioned by the United Kingdom’s Government Office for Science (Foresight 2011). Over 70 peer-reviewed studies have been commissioned and some 350 experts and “stakeholders” have been involved in creating Migration and Global Environmental Change. The report is targeted at a wide readership in academia and in policymaking circles at both national and international levels. The theoretical underpinnings of the report have been published in influential scientific journals and may be regarded as the new orthodoxy on the topic (Black et al. 2011).

Instead of focusing on a typology of environmental migrants or on finding a simple correlation between environmental stress and migration, Black and his colleagues (2011) insist on the complexity of this relation and that migrations are always multicausal. Migrant should be conceptualized as having agency and not simply as passive victims of structural forces. Thus, rather than identifying types of migrant (whether or not environmental), these authors define five drivers of migration (economic, political, demographic, social, and environmental) which may act as barriers or as facilitators of movement. They then argue that it is the interaction between these drivers which should be the focus of researchers’ attention. Environmental change does not produce migration as such, but it may reinforce or inhibit existing migration patterns. For instance, climate change may reduce crop productivity in some places and thus affect the income of rural households. This in turn may affect (as an economic driver) the choice of these households to migrate, but it may also reduce their ability to migrate (by reducing their assets), should they choose to do so. Some critiques of this approach have taken issue with the apparently arbitrary division between these five drivers, and hence the circularity of the argument (why, for instance, should land productivity be considered as an environmental driver rather than as an economic one?). Nevertheless, this new approach has proved to be quite authoritative.

Whereas previous interventions, especially by environmentalists, tended to present migration as a failure to mitigate environmental change,
the new orthodoxy insists on the fact that migration should actually be understood as a strategy of adaptation to climate and environmental change. Migration is thus understood as a risk management strategy by rural households, albeit one which is not universally accessible. Indeed, mobile households show their resilience to adverse conditions such as climate change, and may even increase their resilience by moving, as their migration allows them to send remittances, act as knowledge transfer agents, and so on. In this perspective, the problem actually becomes the fate of those unable to move because of their lack of resources or because of barriers to migration. “Trapped populations,” rather than environmental refugees, are increasingly becoming the new topic of concern, which warrants increasing migration management intervention. Indeed, the new orthodoxy in environment and migration research broadly fits the migration management agenda of international organizations, whereby these institutions seek to organize human mobility in order to make it productive for economic accumulation (Felli 2013).

Normative and legal responses to the environmental refugee thesis

The plight of environmental refugees has also attracted the attention of political scientists, scholars of international relations and international law, and normative political theorists and philosophers from the early 2000s onward. Most normative discussions dwelled on the rights of those (potential) migrants, who are portrayed as victims of environmental change, and on the responsibility of Northern industrialized states in this situation. In keeping with the tone of the debate, most of these interventions took for granted some of the catastrophist predictions of an impending refugee crisis, or at least accepted the framing of the issue as an international problem in search of normative and legal solutions.

A vexed question from the beginning was the use of the word “refugee.” Although it was purportedly used in order to suggest a process of forced displacement, some scholars opposed it on the ground that it created an unfortunate association with the juridical language of refugee protection (Black 2001; see Gemenne 2012; Morrissey 2012). At a time when migrants and refugees increasingly came under attack in Northern countries, the forecast of millions of environmental refugees was thought to fuel the anti-immigrant backlash. Notwithstanding this critique, scholars of international law (often of international environmental law rather than of refugee or migration law) advocated various legal schemes in order to offer environmental migrants or refugees protection under international law, through the extension of existing refugee conventions or the creation of new international legal instruments. Although these proposals have never gained traction in international law, more deormalized norms have emerged, related to the protection of people “displaced by natural hazards,” such as the Nansen Initiative, jointly launched in 2012 by the Norwegian and Swiss governments. This muddled legal situation is compounded by jurisdictional conflicts over environment and migration between various international organizations such as the United Nations High Commissioner for Refugees (UNHCR) and the International Organization for Migration (IOM), which compete with each other for funding, expertise and legitimacy in this area.

Political scientists have sought to overcome the so-called fragmentation of international environmental governance, and accordingly have devised various institutional forms to govern environmental migration at an international
level. Sometimes these legal and normative endeavors were justified with reference to Northern countries’ responsibility for causing dangerous anthropogenic climate change; taking in refugees was presented as a form of compensation for the environmental harm thus caused. Other scholars eschewed the language of responsibility altogether and merely emphasized the humanitarian needs of environmental or climate refugees. Some scholars have reflected on the legal and normative implications of the physical disappearance of a sovereign state due to climate change (the notion of a sinking island) and the fate of its deterritorialized citizens.

The increasing characterization of environmental refugees in terms of a security issue, or even a threat, is a recent concern of some political scientists and scholars of international relations (White 2011; Bettini 2013). The catastrophist discourse of an impending environmental refugee crisis has been seized by various security actors in the NATO (North Atlantic Treaty Organization) states and in international organizations. In this narrative, environmental degradation, especially climate change, will trigger mass displacements of impoverished populations from Southern to Northern countries. Such visions build on and elaborate some powerful narratives which gained momentum in the aftermath of the fall of the Berlin Wall, when environmental change, rather than Soviet-style communism, became the common enemy of capitalist societies. In the early 1990s the idea that environmental conflicts would be triggered by increasing resource scarcity and environmental degradation started to be heavily discussed in policymaking circles as well as in academic publications. Some scholars explored the possibility that environmental change could lead to violent conflicts by creating human displacement. Such neo-Malthusian perspectives also circulated in more popular outlets and in the mass media, and they remain part of the political “common sense” about climate change. For instance, in 2007 the Secretary-General of the United Nations, Ban Ki-moon, suggested that the violence in Darfur was attributable to resource scarcities caused by climate change.

By framing climate change and environmental degradation as a threat to national (state) security, these actors have sought to “securitize” environmental migration; that is, turn it into a security issue. Traditionally, security matters are considered as more important than “softer” issues such as the environment. By securitizing the issue of environment and migration, these actors have sought to bring it into the realm of high politics and to the attention of policymakers. But, precisely because it is framed as a national security issue, this move implies tighter control of international migration, the reinforcement of borders, more authoritarian governance, and the reassertion of an exclusivist understanding of sovereignty (that is, a neat separation between insiders and outsiders). For instance, some semiperipheral states strategically positioned in the transit of migrants from Sub-Saharan Africa to Europe seem keen on reinventing themselves as migration managers vis-à-vis the European Union in a context of growing environmentally induced migrations. Thus the securitization of the environment and migration has certainly given these issues a higher profile in international and national politics, but this may be detrimental to the situation of the migrants themselves, who are cast as a threat to state security (White 2011).

**Current research in environment and migration**

The literature discussing linkages between the environment and human migration has grown exponentially since the mid-2000s and includes
different focuses and methods. It is possible to identify different types of study within the field.

Quantified estimates of existing or future climate or environmental refugees

As mentioned earlier, these studies are often done by projecting the forecasted impacts of climate change onto population growth (e.g., Myers and Kent 1995). Although these studies are now widely discredited in the scientific literature for their reductionist understanding of human migration, they have proved instrumental (even if problematic) in drawing attention to this issue, and often remain the source of much public debate on this topic, as their estimates of tens of millions of climate refugees regularly resurface in the media, or in reports by international organizations or NGOs.

Conceptual clarifications, typologies, and literature reviews

These are quite prominent in the field. Important distinctions have been offered on the causes of migration and the forms of migration, and on the analytical and political consequences thereof. Classical distinctions were made between catastrophic events (e.g., earthquake) versus slow-onset degradation (e.g., desertification), between long-term and short-term migrations, between forced and voluntary migrations, and between local, internal, and international migrations, and so on. Yet, these typologies were often not backed up by dedicated empirical research and have been criticized for not conceptualizing the mechanisms through which environmental change actually leads to decisions to migrate. More recent theoretical interventions have, instead, insisted on the multicausal nature of migration and on the complex linkages between the environment and other drivers of migration.

Empirical quantitative studies

These studies try to assess the relationship between environmental variables and human migration based on data aggregated at a national or regional level. Various methods and sets of data are used, and generally other variables (economic, demographic, social, etc.) are controlled for. The usual debates on the choice of methods, variables, and indicators apply. Some researchers use existing datasets while others also produce their data, for instance through household surveys, interviews, focus groups, and mixed methods.

Some studies are interested in the interaction between the exposure of specific places to environmental stress or hazards and the adaptive capacity of the population; both exposure and adaptive capacities are unevenly distributed and migration is only one possible outcome of a specific set of socioenvironmental relations. Environmental stress tends to reinforce dominant social relations and to shape migration decisions through complex political-economic processes.

Other authors posit migration as a risk management strategy when households are faced with uncertainties stemming from environmental changes. From this perspective, temporary migration increasingly appears as a coping or an income diversification strategy in rural areas faced with environmental uncertainties such as rainfall variability, but it is restricted to households with sufficient resources. Those moving may increase their adaptive capacity, thus becoming more resilient. On the other hand, poorer (or more vulnerable) populations may simply lack the resources for such a strategy and thus become trapped in their territory. The normative challenge from this perspective is to lower the barriers to migration for vulnerable households.

Some researchers are turning to agent-based migration models, which simulate autonomous
actors’ decisions and interactions in order to understand the aggregate effect of such interactions. Such models are held to be better at predicting future migration patterns than simple projections, yet they do not explain migrations. Similarly, past migration patterns are being re-examined (e.g., by means of event history analysis) in order to take into account possible environmental drivers of (non)migration. These studies tend to confirm that households respond quite differently to environmental change and that migration is by no means the favored option.

For instance, in their quantitative study of out-migration in a valley in Nepal, Bohra-Mishra and Massey (2012) use event history analysis in order to account for the impact of environmental degradation (mainly deforestation) on human mobility while controlling for economic, social, and demographic variables. Their essential conclusion is that, while environmental degradation is indeed associated with greater mobility, such mobility remains strongly local within the valley investigated, rather than internal or international. While the authors are careful to restrict their conclusions to their specific case (one involving slow degradation of resources), nevertheless they point out that the quasi-absence of international migration as a result of environmental degradation may simply be because those affected lack the resources to undertake such migrations.

Empirical case studies of specific places/regions

These studies tend to be of a more qualitative sort and are generally influenced by a political ecology perspective. Depending on the particular theoretical inclinations of the researchers and on the subject at hand, social, political, and historical factors such as unequal statuses, social positions and power, access to resources, social relations of production, land tenure, sexual division of labor, local institutions, livelihoods, and so on are given explanatory priority over environmental determinism. Within specific regions, not all inhabitants have the same access to resources or are equally able to shield themselves from natural hazards. A closer study of the local structure of power is warranted in order to understand these differentiated vulnerabilities and their relation to whether or not it is possible for some groups to move. Indeed, power inequalities (resulting, for instance, in denial of land tenure), rather than environmental stress per se, impact the propensity to migrate. Environmental transformations are merely one of several constraints and opportunities which these studies take into account in order to explain human (im)mobility, but also the identity, self-understanding, and representations of the subjects of their research.

Emphasis on the structure of power leads researchers to point to the ability of dominant groups to create security for themselves being predicated on their creating insecurities for other groups. Migratory practices are highly dependent on such socially, economically, and politically created (in)securities. Indeed, environmental stress may lead to forms of migration that in turn reinforce the power structures that were responsible for the uneven vulnerabilities of inhabitants in the first place (e.g., by further concentrating land property into the hands of a minority).

Because these studies insist on the local particularities of their case studies and their specific complexes of social, political, and economic relations, they tend to avoid drawing general conclusions from their empirical findings. Such studies often avoid quantifying in- and out-migration, and are more interested in underlining the socioecological relations at work in specific settings. For instance, Carr (2005) discusses how environmental and economic changes in three villages in rural Ghana (notably
changes in off-farm employment opportunities because of environmental degradation) have led to changes in gender relations within the household, and how, in turn, these changes have influenced a pattern of out-migration over nearly four decades.

Some authors argue that the dominant apolitical framing of the environment–mobility nexus is actually blind to the issue of power, and may thus advocate solutions that could reinforce existing inequalities and oppressions. These sociopolitical features are overlooked when environmental drivers are accorded explanatory primacy, and managerialist solutions are offered. In such cases only structural changes can resolve the crisis. Furthermore, climate change or environmental degradation may be instrumentalized by powerful actors, such as state actors or large landowners, in order to obscure the real (economic and political) reasons for displacing people or resettling them onto less productive land.

Normative, legal, and institutional questions

Contributions from political scientists and international legal scholars remain important in this field. Yet, whereas earlier contributions took for granted the catastrophist account of millions of environmental refugees and sought to offer them legal protection in international law (as discussed earlier), more recent research focuses on improving existing legal standards, “soft” laws, and the governance processes that deal with displaced people. Grand schemes for governing environmental migration at an international level are becoming less prevalent, and more piecemeal approaches are on the rise.

Discursive analyses

An important feature of recent publications on migration and the environment is the growth of discourse analysis, which seeks to reveal the hidden assumptions of much of the literature on this topic. This work by critical geographers, often underpinned by a radical or poststructuralist perspective, has helped to redefine and problematize the whole issue. The catastrophist tone of the early debate had led to both national security and humanitarian perspectives, both of which actually work to deny migrants’ agency and to obscure alternative futures. They therefore act as depoliticizing devices which impede transformative practices. Climate or environmental refugees have sometimes been pictured as passive victims, but sometimes also as a threat to Western modes of life and consumption, thereby reinforcing racial and gender- and class-based stereotypes. Furthermore, framing migration as a strategy of adaptation to climate change reinforces the dominant neoliberal perspective in contemporary environmental governance (Bettini 2013; Felli 2013).

Phenomenological analyses

Finally, some studies are starting to explore the lived experiences of those compelled to move because of environmental transformations. Geographers have shown that the proverbial inhabitants of “sinking islands” in Tuvalu or Kiribati did not essentially picture themselves as potential climate refugees but rather, when confronted with the effects of climate change on their environment, sought to find ways to mitigate climate change and to stay on their land (McNamara and Gibson 2009). Migration is not the primary choice for those faced with environmental degradation. Instead, concerns about “sinking islands” express Western anxieties about climate change rather than the actual experience of their inhabitants, and thus betray a neocolonial gaze.
A potentially fruitful avenue for research may have been opened by Rob Nixon, a scholar of environmental humanities, and his concept of “displacement without moving,” which describes the estrangement caused by environmental degradation, including in the absence of migration. Nixon (2011, 19) discusses a more radical notion of displacement, one that, instead of referring solely to the movement of people from their places of belonging, refers rather to the loss of the land and resources beneath them, a loss that leaves communities stranded in a place stripped of the very characteristics that made it inhabitable.

Environment and regional development

Clint Ballinger
Independent scholar

From the earliest geographical writings through to the beginning of the twentieth century, it was common to attribute differences between social regions to variations in environmental and geographic factors such as climate, soil types, or terrain differences, for example, from Strabo, al-Jahiz, and Ibn Khaldun, through to Friedrich Ratzel, Ellsworth Huntington and Ellen Churchill Semple (note that, in economics, examples of Ricardian comparative advantage also often hinge on environmental differences). However, for a variety of reasons, including associations of this type of geography with colonialism and imperialism, determinism, and relying on overly simplistic correlations, it became controversial by the early to mid-twentieth century and fell from favor in human geography.

After this period human geography was dominated by a succession of intellectual approaches: descriptive regional geography from the 1920s, abstract spatial science from the 1950s, and the various social “turns” from the 1970s to the present: radical, cultural, postmodern, poststructural, cultural economy, and related approaches. Crucially, however, although these approaches varied substantially on many issues, they nevertheless shared the view that environmental factors could not or should not be used to explain variations in regional development. They rejected environmental factors in explanation of social outcomes as either overly simplistic or deterministic or both.

However, in the 1970s and 1980s, in part building on the tradition of Fernand Braudel and similar historical work, a number of influential historians such Edward Whiting Fox, Alfred Crosby, Philip Curtin, and William McNeil integrated environmental factors into their explanations of uneven development. These works were built on in the 1990s by other nongeographers, perhaps most notably Jared Diamond (1997) and economist Jeffrey Sachs, who, along with colleagues associated with the Center for International Development at Harvard University, produced a series of influential working papers that in turn generated significant additional research into the impact of geographic factors on regional development differences. These works by historians and economists were significant for specifically integrating, as causal variables, environmental factors such as spatial patterns of endemic disease, soil quality, climate, terrain, landforms (from continental to local), and other environmental factors into their explanations of variations in regional development.

These modern theories differed in important ways from the earlier use of environmental factors. Critics of earlier uses of environmental factors argued that they were overly simplistic because (i) they often attributed differences in economic and political development to environmental factors alone and (ii) they often made extremely direct associations of climate with human behavior and social outcomes (e.g., the
tropics made people lazy and therefore their societies were undeveloped).

However, modern research seeks to integrate environmental factors into the complex social science understanding of regional differences. The effects argued for are not simple and direct, but are due to the cumulative effect over long time periods of relatively small constraints and incentives on individuals that may have a cumulatively large spatial influence on development outcomes. Some of these explanations involve relatively short-term, direct influences, such as the direct social costs of poor soils or tropical diseases, and possibly the amplification of these through the effect of the resulting poverty and mortality rates on schooling decisions, population levels, and ability to invest in further economic growth. Others are longer-term and/or more socially mediated. For example, rich agricultural areas generally experienced substantially higher degrees of urbanization for longer periods, which in turn fostered the development of institutional structures that in the long run may have been conducive to modern economic development, and that are lacking in areas or cultures that did not experience such long urban histories. Similarly, climate influences the spatial patterns of endemic diseases, which in turn influenced the spatial patterns of migration and colonialism, and thus the spatial distribution of institutions and regional development.

Environment and explanation

The role of the environment in explaining regional development differences is a specific example of the more general philosophy of science question on the role of context in explanation. In physics, there are laws and constants that are regular, such that \(x\) always causes or relates to \(y\) with no exceptions. Discovering these was a crucial step in the development of the sciences, and became a cornerstone in the concept of explanation. Another fundamental concept of explanation is that of description and categorization. The natural sciences, for example, made great advancements not through the discovery of laws of nature but through the acquisition of new data and the systematic classification of these data. These two extremes—nomothetic (“lawgiving” approach) and idiographic (“writing about the unique”) formed much of the foundation for concepts of explanation from the early development of the sciences and social sciences through the twentieth century. This was reflected within human geography by recurring debates on the proper role of nomothetic versus idiographic approaches to geography.

However, among practitioners of the historical sciences such as astronomy, cosmolology, geology, biology, paleontology, and history, the concept of explanation increasingly transcends the nomothetic–idiographic debate. In these fields events do not of course break the laws of physics, but neither can they be explained by them. Explanations in the historical sciences rely on antecedent spatiotemporal facts. For example, in biology, a major question concerns the reasons for the K–T event, the extinction of the dinosaurs. The answer seems to be a meteorite impact and/or the global effects of the Deccan lava traps of India. These are unique spatiotemporal events that altered the context of biological processes, changing their subsequent development trajectory and modern biogeography.

Variations in the spatiotemporal contexts of social processes may, likewise, have been the underlying cause for modern spatial variations in development. This may be especially true given the path-dependent nature of development,
whereby relatively small changes in context can result in widely divergent outcomes. For example, variations in flora and fauna may have affected spatial patterns of urbanization; climate-related endemic disease patterns and poor soils may have affected agriculture and, in turn, the related institutions of what was for many centuries the primary means of production of many societies; disease patterns are known to have deeply affected migration patterns and, thus, the modern distribution of political and economic institutions. The importance of ongoing knock-on effects from the role of environmental factors as “spatial anchors” in spatial explanation is discussed in greater detail in Ballinger (2011).

Criticisms of neo-environmental determinism

The renewed integration, often by nongeographers, of environmental factors into explanations of social processes and regional development outcomes has largely been received negatively by academic geographers. This is evident in the significant number of articles by geographers specifically and strongly criticizing the use of environmental factors in explanations of regional development, what they frequently term “neo-environmental determinism” (e.g., Merrett 2003; Sluyter 2003; Coombes and Barber 2005; Judkins, Smith, and Keys 2008; O’Keefe et al. 2010; Radcliffe et al. 2010). Overall, these criticisms by geographers have several common themes, the most important of those relating to environmental explanations being (i) that they are simplistic, that is, there are not simple causes between some factor such as a warm climate or poor soil and some social outcome such as poverty; and (ii) that they are deterministic, when it is argued that the world, or at least the social realm, is indeterministic and that determinist views are immoral or unethical because they preclude or downplay human agency.

Replies to criticisms of environmental factors

There are a number of replies to these criticisms. In relation to the charge of being overly simplistic, modern studies do not argue that the environment alone is somehow all-determining, nor do they usually posit direct effects of climate on individual behavior. Modern research often focuses on indirect effects and long-term, cumulative, and path-dependent outcomes, and integrates these into the modern complex understanding of society and social change.

Overall, modern studies that integrate environmental factors into their explanations of regional development differences deal with a greater number of factors—environmental as well as sociocultural, political, and economic—than those that exclude environmental factors on a priori grounds. Hence they can be argued to be more, not less, complex than approaches that a priori exclude the large set of environmental factors. It might also be argued that these types of studies are more complex because they deal to a greater degree with the complexity arising from the interactions of social processes that operate on very different scales, the very large-scale and long-term with the local and short-term.

There are a number of possible objections to criticism based on determinism, including the following.

1 It is not clear why the use of environmental factors in geographical explanation is “deterministic” (however defined) when
other factors are not. In the nature versus nurture debate in psychology, for example, a perceived over-reliance on innate biological or genetic factors in the explanation of an individual’s behavior is often characterized negatively as “deterministic” and as needing to be counterbalanced by a greater emphasis on nurture (environment). It is not clear why the nature/nurture argument should reverse on a larger-scale view of explanation, that is, why environmental factors do not have larger-scale cumulative effects on society if they also have strong influences on individuals.

2 If environmental factors are indeed used in a deterministic way, this is not necessarily an error in explanation. A common criticism of neo-environmental determinism is that the world, or at least the social realm, has been proven to be indeterministic, so deterministic arguments must be flawed. However, this rests on the assumption that determinism has somehow been disproven. Yet, in the fields most closely related to the study of determinism – physics, philosophy, and biology/neurology in the life sciences – there is no consensus on the ontological status of determinism/indeterminism (Ballinger 2008a and citations therein).

3 In criticisms of the use of environmental factors as “environmental determinism,” it is frequently implied that this somehow makes these explanations immoral or unethical. However, among philosophers, there is no consensus on the moral implications of determinism (Ballinger 2008b).

Crucially, in points 2 and 3, critics are making claims to knowledge that they cannot possess unless they claim special knowledge concerning determinism, and/or the ethical implications of determinism, beyond that of the physicists, biologists, and philosophers who specialize in these questions. Given the current state of knowledge, either indeterministic or deterministic arguments could conceivably be correct, and neither can be dismissed solely for being one or the other.

Environment and resources, political economy of

Matthew T. Huber
Syracuse University, USA

A curious thing happened over the course of the twentieth century. Political economy, or what is increasingly known as “economics,” stopped paying attention to the relations between capitalism and nature. As Timothy Mitchell (2011, 234) argues, “the availability of low-cost energy allowed economists to abandon earlier concerns with the exhaustion of natural resources and represent material life as a system of monetary circulation – a circulation that could expand indefinitely without any problem of physical limits.” In hindsight, the oversight was relatively brief in historical terms. The age of “abundance” in the postwar mid-twentieth century was “shocked” into confronting the deep, and precarious, entanglements of capitalist economies with flows of energy, materials, and wastes during the 1970s. Since the 1980s, the discipline of economics, and several other social sciences, most notably geography, have attempted to provide theoretical clarity and empirical detail on the precise relations between capitalism and nature. This entry will attempt to review the varied ways in which this relationship has been conceptualized over the past three decades or so.

The entry will proceed in four parts. First, in a theoretical introduction, it will argue that the major perspective on nature and capitalism in geography can be traced back to Neil Smith’s (2009/1984) landmark “production of nature” thesis. Second, it will review the historical context of neoliberalism and the rise of free market environmentalism since the 1970s – and geography’s critical engagement with such policy. Third, it will argue that theories of economy–environment relations in geography often were contingent upon which part of nature was being examined – ecosystems, resources, energy, and biological life itself. Those focused on the ecological “conditions” of production tended to employ theories based on Karl Polanyi’s (1944) concept of “fictitious commodities” and James O’Connor’s (1998) “second contradiction of capitalism.” Critical resource geography built upon Erich Zimmerman’s (1951, 15) famous pronouncement, “resources are not; they become,” to examine the material and sociocultural politics of naming certain parts of nature as resources. Increasingly, those who study energy have focused on the centrality of energy to the social reproduction of capitalism as a whole. This approach sees “nature” as internal, rather than external, “conditions” or resource “inputs.” Finally, this entry will cover recent debates over the relationship between capitalism and “life itself” – that is, new regimes of accumulation based upon the sociotechnical production of biological life forms.

Theory: nature as socially produced

“What jars us so much about the idea of the production of nature is that it defies the conventional, sacrosanct separation of nature and society, and it does so with such abandon and without shame” (Smith 2009/1984, 7). It could
be argued that over the last three decades critical environmental studies have been wholly focused on breaking down this “sacrosanct separation of nature and society.” Certainly Neil Smith was not the only (or first) one to offer this critique – feminist (Merchant 1980; Haraway 1991), actor-network (Latour 1993), and critical race theory (Moore, Pandian, and Kosek 2003) have also done this work – but what Smith’s “production of nature” approach offered was a decidedly political economic approach to understanding the relations between nature and capitalism as a historically specific mode of production. As Smith (2009/1984, 7) pointed out, “It is capitalism which ardently defies the inherited separation of nature and society, and with pride rather than shame.”

Smith’s contribution centers upon the fundamental tension in capitalist societies between use-value (e.g., direct use of nature for subsistence) and exchange value (e.g., the extraction of natural resource commodities for profit). For Smith, only in capitalism, where wage-labor becomes generalized and accumulation becomes the overarching goal of production, does exchange value begin to ultimately dominate the social relation with nature. In other words, if capitalist production is bent toward growth and accumulation (and not simply exchange of commodities), this drive necessarily expands the drive of capital to access nature as critical inputs of raw materials and, perhaps more importantly, seek natural sinks for the voluminous (and often inevitable) wastes/pollution from production. There is a geography to this expansion. As value relations tie global commodity markets together, “capital stalks the earth in search of material resources … [T]he appropriation of nature and its transformation into means of production occur for the first time on a world scale” (Smith 2009/1984, 71). For Smith, most controversially, this global scale channeling of nature into accumulation ensures that most parts of the planet we may classify as “nature” have been “altered through human agency” (2009/1984, 81). This might appear self-evident in our current age of “the Anthropocene” and global climate change, but it certainly was not in 1984.

This thesis could be applied to countless empirical “case studies.” A monoculture of cash crops suddenly was seen as a produced landscape – not only through the direct labor of cultivation, but also through scientific knowledge systems that design hybrid seeds, chemical fertilizers, and pesticides. What we imagine as “pristine” nature – say a national park – is itself a political project to create quarantined spaces of “nature protection” as a hedge against urban industrial capitalism’s expanding encroachment – a political project that almost always involved massive violence and displacement of actually existing communities in the name of creating an unpeopled natural space. Ultimately, Smith used the concept of “production” for specifically political aims. If nature is produced, it also means we can change our social relation with nature: “Truly human, social control over the production of nature, however, is the realizable dream of socialism” (2009/1984, 91).

This perspective on the “production of nature” was surely revolutionary in geography and beyond in understanding capital’s relation to nature. Yet, it was also very broad and lacked specifics. Meanwhile, despite its critical insight and efforts to explode the nature–society dualism, its publication in 1984 was concomitant with a more mainstream way of thinking about the economy and the environment as separate. For an insurgent camp of economists there was the discovery of a whole host of environmental processes and functions that were conceptualized as “outside” the market system.
Historical context: neoliberal natures

Since the 1970s, environmental social movements and forms of knowledge in ecological science have increasingly recognized the planet itself as an interconnected set of biogeochemical processes. On the one hand, what constitutes environmental problems has shifted from predominantly local concerns of landscape destruction or air/water pollution, to include “global” problems of ozone depletion, climate change, and biodiversity. On the other hand, this global ecological outlook has led to increased recognition of a broad set of “services” provided by interconnected ecological systems – from biospheric processes of atmospheric circulation to the hydrological functions of wetlands; from nutrient cycling in soils to the metabolisms of human and nonhuman organisms. Of course, of central importance was the general recognition of the importance of these “services” to the maintenance of life on Earth. Yet, even more important was the idea that these “services” were valuable even if their value was not captured by the market system.

These ideas coalesced around the idea of “ecosystem services” in the subdiscipline of ecological economics, with some audacious scholars even attempting to estimate the global monetary value of such services (e.g., Costanza et al. 1997). While the concept of “externalities” – the idea that the market fails to internalize ecological costs into the price mechanism – has long roots in economic thinking (see Coase 1960), this particular form of critique recognized not only the “costs” of pollution, but also the values provided by ecological systems. Whether one was focused on internalizing the “ecological” costs of various economic activities, or integrating ecological services into market-based logics, the common thread was that market systems could be deployed to solve environmental problems. This ideology created the conditions for a multiplicity of market-based environmental policies: emissions trading (“cap and trade”), pollution taxes, wetland banking, biodiversity offsets, and so on.

For critical environmental scholars in geography it became increasingly obvious that, first, these market-based environmental policies were reflective of the larger political shift toward neoliberalism (Heynen et al. 2007). If neoliberalism as a whole is disdainful toward government regulation, neoliberal environmentalism situated what they called “command and control” environmental rules and sanctions as inflexible, centralized mandates from above. Market schemes were seen as more flexible, allowing the private sector to choose their own pollution abatement schemes, or purchase “offsets” on the market when they engaged in (inevitable) environmental destruction. Second, and more provocatively, McCarthy and Prudham (2004, 276) suggest we need to conceptualize neoliberalism itself as a “distinctively environmental project.” This argument suggests that some concepts at the heart of neoliberalism – such as property rights – found their most logical application in specifically environmental projects such as privatizing water supplies (Bakker 2003). Moreover, just as neoliberalism has been defined through its “roll back” of Keynesian-era regulations and social welfare systems, “assaults on Keynesian-era environmental regulation have been [just as] central…” (McCarthy and Prudham 2004, 278).

There has been no shortage of “case studies” examining the implementation of neoliberal policies in the environmental fields. The definitive collection is Heynen et al. (2007) (see Castree (2008a, 2008b) and Bakker (2010) for discussion of the analytical limits of the empirical “case study” approach). Robertson (2012) examines the contradictions of “wetland banking” as a
project to create homogeneous abstract values for the complex, heterogeneous ecological relationships that wetlands represent. Mansfield (2004) shows how privatizing fisheries (through individual transferable quotas on catches) stands in contradiction to the materiality and mobility of fish themselves. As Castree (2008a, 2008b) has warned, such a focus on “case studies” of particular “natures” subject to neoliberal reforms has led to lack of clarity on the larger explanatory and theoretical conclusions of this literature. A common theme in this literature is not the retreat of the state, but rather the reformation of state power toward creating the conditions for markets to function – via licenses, emission credits, privatization programs, and so on. For the purposes of this entry, one possible lacuna is perhaps linking the historical specificity of neoliberal natures with the broad general “production of nature thesis” reviewed in the previous section. It is clear that the neoliberal natures literature is informed by theories of the production of nature, but exactly how neoliberal capitalism produces nature is left unclear.

One general insight from work on neoliberal natures is that the materiality of nature matters in social efforts to “produce” it in particular ways (Bakker and Bridge 2006). For example, Bridge (2003) shows how the invisible and intangible nature of natural gas sets particular constraints on transport networks. Although Smith (2009/1984) clearly argues “production” does not mean control or domination of nature, he did not pay particular attention to how the materiality of nature together with humans coproduces socio-natures. Moreover, the materiality of nature matters in the kinds of theoretical approaches to understanding nature–capital relations. The rest of this entry will review four different material forms of nature – ecosystems, resources, energy, and biological life – to show how each material form requires different kinds of theories to explain the social production of nature under capitalism.

The nature of capitalism

Ecological conditions of production and the necessary role of the state

As mentioned above, the last four decades have seen science and policy fixate on the concept of “ecosystem services” as a bundled set of “values” that somehow escape the price or market system (see Dempsey and Robertson 2012). While neoliberal economists were somehow sanguine about the market system’s ability to “internalize” such values, critical environmental scholars (including many geographers) tried to think more deeply about how capitalism’s inability to “see” these values represents a larger contradiction. James O’Connor’s (1998) theorization of the “second contradiction” of capital argues that capital systematically destroys its own ecological conditions (in addition to human/labor and communal/infrastructural conditions) precisely because there are no market values attached to things such as wetlands, carbon cycles, and soil fertility. At the heart of O’Connor’s theory is Karl Polanyi’s (1944) notion of nature as a “fictitious commodity” – in other words, many of the resources and life forms capital relies on are not produced like commodities for sale, but rather are products of these larger (and often long-term) ecological and biogeochemical cycles that escape the value form.

The main way in which capital systematically destroys its own ecological conditions is, of course, through pollution of air and water and the exhaustion of resource stocks (whether forests, mines, or soil fertility). For O’Connor, this systematic destruction will ultimately yield an “underproduction” crisis that undermines
the conditions of accumulation for capital as a whole. Another key aspect of the theory is the role of the state as a mediator between capital and the conditions of production (vis-à-vis environmental and labor regulations that limit capital’s self-destructive tendencies). Through environmental regulations, setting aside lands for preservation, and restrictions on extraction, the state attempts to save capital from its own environmentally destructive self. O’Connor’s theory is not only about environmental conditions; following Marx, it is also about personal conditions (social reproduction of labor) and communal conditions (infrastructure and other public resources). Yet, O’Connor’s theory of the second contradiction ultimately argues that the state can only “mediate” so much and that it is an inadequate basis for solving the crisis tendencies inherent in capital’s destruction of its own conditions.

O’Connor (and Polanyi’s) theory is useful to an extent. For example, McCarthy (2004) has used it to understand how the conditions of production become privatized through trade agreements which protect capital’s right to pollute and avoid environmental regulation. Essentially, the plethora of work on various efforts to “marketize” ecological services, such as the carbon cycle through REDD (Reducing Emissions from Deforestation and Forest Degradation) and other forestry projects, wetland banking, and biodiversity offsets, is all examining the conditions of production in O’Connor’s terms. Yet, this theory has its limits for understanding the full spectrum of nature–capital relations. First, it systematically reproduces the nature–society dualism by theorizing “nature” as external to the economy and capital (O’Connor literally uses the words “external conditions of production”). (To be fair, O’Connor might argue it is capital that views nature externally, not him.) Second, this “external” framing ignores the parts of nature that are internal, either as resource commodities or as internal “natural” processes central to the production process itself. These two will be discussed over the next two sections.

Resources: becoming a commodity

Of course, some parts of nature do become commodities. They are called “natural resources.” Indeed, neoliberal environmentalism is itself a project to turn the entire wealth of the environment into “resources” called “ecosystem services.” But, what parts of nature become resources? A strict Marxian approach might flatly say those parts of nature that require expenditures of human labor to extract become “values” (i.e., commodities). While the factory may harness “natural” falling water for free, it must pay by the ton for coal mined from the Earth by human labor. It also must pay for the waterwheel (crafted through timber, iron, and manufacturing sectors) that harnesses this “free” falling water.

A more nuanced view of “natural resources” acknowledges that it is not only strict labor expenditures that determine the commodification of nature, but also culture, historical circumstances, and systems of knowledge. (Indeed, the nuanced view would see all these factors as inherently part of “labor.”) This is summed up by resource geographer Erich Zimmermann’s (1951, 15) famous line, “resources are not; they become.” Take the example of crude oil. It is now seen as the most important commodity fueling the entire global economy. Its central refined products are gasoline and other transportation fuels. Its “use value” – its status as a natural resource – is a product of culture in the sense that systems of automobility are themselves wrapped up in ideas of freedom, national identity, gender, and race (Huber 2013). History matters immensely as well. Historians
of oil always point out that ancient cultures used crude oil for everything from waterproofing and medicine to embalming and flammable weapons. Even in our current history of the Industrial Revolution, crude oil has become useful historically in two different contexts. First, crude oil was a source of illumination (kerosene) before the advent of electric light (and just after the near exhaustion of sperm whale stocks). As a matter of interest, another refined product, “gasoline,” was seen as a dangerous, volatile, and flammable substance that was best deposited into local waterways as a “waste” product. Second, it was during the twentieth century, of course, that the age of automobility transformed oil into a source of transportation fuel and, eventually, a hydrocarbon stew of molecules that could be manipulated into petrochemicals.

Of course, the “becoming” of oil as a resource is also directly a product of systems of extraction and knowledge systems. In recent years, most commentators agree that cheaper-to-extract oil (easy oil) has become harder to find. Thus, oil prices boomed from 2005 to 2014 before collapsing under the weight of mass production in the United States, among other places. The “boom” of high oil prices made difficult-to-access oil (tough oil) economical to extract – that is, new reserves “became” resources (e.g., the tar sands of Alberta reportedly need at least $40/barrel oil to allow profitable extraction). Moreover, as global oil capital has expanded into new frontiers of extraction (e.g., deepwater offshore, tight oil accessed through hydraulic fracturing), so have knowledge systems of petroleum engineering and computer-based exploration techniques.

Several resource geographers have pointed to the historical, social, and ultimately political relationships which shape the extraction and use of resources. A recurrent theme in the literature is that no social form of resource appraisal is purely social – resources are always defined through material forms and processes (Bakker and Bridge 2006). Despite this turn toward the material, and similar theories around ecological conditions, there persists a curious dualism between social (cultural, economic) systems that “define” resources and the material, biophysical aspects of those systems themselves. Perhaps this is because much of this work in resource geography is centered upon the moment of extraction – that is, the moment where “raw nature” and human labor appear to be mostly distinct. If we start to examine the ways in which resources flow throughout society, it becomes much more difficult to maintain these clear nature–society divisions. The recent work on energy in geography has developed a more “internal” theory of economy–environment relations.

Energy and the social reproduction of capitalism

As reviewed above, most approaches to the political economy of the environment approach nature as either a set of processes external to market valuation (ecological conditions) or a discrete set of commodifiable “things” that attain the status of “resources.” The problem with such approaches is they imagine a wholly social world of “capitalism” confronting some external realm of ecosystems and resources. But, as Moore (2011, 34) has recently forcefully argued, we need to see capitalism itself as already fused with ecological relations – “Capitalism doesn’t have an ecological regime; it is an ecological regime.” In other words, too often we imagine a “social system” of factories or mining enclaves extracting from or degrading a “natural” system.

Scholars at the intersection of feminist and political economy have recently focused on the concept of “social reproduction” to explain
the political struggles involved on the terrain of everyday life – simply “reproducing” lived existence entails struggles over food, transportation, care work, and what is increasingly called the “work–life” balance (a capitalist social construction if there ever was one) (Mitchell, Marston, and Katz 2004; Huber 2013). It is this terrain of everyday life that Lefebvre (1973, 89) referred to as, “the very soil on which the great architectures of politics and society rise up.” Therefore it is an important concept to understand the “internal” ecology of capitalist social relations.

When we approach energy it is obvious why social reproduction is a useful concept. Energy systems are ingrained in the basics of lived existence. Whether the focus is on peasant struggles for wood (fuel) resources, or industrial consumers calling for public ownership of electric utilities, energy systems are also usually highly politicized. Of course, energy is not the only topic one can approach from this perspective. Timber products, minerals, and food (also a form of energy) are all deeply embedded in the reproduction of everyday life and capitalist social relations. The point is, this kind of “ecological” analysis is different from that which might look at the conditions of extraction or environmental degradation. Moreover, particular conditions of extraction and degradation are relationally linked to these same geographies of social reproduction. Sometimes political struggles over/against forms of extraction neglect these connections. This was David Harvey’s (2003) critique of politics centered on “accumulation by dispossession” (which often are environmental struggles against dispossession of land and resources). He argued that such a politics must link with struggles on the “inside” (for lack of a better term) of the “expanded reproduction of capital.”

A focus on the ecologies of social reproduction can also emphasize the cultural and political aspects of resource or energy consumption. As several authors have recently pointed out (e.g., Boyer 2011; Mitchell 2011; Huber 2013), the very basis of ideas of modernity, democracy, and freedom emerge out of socioecological regimes of massive fossil fuel consumption. Chakrabarty (2008, 208) puts it most succinctly: “The mansion of modern freedoms stands on an ever-expanding base of fossil-fuel use.” This approach, what Boyer (2011) terms “energopolitics,” sees energy as central to wider forms of politics. Yet, even with these “internal” social reproduction approaches there still persists a kind of nature–society dualism where the world of “things” (energy resources, food, materials) is seen as formative in creating “social” worlds of urban, industrial life. Part of the problem is that these natural “things” are too often imagined as “inanimate” objects such as iron ore and coal, but are also often living biological systems (such as wheat fields, forests, fisheries). Examining the intersection between capitalism and biological life raises different questions.

### Biological capital

Even the “production of nature” thesis does sometimes revert to dualistic thinking: capitalism does the producing; nature becomes the product. In reflecting on the thesis over 20 years later, Neil Smith (2006) suggested the production of nature has intensified even more. Through the manipulation of “life itself” via biotechnology, DNA coding, and other genetic tools, Smith suggests the production of nature has proceeded “all the way down” to the very basics of biological existence. Boyd, Prudham, and Schurman (2001) developed an interesting theoretical approach to this shift. Following Marx’s distinction between the formal and real subsumption of labor under capital, they suggest two forms through which nature is subsumed under capital.
The formal subsumption of nature is a basically “extractivist” model wherein capital extracts “things” from nature such as trees, minerals, crops, and so on. On the other hand, the “real” subsumption of nature occurs when capital actively produces the biological content of certain resources themselves. Thus, over the last decade, some major theoretical work has grappled with the relations between capital and the broad field of biotechnology and efforts to produce “life itself” (see Rajan 2006; Cooper 2008).

Many have observed the capitalist production of biological life. Kloppenburg’s (1988) classic work examines not only the historical geography of the genetic manipulation of seed technology, but also how control over seeds allowed for the concentration of wealth and power for capitalist agribusiness. Prudham (2005) looks at how the process of commodification in forests also creates particular strategies for producing plantation-style forests. Kosek (2011) examines the honeybee as a critical “technology” in the production of other kinds of life in agriculture. Life is also examined via struggles over viruses, bacteria, and what Braun (2011) calls “the molecularization of life.” Of course, the ultimate way to break down the nature–society dualism is to examine the human body itself as a particular kind of produced nature via foods, chemicals, genes, and sexual reproduction (Guthman and Mansfield 2013). The politics of the body often reproduces larger power relations and geographies of inequality and difference based on race, gender, and class.

**Conclusion**

In the end, it should be re-emphasized that the problem of segmenting nature from society is not even primarily a problem for academic theorists or intellectuals. It is a problem that is itself produced through capitalist social relations. It is capitalist value systems that do not take into account larger “ecological” processes—and appropriate those systems for “free.” It is capitalists who view resources as a stock of discrete “things” that can be transformed into commodities and, ultimately, money. It is capitalism that requires the majority of us (who are wage workers) to rely on a bundle of commodities torn from nature simply to reproduce our lives. It is capitalism that is now looking toward genes, nanotechnologies, and biological life itself as a new frontier of accumulation. Moving forward, geographers will continue to do research to uncover the illusory nature of these nature–society divides that capitalism insists upon.

ENVIRONMENT AND RESOURCES, POLITICAL ECONOMY OF

State environments and environmental states

The Somerset Levels provide a valuable geographical setting in which to begin our discussion of environment and the state. The Somerset Levels is a coastal plain and wetland area that is located in the southwest of England. As with many low-lying coastal areas, the Somerset Levels are prone to flooding. Since medieval times the Somerset Levels have been synonymous with attempts to settle and cultivate the area alongside regular inundation events. The heavy storms that hit the UK during late 2013 and early 2014 served to bring local flooding in the Somerset Levels to national attention. Significantly, in the context of this entry, these floods exposed some of the complex ways in which states and the environment are connected.

In total, the flooding of the Somerset Levels affected 35 homes, 17,000 acres of land, and led to the closure of a busy section of the national rail network for two months. The severity of flooding resulted in many villages being cut off and having to be abandoned for days on end. While the British Prime Minister was quick to establish a connection between the storms and floods that affected the Somerset Levels and climate change, public and media attention quickly focused on the role and responsibility of the state in managing flood events. At a local level, the UK government’s Environment Agency was criticized for failing to adequately dredge the rivers that run through the Somerset Levels. At a national level, the flooding of the Levels (and the wider storms of which they were a part) led many to question the 25% cut in flood defense spending the Coalition Government had imposed in 2010 (Carrington 2014).

The case of the Somerset Levels exposes the complex ways in which states and the environment come together. States are seen to have a responsibility for protecting national environmental assets – such as the farmland of the Somerset Levels – as part of its broader remit to support economic development. The UK state has also been instrumental in establishing the 32 sites of special scientific interest that are scattered throughout the Levels. These sites have been formed to protect the flora and fauna of this wetland environment. While protecting the flora and fauna of the Levels, the local and national state has also been instrumental in helping to drain large sections of the Levels so that they could be put to productive use. The recent flooding of the Somerset Levels also reveals the state’s assumed responsibility for protecting people from environmental risk and perturbations, such as storms, floods, and inundations. In these contexts it becomes clear that the state occupies a difficult position between the priorities of environmental conservation and securing the resource needs of its population, and of protecting the environment from people and people from the environment.

This entry seeks to explore in greater detail the nature of the relationship between states and the environment. In doing so it will reflect
ENVIRONMENT AND THE STATE

upon the history of state–environmental relations in different geographical contexts and introduce key theoretical frameworks that can help us understand these relations in new ways. Because there are many different ways in which both the state and environment can be defined, this entry explores the various ways in which it is possible to understand states and environments and how these different perspectives can enable us to see the various ways in which environments and states are connected.

While this entry deliberately avoids firm definitions, it is helpful to propose some loose frames of reference for understanding what is meant by state and environment. This entry understands states as collections of institutions (such as parliaments, departments, and courts of law) which tend toward forms of central coordination, have a responsibility for a territorially demarcated area, and maintain monopolies in relation to rule making and the legitimate use of physical force (see Mann 1993, 185). While this may be a useful working framework within which to comprehend states, it is important to note that many argue that the operation of states is not limited to the work of formal state institutions (in the case of the Somerset Levels, for example, the area was initially drained by private interests who were working under license from the king); that many forms of state power do not radiate out from a center of power; that state influence is neither absolute within a territory nor limited to by territorial borders; and that legitimate rule making and violence are no longer the exclusive preserve of states.

The environment can be understood in two broad ways. First, environments can often simply refer to contexts and can take the form of built/manufactured structures (cities, houses, offices, roads) or more natural settings (forests, wetlands, savannah). More usual, when people refer to environmental issues they have in mind specific ecological understands of the environment. Second, notions of ecology (or the economy of nature) tend to see environments less as contexts and more as processes. Ecological processes could, for example, refer to the greenhouse effect, nitrogen fixing, or the water cycle. It is important to note that when people refer to the environment in these more ecological terms there can be a tendency to understand related processes in isolation from human activity (a so-called external views of nature, see Smith 1984). What is now clear, however, is that in the context of growing human influence on ecological systems (from climate change to the acceleration of the nitrogen cycle that is product of the global use of inorganic fertilizers), ecological systems cannot be understood as separate from the human world. In these contexts, this entry understands the environment as both a series of contexts and ecological processes that are the product of both the work of nature and humanity.

This entry explores state–environment relations through three interconnected perspectives. The first section of the entry considers the historical relations between states and environments. In this section particular attention is given to the role of states in shaping human knowledge of environmental systems, and the importance of environmental resources and issues in justify expanded forms of state power and influence. The second section of this entry considers the emerging role of the state in managing environmental externalities. Environmental externalities refer to situations were environments and the people who depend on them are subject to forms of pollution and exploitation that have been caused by a third party who does not bear the costs of such activities. This entry will show that environmental externalities have been central to the expanded powers and responsibilities of the modern state. The final section
of this entry considers the constitutional implications of emerging forms of state–environment relations. Particular attention is given in this section to the ecological responsibilities of states and emerging understandings of environmental rights. Throughout these sections, different ways of understanding both states and environments are introduced, but consistent emphasis is brought to the contradictory nature of the historical and contemporary interactions of states and environments.

Environmental history of the state and governmental history of the environment

One way in which it is possible to understand the connections between states and environment is through the lens of history. In many ways, modern understandings of the state and environment share common origin stories. These stories help us understand that centrally orchestrated systems of territorial government were developed in order to exploit environmental systems and resources (such as the Somerset Levels). At the same time, these stories reveal how modern understandings of environments (particularly as scientifically quantifiable objects) are products of emerging state systems.

Prehistories of states and environments

In order to understand the coevolutionary history of states and environments it is important to consider the prehistory of states and environments. The term prehistory referred to here means the periods that predate the emergence of modern understandings of states and environments. The term modern is used here both to denote our contemporary “of the moment” understandings and to refer to something more historically specific: modernity. Modernity refers to a scientifically oriented shift in socioeconomic and political life that began in Europe in the sixteenth and seventeenth centuries. This societal shift was broad ranging and affected moral codes, industrial practices, politics, economic thinking, and technological development. At its center, modernity involved the (partial) rejection of religiously oriented modes of understanding of the world and associated theological ways of organizing society.

Before the advent of modernity political society was organized in ways that are very different from contemporary state systems. While power still had a central focus, it was not organized around a bureaucracy, but instead focused on the figure of the monarch or emperor. The prince or Caesar who sat at the center of premodern systems of government justified and secured their power on the basis of divine purpose and their position in the cosmic order of things. The purpose of premodern systems of government was also very different from modern states. While modern states have a governmental responsibility of care toward their people and territory, premodern monarchs were primarily concerned with securing their leadership through the use of military power and influence (Foucault 2007). In addition to its underlying purpose, the geographical form of premodern states was also very different from its modern counterparts. While modern states are based upon clearly demarcated forms of territorial power, premodern states were much more geographically nebulous. Not only were the boundaries of premodern states in a state of regular flux (as military struggles saw borders shift), but there was much more limited understanding of what actually existed within the boundaries of a fiefdom or empire.

Premodern understandings of the environment (or more accurately creation) were also at odds with contemporary sensibilities. Indeed
ENVIRONMENT AND THE STATE

in the premodern world it appears that the category of environment (at least as something that is separate from humans) may not even have existed. Certain premodern worldviews saw nature as a holistic realm of existence through which all things were connected together within a broader religious order of things. On these terms it was believed that the environment could be read much like a book in order to reveal God’s purpose. As a realm of divine creation, premodern environments were places of mystery and discernment, which demanded the respect of humans who were themselves part of the broader web of life of which the environment was a central component.

The rise of modernity: timber, food, and water

The rise of a modern, more scientifically oriented society in the sixteenth and seventeenth centuries had a significant impact on state-environmental relations. The rise of modernity represented something of an existential threat to states. As science increasingly exposed the laws of nature and challenged religious orthodoxies it became increasingly difficult for sovereigns to justify their existence on the basis of divine authority or the eternal order of nature. In this context, states became increasingly governmental in nature and sought a more practical basis for their existence. This practical basis was to be found in providing coordinated care, protection, and sustenance to national populations. This newfound purpose within states had significant implications for the relationship between states and the environment.

In his classic analysis of the emergence of the modern state, Seeing Like a State, James C. Scott exposes how the emergence of modern manifestations of governmental power was intimately tied to the control and management of the environment (1998). In order to consolidate their territorial power and provide care and sustenance for their population, Scott describes how early modern states developed new bureaucratic systems and sciences that enabled them to understand and manage their environmental resources better. These new bureaucratic sciences of environmental management are most clearly expressed in the emergence of modern state forestry. Timber resources were vital to early modern states. Timber was a key source of fuel, was widely used in building, and, through its use in shipbuilding, was a vital part of a nation’s commercial and military security. But premodern forests presented thickets of confusion for state administrators. The organic nature of woodland made it very difficult for states to effectively estimate the amount of timber resources they had in reserve. It was in this context that governments supported the emergence of more scientific systems of forest management (Scott 1998). Scientific forestry involved the gradual replacement of organic woodland with the regimented spaces of tree plantations. With their geometrically ordered form and straight lines of carefully planted trees, scientific forests could be administered more effectively. At the heart of this administration process was the goal of legibility (Scott 1998). Legibility, or the ability to see things clearly, lies at the very heart of all forms of governmental power (from secret service surveillance to tax returns). Scientific forests meant that woodlands could be measured more accurately and became legible entities within the economic planning of the state (see Demeritt 2001; Whitehead, Jones, and Jones 2007).

Ultimately, making the environment more legible was connected to the procedures through which states made the environment quantifiable. In the context of woodlands, the increased legibility afforded by scientific woodland enabled nature to be more easily quantified. Instead
of vague estimates of available woodlands, state-sponsored scientific forestry was central to the emergence of more universal measures of forestry that indicated the acreage and tonnage of available timber. The scientific quantification of nature in this way was not limited to woodland. Early modern states were also keen to measure agricultural lands more accurately. During the early modern period many states conducted extensive land-use surveys that sought to accurately map the territorial scope of available environmental assets (Whitehead, Jones, and Jones 2007). The mapping of land resources not only facilitated the spatial quantification of the environment, it was also pivotal to the consolidation of states’ control over the territories of which they often only had an opaque awareness. Ultimately, accurate land-use surveys helped states to estimate available agricultural resources and estimate likely harvest yields. They were, however, also vital instruments for the administration of taxation throughout different territories.

What the emergence of scientific forest and land-use surveys have in common is that both changed the ways in which states understand and relate to the environment. Ultimately, they resulted in a narrowing of vision in relation to the natural world as the environment was simplified and quantified. This simplification process is seen nowhere more clearly than in the notion of environmental resources. The accurate quantification of environmental resources such as timber and harvests are sine qua non to the establishment of states as large-scale territorial systems for organizing society. But the very notion of an environmental resource tends to axiomatically define the environment on the basis of its socioeconomic utility. On these terms it is clear that the history of the state is a history that has seen human understandings of, and relationships with, the things of nature become increasingly divorced from the broader web of ecological processes of which they are a part. The history of state–environment relations is essentially a history that connects the emergence of scientific forestry and land-use surveys with the declining awareness shown by many children of what crops produce certain food types.

The modern history of state–environment relations is, however, not restricted to territorial phenomena such as trees and crops. The historian Karl Wittfogel, for example, has drawn attention to the connections between early state systems in Asia and the establishment of complex water management and distribution systems. In his much-discussed book Oriental Despotism: A Comparative Study, Wittfogel argues that the construction of the extensive irrigation systems upon which many Asian societies depend required large-scale systems of bureaucratic coordination (Wittfogel 1957). Such bureaucratic coordination, which involved connecting water supply networks over large-scale areas, required the organization (and manipulation) of cheap labor and depended on large-scale systems of government that were often despotic in nature. In this context, the systems of government outlined by Wittfogel appear to embody a mix of premodern sovereignty and control alongside an evolving bureaucracy that is more typical of modern states. While the despotic states of Wittfogel are very different to modern systems of government, they do reflect precursors to modern states. What is clear, however, is that throughout history states have continued to play a pivotal role in the consolidated supply of water to national populations. In particular, states have been instrumental in the production of supply networks that could carry water from where it was most abundant to where it was most scarce (Swyngedouw 2007). It is interesting in this context to note that during World War II the British government sought to combine efforts to drain the Somerset Levels in order to secure
valuable agricultural land with a plan to facilitate enhanced forms of water supply to a local munitions factory. The building of the artificial Huntspill River in the Levels thus sought to meet draining and water supply needs and was seen as a war priority by the state (Williams 1970).

What these examples illustrate is that the history of the modern state is intimately tied to the environment and modern understandings of the environment are products of their coevolution within territorial governments. To put things another way, histories of human–environmental relations that ignore states, or accounts of the history of states that neglect the environment, are likely to be very partial accounts of the respective pasts of these complex entities.

Externalities: the state and the rise of environmental regulation

Introducing environmental externalities

If the longer-term history of state–environment relations is one that centers on the construction, production, and management of environmental resources (such as timber, food, and water), recent history has focused on another environmental phenomena: externalities. Externalities are actually economic phenomena that pertain to situations where a particular process or transactions causes harm to an innocent third party who receive no form of compensation. Environmental externalities can take two basic forms. First of all they refer to situations when members of a society are subjected to forms of environmental pollution they had no direct role in producing. These forms of environmental externality can be witnessed by those who live along busy transport routes, have made their homes near to waste treatment plants, or who happen to inhabit areas that are downstream or downwind of major industrial facilities. The second type of environmental externality relates to the uncosted exploitation of environmental systems and resources. These forms of externality are produced when chemical plants release their untreated waste products into rivers and oceans or timber companies raze woodlands and destroy the habitats that they constitute at no additional costs. The case of the Somerset Levels provides us with an interesting example of an environmental externality. As with many modern agricultural areas, the Somerset Levels developed on the basis of the application of inorganic fertilizers. These inorganic fertilizers, which contain nitrates and phosphates, have supported the expansion of agricultural yields in the Levels, but they have had environmental consequences. The inorganic fertilizers that run off the agricultural lands of the Levels enter local river systems and eventually make their way to the ocean. Elevated levels of inorganic fertilizers in river and ocean waters lead to the production of blooms of algae (whose growth is accelerated by the fertilizers). These blooms can reduce the amount of sunlight penetrating the water’s surface and have detrimental impacts on the ecologies of the water systems where they are found. As with many forms of environmental externality, the impacts of the use of inorganic fertilizers are often experienced at great distances from the original point of pollution, and those who have benefited financially from the pollution event do not meet the ecological costs.

There are two things that it is important to note about externalities. The first is that they are clearly unjust, with those suffering the effects of externalities not being able to reap any of the benefits associated with their production. The second is that they are an inevitable outcome of unregulated market systems that promote economic freedom and the pursuit of profits. As an institution that sits partially outside of the market
system (for a more detailed discussion of this issue see below), the state has played an important role in regulating a series of externalities.

The state as environmental arbiter

If externalities are a product of market failure (or success, depending on which side of the externality relation you are on), and if the state has a role in regulating externalities, it is important to consider the relationship between the state and the market. At one end of the spectrum are those who advocate a strict Marxist interpretation of the state–environmental externality relation. These perspectives on the state claim that states are largely in the service of private sector interests, and will, where and whenever possible, limit the amount of environmental regulating it completes in order to preserve market efficiency and profit. There are others, however, who argue that states are able to achieve a degree of partial independence from the market system. In this context it is argued that states are able to position themselves within the relationship between markets and the environment in order to pursue the just treatment of the environment and a more equal distribution of the benefits that emerge from its utilization (Johnson 1996).

The modern state is able to exercise some form of regulatory power over the social uses of the environment for three broad reasons. First, many states have been founded on a constitutional commitment to equity and justice among its citizens. As the narrow pursuit of environmental gain, which mostly only benefits the few, can often lead to the unequal distribution of ecological harm, the state has a moral imperative to act. Second, as one of the key roles of the modern state is to think about the longer-term needs and welfare of its people, it has an inherent commitment to ensure that the narrowly focused individual pursuit of profit does not compromise the long-term sustainability of a nation’s resource base. Third, the state is arguably the only organization that has the administrative reach and expertise to be able to regulate complex environmental systems in a fair and sustainable way. In relation to these three contexts, Rudolf Bahro has suggested that states have the capacity to act as “elite stewards” of the environment, providing expert care for environmental resource to ensure long-term social and ecological justice (Bahro 1984).

The history of the regulatory relationship between the state and environment suggests that there has been an almost constant ebb and flow between the state’s prioritization of the interest of the economy and the environment. While states have constitutional commitments and bureaucratic capacities that impel them to control the use and pollution of the environment, they must also support the economic vitality of the nation over which they govern. It is often assumed that the state’s role as an arbiter of environmental externalities is a fairly recent phenomena. In reality, however, the state has been intervening in environmental externalities for some time. It was not, however, until the nineteenth century that it is possible to observe the more strategic, national level regulation of environmental externalities. It was during the industrial revolution of the nineteenth century that many industrial cities started to see the debilitating spread of environmental pollution. From power plants, foundries, and domestic chimneys releasing smoke and sulfur dioxide, to chemical plants releasing harmful alkalis into the atmosphere, the industrial city quickly become an unhealthy and unsafe place to live (Whitehead 2009). Early attempts to regulate the pollution of industrial cities was pursued through the enacting of public health legislation, which attempted to set standards of air and water quality and provision more comprehensive water treatment and sanitation systems. In the twentieth century public health
legislation was supplemented by clean air and water acts that not only sought to improve the health of the population, but also to protect terrestrial, riparian, and marine ecosystems which act as sinks for unwanted pollution.

When it comes to more economically developed countries (MEDCs) it would appear that governments have been successful in addressing the production and spread of environmental externalities within their territories. On many measures people living in MEDCs are now able to breathe much cleaner air and drink much purer water than they have ever been able to do since the emergence of the industrial revolution. But this apparent regulatory success has only been possible because many of the activities that produce environmental activities have moved from states with strict environmental regulations to less economically developed countries (LEDCs), which do not subject companies to such stringent regulations and can furnish them with much cheaper labor.

In the context of environmental externalities, it is important to distinguish between two different forms of state activity. In certain instances states have adopted a role as neutral arbitrator between competing private interests. In this context, the state is most obviously present in the development and ratification of legal frameworks relating to environmental nuisance, negligence, and trespass, which can help to arbitrate between the competing demands that are being placed on the environment. In other contexts, states have developed more overtly regulatory capacities in relation to environmental management. The regulatory state apparatus can be seen in relation to statutory prohibitions against certain environmental activities such as air and water pollution, which are designed to maintain certain pre-established thresholds of environmental quality. The first major acts of statutory prohibition against environmental pollution emerged in the decades following the end of World War II. In order to support environmental prohibitions many states formed environmental agencies and ministries. These state organizations were given responsibility for monitoring compliance with environmental law and ensuring that established levels of environmental quality were maintained. In more recent years, the command-and-control strategies of regulatory states have given way to more market and incentive-oriented state policies. In relationship to climate change, for example, certain states (and collections of state) have sought to create markets within which carbon credits can be traded and addressing climate change is financially incentivized. In other instances, states provide direct financial incentives to agriculturalists that farm in ways that do not undermine the broader ecosystem services that their land provides. These forms of post-regulatory policy reflect the fact that generating incentives for people to protect the environment are often more effective, and more easy to deliver, than heavy-handed strategies of regulation.

The limits of the liberal environmental state

The changing nature of environmental externalities has raised questions about the ability of states to effectively manage social relations with the environment. Some have argued that the planet has now entered a new geological era in which the power of humans to transform the global environment rivals the power of the natural world. This new area has been termed the Anthropocene. The Anthropocene is characterized by global-scale changes in the ecological balance of the planet, which include climate change, transformations in the nitrogen cycles (associated with the use of artificial fertilizers), acid rain, and the pollution of marine ecosystems. What unites these varied processes is that
they tend to transcend the jurisdictional boundaries of states. These are forms of environmental externalities that often involve situations where the perpetrator of environmental pollution is located in a different state to those who are directly affected by pollution. In the context of such transboundary issues, the environmental movement and national governments have often had to turn to international level organizations such as the United Nations to establish agreements on the fair and just treatment of ecosystems. Establishing effective environmental agreements at this level has proved difficult with many states being unwilling to sacrifice their long-held sovereign rights to use and exploit their national resources.

William Ophuls has suggested that the extensive use and exploitation of environmental resources (including agricultural land, water, and minerals) may ultimately result in new forms of environmental state (2011). According to Ophuls (2011), liberal systems of government prioritize the relatively free use of environmental resources, except when the use of those resources significantly impinges on other people’s well-being or freedom. Ophuls argues that liberal systems of government have only been able to be sustained because of the relative abundance of environmental resources and the ongoing ability of natural systems to absorb the environmental externalities that humans produce. In the context of relative environmental abundance, the use of a resource by one person is not seen to have a particularly detrimental effect on the ability of other people to use that resource. Ophuls claims that as resources become scarce and environmental systems become less able to absorb environmental pollution (as appears to be the case with observed climate change), governments will inevitably have to become more authoritarian.

The state regulation of environmental externalities clearly reflects a changing environmental ethos in the government. Over the last 150 years, states have not only facilitated the human use and exploitation of the environment, they have also sought to ensure a fairer and more sustainable relationship between society and environments. Despite this changing emphasis within environmental government, many claim that current environmental problems (from desertification to climate change) indicate the failure of states to effectively control the unsustainable use of the planet’s environmental resources. Some have claimed that the failure of states to adequately manage human–environmental relations stems from the fact that states are ultimately anthropocentric. That is to say that they tend to prioritize the rights and needs of people over those of nature (Bullen and Whitehead 2005; Eckersley 2004).

In her groundbreaking work on the relationship between states and the environment, Robyn Eckersley argues that in order to effectively address the environmental challenges that are associated with the Anthropocene more ecocentric forms of government (2004) are required. According to Eckersley, the modern state is constitutionally ill equipped to deal with the complex, environmental challenges that the planet now faces. The state is constitutionally limited by the fact that it only defines and protects the rights of people and not those of nature. This bias will always ultimately lead to the prioritization of the rights of humans over those of the natural world, even when the long-term wellbeing of humanity is indisputably connected to ecological sustainability. Furthermore, the territorial nature of the state means that governments tend to be locked into
the narrow defense of national environmental interests even when the environmental systems upon which those interests depend constantly transcend sovereign boundaries.

In her book, The Green State: Rethinking Democracy and Sovereignty, Eckersley outlines a new vision of the state, which she terms the green democratic state. This green state is different from the modern state to the extent that it is interested not only in the rights of people, but also of nature. It is also defined by a concern not only with the rights of those living within a given territory now, but also of the needs and rights of those living in other territories and who will live there in the future. Eckersley’s vision of the green state is deliberately idealistic as she seeks to explore what it may take to develop systems of government that are fit for purpose within the Anthropocene. Notwithstanding the deliberately idealistic nature of Eckersley’s work, it is important to note than some aspects of the green state are starting to come into existence. For example, in 2010 the Bolivian government passed a new law entitled the Ley de Derechos de la Madre Tierra: Law of Rights of Mother Earth. The law declares that “life systems” and “Mother Earth” (which are inclusive of human and natural systems) are titleholders of rights specified in national laws. This law is important because it is considered the first to give official rights to nature and, in so doing, make it possible for people to legally sue others who perpetrate actions that affect the sustainability and integrity of life systems. At present it is difficult to assess whether Bolivia’s Law of Rights of Mother Earth reflects the first step in the much broader evolution of green states throughout the world. What is clear is that Bolivia’s attempt to develop a greener form of state is more ethically palatable than Ophuls vision of an eco-authoritarian future.

Conclusions

This entry has charted the different ways in which it is possible to think about and observe the relationship between states and the environment. An historical perspective reveals how states and the environment have been in a constant state of coevolution, with the use and exploitation of the environment being central to emerging power of states and the practices of the state being crucial to the ways in people collectively understand and relate to environmental resources and systems. Considering state–environment relations through the lens of externalities reveals the ways in which states have been positioned at the intersection of the relationship between people, economies, and environments. Certain theories suggest that when it comes to managing environmental externalities that states tend to favor the interests of economic growth over those of the natural world. Others suggest that the state is able to act as an independent referee or arbiter of socioenvironmental relations. A constitutional perspective on the relationship between states and environments reveals how states have been historically constituted in ways that tend to favor the rights and needs of people over those of the environment. Constitutional perspectives raise the interesting question as to whether the formation of a green state, which recognizes and protects the rights of nature, could provide a long-term context within which to sustainably manage socioenvironmental relations. What this entry has illustrated is that the relationship between states and environments has been central to broader social relations with the natural world. Whether it is in the context of a new green state or eco-authoritarian form of government, it appears that state–environment relations are only likely to grow in significance as the twenty-first century progresses.

Media communication on environmental issues

Media range from entertainment to news media, spanning traditional or mass media such as television, films, books, flyers, newspapers, magazines, and radio, as well as new media such as the Internet in general, Web 2.0, and social media. Traditional media rely on one-to-many (often monodirectional) communications and are sometimes referred to as “mass media,” whereas new or social media involve many-to-many, more interactive, webs of communications. Since the 1990s, the shift from traditional to new media has signaled substantive changes in how people access and interact with information, who has access to it, and who are considered “authorized” definers (e.g., actors with more power and influence than others) of the various dimensions of environmental issues. It is argued that new and social media have democratizing influences, as these channels of communication often offer a platform for more people to become content producers, and therefore have the potential to more readily shape the public agenda.

In all media, actors such as publishers, editors, journalists, and other content producers such as online bloggers generate, interpret, and communicate images, information, and imaginaries for varied forms of consumption. These “media representations” are therefore critical inputs to what becomes public discourse on today’s environmental issues.

As an example, climate change as a highly politicized media topic, especially in the United States, illustrates how (powerful) groups with diverging political ideologies, worldviews, or economic interests heavily influence the public debate on climate change. Recent studies on worldwide media coverage of climate change (Boykoff et al. 2015; see Figure 1), as well as on climate discourse and the interconnection of media, politics, and public opinion, suggest that media agendas match public agendas on the perception of climate change and policy implications (Hmielowski et al. 2014; Brulle, Carmichael, and Jenkins 2010; McCright and Dunlap 2011; Boykoff and Roberts 2007; Boykoff and Boykoff 2004; Weingart and Engels 2000). Through a web of interactions, the media have thereby influenced a range of processes from formal environmental policy to informal notions of public understanding about the environment.

Illustrating how this influence has changed over time, Figure 1 shows media attention on the terms “climate change” and “global warming” in English- and Spanish-language newspapers around the globe. The attention spikes can be attributed to certain events, for example the publication of the Stern Review and Al Gore’s film An Inconvenient Truth in 2006, the Fourth Intergovernmental Panel on Climate Change (IPCC) Assessment Report and the Bali Summit on Climate Change in 2007, President Obama’s inauguration and making climate change a
ENVIRONMENT AND THE MEDIA

Figure 1  World newspaper coverage of climate change or global warming in 50 newspapers across 25 countries and six continents, 2004–2015 (Boykoff et al. 2015; reproduced from Center for Science and Technology Policy Research International Collective on Environment, Culture & Politics).

political issue, the Climate Change Conference in Copenhagen in December 2009, and the United States–China joint announcement on climate change and green energy cooperation by the end of 2014. However, the figure also shows that the Fifth IPCC Assessment Report, published in 2014, had lower media visibility and public attention compared to the Fourth IPCC Report, although it provides better knowledge on the causes and effects and on the predictions of climate change in the future (Fernández-Reyes, Piñuel-Raigada, and Vicente-Mariño 2015).

Media coverage and journalistic norms

Mass media follow ethical codes of pursuing fair, accurate and objective journalistic work. These codes, mainly referred to as professional norms, consider journalism as a platform for an open and transparent discourse between different sectors of society. In this context, media strive for independence, truth, and accuracy in coverage (ASNE 2002), which are reflected in similar values and attitudes toward their professional work (Bennett 1996). However, these ethical codes or norms can also be considered as styles of storytelling that focus on how these rules critically shape media content and become an inherent part of communication (Boykoff and Boykoff 2007), also known as “news values” (Galtung and Ruge 1965). In this context, journalists follow the newsworthiness of a message according to a set of criteria such as familiarity, negativity, meaningfulness, unexpectedness, personalization, conflict, and others. Galtung and Ruge call these criteria the “conditions for news,” which turn facts or events into media messages. These norms also intersect with the journalistic norm of balance, that is, the common practice of
providing both sides of any dispute with roughly equal attention (Boykoff and Boykoff 2004). This is an activity that often appears to fulfill pursuits of objectivity (mainly prevalent among US media). In coverage of complex issues such as stem cell research, nuclear power, or genetic engineering, balance can provide a validity check for reporters who are on deadline and do not have time nor scientific understanding to verify the legitimacy of various truth claims about the issue (Dunwoody and Peters 1992).

Media coverage is also informed by authority-order bias, where journalists tend to rely more heavily on authoritative, legitimate, and official sources. While in some cases these authorities step in to restore order, at other times they serve to increase political concern.

Media interventions seek to enhance understanding of complex and dynamic human–environment interactions such as climate change. However, the characteristics of such interactions often run contrary to journalistic norms and values like personalization or novelty. As a result, vague and decontextualized reporting confuses rather than clarifies understanding and engagement on environmental issues. The *New York Times* journalist Andrew Revkin (2007) has referred to reporting without context as “whiplash journalism.” Context helps sort out marginalized views from counterclaims worthy of consideration on various aspects of environmental issues.

Values and ideological influences on media messages

As scientific understanding improves, it often unearthed new and more questions to be answered (Sarewitz 2004). What seems like a simple process to define what constitute “environmental problems” is actually influenced by priorities, ideologies, experiences, and perspectives. In other words, anytime the biophysical is captured and categorized, it undergoes varying degrees of interpretation, as influenced by power and scale via temporal and spatial contexts. The media play an inherent role in representing certain interpretations of the biosphere.

For example, in the case of climate change, media coverage of environmental issues is thus not a simple collection of news articles and clips produced by journalists; rather, media coverage signifies key frames derived through complex and nonlinear relationships between scientists, policy actors, and the public that is often mediated by journalists’ news stories (Trumbo 1996). These frames emerge in media representations regarding a certain issue to make it “more salient in a communicating text, in such a way as to promote a particular problem definition” (Entman 1993, 52). Asymmetrical influences also feed back into these social relationships and further shape emergent frames of “news,” knowledge, and discourse. For example, frames regarding climate change coverage in the media can be associated with different actors by emphasizing problems and causes (scientists) or judgments and remedies (politicians). The number of scientists in the media as news sources may decline “as the issue becomes increasingly politicized” (Trumbo 1996, 269). As another example, positivist approaches work to understand and interpret already existing social reality; meanwhile, constructivist positions emphasize interrogations regarding how power and scale construct, reflect, and reveal varied and complex phenomena such as language, knowledge, and discourse (Forsyth 2003). With these varied approaches into the complex and nonlinear interactions shaping public perceptions of environmental issues, geographical research has converged on the notion that media representations and its framings are not simply translations.
Humans contribute to climate change

US federal cap-and-trade legislation will have a discernible influence on the wider economy

Anthropogenic climate change has contributed to increases in hurricane intensity

UNFCCC architectures optimally address Global North/Global South issues

Figure 2  This schematic shows the distribution of relevant expert agreements and disagreements on climate science and governance issues (over time from left to right). The curve illustrates the relative strength/weakness of agreement or disagreement. The figure is adapted from Boykoff (2011) and comments by New York Times journalist Andrew Revkin at an annual Society of Environmental Journalists meeting.

of the “truth.” This becomes even more evident in the context of climate change and its polarized perception between different societal groups. Taking climate change as an example of a key environmental issue, Figure 2 shows facets of science and environment, where agreement is strong and others where there is disagreement.

Consider panel (a): “Humans contribute to climate change.” Over the past decades, reports and findings have increasingly signaled a broad scientific consensus – despite lingering uncertainties regarding the extent of attribution – that human activity has significantly driven climate changes in the past two centuries, and that climate change since the Industrial Revolution has not been merely the result of natural fluctuations. In other words, detection (of climate change) and attribution (to human activities) research has improved significantly. Noting this improved understanding, the United Nations’ IPCC has articulated this evidence-based view through multiple assessments of emergent
peer-reviewed climate research and many stages of consensus-driven processes. The steady flow of IPCC reports since the 1990s has represented “critical discourse moments” (Carvalho 2005) that describe happenings within an established discourse (e.g., on climate change) that may challenge the dominant and established positions on the topic. Those critical discourse moments have solidified a narrative of consensus, supported too by similar declarations from national science academies and other scientific groups over time. Despite this convergence, when mass media report on this issue, excessive attention can be paid to the tails in this schematic: outlier viewpoints at the ends of the distribution, rather than those under the bell curve that converge on agreement, have actually been found to have received amplified attention in media representations in particular country contexts such as the United States and United Kingdom (Boykoff 2011).

Panel (b) considers relevant expert-based views on the statement that “US federal cap-and-trade legislation will have a discernible influence on the wider economy.” As shown, a more flat and wavy line most accurately depicts the relative strength of agreement from “positive effect” through “no effect” to “devastating effect” (in schematic from left to right). In other words, panel (b) shows that there are a variety of legitimately divergent views on the potential effects that the implementation of cap-and-trade legislation may have on the wider US economy. Panels (c) and (d) illustrate further climate science and governance questions that have a range of perspectives, views, and opinions. The bimodal distribution of panel (c) captures that the relevant expert community working on questions of links between hurricane intensity and anthropogenic climate change may cluster around two peaks of consensus rather than one; that is, this represents what can at times be an issue where there are two convergent and rival explanations for an issue, within legitimate expert communities of researchers.

Overall, broad-brush treatment by mass media can then both privilege marginal views as legitimate, by giving them media coverage although they lie far from the main consensus (see panel (a), and unduly dismiss legitimate claims where consensus is less strong (exemplified by panels (b) and (d)). Numerous factors – within the issues themselves, as well as external contextual factors – contribute to the changing shape of these distributions over time.

This shows that fair, accurate, and precise media portrayals of environmental issues become even more perennial, central, and fundamental challenges. By more accurately, precisely, and fairly portraying the contours of the varied aspects of environmental change, understanding, meaning, and potential public engagement have greater opportunities to succeed.

Media and cultural politics of the environment

Media and environment interactions – from processes to effects – are usefully situated in a wider cultural politics of the environment. Cultural politics refer to processes involving how meaning is constructed and negotiated across space and place. This involves not only the representations and messages that are present in media discussions but also those that are absent. These discussions then shape how members of the public perceive possible actions and social practices at the human–environment interface. In other words, media frames influence the ways that the environment is perceived and discussed and how the public then view environmental issues, from formulations of what are “problems” to considerations of potential, feasible, or desirable ways to alleviate problems (sometimes referred to as “solutions”). These
ENVIRONMENT AND THE MEDIA

elements are also inextricably shaped by ongoing environmental processes themselves.

Mass media representations arise through large-scale (or macro) relations, such as decision-making in a capitalist or state-controlled political economy, and individual-level (or micro) processes such as everyday journalistic practices. Whether media are state-run or corporate-run shapes media coverage differently in countries and contexts around the world. While the main principle of democratic news production has been that media organizations then serve as a check on the state, in practice, corporate-controlled media have been argued to have acted systematically in the service of state power (Curran 2002).

For example, in the United States, Fox News (owned by Rupert Murdoch’s News Corporation) was seen to have inordinate power over the Republican primary elections leading up to the 2016 presidential election to succeed Barack Obama. While over 17 candidates declared that they were running for the Republican nomination at the time of the first televised debate, Fox News declared that only 10 candidates were going to be able to participate in the first Fox-televised debate. Consequently, candidates were held hostage to Fox’s power to determine the rules of selection of candidates to participate in this high-profile event. Meanwhile, billionaire brothers Charles and David Koch – who own Koch Industries, a conglomerate of oil and gas interests – budgeted to contribute nearly $900 million to candidate coffers and effectively influence the overall 2016 election, in which this episode took place. In this context, the Koch brothers have been prominent climate contrarians, calling into question the wisdom of regulatory interventions to address twenty-first-century climate changes as well as whether humans contribute to climate change at all, and their moneyed influence has particularly tilted the US Republican Party away from broad scientific evidence as well as public opinion on the subject of climate change. Together, Fox News’ and the Koch brothers’ influence has meant that candidates vying for the Republican nomination and eventually the US presidency may act in the service of corporate and corporate-controlled media power in order to meet their objectives. As such, productive public discourse on climate change – via media and elsewhere – suffers.

Over time, numerous researchers have explored how economic pressures and ownership structures have impacted news production (Carvalho 2005). Environmental journalism around the world is fraught with capacity challenges (in terms of time, personnel, and financial resources) to collectively cover complex and dynamic stories at the human–environment interface. Journalists, producers, and editors striving for fair and accurate reporting get swamped by these large-scale (macro) political economic pressures. Decreased mass media budgets for investigative journalism have adversely affected the communication of scientific information in that complex scientific material has often been oversimplified in media reports. Moreover, critical environmental issues have failed to garner coverage at all. In the name of efficiency, many reporters have increasingly covered a vast range of topics (called “beats”) under tighter deadlines, making it as difficult as ever to satisfactorily portray the complexities of environmental issues amid numerous demands. Moreover, content producers in publishing organizations that have withstood newsroom cuts and shortfalls have faced increased competition from other information platforms, especially from social media (video, audio, and text, along with blogs, Twitter, Facebook, Instagram, YouTube postings, etc.).

These numerous political economic challenges have damaged communication of environmental issues. For example, in many places in the Global
South, journalists often lack the capacity and training to cover the intricacies of environmental science, politics, and governance, as well as access to clear, timely, and understandable environment-related resources.

Other individual-scale (micro) factors include the mobilization and deployment of journalistic norms. The tendency to personalize stories means that coverage focuses on individual claim-makers and sensationalized stories, often subsuming deeper structural or institutional analyses. This connects to dramatization, where coverage of dramatic events tends to downplay more comprehensive analysis of the enduring problems, in favor of covering the surface-level movements. Novelty is important. Commonly, journalists mention the need for a novel “news hook” in order to translate an event into a story. These “new” things are actually novel ways of portraying or depicting already existing things, in the context of ongoing storylines and historicized or pre-existing norms and pressures. In tandem, journalistic valuations of drama, personalities, and novelty can serve to trivialize news content, as it can also lead to the blocking out of news that does not hold an immediate sense of excitement or controversy. However, pursuing these norms is not necessarily linked to reduced coverage.

An example of a dramatic, personalized, and novel event that generated tremendous news coverage is Hurricane Sandy, which struck the East Coast of the United States in late October 2012. Despite scientific uncertainty regarding links between hurricane intensity and anthropogenic climate change (see Figure 2), the event nonetheless spurred coverage focused on conflict and debate, and political actors as well as journalists pointed out that more has to be done in terms of disaster risk reduction, climate mitigation, and adaptation (Eilperin 2005).

In summary, media practices powerfully shape and negotiate meaning, influencing how citizens make sense of and value the world. Media representations thereby bridge different ways of knowing about the environment, and often mediate public perceptions, attitudes, perspectives, and behaviors related to environmental issues. This can have far-reaching consequences in terms of ongoing environmental scientific inquiry as well as policymaker perceptions, understanding, and potential decision-making. Media representations are at the same time shaped by framings, journalistic norms, and cultural politics of media economy that are inextricably linked with each other.

Going forward, the stronger convergence of traditional and new media means that we should rethink how or if media can still be considered as the democracy watchdog in times of digital turmoil. Climate change as a media topic has so far vividly illustrated how polarizing opinions from traditional media, and increasingly from new media beyond professional journalism, influence public perception and the agenda on the issue. It will therefore become more crucial for geographical research to consider and analyze future roles that various claim-makers have in the creation, maintenance, or silencing of discussions of environmental issues.

A priori, it is not clear why international trade should have a major environmental impact. The vast majority of pollution is generated at the point of producing and consuming goods and services. The transport of goods and services across country borders via trucks, trains, ships, or aircraft does generate air, water, noise, and other pollution, but it is relatively minor compared to total pollution levels. So why has there been so much activist, media, and academic attention on the environment and trade relationship? Key to understanding this is that, while the direct environmental impact of trade is small, there are myriad indirect effects which can be more significant. Analytically, it is useful to distinguish six effects of trade liberalization on the environment: scale, compositional, transport, static efficiency, dynamic efficiency, and governance effects.

Trade liberalization is supposed to boost the size of the economies participating in the liberalization, making people richer on average. In fact, this seems to be the main reason why policymakers sign up to relevant treaties. The scale effect could be static, that is, a one-off increase in economic size, or it could be dynamic, that is, increasing the growth rates of participating economies. Theoretically, the case for a sizable scale effect is well established since David Ricardo (1817) proposed the theory of comparative advantage, though some economists point out that, under special circumstances, trade liberalization may not only benefit some countries more than others but also positively harm some countries (Samuelson 2004). There is no consensus in the empirical literature on the size of the scale effect, however. In part this is because it is extremely difficult to establish the counterfactual, that is, what would have happened in the absence of trade liberalization. Inasmuch as there is a sizable scale effect, the impact on the environment is complex since the relationship between economic growth and the environment is complex. Some aspects of the environment seem to become better with higher per capita income (e.g., access to clean water and safe sanitation), while others become worse (e.g., carbon emissions). Some pollutants seem to follow an inverted U-shape with emissions first increasing with higher income up to a maximum point after which they tend to decrease again, a phenomenon known as the environmental Kuznets curve (see Neumayer (2013, 81–94) for a review of the theoretical and empirical literature on economic growth and the environment).

Trade liberalization impacts the compositional structure of participating economies. It typically spurs compositional changes already underway; for example, it allows postindustrial countries like Western developed countries to specialize even faster in the services sector since they can import manufactured goods from elsewhere. Mining and agriculturally oriented economies can specialize in this primary sector since liberalized trade allows them to sell their products in a bigger market. The environmental consequences are very much country-specific and a function of where in the process of compositional change a country is. Put simply, liberalized trade benefits the environment in countries that specialize
in the production of services since services are cleaner in production and manufactured goods, which are dirtier in production, are imported from elsewhere. Conversely, the massive increase in pollution in places like China and others is in part the consequence of a compositional change from agriculture to heavy industry and manufacturing, which in turn is partly spurred by trade liberalization allowing Chinese producers to sell their products globally rather than nationally. The environmental effects of countries specializing in agriculture will depend on the type of agriculture and whether it results in deforestation (e.g., palm oil plantations in Indonesia or soybean plantations and cattle farming in Brazil). The effects of countries specializing in mining are likely to be predominantly negative.

Understanding the transport effect is straightforward: more international trade requires more transport, which creates more emissions. Shipping is less environmentally intensive than moving goods via freight trains, which in turn is less intensive than trucking or flying cargo, but this direct effect of trade on the environment is unambiguously negative. The problem is exacerbated by the fact that often transport is either subsidized or any tax imposed on it is typically insufficient to cover the full environmental external cost.

All other things remaining equal, trade allows countries to specialize in the production of goods and services in which they have a comparative advantage, that is, that use factors of production intensively that are abundant in a country. This static efficiency effect should, on balance, have positive, if small, environmental consequences. For example, fewer chemical and energy inputs are needed to grow oranges in sunny climates than in gloomy and cold northern Europe. More generally, if goods and services are produced according to comparative advantage then no resources are wasted and no environmental pollution is created unnecessarily.

More important than static are dynamic efficiency effects of international trade. Producers in economies that are open toward trade can continue to produce profitably only if they operate at what economists call the production frontier, which implies that they need to keep up with the latest technological advances and to update their capital stock continually. Globally integrated markets also facilitate the more rapid diffusion of modern technologies to latecomers (Perkins and Neumayer 2005). Conversely, producers that are shielded by protectionist barriers can get away with hugely outdated capital stocks and technologies, as the experience of South America and India before the gradual opening of markets in the 1990s testifies. More modern capital stocks and the latest technologies tend to be less resource- and environmentally intensive. All other things being equal, this effect should therefore benefit the environment.

The effect of trade and trade liberalization on governance is perhaps the most complex of all the effects. First, environmentalists fear that trade liberalization takes away power from sovereign nation-states to enact strong environmental policies as these might clash with the obligation of countries to abide by “free trade” rules (Neumayer 2001, ch. 8). Much of this suspicion and criticism has been raised at the World Trade Organization (WTO) and its predecessor, the General Agreement on Tariffs and Trade (GATT), but similar fears have also been voiced with regards to the North Atlantic Free Trade Agreement (NAFTA) and other regional and bilateral free trade agreements. A related second fear is that free trade rules will inhibit countries from inserting trade measures into multilateral environmental agreements (Neumayer 2001, ch. 9). Third, environmentalists are concerned that trade liberalization will deter countries from
further raising their environmental standards out of fear that doing so will induce footloose capital to invest in other places with lower environmental standards—a phenomenon known as “regulatory chill” (Neumayer 2001, ch. 4). In the extreme, mobile capital would be drawn to countries with particularly lax environmental standards (so-called pollution havens), which may in turn force countries with higher standards to lower theirs in order to stay competitive—a phenomenon known as the “race to the bottom” (Daly 1993; Daly and Goodland 1994; Neumayer 2001, ch. 3; Eskeland and Harrison 2003; Clapp and Dauvergne 2011). Trade represents an important causal mechanism in this concern because it is liberalized trade that allows producers to take advantage of lower environmental standards in foreign places and yet export their products to places of higher environmental standards where consumers tend to be richer. It should be noted, however, that it is not legitimate to attribute lower environmental standards (or less enforced standards) to a deliberate intention to provide a pollution haven. Differences in existing amounts of environmental pollution, differences in the pollution absorptive capacity of environments, and differences in the intensity of environmental preferences can all cause differences in environmental standards between countries. Only where environmental standards are set inefficiently or suboptimally—where efficiency or the social optimum is defined as the level of pollution where the marginal social cost of pollution is equal to the marginal social benefit—or are deliberately not enforced in order to attract foreign capital is the charge justified. This is more likely to be the case in autocracies where free media and civil society groups are repressed, and in countries where polluting business groups can buy significant influence over the political process, such as in economies heavily dependent on fossil fuel extraction.

Of all the effects of trade and trade liberalization on the environment, the governance effect has probably attracted the most attention, particularly outside academia. As concerns the first fear, there is very little evidence that the WTO or other “free trade” institutions have actively restricted countries’ sovereign right to enact strong environmental regulations, as long as these are not aimed at process and production methods (PPMs) abroad, that is, as long as these do not aim at imposing trade sanctions on products imported from countries that produce these products in a way that is polluting or harmful to animals such as dolphins and sea turtles (Neumayer 2004; Charnovitz 2008). Where the adjudication panels of these organizations have ruled against a trade restrictive measure, it has typically been because the policy was not fairly and evenhandedly designed or applied, discriminating against foreign producers rather than imposing the same requirements on both domestic and foreign producers, or because the scientific basis for a health protection measure is thin (e.g., the European Union ban on beef imports from cows raised with growth hormones). That countries cannot, in general, impose their own environmental standards on the process and production methods outside their own jurisdiction may disappoint environmentalists, but this is not surprising: sovereign nation-states do not like to be told by other countries what to do within their own borders. Even here, however, WTO panels have allowed restrictive trade measures under stringent specified conditions, as the long-lasting WTO dispute between Southeast Asian countries and the United States, which imposed import bans on shrimp and shrimp products from Southeast Asian countries whose harvesting methods incidentally killed endangered sea turtles, testifies. Essentially, if the species meant to be protected by the import restriction is
endangered, the import-restricting country has shown good faith through efforts to negotiate a multilateral environmental agreement and has offered technical assistance and aid to exporters in a fair and nondiscriminatory manner, then trade restrictive measures aimed at PPMs abroad can be WTO-compliant. Moreover, countries are allowed to use labeling and similar measures to make consumers aware of different PPMs.

As concerns the second fear, anecdotal evidence seems to suggest that negotiation parties do worry about potential clashes of any considered trade measures in multilateral environmental agreements (MEAs). Those opposed to a MEA find it convenient to cite potential clashes with rules in trade treaties to buttress their opposition. However, there is no evidence that such worries are anything but marginal reasons why more MEAs do not exist and why any existing ones are not more ambitious. Rather, the lack of political will on the part of participating countries is to blame for that. One also has to keep in mind that several existing MEAs contain fairly strong trade-restrictive measures – for example, the Montreal Protocol and its amendments phasing out ozone-depleting substances, the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the first amendment to the Basel Convention that essentially bans trade in hazardous waste between developed and developing countries, the Rotterdam Convention which regulates industrial chemicals and pesticides, the Agreement on Persistent Organic Pollutants, and the Cartagena Protocol on Biosafety.

The fear that countries would engage in a race to the bottom in environmental regulation are certainly unfounded, as are similar concerns of a race to the bottom in the different area of labor standards. There is not much evidence that any high-standard countries have actually lowered their environmental standards as a response to trade liberalization. That foreign direct investment increasingly goes to low-standard developing countries and that the exports of these countries become increasingly pollution-intensive need not be a result of the pollution haven phenomenon but may be the consequence of shifting comparative advantage, compositional changes in the economies of countries, and the fact that economies of the developing world tend to grow faster than economies of the developed world, a phenomenon known as economic convergence. One also has to keep in mind that the share of costs spent on complying with environmental regulations are typically dwarfed by costs spent on labor and capital, such that the incentive to channel investment to a particular place is typically not dominated by environmental cost-saving considerations though these can additionally play a role.

The regulatory chill concern is not easily dismissed, however, and may well be a real and very significant effect. Corroborating empirical evidence is hard to come by since the concern makes a counterfactual argument, namely how countries would have raised their environmental standards further were it not for the fear of capital flight. Arguably, European Union countries may well have enacted stricter carbon reduction policies were it not for the concern that such stricter policies would drive both existing and, more importantly, new direct investments abroad into unregulated countries (Neumayer 2001, 69–71). Naturally, it is easier to channel new direct investment abroad than to try and relocate existing investments (direct investments consist of cross-border mergers and acquisitions or the setting up of new plants as opposed to the much more short-term and speculative portfolio equity investments). As the example of greenhouse gas emissions shows, unregulated countries posing a regulatory chill threat on regulating countries like the European Union countries can include
even developed countries like the United States, which in many ways provides an ideal substitute for foreign investors because of its similar political stability and economic conditions.

It would be wrong, however, to assume that trade and trade liberalization can only have negative effects on environmental governance. Liberalization in the trade of environmental pollution control technologies and environmental clean-up services will benefit the environment as will the reduction of environmentally damaging production subsidies that sometimes forms part of trade liberalization. The same might be true for the increased flow of information that typically accompanies trade liberalization: countries open toward foreign trade are typically open toward many things. Finally, countries exporting to high-standard countries may over time adopt the higher product standards of the foreign countries they export to; a phenomenon known as the trading-up effect (Vogel 1997). This is because exporters may lobby the domestic government to ratchet up domestic environmental standards since producing a single product for both home and export markets allows firms to benefit from greater economies of scale, and tightening domestic environmental product standards may grant exporters a commercial advantage over their home market competitors lacking the requisite compliance technologies by raising the latter’s relative costs. Additionally, governments may embrace regulatory tightening as part of a strategic industrial policy, raising domestic emission standards in order to increase the competitiveness of domestic firms in higher-regulating export markets. For economies of scale to kick in, the higher-regulating foreign country market should be significantly larger than the domestic market; for example, German car manufacturers’ exports to the higher-regulating United States market induced them to lobby the German government to raise domestic emission standards in the 1980s.

The trading-up effect points in the opposite direction of the pollution haven argument. Note, however, that any trading-up effect is likely to be restricted to product standards (e.g., the exhaust pipe emissions of cars) rather than process and production method standards (e.g., the environmental standards faced by a factory producing cars). For process and production method standards there could potentially be an investing-up effect as transnational corporations (TNCs) bring more environmentally advanced technologies with them and may lobby governments in countries in which they invest to ratchet up domestic environmental standards. TNCs often have access to environmentally superior technologies, which they may deploy to their foreign affiliates and subsidiaries in lower-regulating countries. This is because it may be costly to substantially re-engineer technologies to suit different environmental regulatory requirements and higher-profile TNCs can face criticism from civil society if they are seen to deploy environmentally inferior technologies in host countries (Zarsky 2008). In turn, the transfer of standardized, beyond-compliance technologies creates incentives for TNCs to lobby for the upward harmonization of environmental standards in order to ensure regulatory consistency across the different markets in which they operate. Higher emission standards are likely to be especially advantageous for TNCs because they help to remove one of the key competitive advantages enjoyed by indigenous manufacturers, that is, their ability to produce low-cost, albeit higher-polluting, products using vintage technology.

In sum, with multiple effects pointing in different directions and having different strengths for different pollutants and in different countries, no verdict is possible as to whether trade liberalization is unambiguously positive or negative for the environment. However, on balance, one can
be fairly confident that the overall effect is overwhelmingly negative. This is based on the plausible presumption that, in most countries and for most aspects of environmental degradation, environmental regulations are insufficiently stringent (they fail to fully internalize the environmental externalities) because of the larger lobbying and other political power of polluters. Environmental regulations are bound to be suboptimal, in particular, as relates to transboundary and global environmental pollutants, since the benefits of regulation have to be shared with others, whereas the costs are borne domestically. Given that environmental policies are suboptimal, trade liberalization will act like the equivalent of a fresh breeze of wind on a house that is already set on fire – it exacerbates the negative environmental consequences of suboptimal policies, predominantly because, with policies being suboptimal, the negative effect of increased transportation and scale as well as, depending on the country, compositional change will dominate any positive effect from static or dynamic efficiency. Liberalized trade in turn may render it more difficult to achieve more stringent environmental policies as policymakers shy away from enacting policies that move closer to the efficient level of environmental pollution, where environmental externalities are optimally internalized, for fear of their economies losing competitiveness and footloose capital moving elsewhere.

Even if trade and trade liberalization can be expected to often result in more environmental degradation due to suboptimal environmental policies in trading partners, it does not follow that trade restrictions are the best answer. In fact, the optimal solution comes from more efficient environmental policies and trade liberalization. Also, there are still many win–win situations, where measures could be taken that are good for both trade and the environment. For example, more progress could be made toward removing trade barriers that are detrimental to the environment as well as fishery, agricultural, energy, and transport subsidies and toward removing restrictions on trade in environmental goods and services such as air, water, and noise pollution abatement technologies, and waste management techniques.

More progress could also be made by “greening” the WTO as well as regional and bilateral trade agreements. However, particularly at the WTO level, the prospects for this are slim. While practically all developed countries are in favor of some greening – partly by conviction, partly as a result of pressure from civil society – developing countries do not trust the alleged idealistic intentions and suspect that the greening of WTO rules is old protectionism in a new environmental guise. Regional and bilateral agreements fare a bit better, but not much (Neumayer 2001, 190–193).

This impasse tempts some to call for unilateral action by powerful countries with high environmental standards, imposing trade restrictions on lower-standard countries (Daly 1993). Yet, such unilateral action is not only in violation of WTO and other free trade agreement rules. It also poses the danger of protectionism in green disguise, opening the floodgates for trade protectionists to capture the environmental agenda and further their own selfish material interest. Another problem is that, once the floodgates are opened for unilateral action for some aspect of animal welfare or environmental protection, there will no longer be any holding on the slippery slope toward widespread use of unilateral action, not least because of the support by protectionist groups. There are no limits to the well-meaning idealist in search of targets on which to impose unilateral sanctions. Unilateral action also poisons the international diplomatic climate and runs counter to the spirit
of cooperation, which is needed for multilateral environmental agreements. This leaves the environment between a rock and a hard place. Unilateral action may be more effective in the short run but is undesirable, whereas multilateral action is desirable but hard to achieve, particularly in the short run.

Environment and waste

University of Exeter, UK

Histories of “waste”

For many readers of this encyclopedia the notion of waste is a familiar one. Our lives are seemingly dominated by the accumulation of products and packaging, much of which contains the necessities of everyday life: the food we eat, the liquid we drink, the cosmetics we used to cleanse ourselves, and so the list goes on. Nearly all of these products and their packaging are based on the abundance of cheap and easily available raw materials that can be manufactured into packaging and, given their abundance, can be discarded without the apparent need for reuse or recycling. So it is that we live in what some popular commentators have referred to as the “throwaway society.” This society, or system, is defined by a linear process of material accumulation and discarding, rather than a circular one, in which materials are extracted, manufactured, used, reused, recycled, and used once again. It is the hallmark of contemporary living in most developed nations and is illustrative of a radical shift in our relationship with materials and the environment that provides such resources.

Identifying the point at which this system emerged is not easy, but we can note several key moments in history that have progressively nudged us toward our present position. Not surprisingly, the industrialization of society is an important pretext for the era of mass consumption that we experience now. The discovery of abundant resources and their effective exploitation and manufacture during much of the nineteenth and early twentieth centuries has created a sense that raw materials are unlikely to run out any time soon. Oil, for example, the staple which we use in the production of plastic goods, has become the “black gold” of consumer societies and has facilitated many of the major technological developments of our age.

Built upon this context of abundance, a number of economic and social trends can be identified that have formulated our current relationship to resources and our propensity to discard them after use. The first of these is the economic growth model that has been adopted in many developed nations during the twentieth century. This is founded on the principle of a consumption-based society in which much of the economic wealth is generated by the demand for consumer goods (anything from clothing and footwear to kitchen white goods to mobile phones and computers). A slump in consumer demand is one of the main precursors of economic recession and so nation states have for a long time now set in train policies that attempt to maintain economic growth by encouraging consumers to spend and to create employment that will provide them with the necessary disposable income to do so.

In line with this economic model, the growth of an enriched middle class in many developed (and now developing) nations has been closely associated with the important signs and symbols of what it means to be successful. There has been the rapid development of social norms and expectations surrounding the material culture of being middle class, affluent, and successful, which often requires conforming...
to social practices of consumption that are implicitly wasteful. Such practices include the regular replacement of consumer goods (such as clothing, motor cars, and kitchen products) for reasons of trend and fashion, the consumption of exotic food products (often flown in from abroad) and the over-provision of goods to meet social expectations.

Indeed, the development of wasteful practices in the form of over-consumption is something which contemporary living and working arrangements have afforded many of us to engage with all too readily. As societies have become progressively sub-urbanized and individualized, and as long as commutes and shifting family relationships have put pressure on personal time budgets, manufacturers and supermarkets have created opportunities for “easier” shopping for goods that can be kept longer and are more convenient. The days of shopping in specific stores for particular goods has now largely been replaced by visiting one supermarket and purchasing goods packaged in set (and often inappropriate) sizes. Such shifts in practices have resulted in rising volumes of packaging waste and, through the promotion of bulk buying, increases in food waste.

Finally, increasing health and safety regulations surrounding the preparation and storage of food have increased the volume and diversity of materials that are discarded. Outside of the domestic context, tighter regulations about food preparation and hygiene have often resulted in manufacturers using greater amount of materials to protect food, in particular when longer life is required from perishable products. Within the home, the progressive improvement in cleanliness standards afforded by household cleaning products and a general shift toward reducing the risks associated with harmful bacteria has led to an unwillingness to store compostable materials in spaces like kitchens. Indeed, much of the traditional infrastructure supporting waste management for households has now disappeared. For example, “rag and bone” collectors, farmers collecting food scraps for pig feed, and scrap merchants are now banished from neighborhoods, where once they provided a way of householders providing material for reuse or recycling.

In these varied but interlinked ways, our relationship with materials and their destiny has changed over the last century or so, resulting in a situation where many of the goods we purchase are not immediately reusable and where there is every incentive not to reuse or recycle, but to buy new products, with the associated social and cultural benefits associated with being a good consumer. Within this context, this entry now explores three different lenses through which to view waste and its environmental implications.

The political ecology of environment and waste

Understanding how we have arrived at the situation where we are regarded as such a wasteful society – and why this is so problematic – can only be partly appreciated by a historical narrative. There is an underlying question that we need to address, which is to examine why waste has become such a potent political problem and why, within an environmental context, it has become such an icon of environmental degradation in contemporary society.

To understand the role of waste within the environmental protection movement, we need to engage with the initial stirrings of environmental protestors and protagonists in the 1960s, responding to the work of authors like Rachel Carson (1962) and the scientific arguments of writers like Garrett Hardin (1968), both of whom argued that rates of materials exploitation and the impacts of industrialization on the environment...
were likely to have severe consequences. These popular scientific arguments were institutionalized in the Club of Rome’s (Meadows and Club of Rome 1972) report, *The Limits to Growth*, in which the combined factors of resource exploitation and resultant pollution would have the overall impact of population collapse, a thesis constructed on neo-Malthusian principles.

What such arguments did was to capture the attention of governments and in particular the United Nations, which, during the 1970s initiated a range of programs (including the World Environment Programme and the Man [sic] and the Biosphere Programme) (McCormick 1989). Within these initiatives, the United Nations highlighted the importance of conserving renewable resources, reducing the exploitation of and reliance on non-renewables and controlling waste. Accordingly, during the 1970s, the economic and social practices underlying the so-called throwaway society were explicitly recognized and responses began to be institutionalized in both developments in international law and national regulations.

Yet such developments at a global and national scale were founded on a political framework that was focused largely on the relationships between government and industry, which, in the 1960s and 1970s, were often closely intertwined through formal ownership or political interests. Indeed, the political philosophy of the time was one dominated by a top-down, regulatory regime, in which governments relied on the “hard” policy measures of legislation and public ownership to deliver political goals.

The consequence of this governmental regime was that although significant improvements were made in the production of materials and associated reductions in pollution emitted from industrial processes, the basic economic model on which the consumer society was founded did not change. Indeed, through political developments in the 1980s and 1990s, the role of consumption became even more influential. This process is often referred to as the neoliberalization of society and has placed a much greater emphasis on “soft” policy approaches for achieving governmental goals, such as the use of financial disincentives, incentives and, most notably when it comes to waste management, the application of exhortation as a way of managing the environment. Such political approaches place the individual consumer, rather than the state or industry, center stage in the process of achieving desired outcomes.

It is the political philosophy of neoliberalism that has enabled waste management to come to the fore in the way it has since the 1990s. As Clarke et al. (2007) have noted, the move to a system where individuals are simultaneously regarded as consumers (with the expectations associated with maintain economic growth through increased consumption) and citizens (responsible for exercising sound environmental stewardship) has created a hybridized “citizen-consumer” in which the goals of a neoliberal society can be achieved through a form of ecological modernization. In this way, consumption patterns can be maintained through the use of more efficient and intelligent technologies and materials can be recycled using highly mechanized and efficient processes.

Waste management through recycling has, therefore, become an icon of the ecologically modern society in which economic growth can be maintained and which relies on the goodwill of individuals to sort and specify materials for recycling. Indeed, it is notable that the priority for much of the recent decades has not been on reducing the need to waste nor indeed direct reuse (both of which run counter to a neoliberal economic framing), but rather the reliance on mechanized and industrialized processes of
remaking products through recycling. Such approaches exemplify the broader approach to environmental management in advanced Western societies, which is to find “smarter” ways of managing resources and maintaining consumption levels, with the expectation that individuals can make relatively minor adjustments in behaviors to achieve specific policy outcomes. Within this context, this entry will now move on to explore the academic perspectives on waste as an environmental issue, focusing on the increasingly important role of behavioral change.

Academic perspectives on waste

Although research on waste is implicitly interdisciplinary, there are two broad approaches that can be identified across the spectrum of academic subjects. In the first instance, waste has for a long time been regarded as a technical issue, related to the chemical and physical processes associated with managing materials and their production. In this way, materials engineering has been concerned with exploring the potential for creating products that can be efficiently recycled and remanufactured. Such approaches focus on product life cycles and reusability, as well as the application and development of universal processes for treating discarded materials, usually in mechanized materials reclamation facilities (MRFs).

However, from a geographical perspective, a second body of research has become focused on what we can term the social dimensions of recycling. Set across a range of disciplines, this research tradition focuses on the ways in which waste is defined, the waste management practices that lead to high levels of discarding and the factors that influence the development of such practices. Broadly termed “environmental social science,” there are a number of important and often sharp divisions in the approaches adopted by social scientists for understanding how individuals, communities, and businesses deal with waste.

The first perspective we can identify within environmental social science is dominated by an approach that has a tradition of working on waste and recycling from the 1970s and is characterized by studies of psychological factors influencing consumer choices. Research within social psychology has defined the waste “problem” as one firmly rooted in individual attitudes and resultant behaviors. In this way, reducing waste and promoting reuse and recycling is a function of individual decisions that need to be understood as a precursor to promoting shifts on behavior. Such research adopts a logical positivist perspective, in which the broad epistemological assumptions are that: existing models of behavior can be utilized and adopted to understand attitudes toward waste management; it is possible and desirable to measure attitudes and behaviors and to quantify these measurements through extensive research approaches; the key unit of measurement is the individual on whose psychology the outcome is based.

This epistemological tradition has therefore focused on the application of specific psychological models and frameworks to the waste problem. Although there are many frameworks that could be mentioned here, three are worthy of note. First, Fishbein and Ajzen’s (1975) theory of reasoned action has been adopted in numerous cases to examine the relationships between stated attitudes, social norms, behavioral intentions and reported behaviors. A second, and related, model is the theory of planned behavior (Ajzen 1991), which promotes the importance of “perceived behavioral control” as a predictor of behavioral intention. Finally, Schwartz’s (1977) norm activation theory has been used extensively to examine the ways in which social
norms become mobilized to promote or prevent specific behaviors.

Much of the research that utilizes a social-psychological perspective is concerned with identifying key factors that determine behavioral commitment and an example of this type of approach, although somewhat dated now, is Schultz, Oskamp, and Mainieri’s (1995) comprehensive meta-analysis of factors influencing recycling behavior. In this paper and in research published subsequently, scholars have highlighted key factors relating to situational or structural characteristics (such as demographic characteristics, access to services and facilities, and explicit knowledge and behavioral experience), psychological factors (such as social norms, perceptions of convenience, response efficacy, self-efficacy, and attitudes), and underlying social and environmental values (such as the propensity of individuals to express environmental concerns). Barr (2002) subsequently developed a framework for understanding the relationships between these key factors in a framework of pro-environmental behavior, which illustrates some of the complexities of the psychological approaches for identifying and characterizing waste behaviors.

It is without doubt that the majority of social science research on waste has been from this social-psychological perspective. However, since the late 1990s, there has been growing unease within other parts of social science at the apparently deterministic and objectivist approaches that characterize this kind of approach. Most notably, Owens’s (2000) critique of rationalistic perspectives on issues like waste management has spurred social scientists from disciplines like human geography and sociology to explore waste and other environmental practices from the perspective of interpretivist and intensive social science perspectives.

In a ground breaking study, Gregson, Metcalfe, and Crewe (2007) highlighted one of the key critiques of such deterministic approaches by highlighting the very understanding that many social scientists have of the term “waste.” Building on research from the Waste of the World project, they argue that problematizing “waste” is the wrong approach, because it simplifies how human societies relate to material possessions and the ways that they have done so over time. In particular, they argue that linear conceptions of materials entering the home context and leaving as worthless discards hides the complexity of households’ interaction with “things” – possessions which are differently valued and often reused, reclaimed, reformed and “ridded” within the home. At the heart of their argument is for researchers to recognize the relationship between what appears to be individual behavior and broader social practices, which are routine-driven and historically shaped acts shared by groups (households, communities, classes). This, they argue, enables a richer understanding of how particular ways of living and being become shaped across society and which are re-enforcing, making the process of behavioral change much harder.

The intellectual tradition underlying this second approach is epitomized by Shove’s (2010) call for a deeper understanding of social practices that are relevant to the environment. In this and her earlier work, she calls for a focus on the broader underpinnings of contemporary practices, which are intricately related to the economic system, driven by a consumer-based culture. In this way, the focus needs to be less on the environment and more on the factors that shape everyday practices. So, for example, one could use this approach to argue that our focus should be less on the factors that shape negative attitudes toward recycling as a specific act, but more on the influences that have led to “wasting” in contemporary society and the systems that promote increased consumption and......
the establishment of profligate resource use as a social norm.

Epistemologically, this approach utilizes intensive and qualitative research as a means to explore broad social phenomenon in particular contexts, resulting in deep and rich understandings of practices at particular times. As a result, such research is often based on methods that draw on ethnographic research traditions and which utilize grounded theory approaches, which focus on the depth and richness of research data as a pathway for building a theory from bottom up, rather than the imposition of an objectivist and theory-led perspective.

Whichever of these two broad traditions are followed in the social sciences, the emphasis has very much been on an appreciation of waste in social context. Yet there is a third strand of research within and beyond the academic context, which has sought to explore how change might be effected. It is to this policy context that this entry now turns.

Policy responses to the “waste problem”

The political interest in waste as an environmental problem has emerged in recent years as a potent force in local government decision-making and has, particularly in countries like the United Kingdom, been illustrative of many of the conflicts associated with the promotion of sustainable development. Indeed, studies from North America have illustrated the ways in which waste has become implicated in struggles for environmental justice in marginalized communities.

Many of the political drivers for focusing on waste as an environmental problem have been framed by supranational aspirations to attain certain environmental targets and achieve reductions in harmful carbon emissions, which contribute to anthropogenic climate change. For example, the UK’s recent moves to reduce waste going to landfill sites has largely been the result of European Union directives, which have set out ambitious climate change emissions reductions targets and, more specifically, reductions in certain wastes being sent to landfill sites. The impact of these directives has been to spur national and local governments into developing specific targets for waste diversion and recycling, and in the UK this has resulted in a number of strategies since the 1990s to promote change.

Waste policy has conventionally been formulated in a technocratic environment, where focus has been placed on resource efficiency and mechanized recycling. However, since the 1990s, there has been recognition that greater reliance needs to be placed on reducing the potential for waste arisings in the first place. Accordingly, many policy makers now work with what is generally termed the “waste hierarchy,” in which waste reduction and minimization are placed as the top priority. For those materials that are produced, the second preference is for reuse without the need for major energy input (for example, the resale of clothing or washable nappies). In cases where materials cannot be directly reused, mechanical recycling is the next preferred option, highlighting the role for household collections of recyclables. Finally, if certain products cannot be recycled, the use of waste to produce energy, or “energy from waste,” is the preferred option. It is only when these options are exhausted that waste should be directed to landfill.

Within this framework, policy options have largely followed the political framework that was outlined earlier in this entry. In this way, softer policy options have included encouragement for both producers and consumers to reduce their reliance on packaging and to promote both reuse and recycling. In reality, this has resulted in
a series of voluntary codes of conduct for manufacturers to ensure that materials can, where possible, be recycled and that labeling reflects this. Nonetheless, most policy focus has been on the role of consumers in promoting recycling. Indeed, the way in which this has been achieved is through a very particular framing of consumer engagement that has focused on the need for behavioral change.

Within nations like the United States, Canada, and the UK, promoting behavioral change has been rolled out through programs that have drawn largely on the social-psychological tradition of focusing on the ways in which individuals can be persuaded to change their behaviors. Although policies have traditionally focused on approaches that try to fill the “deficit” in perceived consumer knowledge about recycling, there is broad recognition that there is often a discrepancy between stated attitudes toward recycling and behavioral commitments. This so-called value-action gap has been identified among many policy makers as a key priority and one of the ways in which practitioners are seeking to address this problem is to use approaches from market research to explore how consumers can be engaged to recycle more of their waste. Referred to as “social marketing” (Peattie and Peattie 2009), this approach utilizes the commercial marketing principles of audience segmentation, marketing mixes and setting specific behavioral goals to promote a social (or environmental) good and has been widely applied in health promotion campaigns. Essentially, the principle underlying social marketing is that messages and interventions to change behaviors need to be positive and easy to adopt.

Critically, social marketing is concerned with advocating change within existing consumption frameworks and as such needs to adopt the logic of choice (rather than compulsion) to engage consumers. In this way, it is closely related to a recent theoretical and pragmatic development from the United States, known as Nudge (Thaler and Sunstein 2008). Nudge theory asserts that changing behavior requires alteration of the “choice architecture” surrounding people as they make decisions and in the context of waste management, this would refer to the structures in which recycling behaviors operate, such as waste collection systems and infrastructure and the architectures within domestic settings that promote or prevent change.

The use of social marketing and nudge theory is not without controversy and for many social scientists and critics of instrumentalist policy making, these kinds of intervention are designed to be overly prescriptive and to crowd out alternative and more creative ways of reducing waste. In this way, critics argue that such approaches perpetuate the consumer-based society that has created the waste problem that we are now seeking to deal with.

This concern, which is driven by a different social and environmental ethic, has also been reflected in wider commentaries of the political ecology of waste systems within specific policy contexts. For example, in North America, much of the literature centered on environmental justice has emphasized the ways in which underlying social and economic inequalities can be reflected in and perpetuated by the politics of waste. Pellow’s (2002) compelling account of what his term “garbage wars” in Chicago illustrates are the ways in which established political systems can reinforce inequalities by continually marginalizing communities through the siting and out-working of waste infrastructures, such as MRFs. Put simply, Pellow explores why it is the case that black and minority ethnic communities are more likely to have an MRF situated in their neighborhood and why this often leads to exploitation and environmental injustice.
Waste in emerging economies

Although this entry has largely focused on the role of waste management and recycling within developed world contexts, there have been significant changes in the ways that developing economies have tackled the issue of waste arisings, especially in emerging economies where a growing middle class has greater access to consumer goods. Castillo Berthier (1983) examined the relationship between rapid growth in a transitioning economy and the increase in municipal waste. As the author noted 20 years on, when reflecting on the impact of his work (Castillo Berthier 2003), two key trends have emerged in emerging economies as they seek to deal with the environmental consequences of waste. First, increasing levels of formal household waste collection gradually replace informal ways of dealing with materials at the local level. In so doing, local authorities introduce mechanized and progressively more technical ways of removing and treating wastes, thus replacing previously vibrant and often essential informal economies of exchange for materials within neighborhoods. The enhanced role of the local state in managing waste is rationalized in part by the need to provide greater levels of environmental health and normally results in waste being removed to large municipal dumps and landfill sites on the edges of cities. However, as Castillo Berthier (2003) and Wilson, Velis, and Cheeseman (2006) highlight, the creation of major waste dumps has created new informal economies of scavenging and exchange that have shifted such economic practices away from neighborhoods toward landfill sites. In this way, an informal sector has emerged for creating value out of the growing number of consumer items discarded by growing numbers of middle class households.

Although the emergence of new and informal forms of economic exchange have followed state-led attempts to effectively manage waste, there are concerns in some developing economies that such practices can have negative impacts on the environment and human health. Indeed, several notable and high profile cases have emerged in recent years in China, which have highlighted the health impacts of unregulated recycling of products, many of which have been sent for recycling by developed nations and which have been processed in dangerous and often toxic conditions. Such examples serve to highlight that although waste is often dealt with in the localities in which it is produced, there is a growing globalization of waste and recycling that often means the “problem” of unwanted materials becomes one that is “out of sight and out of mind.”

Conclusion

Waste is both a contested and problematic term in social science and geographers have contributed a great deal to the understanding of how human societies have come to relate to and deal with materials that transform from having value to becoming value-less. Much of the focus of recent research has been on how to reach specific environmental targets associated with the diversion of waste from landfill and to increase recycling rates. Yet there are disagreements within social science about the most effective way to understand how practice of waste management develop and the ways in which researchers can use such understandings to inform and influence policy. Indeed, the ways in which waste is defined and managed are politically implicated, with a strong focus on soft policy approaches for attaining environmental goals. In conclusion, waste is a topic that is both academically and politically
complex and reflects the often stark differences in opinion about how we should manage the environment for future generations.

To the casual observer, towns and cities around the world often appear as heavily degraded environments. Open rubbish dumps, palls of smog, long lines of traffic, and dirty bodies of water all contribute to the common perception that urban areas are causing environmental problems. But the relationship between urbanization and the environment is far more complex than this. Many of the most significant environmental consequences of urbanization are felt far outside city boundaries, whether in river basins that have been affected by water extraction to meet the needs of towns and cities or at the scale of global climate change driven by emissions from (and associated with) city activities. At the same time, while the concentration of settlement, industry, and infrastructure in urban areas may result in localized pressures on the environment, towns and cities have the potential to generate significant environmental achievements through economies of scale and agglomeration, through being sites of innovation of new responses to environmental challenges, and through acting as leaders to other cities and countries.

This entry reviews the evolving ways in which the relationship between the environment and urbanization has been understood and addressed in empirical and policy-oriented circles, while making some reference to more theoretical approaches. It does this through describing the characteristic environmental challenges facing cities, assessing recent policy efforts to address these, and describing some of the trends in academic thought that have engaged with these processes. It closes by identifying some of the key current and emerging issues that seem likely to influence the relationship between the environment and urbanization in the coming years and decades.

The extent and nature of urban environmental challenges

One key starting point for understanding the relationship between the environment and urbanization is to look at global patterns of urbanization. In 1950 only 29.4% of the world’s population (or 745.5 million people) lived in urban areas – by 2010 that had increased to 51.6% (3.56 billion people), and by 2050 it is expected to rise to 67.2% (6.25 billion). It is not only the global proportion of urban residents that has changed significantly, but also the distribution of these across continents. In 1950 14.4% of Africans (or 33.0 million people) lived in towns and cities – this had grown to 39.2% (400.7 million people) in 2010; for Asia the 1950 figures are 17.5% (245.1 million people) and the 2010 figures 44.4% (1.85 billion people). Any conclusions about the effects of urbanization on the environment should therefore deal increasingly with how this is played out in the towns and cities of the Global South (all figures UN DESA 2012).

A second starting point is to frame the significant environmental issues related to urbanization at different scales. Cities occupy only a small
amount of the world’s land area – approximately 2.8%, according to the Millennium Ecosystems Assessment (McGranahan and Marcotullio 2005) – and many of the environmental impacts of urbanization are concentrated within city boundaries. This is particularly true of the direct activities that take place in urban centers: the use of water, the production of sewage and solid waste, and the generation of air pollution. But, as cities become more successful and wealthier, many of these immediate impacts on the environment are reduced – through improved sanitation and solid waste management, through regulations that improve local water and air quality, and through the movement of “dirty” industry to locations with cheaper land and labor and less stringent regulations. But cities that appear “clean” on the surface may exert even more considerable environmental impacts at a global scale: while increased affluence can help to remove many local problems, it is associated with higher consumption of energy, goods, and services which has the potential for greater negative impacts on global environments and ecosystems.

Taken together, the increasing scale of urbanization and the increasing reach of environmental problems generated by towns and cities force a re-examination of the relationship between the environment and urbanization. This can no longer be seen simply as the observed environmental changes within municipal boundaries, but rather needs to be considered as the way in which activities in urban centers shape natural systems both in and far beyond their immediate surroundings. These impacts are frequently negative but, as cities increasingly demonstrate leadership in policies and practices relating to the environment, there is also considerable opportunity for positive outcomes.

Urban programs to address environmental concerns

Many of the key issues and debates about the relationship between urbanization and the environment focus on how different levels of wealth and poverty shape this. Several sets of ideas developed during the 1980s and 1990s explain this in different ways – sometimes at the level of the individual or community (the local environmental consequences of urbanization), sometimes at the level of the city (and how particular cities function), and sometimes at a global level (the way in which cities address one set of environmental challenges while making contributions to another).

Perhaps the most significant linkages between the environment and development in recent decades emerged in the wake of the United Nations Conference on Environment and Development (the 1992 Rio Earth Summit), much of which was reflected for the urban context through Local Agenda 21. Various planning guides, including a highly influential publication from the International Council for Local Environmental Initiatives (now ICLEI – Local Governments for Sustainability) (ICLEI 1996), were produced and implemented to various extents in hundreds of cities around the world. Other international programs initiated in this period included the Sustainable Cities Programme (UNEP and UN–Habitat), Localizing Agenda 21 (UN–Habitat) as well as several bilaterally funded programs (e.g., Danida’s Green Cities program), while many countries also developed their own versions of Local Agenda 21 to support their local authorities in addressing the new sustainable development agenda. Each of these had their particular features, but all attempted to include a concern for the environment and sustainability into urban planning, and to include civil society and the private sector.
in the planning process. Many of them also fell under the broader banner of “green urbanism” or “sustainable cities.”

These urban concerns for global environmental issues were sometimes criticized for prioritizing newly emerging ecologically oriented concerns over the long-standing environmental health and pollution problems that were still prevalent in many cities in low- and middle-income countries, and for lacking sufficient relevance to low-income groups. An alternative approach that also achieved prominence in the 1990s was to categorize environmental concerns in urban areas as being part of either a “green” or a “brown” agenda. The green agenda represents a more traditionally environmentalist approach to assessing the environmental consequences of urbanization – highlighting the impacts of urban areas on ecosystem health on a regional and global scale. In contrast, the brown agenda emphasizes not only local air and water pollution, but also the effects of environmental problems on low-income groups within cities (Table 1).

However, the “green” and “brown” agenda approach unnecessarily polarizes a set of environmental priorities that can be dealt with more effectively in tandem. This can be seen particularly in the emerging issue of climate change, in which the more “global” concern of mitigation (reducing the atmospheric concentration of greenhouse gases) directly shapes the extent to which adaptation (adjusting to moderate the harm of actual or expected changes in the climate) will be necessary at the “local” level. At the same time, however, by highlighting the environmental burdens of poverty, engagement with the brown agenda contributed significantly to keeping these issues in the realm of research and urban policy. A more sophisticated approach to these different dimensions of urban environmental challenges is the model of urban environmental transitions, which posits that, as cities become wealthier, the environmental benefits that they generate are gradually displaced (McGranahan and Marcotullio 2005) – from being primarily experienced at the local level (particularly inadequate access to water and sanitation, associated with informal settlements) to the city-regional scale (particularly air and water pollution associated with rapid industrialization) to the global scale (greenhouse gas emissions and high levels of resource consumption).

Integrated approaches to environmental management in urban areas lost momentum in the 2000s to more issue-specific approaches (such as water and sanitation, or climate change). While many of them had been successful at generating dialogues about how environmental issues should be addressed in urban centers, they had made fewer inroads in shaping the flows of investment that significantly influence the environmental futures of cities. In addition, they were often perceived of as being externally driven by “environmental” actors – while city officials were more concerned with more developmental social agendas or with attracting external investment. More recently, City Development Strategies (widely supported by the World Bank and Cities Alliance) have encouraged integrated, participatory, and sustainable approaches to planning that recognize the pressures that economic growth places on the environment while simultaneously offering opportunities for resource efficiency. However, neither Local Agenda 21 and its associated programs nor the City Development Strategies has explicitly engaged with the underlying issues of the urban political economy (Dodman, McGranahan, and Dalal-Clayton 2013).

Research trends on urbanization and the environment

In contrast to this, much research and academic analysis of the relationship between urbanization and the environment has taken a more strikingly radical approach. Political economists began to consider environmental concerns seriously, and to break the nature/society dichotomy – starting with Neil Smith’s analysis of *Uneven Development* (2008/1984), and reaching its apogee with the two influential volumes on society and nature by Noel Castree and Bruce Braun (Braun and Castree 1998; Castree and Braun 2001). These ideas were consciously absorbed and developed by urban scholars including David Harvey, who recognized that “the distinction between environment as commonly understood and the built, social and political-economic environment is artificial and that the urban and everything that goes into it is as much a part of the solution as it is a contributing factor to ecological difficulties” (Harvey 1996, 435; emphasis original). By the early 2000s, urban political ecology had become a recognizable field of academic endeavor, bringing together analysis of “the power-laden socioecological relations that shape the formation of urban environments” with a political program to achieve “a more equitable distribution of social power and a more inclusive mode of environmental production” (Swyngedouw and Heynen 2003, 898).

Some of the first research that explicitly adopted urban political ecology approaches and terminology involved detailed examination of the politics of water supply and distribution in Latin America (Swyngedouw, Kaika, and Castro 2002; Swyngedouw 2004) and southern Europe (Kaika 2005), as well as broader examinations of urban environmental processes and politics in Toronto, Los Angeles (Keil and Desfor 2004) and New York City (Gandy 2002). By 2003 there had been sufficient work under this general banner to warrant a series of “progress reports” (Keil 2003; 2005) – an effort that has recently been revisited (Heynen 2013). In this report, Heynen (2013, 2–3) lists a range of “vectors” that have been used to interrogate urban political ecology during the intervening years, ranging from air pollution, urban forests, gentrification, gardens, and waterfront transformations. He further suggests that more recent research aligned with the broad project of urban political ecology has moved from “resource domains” into “more traditional urban geographic themes” – although
much of this does retain an explicitly Marxist orientation (Loftus 2012).

A more policy-engaged and practically oriented stream of work on this topic is also represented in the journal *Environment and Urbanization*, first published in 1989. The publication has an explicit intent to fill a perceived gap in the coverage of urban issues in Africa, Asia, and Latin America, and has two sister journals (*Medio Ambiente y Urbanizacion*, with a focus on Latin America, and *Environment and Urbanization Asia*) which engage more directly with particular geographical regions. In recent years, a growing number of titles have sought to cover this area, including (but by no means limited to) *Local Environment* and the *International Journal of Urban Sustainable Development*.

The more general description of relationships between urbanization and the environment has become less of a research focus in recent years, with work tending to focus either on specific issues (such as climate change) or on some of the emerging themes discussed later in the entry (such as the urban green economy). The second half of this entry attempts to identify current issues and trends in environment and urbanization. Some of these (particularly around unmet basic needs) are residual agendas which, despite decades of attention, are yet to be resolved, while others (particularly the urban green economy) anticipate what may become key concerns in coming years.

**Current and emerging issues**

**Unmet basic environmental needs**

Despite the wide range of policies and programs mentioned earlier, many of the most basic local environmental needs remain unmet for residents of urban areas in the Global South. The United Nations Water Conference in 1977 declared 1981–1990 the International Drinking Water Decade, with the aim of ensuring universal access to clean drinking water; yet, by the time the Millennium Development Goals (MDGs) were declared, this commitment had been diluted to only halving the proportion of people without access to improved sources of water. Despite some progress in this area, 2.5 billion people in developing countries still lack access to improved sanitation facilities, and 768 million people remain without access to an improved source of drinking water. Similarly, many urban residents in low- and middle-income countries remain in a state of food insecurity. In urban areas this is primarily a challenge of access to and affordability of food rather than an issue of agricultural productivity. Whether this is seen as an environmental issue in cities is very much a matter of definitions, but it is a critical component of wellbeing for hundreds of millions of city dwellers. These examples of water, sanitation, and food illustrate that many of the issues that have long been seen as central to local environmental improvement in urban areas remain critical – indeed, they are frequently reframed as “rights” issues – and require ongoing research and policy attention even as new agendas are developed.

**Urban green economy**

One of the most significant emerging policy discourses linking environment and development concerns is that of the green economy. This is increasingly applied to urban contexts – indeed, a chapter of UNEP’s significant report *Towards a Green Economy* was dedicated to this (Rode and Burnett 2011). While there is not a single coherent definition for an urban green economy, most of the definitions build on the local environmental concerns identified earlier, but with an explicit effort to explain how these can be achieved through particular forms of economic activity. An urban green economy will
therefore contribute to cities achieving lower levels of pollution and carbon emissions, lower energy and water consumption, improved water quality, lower waste volumes, higher recycling rates, greater areas of green space, and reduced amounts, of agricultural land loss.

Advocates for urban green economies see the potential for these to simultaneously address economic development, poverty, and environmental improvement – including in low-income cities. For example, Simon (2012) argues that this can be achieved in African urban areas through the creation of “green jobs,” environmental rehabilitation that can enhance ecosystem services, expanding access to energy through greening energy supplies, recycling initiatives that reduce the amount of solid waste while providing employment, and greening urban areas.

Cities are also seen as being important sites for driving the green economy more generally. Rode and Burnett (2011) suggest that this is the case for three key reasons:

1. the proximity, density, and variety intrinsic to cities deliver productivity benefits for companies and help stimulate innovation;
2. green industries are dominated by service activity – such as public transport and energy provision, installation, and repair – which tends to be concentrated in urban areas where consumer markets are largest;
3. some cities will also develop high-tech green manufacturing clusters in or close to urban cores, drawing on knowledge and skill spillovers from universities and research labs.

Many of these principles are also evident in the discourses of transition towns and resource efficiency, which link some of the ideas of the green economy with responses to climate change. Transition towns originated in the United Kingdom, but have now spread to over 300 communities in the United States, Australia, Japan, and Chile; yet the diverse range of communities and interests found in the urban arena means that the underlying principles of resilience and self-sufficiency have been challenging to achieve (A. Smith 2010). Resource Efficient Cities is an approach championed by the United Nations Environment Programme (UNEP) which aims to reduce the total environmental impact of the production and consumption of goods and services in order to achieve financial savings and reduce pollution levels – while simultaneously opening up opportunities for the expansion of services to underprovided groups within the city. In contrasting ways, these two approaches address the concerns of the overuse of resources in urban areas, and similarly link this to broader economic concerns around affordability and competitiveness.

Cities and climate change

The release of the Fifth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC) in 2013 and 2014 has been paralleled by a growing focus on the role of cities in contributing to and responding to climate change. One strand of research and practice focuses on the role of urban areas in generating greenhouse gas emissions and the potential of cities to reduce these. Some of this analysis has attempted to quantify the relative “responsibility” of cities for greenhouse gas emissions (e.g., Hoornweg, Sugar, and Trejos Gomez 2011), while another focus has been on the governance relationships that can contribute to their reduction (e.g., Bulkeley and Castán Broto 2013). In the arena of policy and practice, there have been considerable efforts to develop city-based greenhouse gas inventories that mirror the “measurable, reportable and verifiable” characteristics
required for nation-states under the United Nations Framework Convention on Climate Change, such as the carbon climate change registry (http://carbonn.org/) under which (as of April 2016) more than 600 reporting entities in more than 60 document and report their emissions.

The IPCC Fifth Assessment was the first version of this report with a dedicated chapter assessing the impacts of, vulnerability, and adaptation to climate change in urban areas (Revi et al. 2014) (the Fourth Assessment had addressed this in the broader sense of “Industry, Settlement and Society”). In contrast to the previous assessment which highlighted the vulnerability of cities, there is growing research and reflection on specific measures that are being taken by cities to reduce risk. Many of these have been carried out under the framework of “resilience” (Tyler and Moench 2012) or “transformation” (Pelling 2010), recognizing that, for the rapidly growing urban centers in the Global South, maintaining existing functions in the face of an uncertain climate is an insufficiently ambitious goal.

Key frameworks for understanding mitigation and adaptation in cities include focusing on the role of different stakeholders and governance arrangements. However – in common with the analyses of other environmental problems in cities – much of this has not engaged explicitly with power relations and political dynamics, and how they shape the vulnerability of cities or their ability to contribute to solving climate change.

Urban governance, global leadership, and the environment

The ways in which city governments function have also evolved substantially over recent decades, at the same time as the urban environmental agenda has become increasingly prominent. This is encapsulated in the shift from “government” to “governance,” which has been reflected by city governments becoming increasingly purchasers rather than providers of services. To an extent, this has removed some of the potential for direct action on the environment by municipal authorities by reducing the amount of control that they may have over waste management or other environmental services. At the same time, however, this has encouraged a new wave of entrepreneurial action, with cities actively competing to attract external investment – and environmental improvements or leadership can be one component of this.

Cities and city leaders have become increasingly vocal about the role of urban areas in engaging with global concerns, including those related to the environment. While environmental treaties remain the domain of the nation-state, groups of mayors and cities have coordinated their voices and actions to demonstrate leadership in this area. Significant efforts include those coordinated by ICLEI – Local Governments for Sustainability and C40 Cities Climate Leadership Group. In contrast to the international environment and urbanization agendas of the 1990s, these are driven in a more endogenous manner, and seek to use the mobilizing power of cities to encourage other cities to engage with environmental issues, and to demonstrate potential areas for action to national governments.

Conclusion

Scholarship and practice in recent years have significantly shifted perceptions on two key issues relating to the environment and urbanization. First, the environment and the urban environment are no longer seen as being distinct but as being closely related to each other. Second, towns and cities are recognized as not only
harming the environment but as representing significant opportunities for engaging with some of the most substantial global environmental challenges. As the world’s urban population continues to increase – indeed, almost all net population growth in the coming decades will be in towns and cities in the Global South – the environmental agenda will of necessity have to continue and deepen engagement with urban concerns. Equally, the decisions that are made and the actions that take place in urban areas will be the main features shaping the future of the global environment.

The continued growth of urban areas, and the ongoing (and in many cases worsening) environmental problems they face, mean that linking research to policy and practice in this area is increasingly important. At the same time, urban residents in many places have become increasingly involved in planning, managing budgets, and setting priorities for their cities through the opening up of urban governance systems and efforts to foster broader citizen participation. The potential – perhaps even need – therefore exists for greater coproduction of strategies and responses to address environmental challenges in towns and cities, particularly in the Global South. As urban political ecology and sustained political engagement have both shown, this can be achieved only through simultaneously engaging with the social relations and inequality that cause different groups to gain and lose from contestations over the urban environment.

Environment, democracy, and public participation

Patrick Devine-Wright
University of Exeter, UK

Introduction

Public participation can be broadly defined as the ways that the public are enrolled into procedures of policy formulation and decision-making on environmental issues. Over the past 20 years, public participation has become a cornerstone of many different sectors of policy and decision-making, encompassing the environment and sustainable development, science and technology, spatial planning, and more recently climate change. The United Nations-led Aarhus convention introduced a legal commitment upon individual states to enable public access to environmental information, participation in environmental decision-making, and access to justice on environmental matters. To date, it has been ratified by 46 countries, chiefly in Central Asia and Europe (United Nations 2014).

Public participation is related to a broader term – public engagement – that encompasses diverse methods of educating the public (e.g., awareness raising campaigns), consulting and involving the public (e.g., through surveys or deliberative discussions) as well as engagement by the public (e.g., petition signing or protest activities) (Walker et al. 2010). Advocacy for greater public participation stems from several opinions. First, it is based upon positively valuing lay knowledge, seeking to bring this into formal procedures of decision-making or policy formulation. This positive valuation also critiques public engagement that is undertaken to remedy a presumed “information deficit” or lack of knowledge held by the public about environmental problems (Owens 2000). Second, advocacy for public participation can be based upon a lack of public trust in the role of experts or concerns about the legitimacy of expert contributions to environmental decision-making (Collins and Evans 2003).

Types of public participation and engagement

Rowe and Frewer (2000) distinguish three types of engagement activities: communication, consultation, and participation. These differ by the flow of information occurring between the parties and by significance in the policy or decision-making process. Communication is the most basic type, involving one-way information flow from the “sponsor” (typically a government organization or private company) to the public. In this context, the public are simply informed of policymaking or planning decisions with no power to influence these. Consultation involves two-way information flow between “sponsor” and the public, but the information flows back without any dialogue. Participation involves a two-way exchange of information between sponsor and public with the possibility for transformed opinions in both parties. This typology builds upon the classic framework proposed by Arnstein (1969) involving a ladder of public participation from “manipulation” at the bottom to “citizen control” at the top. Participation is
often regarded as the optimal form of public engagement since it provides participants with a greater degree of influence or control by comparison with communication or consultation that can be viewed as tokenistic or manipulative.

Multiple rationales for public engagement

Public participation can occur for many reasons. The literature identifies three predominant rationales or motivations: substantive, normative, and instrumental (Stirling 2005). The substantive rationale means that public participation is undertaken because it is believed to improve the quality of policy formulation or decision-making. This links to the valuing of lay knowledge mentioned above. The normative rationale for public participation is the view that involving members of the public should be undertaken because it is the right thing to do, for example, in a democracy it can be thought right and proper to seek citizens’ views before making decisions on their behalf. Finally, an instrumental rationale means that public participation is undertaken because it is believed to increase the likelihood of achieving a predetermined goal, for example, to promote greater social acceptance of a specific policy. This is based upon the presumption that the public will be more likely to accept certain policies or planning decisions if they are invited to participate in formulating those. Attempts to engage with the public for the purpose of dispelling ignorance and misunderstanding – most common under the instrumental rationale – may therefore presume that this will then lead to greater social acceptance (or at least less opposition) to policies or decisions. By contrast, the substantive rationale presumes that lay knowledge is a valuable resource that can be usefully incorporated into decision-making procedures, particularly those involving scientific and technological innovation associated with uncertain or risky outcomes.

Normative and substantive rationales for public participation are central to the concepts of sustainable development and sustainable communities. These rationales claim that citizens in a democratic political system should be empowered to participate in decision-making processes, that resulting decisions are better quality, that citizens’ consent and trust can be gained in addition to fostering change to attitudes and behaviors. Policymakers have emphasized the value of inclusive engagement strategies that aim to secure input from marginalized or vulnerable social groups on the grounds of equity, fairness, and justice, and promoting community involvement in local planning decisions. Thus a sustainability perspective would generally opt to “open-up” discussions on policy or planning (Stirling 2005) by means of participatory, two-way mechanisms of public engagement (see the Rowe and Frewer typology above), rather than “close-down” debate through the use of one-way mechanisms of communication.

Recognizing these diverse rationales for public participation in environmental policy and decision-making is important, since a single participatory initiative may be delivered or supported by organizations holding quite different rationales which, left implicit, can create tensions and difficulties. At minimum, it suggests the value of a critical approach to rhetorics of democracy or public participation in environmental decision-making propagated by powerful actors.

Methods and timing of participation and engagement

Methods of public participation and engagement are multiple and varied, including:
one-way information provision (e.g., leaflets, posters, newspaper adverts, and web-based materials);

two-way consultation (e.g., public exhibitions where the public can learn about proposals and register their opinions about it, phone lines, and questionnaires);

deliberation (e.g., citizens panels or juries where individuals have more time to learn about the issues at stake, to question experts, and to discuss potential outcomes).

In the United Kingdom, the National Consumer Council (NCC 2008) considered deliberative engagement valuable for improving public services, social cohesion, and democracy. An engagement process was defined as deliberation if it (a) involves discussion between participants; (b) involves a range (diversity) of people and information sources; and (c) has a clear task or purpose relating to, for example, a policy or project question or topic.

Three main types of deliberative public engagement are currently used in the United Kingdom:

- deliberative research, which builds on market research techniques (e.g., national citizens’ summits and policy consultations);
- deliberative dialogue, which builds on dialogue and consensus-building techniques, to develop an agreed view or set of recommendations (e.g., national dialogues on science and technology); and
- deliberative decision-making, which builds on partnership methodologies to enable participants and decision-makers to decide jointly on priorities and programs (e.g., participatory budgeting exercises) (NCC 2008).

Each of these forms of deliberative public engagement has been practiced in relation to environmental policies and decision-making. Both deliberative research and dialogues have been used to inform policymaking (e.g., a citizens’ summit to inform development of the Climate Change Bill in the UK).

The principles that should be applied when practicing deliberative public engagement are that the process (i) makes a difference; (ii) is transparent; (iii) has integrity; (iv) is tailored to circumstances; (v) involves the right number and right types of people; (vi) treats participants with respect; (vii) gives priority to participants’ discussions; (viii) is reviewed and evaluated to improve practice; and (ix) participants are kept informed (NCC 2008, 6).

The timing of engagement with the public is important in determining how it is perceived and responded to, and what opportunities are open to affected groups (e.g., communities in a locality) to materially influence the issues at stake. “Upstream” engagement implies actions taken to engage with communities at an early stage of project development; “downstream” engagement implies engagement taken at a later stage where little opportunity to substantially revise proposals may exist. There is considerable advocacy for “upstream” public engagement – for example, of communities affected by planning decisions – yet there is also some concern among academics that this will continue to be problematic unless differences in power and status between developers and communities is addressed. Upstream engagement is also challenging in contexts of emergent technologies where there may be very low levels of public awareness and knowledge. In such contexts, what works when engaging the public will have to be tailored to the specific technology, and more deliberative methods of engagement are especially useful to solicit informed opinions and judgments from public participants.
Imaginary publics, rationales, and methods of engagement

The siting of low carbon energy technologies is one area of environmental policy where public participation has been strongly encouraged, often from an instrumental perspective of lessening “NIMBY” (Not In My Back Yard) conflicts with local communities. Research has shown that energy companies typically conceive the public as emotional individuals that are deficient in technical knowledge (Cotton and Devine-Wright 2012), leading to engagement by “communication” (Rowe and Frewer 2000) that aims to undermine “myths” about certain technologies and address public concerns. Such ways of thinking lead to the use of certain engagement methods (e.g., exhibitions, internet communication, and focus groups) and the avoidance of others (e.g., public meetings), in order to diffuse and render invisible conflicts between companies and residents (Barnett et al. 2012). As a result, opportunities for two-way dialogue and the empowerment of communities are overlooked.

Evaluating public participation in environmental decision-making

Although judging the quality of public participation is far from an easy task, in principle such judgments refer to the quality of the inputs (e.g., information provided), processes (e.g., how participatory procedures are organized), and the outcomes or outputs produced. Rowe and Frewer (2000) identified a set of generic criteria for judging the quality of participatory processes, distinguishing criteria for public acceptance and good process. Public acceptance criteria included:

- the representativeness of the participants and their views;
- independence – participation should be practiced in an independent, unbiased manner;
- early public involvement – as soon as value judgments became important with regard to the issue under question;
- influence – where the output of the procedure genuinely impacted on policy; and
- transparency – for both involved and interested parties.

Process criteria comprise resource accessibility, including information, and time to enable the public to achieve objectives; and task definition, which refers to how well specified or defined the tasks for participation are with regard to the scope of the exercise, its expected outcome/s, and mechanisms of procedure. In addition, participation in decision-making requires mechanisms for structuring and displaying the decision-making process (for example, flow-charts or pictures), efficiency and transparency of process and documentation of process.

On the value of public participation in the environmental domain

One of the most comprehensive reviews conducted on the role and value of public participation in the environmental domain was conducted by a panel convened by the US National Research Council (Dietz and Stern 2008). The review was based upon a series of workshops, meetings, and working papers that sought to integrate both academic and practitioner expertise, and to analyze empirical evidence of processes of public participation and relevant social science theories and concepts including governance, conflict resolution, risk
perception, group processes, and public understanding of science. The principles advocated by the authors were drawn from a broad range of environmental domains including pollution, forestry, watershed management, and climate change.

The review argued that public participation should be judged on three criteria: improving the quality of assessments and decisions, enhancing their legitimacy among those involved and potentially affected, and increasing understanding and decision-making capacity among all those involved. The three criteria (quality, legitimacy, and capacity) may also be used to evaluate public participation in environmental assessment and decision-making; in particular, they suggest the following indicators of success.

- **Quality**: public concerns are addressed, more information is considered and innovative ideas generated, outputs reflect a broad view of the situation, conclusions reflect best available evidence;
- **Legitimacy**: mistrust among participants is reduced, participants accept the decision process as fair even if they do not agree with the recommendations for action;
- **Capacity**: participants (including scientists) are better informed about environmental (or related) issues and gain a better understanding of each other, organizers and participants develop skills in participatory decision-making.

The evidence for the effects of public participation was examined, drawing upon practitioners’ experiences with dispute resolution, planning and environmental assessment, and upon empirical studies (single and multicase studies, experimental and quasi-experimental research) of environmental public participation processes. They concluded that public participation does improve decision-making along the three dimensions of quality, legitimacy, and capacity. Not only this, the evidence shows that these criteria are positively correlated: processes that enhance decision quality simultaneously tend to improve legitimacy and enhance capacity. Thus, there need not be a trade-off between making “better” and “more acceptable” decisions.

The review also presents key principles for effectively managing and organizing public participation in the environmental domain and for integrating science within this process. A well-managed participatory process is defined as having a clear purpose, adequate resources, commitment from those involved to support the process and take the results seriously, and a focus on learning and implementation. Five key attributes were identified: breadth, intensity, openness of design, influence, and integration of science. In terms of breadth, a more successful process is based upon the involvement of a full spectrum of both interested and affected parties. Intensity refers to the length of time participants spend in the process and particularly the amount of face-to-face contact: in general, there is a positive association between intensity and desired results, but this can depend on the particular context or aims of the process. Influence and openness of design are closely related concepts, and imply collaborative problem formulation, transparency of process, and good faith communication, all of which improve the success of decision-making processes.

In terms of the optimal timing of public participation, involving participants early in the process is beneficial for a number of reasons. It allows for collaboration in problem formulation and option generation and the “frames” or lenses through which new information is interpreted and are co-constructed to reflect the broad values of all participants (not only the agency or sponsor organizing the process). Integrating public views
from the outset improves the substantive quality of decision-making (by illuminating the problem from a range of perspectives) but also enhances its legitimacy by representing a range of interests, which in turn means the public is more likely to see the process as fair and accept its outcomes. From an instrumental perspective, early involvement tends to avoid trouble later on whereby participants seek to express their concerns outside the participation process (for example, through litigation or protest). Finally, there should be iteration between analysis and deliberation, so that participants shape the focus of scientific analyses and in turn able to evaluate (as in an extended peer review) and use that technical information in their decision-making. From this perspective, public engagement is not merely an add-on to scientific investigation; rather, the authors argue that integration of science and public deliberation is mutually beneficial.

The review addresses why public participation sometimes fails to produce expected instrumental, substantive, or normative outcomes, and identified several challenges that must be overcome to deliver a successful participatory process. The review does not conclude that there are any environmental issues or problems, in principle, that are not amenable to participatory engagement. However, it does recognize that the more complex, uncertain, invisible, or remote an issue, the more difficult it will be to implement participatory processes effectively and successfully, and climate change was identified as an example of an issue that posed challenges of this kind.

To this end, two categories of challenges are identified: issue-related and people-related. Inclusive participation is harder to achieve with global scale issues, where everyone is potentially affected, or in cases where there are disparities in power or resources (e.g., finances, time, education). Similarly, motivation to participate is likely to be lower where a problem is intangible or invisible. Scientific uncertainty and complexity may also make decisions more difficult to agree upon. However, the authors concluded that these challenges are not insurmountable. For example, the participation of geographically dispersed communities may be facilitated by convening online participation or workshops in multiple locations. Incentives to participate in the form of assistance grants and the use of collaborative design requiring participants to work together help to address inequalities in power or status. Formally characterizing uncertainty and seeking to communicate in plain language may help when the scientific evidence is uncertain or complex.

The review concludes by noting the deficiency of the evidence based on public participation. In particular, the authors advocate the development of a “science” of public participation that seeks to purposefully experiment with different aspects and methods of participation to better identify how best they should be designed and evaluated. They are critical of the current research because of a preponderance of single case study analyses, and a dearth of experimental designs.

Problematising public participation

Skeptics of the increasing use of public participation have claimed that it rarely leads to the empowerment of participants as is often presumed. Cooke and Kothari (2001) denigrated a “tyranny of participation” in which the involvement of the public has become little more than a box-ticking exercise, formulaically conceived and delivered, with minimal chance to achieve lasting change. Hindmarsh and Matthews (2009) decried the use of “deliberative speak” in Australia, where public participation was paid lip service in contexts of renewable energy planning
and decision-making. Without a genuine attempt to involve communities in order to build consensus about where wind farms should be sited, a situation of “placation” was diagnosed, echoing Arnstein’s judgment of “tokenistic” participation (Hindmarsh and Matthews 2009). Moreover, use of the very concept of “the public” (as well as related terms such as “individuals,” “households,” or “communities”) can easily lead to overtly homogeneous conceptions of the people targeted by specific engagement initiatives, underplaying their diversity and overlooking marginalized social groups.

These tensions between seeking to enhance and deepen public participation on the one hand and, on the other, to reduce it to a shallow, formulaic approach that leaves power relations or environmental competencies undisturbed are increasingly prevalent and discussed in the literature. Recent UK planning law has been said to simultaneously centralize power and to localize participation. The publication by government of national policy statements has provided a backdrop that strongly supports low carbon energy generation, making it difficult in principle to oppose certain forms of low carbon energy. Local authorities no longer make decisions about major energy projects (e.g., wind farms over 50 MW); instead decisions are made by the Secretary of State, without the need for locally based planning tribunals. Concurrently, the Localism Bill (2011) proposed the devolution of powers to local communities, including the retention of a proportion of business rates at the local level, amidst rhetoric of a “Big Society” that extols the virtues of volunteerism, communitarianism, and local empowerment. Yet such rhetoric has been criticized for being undermined by other policies to reduce local funding or to centralize decision-making.

Increasing efforts are being made to “marketize” aspects of environmental planning and local impacts of development projects in particular through the provision of “community benefits packages” that are distributed by project developers to locally affected residents in an effort to redistribute the costs and benefits of development. Whether local impacts (e.g., landscape change) can or should be equated with a monetary value has been strongly queried and may inflame rather than reduce public objections. For example, it has been shown that offering a financial incentive can reduce the moral motivation to support specific goals (Walter 2012). Such packages are just one example of attempts to supplement traditional hierarchies of environmental decision-making with numerous additional “instruments” that involve information provision, communication, and incentives in order to better ensure the delivery of national policies at the local level.

Environment, democracy, and public participation beyond national boundaries: the case of climate engineering

While much of this discussion has been oriented toward national policies and local development projects (e.g., wind farms) as important environmental domains for public participation and deliberation, these present only a partial picture of the contexts of environmental decision-making unfolding in the twenty-first century. Given the globalization of economic, cultural, social, and political processes over the past few decades, it is pertinent to “upscale” this discussion with reference to a challenge that goes beyond any particular local or national interests – climate change. In particular, the emerging possibility of large-scale, intentional modification of the Earth’s climate in order to prevent harmful impacts of increasing greenhouse gas
emissions raises profound and complex social, moral, legal, and ethical uncertainties that are beyond issues of technical feasibility. Of relevance is the question of how such modification should be governed and how democratic and participatory principles can inform both the research and potential implementation of climate engineering in a just and legitimate manner.

Aside from whether suitable institutional structures exist at the global level to govern climate engineering, efforts to encourage public participation on this subject will face significant challenges, including the fact that this is an emerging set of technologies with low levels of public awareness. Given this, methods of engagement such as public dialogue are more suitable than questionnaire surveys, for example, since they allow the possibility to both raise awareness and solicit informed responses from participants. Two studies applying deliberative methods have been carried out involving the structured presentation of factual information on climate engineering to small samples of the public (Pidgeon et al. 2013; Macnaghten and Szerszynski 2013). These studies suggest a position of “qualified” or conditional acceptance in which support for small-scale research does not correlate with support for large-scale deployment, as well as strong concerns about the virtue of “interference with nature,” issues of reversibility, and control. Furthermore, informing the public regarding more critical discourses, including past attempts to shape weather and climate and allowing deliberative discussions of the implications, led to a lessening of support for research (Macnaghten and Szerszynski, 2013). This demonstrates the significance of “framing effects” in public deliberations: public acceptance of climate engineering will be influenced by how it is presented, what issues or technologies it is associated with, and so forth.

While these studies are a useful start, the fact that both were conducted in the United Kingdom shows a clear limitation in terms of geographical scope – there is a dearth of social science research on climate engineering conducted outside of developed country contexts. But specific forms of climate engineering (e.g., ocean iron acidification) raise questions about who should participate and how they might do so. Who are the affected public that should be engaged with regarding either research or actual deployment of such techniques in a context such as the Pacific Ocean? And what mechanisms could be employed to enable their engagement? This is an important issue since physical science modeling of the potential impacts of climate engineering shows the possibility of negative climate impacts on other global regions; for example, research has found that releasing aerosols into the atmosphere in the Northern Hemisphere (a technique known as solar radiation management) could lead to drought in Sahelian regions of Africa. It is unsurprising, then, that research on climate engineering has revealed public concerns about the potential for international conflict following unilateral actions by nation states, together with skepticism concerning the ability of national governments and international institutions to effectively govern interventions such as solar radiation management in light of stuttering progress on climate mitigation (Macnaghten and Szerszynski, 2013).

It is also evident that new mechanisms – likely involving the use of Internet and digital media that can enable the participation of both larger and more diverse samples of the public – will be required to feed into and inform future efforts to govern climate engineering at the supranational scale. One exemplar that
could be followed is “World Wide Views,” an initiative that emerged from methods of technology assessment developed in Denmark and which has been implemented on environmental issues such as global warming (see http://www.wwviews.org/). The deliberation on global warming involved 4400 participants from 38 countries. Although it was successful in involving and collating the opinions of citizens at an unprecedented scale, it raises many challenges, such as the method and scope of evaluation, sample representativeness (e.g., both China, with a population of 1.3 billion and St Lucia, with a population 161 000, each had roughly 100 participants), standardization across diverse economic, political, and cultural contexts, and a lack of country-level information. It is also costly – the tentative budget for an envisaged 2015 global deliberation on energy and climate is 7.2 million euros, with the aim of enabling participation of a total of 10 000 individuals in 100 countries. Nevertheless, as an experiment, it does point to ways that future public deliberations on global scale environmental problems and potential solutions to these problems might be implemented.

Environment, nation, and “race”

Lisa Palmer
University of Melbourne, Australia

The intertwined concepts of environment, nation, and “race” have long fascinated and preoccupied geographers. As a trio of concepts, their historical contingencies and interrelationships provide critical insights into geography’s core disciplinary concerns of place, social and cultural transformation, and human–nature relations. Always being negotiated as a result of social and political change and power, the inherent instability of ideas of environment, nation, and “race” remain central to twenty-first-century processes of environmental governance.

Writing nature, controlling environments

The first geographers, loosely defined as those who sought to write about the world (geo = earth, graphy = description), were travelers and explorers like Herodotus, Marco Polo, Columbus, and perhaps most famously the lettered entourage accompanying the eighteenth-century “scientific expeditions” of James Cook. Handmaidens of empire, the men who followed set out to describe, catalog, and order new nature and new peoples for an attentive and knowledge-hungry European public, fashioning the world less through imperial plunder and more through what Pratt (1992) refers to as a scientific “anti-conquest,” or the hegemonic possession of other people and places through the ideas and gaze of objective science. This period between the mid-eighteenth and the late-nineteenth centuries was the triumph of an empirical naturalism which produced systematic accounts of nature and humans (Pratt 1992). Meanwhile, the early nineteenth-century accounts of the German geographer Alexander von Humboldt, and his enormously influential South American travel accounts of “wild and gigantic nature,” introduced the European public to an entirely new style of nature discourse to narrate the science of the natural world. Humboldt’s writings, which fused science with the Romantic literary tradition, conjured up “a dramatic, extraordinary nature, a spectacle capable of overwhelming human knowledge and understanding” (Pratt 1992, 120). His accounts stimulated an interest in travel among many other artists and naturalists, most notably Charles Darwin, and legions of other men who set out to document and describe the environments and peoples they encountered in these new worlds. By their contributions to “knowledge,” they also enabled the possession of immense territories, fertile abodes awaiting the imprint of “civilized” man.

This modern scientific inquiry and method expounded by Enlightenment thinkers influenced the responses of explorers to the non-European peoples they encountered (Thomas 1994). Whereas the period up to Columbus had identified the peoples of other lands as “barbarians,” this was not a difference certified on racial or national grounds. Rather, the distinction was drawn on religious grounds, in comparison with Christianity, where there was always the possibility that the “barbarians” would be converted. However, modern ideas “entailed
new models for constructing otherness; these were couched in a narrative of natural history rather than salvation and privileged distinctiveness in character and physique rather than faith” (Thomas 1994, 77). Gradually, through the investigation of scientists and others, Europeans became aware of factors of physical and social differentiation between people, and this awareness corresponded with the emergence of the organizing idea of race.

In the late nineteenth century social Darwinists decreed that Darwin's theory of natural selection also applied to the social and political realms. This led to the emergence over time of another key geographical concept, that of environmental determinism or the idea that the “environment” has a dominant or controlling effect over human characteristics and society. This idea justified the dominance of imperial powers over colonized regions as a result of their own superior environmentally conditioned racial characteristics. Colonial underdevelopment and the moral backwardness of local populations could, it was hypothesized, be overcome via colonial improvement to these physical and social landscapes.

Meanwhile in Europe, the ascendancy of the concept of the nation-state in the sixteenth century saw the meaning of landscape (Landschaft), understood until then as the commonplaces of “a polity’s area of activity,” gradually change to mean scenic spaces unified under the single body politic of the nation-state (Olwig 2002). By the nineteenth century the doctrine of the nation-state excluded recognition of alternative traditions of governance and sovereignty, including the customary polities of those encountered in the new world who had their own relationships with and configurations of landscape. This positivist legal doctrine of civilized nations became the primary intellectual instrument of nineteenth-century colonialism, and up to today the nation-state remains the normative model for the recognition of sovereignty in global politics.

In the 1970s, reflecting on geography’s complicity in imperial discourse and in the colonial disciplinary machinery, human geographers began to critically address the historically contingent imaginings, impact, and continuing import of the intertwined concepts of environment, nation, and “race.” Out of the postcolonial concern to theorize ongoing processes of neocolonialism emerged powerful geographical critiques of empire, nature, and cultural difference (see Postcolonial geographies). In the vast “emptiness” of the settler nations of Australia, the Americas, and Africa these geographers and other cultural theorists argued that landscapes remained colonized as much by settler national imaginaries of “nature” and “culture” as by legal and political institutions. Material possession was shown to be conjoined with powerfully wondrous, subliminal, and Romantic colonial discourses and images. These tropes of Romantic redemptive nature and noble savages were, moreover, shown to still permeate the imaginaries of a new breed of late twentieth-century nature-loving activists and “explorers.”

“Race,” nation, and primordial nature

As a part of the cultural turn in socio–nature studies, geographers increasingly paid critical attention to the lingering effects of the Enlightenment and the associated Romantic othering of nature and primitives, to the production of the idea of natural landscapes and environments, and eventually to a critique of settler tropes such as wilderness. They interrogated the ways in which the changing value of land and human labor under industrial capitalism in the eighteenth-century European “home” environment saw an emergent
ideological appreciation of wild lands. As the moral order of society, configured as the domain of social relations, was displaced by an alienated and “unnatural” economic order, the idea emerged that if morality was to be discovered it must be in “pure” nature, where human society had not intervened. A central part of the English celebration of national pride was shown to have developed in the late eighteenth century through the English Romantic poets, for example Wordsworth, who venerated the landscape of the Lake District, and the picturesque rural idyll combined with a mountainous wild nature. In the United States, geographers developed the thesis that a Romantic appreciation of nature was an integral part of the forging of national identity, and natural vast landscapes known as “wilderness” became a dominant imprint of (white) national identity on the American mind. These Romantically venerated environments in Europe, the Americas, Australia, and elsewhere became something to be seen and appreciated by vista-seeking tourists, a process Matless terms “a pilgrimage of scenery” (1995, 107).

Writing from the edge of empire, Jacobs argued that in the twentieth century, particularly in the West, nature became a sought-after commodity: “Part of the legacy of the cocktail of Enlightenment thinking and the transition to capitalism was the invention of ‘external,’ ‘primordial’ Nature” (1996, 135). By the end of the century this fantasy of the primordial was played out through capitalism’s appropriation and mediation of nature in the discourses of conservation, sustainability, tourism, and environmentalism (see Environmental discourse). In this popular reality, nature and associated images of wilderness landscapes were treated by capitalist cultures as a commodity that was both good for people and good for business. Capitalism created objectivist categories, such as primordial nature, and encouraged the culturally naive acceptance of an objective or reified world existing outside social relationships.

Within the global capitalist imaginary, images of nature and of primitive peoples continue to be subjected to a process of ideological mystification that Marx called “the fetishism of commodities.” Postcolonial geographers and others have shown how settler nation-states have drawn on such reified “natural” assets as unique flora, fauna, and landscapes, as well as emblematic images of “first peoples,” to provide their nation with a sense of national antiquity, purity, and distinctiveness. These now highly valued “indigenous” attributes have become central to new environmental moralities which view the presence of introduced species (and nontraditional practices) in wilderness as mongrelizing the environment. In contrast, many writers have documented the ways in which indigenous peoples embrace this transformed ecology in their “wilderness” homelands, understanding introduced species as coming to “belong” through social relationships and historical contingency. At the same time, settler societies in their new environmentalist guise have been shown to place such ideological value on pristine environments that they are “reluctant to grapple with the conceptual demands and responsibilities of new ecosystems, couching many environmental debates in terms of returning things to a previous state” (Head 2000, 231). As nature is valued in its “primordial” state, so, too are indigenous peoples valued in their primordial state as “timeless” hunters and gatherers who speak “authentically” for the unique landscape of the nation. These voices are, however, authorized to speak (politically and culturally) only from outside of history and preferably in translation. In this process of translation, others have shown how “indigeneity” is made and remade over and over in a process of intertextual dialogue, imagination, representation, and interpretation (Langton 1993). These dialogues,
drawing on the colonizing acts of explorers and pioneers, reconstitute the fetish of indigeneity in the contemporary preservationist ethos of the environment movement. As Jacobs argued, this discourse of primordial nature cemented its “othering” by placing indigenous people back in First Nature as the First People of the world who were “then reabsorbed into a global chronology of planetary survival, which begins with ‘them’ but ends with an environmentally sound ‘us’” (Jacobs 1996, 137).

“Race,” nation, and environmental governance

By the late twentieth century, environmental governance in the (neo)liberal public sphere of nation-states was critiqued as underpinned by the powerful effects of a racialized and naturalized concept of nature, what Braun (1997) termed a “culture of nature.” In such Western scientific commonsense categories of “nature” and “resources,” natural landscapes were shown to be an empty space to be accounted for, and the authority of Western science became the basis for moral and political ideas and practices of resource use and conservation. In this schema indigenous and local people’s concepts of nature (replete with integrated social systems) linked with local cultural and political contexts were (and are) displaced in favor of the authority of the “nation” or the “public” to speak for and manage an unmediated nature (Braun 1997). This managerial Western culture of nature underpinned by science and the “anti-conquest” came to constitute the “commonsense” view of environmental governance. Recognition of “culture” in such “natural environments” was ceded only as an exotic overlay on a universal and pre-existing nature.

In settler societies such as Canada and Australia, despite legal regimes which seek to recognize indigenous property rights, the pervasiveness of this “culture of nature” continues to impede the recognition of indigenous regimes of social and environmental governance and indigenous peoples’ full participation in local, regional, and national natural resource management regimes. Simultaneously, as many geographers have noted, the ongoing reification and racialization of indigenous “subsistence” communities in such contexts creates them as naturalized prepolitical and pre-economic spaces excluded from the politics of governance and the full recognition of their economic rights.

Others have argued that since the late twentieth century an emerging multiscalar values-based politics has resulted in the rise of civil society and nonstate actors who are actively challenging the nation-state’s dominance on issues of governance and sovereignty, particularly in relation to environmental issues. Governance, they argue, is now less linked to territorial control. Yet, as other scholars have noted, many indigenous peoples continue to construct their worlds around vibrant socio-natures and deep relationships with particular places. Such relationships to place are configured through a politics of unique eco-social rights and responsibilities enacted in a multitude of dynamic, practical, and creative ways. The continued observance of many indigenous peoples to socioterritorial forms of political formation challenges both the ideology of the nation-state and the democratic ideals of an emerging multiscalar (nonplace-centered) civil society.

In this sense, a range of theoretical contributions have elucidated the political inadequacy of democratic projects that seek to merely create spaces of recognition and inclusion for indigenous peoples within existing nation-state and local-level environmental governance arrangements. In contrast to such inclusionary social justice models, these theorists argue that more
thoroughgoing political engagements are needed to refashion the norms and principles of existing environmental governance arrangements. Especially in the context of postcolonial settler societies, geographers have highlighted the importance of understanding so-called natural environments as political, as embedded in social relations. This body of research shows that indigenous peoples’ relations with place and nonhuman nature are not only expressions of deeply felt attachment to particular environments, nor are they relics of a conservative, closed, and parochial past; rather, these relations are shown to be central to the constitution of dynamic and engaged indigenous lifeworlds. It is argued that it is only because of postcolonial contexts of unequal symbolic and economic power that the formation of distinct fixed identity boundaries such as indigenous/nonindigenous has emerged as a necessary political strategy for cultural and economic survival (see Ethnicity).

Others have argued that, viewed from the perspective of diverse societies, liberal, nationalist and communitarian theories of modern constitutionalism serve to reinforce the hegemony of the European nation-state tradition, giving only the appearance of constituting diversity. As a result of these failures, Borrows (2002), in his book on the resurgence of Indigenous law in Canada, considered the need for refashioning the underlying principles and normative features of the Canadian Federation. He argues that a limited settler conception of the jurisdictions of indigenous polities has contributed to the failure of the settler state to fully incorporate indigenous governments as active and meaningful participants in the Canadian Federation, and suggests that a useful starting point in the process of creating a shared and multidimensional citizenship would be for non-Aboriginal Canadians to recognize and incorporate the indigenous notion of “landed citizenship” wherein “the land is animate and perceived as having rights and obligations in its relations with humankind” (Borrows 2002, 146). Arguing that for indigenous peoples the politics of place-making is based on the need to recognize and negotiate relationships with significant others including nonhuman nature, Borrows writes that Aboriginal people’s values where the land is concerned “could to be entrenched in Canada’s governing ideas and institutions” (2002, 146).

Indeed, as many geographers have shown, it is often through environmental governance issues that indigenous peoples are starting to refashion their stake in the governing ideas and institutions of regional, provincial, and national polities. As these institutions of the nation-state engage in a new multiscalar and values-based cultural politics, risk and opportunity abound for indigenous peoples. These new spaces of environmental governance can enable productive encounters between diverse political actors, creating places where indigenous peoples can begin to engage in conversations about their rights and ways in which these rights can reconfigure the whole. In contrast to the suppression of indigenous peoples’ moral and political subjectivities in state-centric environmental governance arrangements, these more open environmental governance approaches signify a political moment for new arrangements of power to be created.

Critical ecologies and socio-natural difference

With the ascendancy of new environmental governance processes, the concepts of environment, nation, and “race” are also perpetually in motion, responding to and reasserting themselves in the light of historical contingency. Meanwhile, a new critical ecologies literature works to denaturalize both the environmental
ENVIRONMENT, NATION, AND “RACE”

governance project and nature itself. Given the increasing recognition that to naturalize “nature” is to paralyze politics, in these new multinatural configurations of “nature,” geographers have begun revisiting the cultural turn in socio-nature studies (Lorimer 2012). They seek to weave its key ideas into a plurality of socioecological worlds and to explore the diverse ways of being (ontology) and knowing (epistemology) which frame environmental governance possibilities. Going beyond conventional Marxist notions of political ecology (underpinned by a concern to interrogate matters of political economy as they relate to natural resource use), these critical ecologists are interested in “the multiple trajectories along which any ecology might evolve and the various ways in which they can be sensed, valued and contested” (Lorimer 2012, 594). Many of these writers are concerned with the question of “what it means to be and become human today, in dynamic relationship with non-human worlds” (Sullivan 2009, 24). Such a question is profoundly connected, as Kay Anderson (2008) has shown, to the history of the idea of race. As well as moments for asserting racial rule and Enlightenment othering, colonial encounters with nature and the racialization of aboriginal peoples in places like Australia were critical to the ways in which European classificatory schemas grappled uneasily with ideas and assertions of humans as nature-transcending and as distinct from the nonhuman world (Anderson 2008).

Wishing to bring the new posthumanist critical ecologies literature into conversation with practices of environmental science and governance in the Anthropocene, Lorimer (2012) proposes the necessity of developing new biogeographies through an engagement with critiques of nature which are sensitized to nonhuman difference and to ontological politics and frictions. The aim, he argues, must be to think beyond the preservationist species presentism, or steady statism of biodiversity conservation and the social and economic distributive justice concerns of political ecology to include accounts of the agency of nonhuman nature. At the same time, in order to sustain critical attention on the politics of human difference, Lorimer acknowledges that there is a need to retain the “sophisticated understandings … of political and regulatory contexts” developed in the work of political ecologists and others (2012, 606).

Taking up the challenge of tracing an ontological politics, Lorimer writes that emerging multinatural geographies are concerned with the posthumanist ways in which context-specific forms of ethical and political action and responsibility produce “respect for the radical alterity and unpredictability of organisms, their ecologies and the multiple constituencies who have a stake in their conduct” (2012, 604). His discussion explores the way that an emerging posthumanist ethics strives to recognize a concern for “flourishing,” even seeking in the tradition of ecocentricism to hold firm to a distinction between the human and nonhuman as an ethical space of action. Yet, in this new critical ecological sensitivity to diverse ontologies, we are also cautioned to remember that specific ontologies are not theories of an imagined world but specific ways of enacting and bringing a world into being. As such, in their search for new social and political imaginaries, social studies of science theorists and others from geography and anthropology have argued that theories of ontological pluralism are the praxis for radically decolonizing thought.

While the new critical ecologies literature clearly breaks with past deployments of the intertwined concepts of environment, nation, and “race,” posthumanist thought often has little to say about existing forms of human and nonhuman sociality within alternative and long established forms of property relations. While
foregrounding the importance of nonhuman agency reconceptualizes both nature and the environment as a part of an ethical constituency, it also risks recreating a homely universal nature that has little to say about socio-natural configurations wherein nonhuman agency and property already link together humans and nonhumans in specific rights-based configurations. For example, in their ethics and politics of recognizing nonhuman presence and agency, many indigenous groups already have clearly defined rights-based pathways for communicating with and relating to nonhuman nature. As such, newer understandings of posthumanism propounded by the critical ecologies literature need to be integrated with careful ethnographic work which draws out in a place-specific sense what forms and trajectories of difference matter, who decides, on what grounds and through what processes (Lorimer 2012). As we look to the future, it is also clear that we need to look to the past and carefully understand the present to ask questions about the impact and beneficiaries of different multinatural futures.

New environmental governance possibilities

The approaches of the critical ecologies literature raise important questions as well for how nation-states and transnational conservation organizations recognize rights to “speak for” nature. Here, more than ever, others have argued that it is how we engage in relations that is critical to the reconfiguration of historical concepts of environment, nation, and “race.” In spite of the formal reserve focus of global conservation and environmental governance, most “protected areas” in the world are not a formal part of the global protected areas network; rather, they are areas which have long been managed and conserved by indigenous and local peoples. Tallied up, these community conserved areas would exceed the size of the total area of formal protected area reserve globally (Stevens 2014). While community-based natural resource management has now long been trialed by an array of international conservation and environmental governance initiatives, there have been very mixed results. According to Stevens (2014), the failure of these processes to generate success in the area of conservation (and their linked agenda of development) is because these programs are mostly concerned with incentivizing people to follow the conservation agenda of others and lack a lexicon of keywords to transform lingering colonial relations, including “justice,” “rights,” “equity,” “collective tenure,” “restitution,” “self-governance,” “cultural integrity,” and “indigenous knowledge” (Stevens 2014). Escaping from the legacy of its racial origins, twenty-first-century global conservation policy has at least now shifted toward a recognition of community-controlled nature conservation which has at its core a rights and social justice agenda. While this change was brought about by the skillful political intervention of indigenous peoples themselves, there is, according to Stevens, still much “political work ahead” (2014, 80).

As others show, the insidious history of colonial relations is such that emerging environmental governance regimes are often (unthinkingly) reinstating past practices of domination and control over racialized others. Baldwin (2009) has coined the term “carbon nullius” in his consideration of the implications of apolitical and ahistorical approaches to climate mitigation in Canada’s boreal forest. He argues that emerging carbon sequestration discourses and practices have manipulated concepts of “race,” nation, and environment, enacting “a political geography of racial difference, one that seeks to
accommodate an imagined mode of traditional aboriginal life to the exigencies of global climate change mitigation and, importantly, to a logic of global capital now well into its ecological phase” (Baldwin 2009, 231). Examining this shift to market-based environmentalism and the continued centrality of forests to the global environmental imaginary, Baldwin’s work draws out the ways in which racialized understandings of nature and its others inform national responses to climate change mitigation through an engagement with new capitalist logics such as carbon markets. He shows how, as Canada’s boreal forests enter global carbon markets as carbon reservoirs and wilderness zones, Indigenous peoples and their practices of environmental governance are alternatively elided as absent or contorted through a veil of managerial environmental governance which cedes them a history but not a politics or an economic stake. He writes that the “imperial racism of terra nullius [the empty land] is re-enacted at the very moment the space in question is reordered through a discourse of climate change, carbon and the corresponding taxonomy of exchange value” (Baldwin 2009, 241). This suggests that “carbon valorization, racialization and dispossession are here not just coincident processes but constitutive features of the same process” (Baldwin 2009, 242). Such instances of racial violence in emerging modes of market-based environmentalism (or ecological modernity) have given rise to a far-ranging geographical critique, much of which addresses the dangers of the marketization of nature and its failings, particularly for local and indigenous peoples. At the same time, other writers and activists, conscious of heterogeneity and the ambivalence of these trends and their applications in diverse environments, have also been keen to interrogate such processes for their social, economic, and environmental possibilities and for their potential capacity to circumvent dominant concepts of environment, nation, and “race.”

What is clear is that, in the most pressing realms of global environmental governance, such as climate change and associated policy debates, immutable understandings of “nature,” while useful for some agendas some of the time, continue to reify the world, excluding and dominating its others. As the world embraces a late capitalist ecological phase of market-based environmentalism, Neil Smith (2007, 38) has powerfully argued that “Capital is no longer content simply to plunder an available nature but rather increasingly moves to produce an inherently social nature as the basis of new sectors for production and accumulation.” In these ongoing processes, for better or worse, the entwined concepts of environment, nation, and “race” will continue to be materially and culturally reconfigured in old, new, and creative ways.

Environmental (in)justice

Noriko Ishiyama
Meiji University, Japan

Environmental (in)justice is a philosophical and political notion created and espoused by activists, policymakers, and academics to articulate important connections between environmentalism and place-based struggles for social justice. The sites of environmental (in)justice occur at different geographical scales ranging from the individual bodies of humans and nonhumans to global ecological arenas past, present, and future. The concept of environmental (in)justice challenges the narrowly defined notion of environment focused solely on wilderness in a US cultural context, and is also embedded in geographical and historical processes, social relations, and political-economic power structures, which are themselves intertwined with issues of class, race, gender, sexual orientation, and colonization. Scholars and activists involved in the field of environmental (in)justice analyze the ecological dilemmas experienced and reproduced at the sites of daily living—in other words, the spaces of home in which we actually live. Their aim is to enable peoples and groups with different cultural backgrounds to live their lives without worrying about environmental threats and risks relating to their socioeconomic status, as well as to participate in environmental decision-making forums for addressing and resolving issues of environmental (in)justice. The following introductory story illustrates the complexity, difficulties, and possibilities inherent in environmental (in)justice struggles.

In 1975 Dr Masazumi Harada (1934–2012) visited Grassy Narrows and White Dog, First Nation reserves in Ontario, Canada, for the first time. Harada was a medical doctor and scholar from Japan who specialized in Minamata disease, a neurological condition caused by methylmercury that had been dumped into the sea as industrial wastewater from the 1940s to 1968 by the Chisso Corporation, located in Kumamoto Prefecture. The discharged mercury accumulated in fish and shellfish that were then consumed by coastal communities around Minamata Bay, in the southern part of Japan. Far away from the political-economic center of the nation, Minamata was a place inhabited predominantly by low-income fishermen and their families, who fell ill as a result of their exposure to mercury and yet remained invisible in the political processes concerning environmental decision-making at the local, regional, and national levels.

Across the globe, in small indigenous communities in Ontario, Harada found a number of patients suffering from neurological, physical, and mental disorders also caused by mercury that had been emitted from the caustic soda plants operated by the Dryden Chemical Company, part of the local paper mill located upstream along the Wabigoon River, between 1962 and 1970. At the request of the First Nation communities, Harada and his team from Kumamoto Gakuen University conducted follow-up clinical surveys in 2002, 2004, and 2010. Their studies observed the prevalence of symptoms similar to those that had been observed over several generations in the Minamata region (Harada et al. 2011).

In both cases, the livelihoods of the surrounding communities depended heavily on
ENVIRONMENTAL (IN)JUSTICE

fishing. Mercury poisoning via water devastated public health, local economies, and cultures in these already socially marginalized populations. The sick individuals remained unrecognized, neglected, and almost abandoned by the municipal and national governments, which for many years prioritized corporate interests and industrial growth over environmental protection. Recalling his transnational experiences as a medical professional, Harada later told a newspaper reporter based in Tokyo: “I used to think that Minamata patients were discriminated against because they were sick. However, after visiting a number of contaminated sites all over the world, I now realize that environmental pollution haunts places where discrimination already exists” (Harada 2011). With his clinical expertise, as well as first-hand experience of diagnosing and offering medical treatment to thousands of patients, which included testifying for the victims in numerous lawsuits filed against Chisso Corp. and the prefectural and national Japanese governments, Harada knew exactly what was going on in Ontario – namely, that it was another case of environmental injustice.

Even though Harada did not use this particular vocabulary to articulate his struggles as a doctor and an advocate for grassroots movements, what he had witnessed and experienced on various geographic scales brought to the forefront issues of environmental injustice across time and space. The stories arising in Minamata and the Canadian First Nations highlighted the intertwining dynamics involved, such as ecological devastation in relation to human as well as nonhuman bodies; anxiety over reproduction, local food and cultures, livelihoods and resources, and the political economy on a larger scale; state support for the accumulation of corporate capital; lack of societal recognition of issues and peoples at the social periphery, as well as the structural limitations on their participation and capabilities in terms of environmental decision-making; classism, racism, sexism, heterosexism, and colonialism underlying the unequal power structure that developed spatially through the course of regional and national history; international and intergenerational ecological problems that threatened sustainable futures, as well as the growing networks among activists and scholars. All of these factors contain elements that inform the notion of environmental (in)justice, an issue which is profoundly geographical.

Since the concept of environmental (in)justice was first recognized and gained legitimacy in the United States through activists, public policy, and scholarly circles, as well as through media coverage, this entry primarily addresses US cases. It will review the emergence of the environmental justice movement, which aims to resolve dilemmas concerning environmental (in)justice, and the historical roots of the movement; the environmental justice movement as an antithesis against traditional environmentalism; policy development; and scholarly exploration of environmental (in)justice as a theoretical framework. The final section on academic theorization clarifies the pitfalls of the distributive paradigm combined with the overt racism prevalent in early studies, and then introduces the growing field of critical studies on environmental (in)justice.

Emergence of the environmental justice movement in the United States

As exemplified in the story of Minamata disease, communities with diverse histories and cultures all over the world have been fighting for centuries against environmental injustices that threaten their welfare, even though they have not referred to it by this particular term. Nonetheless, the development of environmental (in)justice as an activist agenda and a theoretical
framework is relatively new. The origins of the movement, along with the creation of this specific term, are found in the United States. Many activists and scholars point to the non-violent civil disobedience against a major case of environmental injustice – the construction of a hazardous waste landfill in Warren County, North Carolina, in 1982 – as the official birth of the environmental justice movement. The story dates back to 1978, when truckloads of liquid contaminated with polychlorinated biphenyl (PCB) were illegally dumped along a rural state highway. Consequently, 400,000 cubic yards (305,822 m$^3$) of soil along 240 miles (386 km) of road in 14 counties were contaminated with PCBs, and the state government was forced to take the lead in cleaning up the mess. Eventually, the government designated Afton, in Warren County, as a future dumping site, but made this decision without local consent. One of among 90 proposed sites, Afton was an economically depressed town in a county with the highest percentage of African Americans in the state of North Carolina. In the following year, angry residents and their supporters filed lawsuits to block the disposal plan. Their litigations failed and, as a result, hundreds of trucks loaded with hazardous waste started coming into Afton in the fall of 1982.

Lying on the ground in front of the trucks, residents and their allies tried to stop the disposal plan, which constituted a major health threat to the surrounding communities. The civil disobedience continued for six weeks, but eventually the police were called in and more than 500 demonstrators were arrested. While the construction project proceeded and the landfill was eventually built, the nonviolent protests, initiated by local blacks and supported by a number of civil rights and antitoxics activists, were reported on a large scale. Moreover, the Warren County event rallied a number of people who considered environmental destruction as a violation of basic human rights to live, work, and play in safety (Bullard 1990; Taylor 2011).

At the request of the leaders of the Warren County protests, in 1983 the United States General Accounting Office (known as the US General Accountability Office (GAO) after 2004) conducted a sociodemographic study in eight southeastern states, including North Carolina, of the relationship between the location of hazardous waste facilities and the racial and economic characteristics of the neighboring communities. The research concluded that hazardous waste landfills were located disproportionately in low-income black communities (US General Accounting Office 1983). Four years later, in 1987, United Church of Christ published another now classic study of environmental (in)justice, which revealed a national pattern in which race was determined to be the major factor in the siting of commercial hazardous waste facilities (UCC 1987). The Warren County protests and the subsequent GAO and UCC studies gave credibility to the grassroots activists’ claims. These developments marked the beginning of the environmental justice movement throughout the United States.

One highlight of the early environmental justice movement was the First National People of Color Environmental Leadership Summit, held in October 1991. More than 1000 environmental justice activists and academics gathered in Washington, DC, to share their experiences of living with environmental injustice and to pool creative ideas to examine environmental issues in a social justice framework. Rejecting top-down and elitist approaches, the summit’s participants emphasized the importance of grassroots activism and personal accounts. Simply put, they believed that those who had been exposed to risks at pollution sites should also be present at the table of decision-making. Because these bottom-up
tactics have been prioritized and respected, the environmental justice movement has never been exclusively represented by particular individuals or institutions in authority at national or international levels, although a number of umbrella organizations do exist.

At the end of the 1991 summit, the participants, who had cultivated deep connections with local geographies and were beginning to form wide-ranging networks, drafted a list of 17 principles of environmental justice, which consisted of the specific goals they were committed to. The 17 principles embrace such diverse issues as ecological unity and the interconnectedness of all species; rights to self-determination, safe work environments, and health care; and the enforcement of informed consent in medical procedures. They object to the environmental damage and social injustices generated by multinational corporations and military occupation, and by the subjugation and abuse of local peoples and other life forms. The principles support education focused on social and environmental issues, with an emphasis on cultural diversity, while encouraging people to consume the least amount of natural resources and to produce as little waste as possible (Delegates to the First National People of Color Environmental Leadership Summit 1991). As clarified by Pezzulo and Sandler (2007, 5), the principles thus “called for a robust activist agenda and a wide range of spiritual, ecological, sustainable, educational, and social justice commitments. They articulate a desire for universal protection and self-determination domestically and internationally.”

This remarkable event garnered much attention, and encouraged policymakers at local, state, national, and even international levels to recognize the necessity of engaging with this issue. It is now seen as a symbolic turning point in the history of US environmentalism. In particular, the 17 principles became a landmark of a new course of direction in the environmental justice movement, inspiring a variety of groups and peoples at risk.

The summit and the principles presented an inclusive master framework that incorporated, inspired, and resonated with a number of social movements, thus going beyond the boundaries of particular regions or nations. Nevertheless, some scholars pointed out that they remained reformist in terms of setting specific agendas, and argued that the reformist, as opposed to the revolutionary, approach would not challenge the globalized capitalist political economy that perpetuated environmental injustice. For instance, environmental sociologist Robert Benford (2005, 50–51) presented a critical analysis of the movement’s initial reluctance to emphasize the need for radical social changes: “Rather than following the logic of its diagnostic framing by advocating sweeping systemic changes, the movement’s prognoses remain focused on tinkering with a system constructed from slave labor and predicated on the exploitation of disadvantaged people.” While these critiques raise important issues for further consideration, they lack historical perspective. In fact, environmental (in)justice struggles have a long history of challenging existing social systems and power structures.

Environmental (in)justice as a concept for societal change: historical perspective

The concept of environmental (in)justice was directly born from antitoxics and civil rights struggles in the United States in the late 1970s and early 1980s. Among those who participated in the Warren County demonstrations, for instance, were members of the United Church of Christ (UCC), which had been instrumental in the Civil Rights Movement in the 1960s, as well as Lois Gibbs, a mother from a
working-class white neighborhood who stood up and became a leader in the widely publicized Love Canal struggles in the mid-1970s. In order to understand the depth and complexity of environmental (in)justice as a concept, however, its history should be traced further back.

Sociologist Dorceta Taylor (2011) explores the movement’s origins, such as public health efforts in early American cities, antislavery activism, resistance against the appropriation of tribal land in the establishment of national parks, and efforts to develop antizoning and residential segregation in the nineteenth century. She astutely points out that environmental activism among people of color in the United States has often been overlooked “because their discourses and actions are not always couched in environmental terms” (2011, 280). Those who participate in social activism as activists, policymakers, or scholars too often do not realize that what they think is quite innovative and new has actually been explored by others years before in different temporal and spatial settings. It is, therefore, important to acknowledge the historical context of recent developments in the environmental justice movement and to clarify the sort of productive strategies that should be adopted for articulating solutions and accomplishments.

Both now and in the past, environmental justice activism initiated by various groups has consistently challenged unequal power structures as well as legal systems dominated by racist, classist, sexist, heterosexist, and colonial ideologies. Moreover, with their powerful and diverse stories and experiences, their activism has generated multiple meanings in different historical and geographical contexts. In short, at their core, concepts of environmental (in)justice embody an idea of political dissent against oppressions and exploitations in our daily lives as well as an idealistic commitment to achieve social change, with a special focus on those who are vulnerable and at risk of being overlooked or ignored by those participating in environmental decision-making processes.

Indeed, the achievement of environmental justice means that everyone, regardless of socioeconomic and cultural background, has access to safe and happy lives, as well as the hope of an even better future for the generations to come. Geographer Gordon Walker argues: “Looking across academic, activist and policy literatures, environmental justice is most often defined in terms of an objective, something that is sought after and for which certain conditions are specified” (2012, 8). Activists and scholars engaged with the environmental justice movement have been exploring a variety of ways to reconstruct bodies, homes, neighborhoods, and communities on a daily basis, by looking both back and into the future.

One pioneering scholar, sociologist Bunyan Bryant (1995, 6), defined this multifaceted term as follows:

[Environmental justice] refers to those cultural norms and values, rules, regulations, behaviors, policies, and decisions to support sustainable communities, where people can interact with confidence that their environment is safe, nurturing, and productive. Environmental justice is saved when people can realize their highest potential, without experiencing the “isms.” Environmental justice is supported by decent paying and safe jobs; quality schools and recreation; decent housing and adequate health care; democratic decision-making and personal empowerment; and communities free of violence, drugs, and poverty. These are communities where both cultural and biological diversity are respected and highly revered and where distributed justice prevails.

This notion of environmental (in)justice has thus developed in tandem with progressive politics aimed at empowering the socially vulnerable in order to safeguard and improve their everyday lives and spaces. It is clear that the geographical
spheres elucidated in Bryant’s definition of the term are different from those established by more conventional environmental movements.

The uneasy relationship with conventional environmentalism

Environmental justice activists have generally set distinctly different goals from those involved in traditional environmental activism aimed at the preservation of wildlife and the conservation of natural resources. Rather than looking at human experience in dialogue with what surrounds us, preservationists and conservationists have been seen as tending to objectify wilderness and/or natural resources as something to be worshipped, protected, or managed with professional knowledge and technologies. This result was often considered as a detachment of environmentalism from the social and political-economic processes that determine human and nonhuman lives, relations, and cultures.

An innately complicit relationship between environmentalism and eugenics has been an important part of the national identity of the United States. As noted by historian Jonathan Spiro (2009), many of the pioneering conservationists in the late nineteenth century were eugenicists who played instrumental roles in contributing to ideologies of scientific racism. While arguing that it was the duty of the superior white race to maintain the purity of the wilderness, they impeached people of color, new immigrants, and gays and lesbians for polluting pristine and safe environments, and also viewed such populations as a threat to US national security.

In consequence, although both conventional environmentalism and the environmental justice movement shared the core objective of preventing the destruction of environment, their agendas and participants did not necessarily overlap, nor they did always agree on interpretations of the concept of the environment itself. In his provocative and often cited essay, William Cronon (1995, 85), one of the most prominent environmental historians, reflects on this blind spot in mainstream environmentalism, and deconstructs the notion of wilderness:

But the most troubling cultural baggage that accompanies the celebration of wilderness has less to do with remote rain forests and peoples than with the ways we think about ourselves – we American environmentalists who quite rightly worry about the future of the earth and the threats we pose to the natural world. Idealizing a distant wilderness too often means not idealizing the environment in which we actually live, the landscape that for better or worse we call home.”

In order to fill in this gap, environmental justice advocates seek to change the social dynamic itself, by reconstructing spaces of home, rather than limiting their focus exclusively to physically and metaphorically distant mountains, lakes, or rivers that are visited on vacation or that are simply natural resources to wisely manage and use. Needless to say, this dynamic has generated dialectical relationships with political-economic power structures, as well as with prevalent ideologies nested at different geographical scales. For instance, “home” has therefore meant the lead-poisoned public housing in inner cities, pesticide-contaminated farmland worked by undocumented immigrants, deserted buildings and streets in post-Katrina New Orleans, urban parks from which LGBT people have been excluded and/or put under surveillance, and radioactive well water adjacent to abandoned uranium mines on and near southwestern Indian reservations. “Home” also encompasses radioactive land in Fukushima whose residents were forced to evacuate after the nuclear power plant disaster, and the atoll islands that have disappeared as a result of drastic climate change. At
the same time, in many parts of the world, the wilderness preserved in the national parks visited by thousands of nature-loving tourists has always been home to indigenous peoples. These are places where peoples with diverse ethnic, racial, and national backgrounds have lived or have wished to live their everyday lives.

Conceptualizing the environment as “home” enables us to see the reciprocal relationships that humans have developed with their surroundings which offer opportunities and capabilities. The economist and philosopher Amartya Sen has an illuminating interpretation of the values of the environment. He emphasizes the value of the environment as “the opportunities it offers to people” rather than as a matter of what exists (Sen 2009, 248). Another key issue Sen observes is that “the environment is not only a matter of passive preservation, but also one of active pursuit.” He stresses the possibilities of human power to “enhance and improve the environment in which we live” (249). Indeed, these are the values that have been appreciated and sought after by environmental justice advocates through the years.

Through a wide range of place-based experiences, environmental justice activists have observed and apprehended the interconnectedness of their homes with ecological risks, as well as with issues such as social invisibility, the globalized capitalist political economy, classism, racism, sexism, heterosexism, and colonialism, issues which are simultaneously material, institutional, and ideological. These are the environmental issues they confront, whose solutions require fundamental changes in existing social norms and practices. Indeed, in the words of David Harvey (1996, 372), environmental conditions represent “beliefs, institutions, social material practices, and relations, [and] forms of political-economic power.” As a consequence, critical perspectives on environmental (in)justice have redefined the conceptual framework of the environment as something that is constantly reproducing and restructuring social processes and relations.

Environmental justice advocates have criticized the conventional environmental movement for being dominated exclusively by middle- and upper middle-class white males and for having overlooked ecological issues threatening socially marginalized populations. One year prior to the First National People of Color Environmental Leadership Summit in 1990, supporters of environmental justice such as artists, writers, academics, students, activists, and representatives of churches, unions, and community organizations signed a public letter addressed to the “Group of Ten” national environmental organizations, including the Sierra Club, Wilderness Society, and National Audubon Society. They pointed out that these mainstream organizations lacked accountability with regard to communities of color, and that they received financial support from such polluters as ARCO, General Electric, Exxon, and Coca-Cola, multinational corporations notorious for disregarding the wellbeing of their workers and neighboring communities, as well as for destroying ecological health worldwide.

Sociologist Robert Bullard, often called the father of environmental justice, opened his first book, Dumping in Dixie: Race, Class, and Environmental Quality, with the following lines:

The environmental movement in the United States emerged with agendas that focused on such areas as wilderness and wildlife preservation, resource conservation, pollution abatement, and population control. It was supported primarily by middle- and upper-middle-class whites. Although concern about the environment cut across racial and class lines, environmental activism has been most pronounced among individuals who have above-average education, greater access to economic resources, and a greater sense of personal efficacy. Mainstream environmental organizations were late in broadening their base of support to include blacks and
other minorities, the poor, and working-class persons. (1990, 1)

It is noteworthy that the introduction of Bullard’s monumental work on environmental (in)justice, which has been quoted countless times in academic, activist, and policymaking circles for more than two decades, describes conventional environmentalism as a movement of the privileged.

The majority of the environmentalists under scrutiny, however, have espoused liberal politics alongside a critical view of the massive accumulation of capital resulting from rapid industrialization that comes at the expense of ecological health, particularly since the 1970s. Indeed, the organizers of the 1970 Earth Day, an event which helped to establish the Environmental Protection Agency (EPA) and led to the amendments of the Clean Air Act (1970) and the establishment of the Clean Water Act (1972), rejected donations from corporations. The 20 million participants in this extraordinary Earth Day event were not necessarily hostile toward low-income people of color; most of them did in fact support liberal political ideologies. However, from an environmental justice standpoint, those who had been endowed with upper- and middle-class white privilege, and had not shared the geographies of everyday livelihoods, struggles, and memories of the other, were seen as simply indifferent to or ignorant of the ecological problems that existed in social/locational peripheries.

In response, the environmental justice movement has challenged the existing environmental movement for its limited definition of environment and for its exclusion of the underprivileged from its leadership, agenda setting, and practices. Prompted by such harsh criticism, the Natural Resources Defense Council, Greenpeace, and the Sierra Club, along with other Big Ten organizations have been trying to improve communication with the environmental justice movement, to diversify their staffs and members, and to broaden their missions.

Some decry this trend to broaden focus, arguing that conventional environmentalism should not be conflated with the anthropocentric environmental justice movement but should instead remain focused on the protection of wilderness. After all, in their view, local and international efforts to protect wilderness areas are in crisis because of globalizing capitalism and, therefore, environmental movements cannot afford to be divided or distracted from their original objective, which is to speak for nonhuman nature and wildlife. While recognizing the accomplishments of the environmental justice movement, Kevin Deluca (2007 argues that this new activism does not support environmental efforts to protect nonhumans that may have negative outcomes for human rights or interests. What is even more problematic for Deluca is that “environmental justice groups, not content to have their own ‘environmental movement’ focused on people, directly challenge and berate the environmental movement for not focusing on people and their problems, in other words, for being environmental groups” (2007, 30). Hence, Deluca considers the recent policies initiated by large environmental organizations such as the Sierra Club and Greenpeace to integrate environmental justice issues with their objectives to be premature (27–28). Referring to the environmental philosophies elaborated by Henry David Thoreau and Aldo Leopold, Deluca emphasizes the importance of “recognizing that wilderness/nature grounds and circumscribes the human” (41). This leads to a claim that respecting wilderness/nature, which supports the very existence of humanity, should inform the central tenets of environmentalism.

Deluca raises important questions that could contribute to productive dialogue between environmentalists who maintain different and
sometimes contradicting agendas. His criticism of the anthropocentricity of the environmental justice movement remains unanswered. Yet Deluca’s anxiety about mainstream environmental organizations losing their focus on wilderness if they incorporate environmental justice activism reflects that dominant mindset that emphasizes a dichotomous relationship between humans and nonhumans.

Environmental justice advocates would say that it is precisely this artificial dichotomy that should be challenged. Moreover, they stress that environmental organizations that feel the need to speak only on behalf of wilderness underestimate their own vital agency. Those who are committed to environmentalism and/or environmental justice, they argue, should consider ways to deconstruct the simplistic dichotomy between wilderness and society, as well as that between human and nonhumans.

Environmental justice policy in the United States

The vocal activism of the environmental justice movement prompted US governmental agencies to reconstruct their policies, although critics complain that progress has been painfully slow and that much still has to be done to accomplish the goals set forth in the 17 principles ratified over two decades ago. The history of the US government’s efforts to engage with issues of environmental (in)justice reveals how difficult it is for state entities to (i) define this complex term beyond the distributive paradigm, and (ii) support the processes that would bring about structural and institutional change within a society dominated by a neoliberal political economy. Focusing mainly on the path taken by the EPA, whose role is to actively initiate and advocate for environmental justice, this section on the development of US environmental justice policy outlines both the progress and unresolved dilemmas.

Calls for environmental justice first gained the attention of policymakers at various governmental levels in the 1980s and 1990s, which was also when the concept of multiculturalism was spreading across the United States. As mentioned earlier, the GAO (US General Accounting Office 1983) and UCC (1987) studies revealed the connection between hazardous waste facility locations and host communities’ racial and economic backgrounds. As more stories of local dissent against environmental injustice made headlines, governmental officials attended conferences and meetings organized by activists and academics. Finally, in 1990 the EPA created an Environmental Equity Workgroup, which was followed by the establishment of the Office of Environmental Equity in 1992. The symbolic use of the term “environmental equity” has both laid the foundation for, and stymied, the US government’s efforts to correct the unequal allocation of environmental goods and bads. The EPA was forced to function within a strict and limiting framework of distributive justice, even though it had been trying to broaden its missions and scopes.

As it employed the term “environmental justice” more frequently, the EPA created an independent advisory committee in 1993 called the National Environmental Justice Advisory Council (NEJAC), which consisted of a wide range of stakeholders who provided the agency with advice and recommendations. Members of the NEJAC included, for example, community-based activists, officials from the state, local, and tribal governments, scholars, and individuals from businesses, as well as nongovernmental organizations engaged with indigenous issues, civil rights, and environmentalism.
Many celebrated the establishment of the NEJAC for offering a space where various stakeholders could make their voices heard. Environmental justice advocates would argue that it did not challenge the fundamental dilemmas embedded in the neoliberal political economy. Some scholars realized the limited usefulness of what they regarded as simply cosmetic changes in the policymaking arena. Pellow and Brulle (2005, 10), for instance, question the “participatory schemes that a neoliberal US EPA hatched during the 1990s to address EJ demands,” pointing out that the NEJAC and other advisory committees and task forces encourage a “lack of political power, inequalities among participants, [and] a drain on energy away from grassroots issues.”

While the EPA developed the organizational task force, President Bill Clinton issued Executive Order 12898 on February 11, 1994, which marked a major victory for environmental justice advocates. The executive order encouraged each federal agency to “make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations.” With the organizational support of the Clinton administration, the Office of Environmental Equity eventually grew into the Office of Environmental Justice (OEJ) in 1995. The executive order and the OEJ, however, do not have the power to compel federal institutions to actually implement environmental justice policies. Institutions are encouraged to incorporate environmental justice ideals into their projects, but they are not necessarily penalized for failing to do so or even for leaving the issue entirely unaddressed.

As noted by a scholar of environmental public policy, Edwardo Lao Rhodes (2003, 86), who conducted a personnel survey and examined an employment census at the EPA in the early 1990s, the majority of employees initially gave “little more than lip service to the concept of environmental justice.” The passiveness of the agency may partly be explained by the social and technical backgrounds of its staff. According to Rhodes’s study, whites made up almost 74% of the total EPA workforce and accounted for 95% of the executive ranks and 84% of the more senior ranks. Most of these were white men with college degrees in science, engineering, or law (Rhodes 2003, 94). Rhodes concluded that the poor record of the EPA in implementing environmental justice “was not so much the result of deliberate obstruction of justice or planned discrimination” as a “simple result of culture,” one that did not emphasize the social implications of their missions and policies (2003, 92). In short, the majority of the EPA workers with privileged backgrounds were not equipped with the firsthand experience to understand environmentalism as a social struggle to protect the spaces of home. In other words, they were not the ones whose bodies, livelihoods, and homes were at risk on a daily basis.

As a result, since the early 1990s, the agency has made little progress in the arena of implementing its environmental justice policy. In addition, eight years of the Bush administration’s disregard for environmental issues in general undermined the EPA’s capability in terms of human resources and budget. Under the Obama administration, however, the EPA has been trying to renew its mission to further engage with issues of environmental justice. In January 2010 EPA Administrator Lisa P. Jackson, the first African American woman to serve in this position, declared that expanding the conversation on environmentalism and working for environmental justice should be one of the EPA’s priorities.
In a proposed plan entitled EJ 2014, which also recognizes the twentieth anniversary of the signing of Executive Order 12898 on environmental justice, the EPA declared that it would attempt to: “protect the environment and health in overburdened communities; empower communities to take action to improve their health and environment; and establish partnerships with local, state, tribal and federal governments and organizations to achieve healthy and sustainable communities” (EPA 2011, 1). However, although the EPA emphasizes the growing need for strategic implementation, these newly proposed goals contain nothing new, either in terms of policy or philosophy, compared to those specified in the 17 principles compiled over two decades ago.

The administrative history of newly created offices and task forces, the 1994 executive order, and the recent EJ 2014 project all show that the federal government has officially recognized the issue of environmental (in)justice, as well as its historical negligence in addressing it. Dominated by a neoliberal political economy, however, policies have been restricted within a distributive justice paradigm to help overburdened communities to reconstruct their surroundings to have better and safer lives.

The administrative history is at odds with the potential inherent in the more progressive ventures to dissolve unequal power structures, oppressive social relations, and various ideological isms, all of which are fundamental to and inherent in the geographies of environmental (in)justice. Keeping in mind the political dilemmas clarified earlier, the next and final sections of this entry present the development of environmental (in)justice scholarship. Academic endeavors to articulate and pursue environmental justice have intertwined with the history of the movement and policymaking in interesting and instructive ways.

Emergence of environmental (in)justice scholarship

Since the dramatic birth of the US environmental justice movement, a number of important scholarly works have espoused the progressive visions championed by activists at the sites of resistance and struggle. As exemplified by Robert Bullard, a sociologist and former NEJAC member who is both a prolific writer and a passionate advocate of outreach activities, many academics working within a variety of disciplines and methodologies have played crucial roles in making environmental (in)justice issues visible to the general public and encouraging local and federal officials to engage with the prevailing problems.

At the same time, however, the majority of the early literature remained either uncritically celebratory of the new social movement, or superficial, addressing the problems in terms of the unequal distribution of risks combined with intentional racism. Some studies accused corporations and political institutions of being overtly racist and imposing unwanted facilities on impoverished and powerless communities of color, while others were preoccupied with deciding whether it was race or poverty that played a bigger role in the disproportionate mapping of risks. While these studies succeeded in raising provocative questions and conveying powerful statements of protest, they nevertheless remained theoretically underdeveloped.

As noted by a number of geographers, philosophers and others (Lake 1996; Ishiyama 2003; Schroeder et al. 2008; Schlosberg 2009; Holifield, Porter, and Walker 2010; Walker 2012), the distributive justice paradigm initially dominated the discourse on environmental (in)justice, in both academic and political arenas, in a powerful and problematic way. Needless to say, unequal distribution is a critical issue to be

**ENVIRONMENTAL (IN)JUSTICE**

explored and analyzed but it is only one issue among many.

Discussions about distributive justice tended to theoretically reduce environments into entities that could be divided between members of communities, societies, and nations. This reduction opened up the growing field of environmental (in)justice to easy criticism. For example, some academics questioned the legitimacy of the environmental justice movement in terms of a classic chicken-and-egg dispute: which came first, poor communities of color or hazardous facilities? Others tried to quantitatively prove that the aforementioned GAO (1983) and UCC (1987) studies, for instance, were invalid, and that hazardous facilities were not disproportionately sited in low-income and/or minority neighborhoods.

The mechanical quantification and mapping of the final outcomes of distribution neglected the underlying stories that could not and should not be sealed in a fixed and monolithic container. Accordingly, these endeavors ended up presenting rather sterile information and empty discussions based solely on demographic patterns, which were disconnected from the actual struggles of people at various sites. Schlosberg (2009, 45) points out that

> the literature and demands of environmental justice movements, in both the United States and globally, reveal that these movements are less enthralled with defining justice as solely distributional than are many theorists. A critique of the distribution of environmental goods and bads is certainly central to environmental justice movements, but unlike liberal theorists, movements tend to offer a more expansive, plural, and pragmatic notion of justice.

Activists realize that the simple redistribution of risks does not resolve the institutional and structural problems inherent in the processes that create environmental injustice. As Schlosberg points out, there is not one reference to an equal and fair distribution of environmental hazards anywhere in the 17 principles of environmental justice written in 1990 (2009, 49). Even with their liberal politics, early studies obsessed with the conceptual framework of distributive justice overlooked the movement’s core philosophies, which had, historically and geographically, arisen out of marginalized people’s everyday experiences.

Another persistent problem in the first wave of environmental (in)justice studies was a limited understanding of racism. As noted by Benford (2005, 40), the analytical framework of environmental racism was “evocative, provocative, and innovative,” as well as catchy, in terms of commanding the world’s attention. Nonetheless, the emphasis on the dichotomy between a society dominated by whites on the one hand, and victimized communities of color and the poor on the other, neglected the complex dilemmas relating to power structures and social relations among the people concerned. In contrast, people’s struggles to pursue environmental justice for the sake of social change generated a greater number of diverse and complex stories, which were grounded in multiple and anomalous identities.

For example, geographer Laura Pulido’s (1996) case studies on pesticide campaigns and grazing battles against mainstream environmentalists, both of which were initiated by subaltern Chicano communities, and Ishiyama’s (2003) research, focused on the desperate efforts of an American Indian tribe to accept a high-level radioactive waste storage facility for the sake of political-economic survival, reveal the marked and at times contradictory politics of identities, which play important roles in interpreting as well as reconstructing environments. The stories can be even messier, in fact, because justice for one group quite often means injustice for another, even within certain communities categorized
by race, class, gender, and sexuality. Oversimplified good-and-bad stories do not explain the impact of transformative identity politics on the multilayered pursuit for environmental justice.

Moreover, as some scholars have pointed out, the majority of the initial studies portrayed racism as a set of explicit actions that were fixed and without anomaly, but this portrayal neglected how racism works as an ideology, as a sociohistorical process, and as a form of cultural domination (Pulido 1996; Ishiyama 2003; Benford 2005). With the significant exception of Bullard (1990), who from the outset emphasized the institutional aspects of racism, many scholars were initially preoccupied with elucidating the unequal pattern of environmental hazards that victimized poor communities of color, and which were the result of intentional racism instigated by corporations and governments.

This perspective concluded that fundamental causes were to be found in the racist actions (and/or nonactions) of corporate and governmental decision-makers, who naturally denied such accusations. In other words, no environmentally destructive corporation would willingly admit that they were deliberately targeting certain communities to suffer for the benefit of others. As a result, the rather ridiculous question could be raised: If racist bigots were removed from decision-making processes, or if educated and privileged elites with political-economic power became more considerate toward the poor minorities, could environmental racism be eradicated and environmental justice eventually be achieved? The answer is obviously no. In addition to being characterized by overt gestures, racism also assumes various systematic forms rooted in ideas and structural forces. In the geographical and historical processes of environmental (in)justice, racism functions and is reproduced in the same way.

Critical environmental (in)justice scholarship

Moving beyond the scheme of distributive justice in tandem with overt racism, recent scholarship on environmental (in)justice has engendered more critical perspectives. As geographers Ryan Holifield, Michael Porter, and Gordon Walker (2010, 2) observe that scholars of environmental justice today “are situating their work with respect to far broader cross-disciplinary debates about knowledge, representation and meaning, engaging more substantially with explanatory social theory and utilizing a wider diversity of methodologies in investigating the material and political content of socio-environmental concerns.” This section introduces the expansion of critical environmental (in)justice studies arising from its intersections with theoretical considerations of procedural justice, along with recognition and capability, critical race theory, gender and sexuality, just sustainabilities, international/globalized environmental issues, and ecological justice.

Geographer Robert W. Lake was one of the first scholars to articulate the structural issues neglected in the distributive justice paradigm and to propose an alternative perspective with an emphasis on procedural justice. As he writes (1996, 196), “redistributing outcomes will not achieve environmental justice unless it is accompanied and, indeed, preceded by a procedural redistribution of power in decision-making.” Analyzing environmental (in)justice regarding the siting of hazardous waste facilities, Lake stresses the importance of investigating how communities were capable of making their own choices if they were given control over the production of the waste in the first place. In other words, clarifying the social processes, political-economic structures, cultural identities,
and ideologies through which communities participate in or are excluded from decision-making articulates the determinants of environmental (in)justice (Ishiyama 2003, 122). Mathematical readings of the final distribution of hazards mean little when we compare them with careful examination of the spatial dynamics that have created the oppressive conditions and hegemonic ideologies underlying certain forms of inequity.

In his groundbreaking theoretical analysis of the multifaceted concept of environmental justice, David Schlosberg (2009) highlights the procedural interplay of equity, recognition, participation, and capabilities, at both individual and group levels. As an environmental philosopher, Schlosberg emphasizes the importance of considering the complex characteristics of the environmental justice movement, since “one simply cannot talk of one aspect of justice without its leading to another” (2009, 73).

In addition to equitable distribution, conceptual discussions about environmental (in)justice should incorporate the notion of recognition. According to Schlosberg (2009, 16),

- the key to understanding recognitional injustice lies in understanding the social norms, language, and mores that mediate our relation between those who are denigrated and so less well-off in the scheme of justice. The argument is that mis-or malrecognition is a cultural and institutional form of injustice.

Various social movements have thus demanded the recognition of and respect for socially marginalized communities, whose cultural identities have been dominated, undervalued, and/or neglected. The environmental justice movement in particular confronts the connection between a lack of social recognition and environmental risks threatening certain cultural and political-economic groups. In other words, environmental justice is ultimately aimed at enhancing the respect for the place-based identity and survival of communities through institutional changes.

In reference to the important work of Amartya Sen, among others, Schlosberg introduces the capability approach as another useful tool for understanding environmental (in)justice. An analysis of the notion of justice focused on an individual’s and/or community’s capacity to function and to do the things they choose to value is specified here. In *The Idea of Justice*, published in 2009, Sen provides the following explanation:

> The capability approach focuses on human life, and not just on some detached objects of convenience, such as incomes or commodities that a person may possess, which are often taken, especially in economic analysis, to be the main criteria of human success. Indeed, it proposes a serious departure from concentrating on the *means* of living to the actual *opportunities* of living. (2009, 233)

Besides distribution and recognition, this approach examines the process by which goods are transformed into flourishing and well-functioning individuals and communities (Schlosberg 2009, 4).

The examination of what people or communities are capable of doing, whether or not they decide to make use of the opportunities, echoes Bunyan Bryant’s (1995, 6) definition of environmental justice cited earlier: “Environmental justice is saved when people can realize their highest potential, without experiencing the ‘isms.’” Indeed, the ideologies and spatial processes of racism, classism, colonialism, sexism, and heterosexism have historically inhibited the ability of socially vulnerable peoples and communities to function and survive. Because environmental injustice arises when the ability to live safely at home is impeded, the processes and practices that create the underlying ideologies of institutional and structural oppression must be clarified.
This discussion leads to yet another essential perspective for the development of critical environmental (in)justice research, namely its engagement with critical race theory. As Pulido has argued, race is not isolated in a monolithic category; rather, it takes multiple forms in constructing unjust landscapes. Explicating the intersection of capitalism and racism as sociospatial relations and processes is vital for the development of critical environmental (in)justice studies. Moreover, a number of neoliberal states are inherently racial, and therefore play prominent roles in constructing as well as controlling the racial categories in the context of capitalist political economies. In her comprehensive review of the existing literature, Hilda Kurtz (2010, 95) asserts: “Without a more sophisticated consideration of the racialized nature of the state, our understandings of racially oriented EJ activism – its successes, failures and remaining possibilities with regard to the state – will remain woefully incomplete.” Critical race theory will thus “deepen our understanding of the interplay between state apparatuses and institutions and social processes and social movements that delimits the possibilities for achieving EJ” (Kurtz 2010, 112).

Gender and sexuality present another set of vital perspectives that meaningfully contribute to the scholarly and activist conversations on environmental (in)justice. Since environmental (in)justice addresses a diverse range of health and safety issues at home, and since women have been tasked with maintaining this domain in many parts of the world, they have taken crucial roles in activism. Women of color and working-class women, in particular, have taken action to protect their families and communities (Stein 2004, 2). Having firsthand experience of patriarchal, colonial, and racial domination over their bodies, minds, and territorialities, women of color easily recognize the intersection of environmental destruction and issues of family health and community survival.

In addition, Stein (2004, 7) argues that reframing sexuality issues as environmental justice issues enables us to see that “people of differing sexualities have the human right to bodily sovereignty and the right to live safely as sexual bodies within our social and physical environments” and, even more importantly, to advocate broader alliance with related movements led by men and women with various sexual identities to initiate resistance against the oppression over their bodies, peoples, and lands. Building on the theoretical frameworks elucidated by Stein’s edited volume, Montimer-Sandilands and Erickson (2010, 39) elaborate on an innovative term, “queer ecology,” which “embraces deviation and strangeness as a necessary part of biophilia, sexual pleasure and transgression as foundational to environmental ethics and politics, and resistance to heteronormativity as part and parcel of ecological science and green strategy alike.” The conceptualization of nature from a viewpoint of queer sexualities challenges and liberates heteronormative bodies and spaces, radically reconstructing the ideas and politics of environmental (in)justice.

Looking at bodies as procedural and transforming sites of domination and dissent from a feminist perspective, geographer Giovanna Di Chiuro (2008) explores the intersections of environmental and reproductive justice. Without their informed consent, the bodies of impoverished women of color have too often accumulated toxins and become agents of reproductive risk for future generations. By interpreting the notion of social reproduction as “the intersecting complex of political-economic, socio-cultural, and material-environmental processes required to maintain everyday life and to sustain human cultures and communities on a daily basis and intergenerationally,” Di Chiuro...
ENVIRONMENTAL (IN)JUSTICE

(2008, 281) presents a compelling argument that all environmental issues, both local and global, are after all reproductive issues, and, moreover, that environmental justice struggles ultimately seek to achieve healthy social reproduction at and across different geographical scales.

The pursuit of reproductive justice is directly related to what Julian Agyman and his colleagues have clarified as “just sustainabilities” in their attempt to make a connection between the discourses and movements of sustainable development and those of environmental justice. Defined by Agyman, Bullard, and Evans (2003, 5) as “the need to ensure a better quality of life for all, now, and into the future, in a just and equitable manner, whilst living within the limits of supporting ecosystems,” the concept of just sustainabilities looks broadly at our responsibilities in intergenerational and ecological spaces. A framework of just sustainabilities has thus added another important perspective to broaden the sphere of environmental (in)justice.

Furthermore, the growing field of critical environmental (in)justice studies has also considered international and transnational perspectives. Geographies of environmental (in)justice cover a wide range of spatial scales, from individual bodies, which could be those belonging to humans, fish, or even grains of rice, to transnational and global ecological systems. Indeed, environmental (in)justice issues, activism, and scholarship have not been limited to those existing within the national boundaries of the United States. Many cases of environmental disaster and resistance occur in and across different locations, and possess a variety of historical and cultural backgrounds, which are embedded in the capitalist political economy and intertwined with unequal and oftentimes colonial power structures and relations.

For example, multinational corporations have initiated and managed labor-exploitative and ecologically devastating natural resource development projects in cooperation with international organizations and local governments that could be labeled as oppressive. A number of toxic industries originating in North America, Europe, and Japan have relocated their production sites to other locations where they can secure cheap labor and where environmental regulations tend to be less stringent. The crisis of climate change is most apparent in the Arctic marine ecosystem, and currently endangers the livelihoods of the ecosystem’s residents, both human and nonhuman. In reality, however, the entire planet is affected, and the effects of climate change will only grow more severe in the future. The geographical inequity of who generates the causes for climate change and who is or will be affected has historically been related to the global political economy. In consequence, environmental (in)justice issues are broadening and growing more intricate in terms of social and geographical processes and international relations. The complexities of spatial politics pose difficult but important questions to be addressed by critical environmental (in)justice scholars. As Schroeder et al. (2008, 548) write:

Ever-increasing capital mobility, adjustments in trade governance, agrarian restructuring, neocolonial conservation projects, expanding suburban frontiers, and displacements induced by war and violence have also contributed to a sense that environmental justice concerns are increasing in scope. In effect, environmental justice scholars have been confronted with circumstances that require them to reconsider their core analytical constructs – across scales, within spaces defined by new concepts of territoriability, and in the context of complex and shifting network of global interconnections.

As these geographers specializing in political ecology assert, “[T]he core issues at the heart of environmental justice struggles are universal”
(Schroeder et al. 2008, 554). Needless to say, they are also transnational, crossing national borders. The Minamata disease story described earlier, which impacted both fishing villages in Japan and the First Nations in Canada, attests to these universal and transnational dynamics quite eloquently.

Finally, but most importantly, environmental justice movements and studies have searched for explicit and integral connections to ecological justice. Humans and their everyday lives are part of broader ecological systems at both the local and the global levels. Despite the fact that, with its emphasis on the security of daily livelihoods, the concept of environmental (in)justice possesses an anthropocentric implication, human lives are inherently ecological and are intertwined in reciprocal relationships with their surrounding landscapes and various other forms of life. In reference to indigenous environmental activism as well as food and climate justice movements, Schlosberg (2009, 6) argues that “we can draw parallels between the application of notions of justice as distribution, recognition, capability, and participation in both the human and nonhuman realms.” There is no clearly definitive boundary between human and nonhuman worlds, and, moreover, every living thing, be it a plant or a dog, has its own spirit and agency. Acknowledging the integral link between ecological and environmental (in)justice at the sites of reproducing risks seems to be important for us.

Future prospects for critical environmental (in)justice scholarship

Concepts of environmental (in)justice have covered a remarkably diverse range of social and ecological issues relating to struggles for place-based self-determination and livelihoods, all of which are inherently geographical. There are disputes over the extent of the movement itself, as some are concerned that proponents of environmental (in)justice have broadened their scope too far, and therefore fail to embrace its plurality. Regarding the possible diffusion of the movement, Pellow and Brulle (2005, 16) remark that “the difficulty in drawing boundaries for the EJ movement may stem from its multi-issue focus, its multi-ethnic and multi-racial composition, its multi-national scope, and its origins in multiple related movements. EJ activists must bound and limit the purview of their concerns.” If they do not set some limits on their agendas, these authors warn that the movement “will lose its explanatory (and mobilizing) power.” They propose a move toward critical environmental (in)justice studies that emphasizes evaluating the effectiveness and achievement of the movement in terms of its original goals.

According to Pellow and Brulle, critical environmental (in)justice studies should be focused on linking theory to practice in order to accomplish a more effective movement to create just and sustainable societies (2005, 17–18). Their objection to the further expansion of the environmental (in)justice framework is based on their frustration with the painfully slow implementation of environmental justice policy and the persistent spatial injustice that lingers in impoverished communities of color across the globe. And indeed, their claims make sense when we try to prioritize and set practical and realistic agendas.

Nonetheless, this approach may encumber the fundamental core of environmental justice ideas, whose authors, cultivated in multiple and complex geographies, explore societal changes with great creativity. Refuting Pellow and Brulle’s approach, which was derived from pragmatic reasoning, Schlosberg (2009, 8) presents the following compelling argument:
The proposition here is that a more thorough definition of justice – one that encompasses the expressed concerns of environmental justice groups, the conception of justice to the non-human world, and the recent contributions of justice theory – can offer a broadly accessible, plural and workable frame. I am not arguing for a single, all-inclusive, holistic theory of environmental and ecological justice; rather, the point is to expand the discourse of justice, and legitimize the use of a variety of tools and notions as they apply to various cases.

Understanding the multiplicity and complexity of environmental (in)justice studies and activism would further help in developing our ability to reconstruct just and healthy spaces in which all the living things, including humans with various political-economic, racial, national, gender, and sexual identities, as well as animals, plants, and other forms of life, are capable of living happily, and with the hope of a better future.
